Emergency Medicine: A Comprehensive Study Guide

CONTENTS

Section Eight   Gastrointestinal Emergencies

Section Nine   Renal and Genitourinary Disorders

Michael S. Weinstock, Michael S. Catapano

Section Twelve   Infectious Diseases

Section Thirteen   Toxicology

Section Fourteen   Environmental Injuries

Section Fifteen   Endocrine Emergencies

William J. Brady, Richard A. Harrigan

Section Sixteen   Hematologic and Oncologic Emergencies

Section Seventeen   Neurology

Section Eighteen   Eye, Ear, Nose, Throat, and Oral Surgery

Rudolph J. Triana, Jr., Theresa A. Hackeling

Section Nineteen   Disorders of the Skin

Section Twenty   Trauma

Section Twenty-One   Injuries to Bones, Joints, and Soft Tissues

STEPHANIE B ABBUHL, M.D. [296]
Associate Professor and Medical Director
Department of Emergency Medicine
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania

RIYAD B. ABU-LABAN, M.D., M.H.Sc., F.C.R.P.C. [83]
Assistant Clinical Professor of Surgery
University of British Columbia
Attending Physician and Associate Research Director
Department of Emergency Medicine
Vancouver General Hospital
Vancouver, BC, Canada

WILLIAM R. AHRENS, M.D. [128]
Director of Emergency Medicine for Pediatrics
Department of Emergency Medicine
University of Illinois at Chicago College of Medicine
Chicago, Illinois

MICHAEL F. ALTIERI, M.D., F.A.A.P. [136]
Pediatric Section Chief
Department of Emergency Medicine
Inova Fairfax Hospital
Falls Church, Virginia
Associate Clinical Professor of Emergency Medicine and Pediatrics
Georgetown University School of Medicine
Washington, DC
George Washington University School of Medicine
Washington, DC
Associate Clinical Professor of Pediatrics
University of Virginia School of Medicine
Charlotte, Virginia

DAVID C. ANDERSON, M.D. [227]
Department of Neurology
Hennepin County Medical Center
Minneapolis, Minnesota

ERIC ANDERSON, M.D., F.A.C.E.P. [60]
Clinical Faculty
Department of Emergency Medicine
Case Western Reserve University
MetroHealth Emergency Medicine
Cleveland Clinic Foundation
Cleveland, Ohio

WILLIAM T. ANDERSON, M.D., F.A.C.E.P. [144]
Department of Emergency Medicine
William Beaumont Hospital
Troy, Michigan

PAUL S. AUERBACH, M.D., M.S., F.A.C.E.P. [190]
Clinical Professor of Emergency Medicine
Department of Surgery
Stanford University School of Medicine
Stanford, California
Life Sciences Advisor
garage.com
Palo Alto, California

TOM P. AUFDERHEIDE, M.D. [81]
Associate Professor
Research Director
Department of Emergency Medicine
Medical College of Wisconsin
Milwaukee, Wisconsin

CHENICHERI BALAKRISHNAN, M.D. [194]
Assistant Professor
Department of Surgery
Wayne State University School of Medicine
Detroit, Michigan

J. MICHAEL BALLESTER, M.D. [195]
Clinical Instructor
Department of Emergency Medicine
Southern Illinois University School of Medicine
St. Johns Hospital
Springfield, Illinois

JEFFREY D. BAND, M.D. [142]
Division of Infectious Diseases
William Beaumont Hospital
Royal Oak, Michigan

ROBERT A. BARISH, M.D., F.A.C.E.P., F.A.C.P. [72]

Professor of Surgery and Medicine
Associate Dean of Clinical Affairs
University of Maryland School of Medicine
Baltimore, Maryland

STEVEN BRENT BARNES, M.D. [187]
Assistant Professor of Emergency Medicine
Associate Residency Program Director
Department of Emergency Medicine
University of Oklahoma Health Sciences Center
Oklahoma City, Oklahoma

L. JARRETT BARNHILL, M.D. [302]
Associate Professor
Department of Psychiatry
University of North Carolina Chapel Hill School of Medicine
Chapel Hill, North Carolina

BONNY J. BARON, M.D. [248, 250]
Assistant Professor
Department of Emergency Medicine
State University of New York Health Science Center at Brooklyn
Attending Physician
Department of Emergency Medicine
Kings County Hospital Center
Brooklyn, New York

WILLIAM G. BARSAN, M.D. [220]
Professor and Chair
Department of Emergency Medicine
University of Michigan Health System
Ann Arbor, Michigan

CHRISTOPHER W. BARTON, M.D., F.A.C.E.P. [20]
Associate Professor
Head, Division of Informatics
Department of Emergency Medicine
University of North Carolina Chapel Hill School of Medicine
Chapel Hill, North Carolina

DANIEL G. BATTON, M.D. [113]
Chief, Neonatology
Department of Pediatrics
William Beaumont Hospital
Royal Oak, Michigan

NORMAN J. BEAUCHAMP, Jr., M.D. [229]
Assistant Professor
Division of Neuroradiology
Department of Radiology
The Johns Hopkins Hospital
Baltimore, Maryland

RONALD W. BEAUDREAU, D.M.D., M.D., F.A.C.E.P. [234]
Assistant Director
Department of Emergency Medicine
Columbia Augusta Medical Center
Augusta, Georgia

AMY J. BEHRMAN, M.D. [105]
Assistant Professor
Director of Occupational Medicine
Hospital of the University of Pennsylvania
Department of Emergency Medicine
Philadelphia, Pennsylvania

WILLIAM A. BERK, M.D., F.A.C.E.P. [17, 160, 299]
Associate Professor
Department of Emergency Medicine
Wayne State University
Detroit, Michigan

CAROL D. BERKOWITZ, M.D., F.A.A.E.M. [110, 114, 289]
Acting Chair and Professor
Department of Pediatrics
Harbor-UCLA Medical Center
Torrance, California

EDWARD BERNSTEIN, M.D., F.A.C.E.P. [287]
Professor of Emergency Medicine
Boston University School of Medicine and Boston Medical Center
Professor of Social and Behavioral Sciences
Boston University School of Public Health
Vice Chairperson for Academic Affairs
Boston University School of Medicine
Boston, Massachusetts

JUDITH A. BERNSTEIN, R.N.C., Ph.D. [287]
Assistant Professor
Department of Maternal and Child Health
Boston University School of Public Health
Assistant Professor

Department of Emergency Medicine
Boston University School of Medicine
Boston, Massachusetts

HOWARD A. BESSEN, M.D. [186]
Director
Emergency Medicine Residency Program
Harbor-UCLA Medical Center
Torrance, California

EDWARD S. BESSMAN, M.D., F.A.C.E.P., F.A.A.E.M. [18]
Chairman
Department of Emergency Medicine
Johns Hopkins Bayview Medical Center
Assistant Professor
Associate Residency Director
Department of Emergency Medicine
Johns Hopkins University School of Medicine
Baltimore, Maryland

JESSICA L. BIENSTOCK, M.D., M.P.H. [102]
Assistant Professor
Department of Gynecology and Obstetrics
Johns Hopkins University School of Medicine
Johns Hopkins Hospitals
Baltimore, Maryland

ROBERT BILKOVSKI, M.D. [26]
Assistant Professor
Department of Emergency Medicine
Virginia Commonwealth University School of Medicine
Richmond, Virginia

JIM BLAKE, M.D. [43]
Resident
Department of Emergency Medicine
University of Kentucky
Lexington, Kentucky

BARBARA K. BLOK, M.D. [46]
Instructor
Department of Emergency Medicine
Johns Hopkins University
Baltimore, Maryland

DAVID M. BLUEMKE, M.D., Ph.D. [57]
Clinical Director, MRI
Department of Radiology
Johns Hopkins Hospital
Baltimore, Maryland

EILEEN M. K. BOBEK, M.D. [27]
Lecturer
Department of Emergency Medicine
University of Michigan Medical Center
University of Michigan School of Medicine
Ann Arbor, Michigan

MARK P. BOGNER, M.D. [93]
Assistant Professor of Medicine
University of Wisconsin
Madison, Wisconsin

EDMUND BOLTON, M.D. [24]
Emergency Medicine HealthCare Physicians
Westmont, Illinois

MICHAEL J. BONO, M.D., F.A.C.E.P. [87]
Associate Professor
Associate Director
Emergency Medicine Residency Program
Department of Emergency Medicine
Eastern Virginia Medical School
Norfolk, Virginia

MARC BORENSTEIN, M.D., F.A.C.E.P., F.A.C.P. [217]
Vice-Chair and Residency Program Director Department of Emergency Medicine
St. Luke's-Roosevelt Hospital Center
Associate Professor of Clinical Medicine
Columbia University College of Physicians and Surgeons
New York, New York

CARL L. BOSE, M.D. [4]
Department of Pediatrics
Chief, Division of Neonatal-Perinatal Medicine
University of North Carolina
Chapel Hill, North Carolina

GEORGE M. BOSSE, M.D. [158]
Associate Professor
Department of Emergency Medicine

University of Louisville
Louisville, Kentucky

SHARON A. BOSWELL, R.N., C.E.N. [252]
Research Nurse
R. Adams Crowley Shock Trauma Center
University of Maryland Medical Center
Baltimore, Maryland

JAMES K. BOUZOUKIS, M.D., F.A.C.E.P. [78]
Medical Center of Delaware
Wilmington, Delaware

WILLIAM M. BOWLING, M.D. [251]
Resident Physician
Department of Surgery
Washington University School of Medicine
St. Louis, Missouri

WILLIAM J. BRADY, M.D. [81, 155, 202, 237, 241]
Assistant Professor of Emergency Medicine and Internal Medicine
Program Director, Emergency Medicine Residency
Associate Director, Chest Plain Unit
University of Virginia School of Medicine
Department of Emergency Medicine
University of Virginia Health System
Charlottesville, Virginia

G. RICHARD BRAEN, M.D., F.A.C.E.F. [179]
Professor and Chair
Department of Emergency Medicine
State University of New York, Buffalo
Buffalo, New York

ANNE F. BRAYER, M.D., F.A.A.P. [200]
Assistant Professor of Emergency Medicine and Pediatrics
Department of Emergency Medicine
University of Rochester Medical Center
Strong Memorial Hospital
Rochester, New York

JANE H. BRICE, M.D., M.P.H. [147]
Assistant Professor
Department of Emergency Medicine
University of North Carolina Chapel Hill School of Medicine
Chapel Hill, North Carolina

JAMES E. BROWN, M.D. [286]
Assistant Professor
Department of Emergency Medicine
Wright State University School of Medicine
Dayton, Ohio

KATHLEEN M. BROWN, M.D. [119]
Assistant Professor of Pediatric Emergency Medicine
Department of Emergency Medicine
State University of New York Health Science Center at Syracuse
Syracuse, New York

BRIAN J. BROWNE, M.D., F.A.C.E.P. [79]
Head, Division of Emergency Medicine
Director of Emergency Medical Services
University of Maryland Medical System
University of Maryland School of Medicine Baltimore
Baltimore, Maryland

ROBERT A. BROWNSTEIN, M.D. [150]
Attending Physician
Department of Emergency Medicine
Rex Hospital
Raleigh, North Carolina

G. RICHARD BRUNO, M.D. [166, 175, 180]
Assistant Professor
Department of Emergency Medicine
Assistant Director
Emergency Medicine Residency Program
State University of New York-Brooklyn
New York, New York

JAMES H. BRYAN, M.D., Ph.D., F.A.C.E.P. [149]
Assistant Professor of Emergency Medicine
Department of Emergency Medicine
Oregon Health Sciences University
Portland Veterans Affairs Medical Center
Portland, Oregon

TIMOTHY G. BUCHMAN, M.D., Ph.D. [251]
Professor of Surgery, Anesthesiology, and Medicine
Chief Section of Burn, Trauma, Surgical Critical Care
Department of Surgery

Barnes-Jewish Hospital
Washington University School of Medicine
St. Louis, Missouri

JOHN H. BURTON, M.D., F.A.C.E.P. [278]
Research Director
EMS Director
Department of Emergency Medicine
Maine Medical Center
Portland, Maine
Assistant Professor
Department of Surgery
University of Vermont School of Medicine
Burlington, Vermont

CHARLES B. CAIRNS, M.D., F.A.C.E.P. [49]
Associate Professor; Director, Colorado Emergency Medicine
Research Center
Division of Emergency Medicine
University of Colorado Health Sciences Center
Denver, Colorado

MARY CAMARCA, M.D. [136]
Department of Emergency Medicine Inova Fairfax Hospital Falls Church, Virginia

DONNA L. CARDEN, M.D., F.A.C.E.P. [140]
Associate Professor of Internal Medicine, Emergency Medicine, and Molecular and Cellular Physiology
Louisiana Chapter of ACEP
Louisiana State University Medical Center
Shreveport, Louisiana

TERESA M. CARLIN, M.D. [25]
Fellow
St. Christopher's Hospital for Children
Pediatric Emergency Medicine
Philadelphia, Pennsylvania
Instructor
Department of Emergency Medicine
Johns Hopkins University School of Medicine
Baltimore, Maryland

CHRISTINE M. CARR, M.D., F.A.C.E.P. [23]
Clinical Instructor
Department of Emergency Services
Medical University of South Carolina
Charleston, South Carolina

WALLACE A. CARTER, M.D. [36, 39, 166, 175, 180]
Director, Emergency Medicine Residency
New York University/Bellevue Medical Center
Assistant Professor
Clinical Surgery/Emergency Medicine
New York University School of Medicine
New York, New York

MICHAEL S. CATAPANO, M.D., F.A.C.E.P. [131]
Department of Emergency Medicine
Southampton Hospital
Southampton, New York

EUGENE E. CEPEDA, M.D. [9]
Pediatrician
Department of Pediatrics
The Detroit Medical Center
Hutzel Hospital
Detroit, Michigan

ROBERT S. CHANG, M.D. [39]
Clinical Instructor
Department of Emergency Medicine
Boston Medical Center
Boston, Massachusetts

ARJUN S. CHANMUGAM, M.D., F.A.C.E.P. [53, 171]
Assistant Professor
Department of Emergency Medicine
Johns Hopkins Hospital
Baltimore, Maryland

MICHAEL E. CHANSKY, M.D. [203]
Associate Professor and Acting Chairman
Department of Emergency Medicine
UMDNJ-Robert Wood Johnson Medical School at Camden
The Cooper Health System
Camden, New Jersey

BENNETT CHIN, M.D. [57]

HAROLD W. CHIN, M.D., F.A.C.E.P. [261, 262]
Medical Director
Occupational Health

Lake Forest Hospital
Lake Forest, Illinois

ANN S. CHINNIS, M.D., M.S.H.A., F.A.C.E.P. [196, 197]
Associate Professor of Emergency Medicine
Interim Chair of Emergency Medicine
Emergency Department Medical Director
West Virginia University School of Medicine
Morgantown, West Virginia

ANIL CHOPRA, M.D. [55]
Assistant Professor of Medicine
Division of Emergency Medicine
The Toronto Hospital
University of Toronto
Toronto, Canada

RICHARD A. CHRISTOPH, M.D. [132, 135]
Associate Professor of Emergency Medicine and Pediatrics
Director, Pediatric Emergency Medicine
Department of Emergency Medicine
University of Virginia
Charlottesville, Virginia

RICHARD F. CLARK, M.D., F.A.C.E.P., F.A.C.M.T. [188]
Associate Professor of Medicine and Director
Division of Medical Toxicology
Department of Emergency Medicine
UCSD Medical Center
San Diego, California

DAVID M. CLINE, M.D., F.A.C.E.P. [34, 50]
Clinical Associate Professor and Assistant Residency Director
Department of Emergency Medicine, University of North Carolina at Chapel Hill
Chapel Hill, North Carolina
Education Director, Department of Emergency Medicine
WakeMed
Raleigh, North Carolina

WENDY C. COATES, M.D., F.A.C.E.P. [38, 40]
Associate Professor of Medicine UCLA School of Medicine Los Angeles, California Director, Medical Education Department of Emergency Medicine Harbor-UCLA Medical Center Torrance, California

DANIEL J. COBAUGH, Pharm.D. [156]
Managing Director
Finger Lakes Regional Poison and Drug Information Center
Assistant Professor of Emergency Medicine
Department of Emergency Medicine
University of Rochester Medical Center
Rochester, New York

STEPHEN A. COLUCCIELLO, M.D. [249]
Assistant Chair
Director of Clinical Services and Trauma Coordinator
Department of Emergency Medicine
Carolinas Medical Center
Assistant Clinical Professor
Department of Emergency Medicine
University of North Carolina
Chapel Hill, North Carolina

ALASDAIR K. T. CONN, M.D., F.A.C.S., F.A.C.E.P. [253]
Chief of Emergency Services
Department of Emergency Services
Massachusetts General Hospital
Assistant Professor of Surgery
Harvard Medical School
Boston, Massachusetts

JOHN R. COOKE, M.D., J.D. [216]
St. Luke's-Roosevelt Hospital Center
Columbia College of Physicians and Surgeons
New York, New York

RANDOLPH J. CORDLE, M.D., F.A.A.P., D.A.B.E.M. [125, 129]
Director Pediatric Emergency Medicine
Department of Emergency Medicine
St. Luke's Hospital
Boise, Idaho

EDWARD E. CORNWELL III, M.D., F.A.C.S., F.C.C.M. [243]
Associate Professor of Surgery
Chief, Adult Trauma Service
Department of Surgery
The Johns Hopkins Medical Institutions
Baltimore, Maryland

C. JAMES CORRALL, M.D., M.P.H, F.A.A.P, F.A.C.E.P. [115]
Clinical Associate Professor of Emergency Medicine and Pediatrics
Adjunct Associate Professor of Clinical Pharmacology
Department of Emergency Medicine
Emergency Medicine and Trauma Center

Methodist Hospital of Indiana
Indiana University School of Medicine
Indianapolis, Indiana

FRANCIS L. COUNSELMAN, M.D., F.A.C.E.P. [271]
Professor, Chairman, and Program Director
Department of Emergency Medicine
Eastern Virginia Medical School
Staff Physician
Emergency Physicians of Tidewater
Norfolk, Virginia

NATALIE M. CULLEN, M.D. [126]
Assistant Professor
Department of Emergency Medicine
Wright State University School of Medicine
Dayton, Ohio

RITA K. CYDULKA, M.D., F.A.C.E.P. [64, 65]
Associate Professor and Residency Director
Department of Emergency Medicine
MetroHealth Medical Center
Case Western Reserve University
Cleveland, Ohio

FRANK F. S. DALY, M.B.B.S. [189]
Fellow
Medical Toxicology
Rocky Mountain Poison and Drug Center
University of Colorado Health Sciences Center
Denver, Colorado

DANIEL F. DANZL, M.D., F.A.C.E.P. [15]
Professor and Chair Department of Emergency Medicine
University of Louisville Louisville, Kentucky

RICHARD C. DART, M.D., Ph.D. [164, 189]
Director
Rocky Mountain Poison and Drug Center
Associate Professor of Surgery,
Medicine, and Pharmacy University of Colorado Health Sciences Center
Denver, Colorado

ELIZABETH M. DATNER, M.D. [12]
Assistant Professor of Emergency Medicine
Department of Emergency Medicine
University of Pennsylvania School of Medicine
Hospital of the University of Pennsylvania Presbyterian Medical Center
Philadelphia, Pennsylvania

DANIEL J. DEBEHNKE, M.D., F.A.C.E.P. [241]
Associate Professor of Emergency Medicine
Department of Emergency Medicine
Medical College of Wisconsin
Milwaukee, Wisconsin
Director of Clinical Operations
Department of Emergency Medicine
Froedtert Memorial Lutheran Hospital
Milwaukee, Wisconsin

KATHLEEN A. DELANEY, M.D. [182]
Clinical Professor in Medicine and Surgery
Division of Emergency Medicine
Department of Surgery
Southwestern Medical School
Dallas, Texas

KENNETH C. DIRK, M.D. [149]
Resident Physician
Department of Emergency Medicine
Oregon Health Sciences University
Portland, Oregon

GAIL D'ONOFRIO, M.D. [287]
Associate Professor
Yale University School of Medicine
Director of Research
Department of Surgery, Section of Emergency Medicine
Yale University School of Medicine
Yale New Haven Hospital
New Haven, Connecticut

SUZANNE DOYON, M.D. [161]
Assistant Professor
Division of Emergency Medicine, Department of Surgery
University of Maryland Medical System
Baltimore, Maryland

WILLIAM H. DRIBBEN, M.D. [168]
Medical Toxicology Fellow
Indiana Poison Center and Emergency Medicine and Trauma Center at
Methodist Hospital

Indiana University School of Medicine
Indianapolis, Indiana

STEVEN C. DRONEN, M.D. [27]
Associate Professor
Associate Section Head and Residency Director
Department of Emergency Medicine
University of Michigan Medical Center
University of Michigan School of Medicine
Ann Arbor, Michigan

MARY E. EBERST, M.D. [210-215]
Assistant Professor
Departments of Emergency Medicine and Medicine
University of North Carolina at Chapel Hill
Chapel Hill, North Carolina

CHARLES A. ECKERLINE JR., M.D., F.A.C.E.P. [43]
Associate Professor and Associate Chief of Service
Department of Emergency Medicine
University of Kentucky
Lexington, Kentucky

COL. EDWARD M. EITZEN, JR., M.D., M.P.H. [181]
Chief
Division of Operational Medicine
USAMRIID
Ft. Detrick, MD
Associate Clinical Professor
Uniformed Services
University of the Health Sciences
Bethesda, Maryland

CHARLES L. EMERMAN, M.D. [59, 167]
Associate Professor of Emergency Medicine
Case Western Reserve University
Chairman of Emergency Medicine
MetroHealth Medical Center
Cleveland Clinic Foundation
Cleveland, Ohio

STEPHEN D. EMOND, M.D., F.A.C.E.P. [216]
Assistant Professor of Medicine
Department of Emergency Medicine
Weill Medical College of Cornell University
Director of Clinical Research
Department of Emergency Medicine
New York-Presbyterian Hospital
New York, New York

JOHN ENG, M.D. [294]
Assistant Professor of Radiology
Department of Radiology and Radiological Science
Johns Hopkins University
Baltimore, Maryland

BRIAN D. EUERLE, M.D. [31]
Assistant Professor
Division of Emergency Medicine
Emergency Department
University of Maryland Medical Center
Baltimore, Maryland

RAWDEN W. EVANS, M.D., Ph.D. [82]
Assistant Professor
Department of Emergency Medicine
University of Michigan Medical Center
Ann Arbor, Michigan

MARTIN L. FACKLER, MD
President
International Wound Ballistics Association
Hawthorne, Florida

KIM M. FELDHAUS, M.D., F.A.C.E.P. [290]
Associate Residency Director
Denver Health Medical Center
Denver, Colorado
Assistant Professor
Division of Emergency Medicine
Department of Surgery
University of Colorado Health Sciences Center
Denver, Colorado

MADONNA FERNÁNDEZ, M.D. [40]
Chief Resident and Clinical Teaching Fellow
Harbor-UCLA Department of Emergency Medicine
Torrance, California

DENIS J. FITZGERALD, M.D. [74]
Department of Emergency Medicine
University of Cincinnati Medical Center

University of Cincinnati School of Medicine
Cincinnati, Ohio

STEVEN G. FOLSTAD, M.D., F.A.C.E.P. [146]
Mid-Atlantic Emergency Medicine
Associates
Charlotte, North Carolina

MARSHA D. FORD, M.D., F.A.C.E.P., F.A.C.M.T. [178]
Director
Carolinas Poison Center
Assistant Chairman
Director, Division of Toxicology
Department of Emergency Medicine
Carolinas Medical Center
Charlotte, North Carolina

MARK W. FOURRE, M.D. [277]
Associate Clinical Professor of Surgery
University of Vermont
Burlington, Vermont
Program Director
Department of Emergency Medicine
Maine Medical Center
Portland, Maine

HAROLD E. FOX, M.D., M.S. [102]
Professor and Chair
Residency Program Director
Obstetrician/Gynecologist-in-Chief
Department of Gynecology and Obstetrics
Johns Hopkins University School of Medicine
Johns Hopkins Hospital
Baltimore, Maryland

SUSAN FUCHS, M.D. [116]
Associate Director
Division of Pediatric Emergency Medicine
Children's Memorial Hospital
Chicago, Illinois
Associate Professor of Pediatrics
Northwestern University Medical School
Chicago, Illinois

WADE R. GAASCH, M.D., F.A.C.E.P. [72]
Assistant Professor of Surgery
Clinical Director
Adult Emergency Services and Medical Director
Maryland ExpressCare
Division of Emergency Medicine
University of Maryland School of Medicine
Baltimore, Maryland

E. JOHN GALLAGHER, M.D. [68]
University Chair
Department of Emergency Medicine
Professor of Emergency Medicine, Medicine, Epidemiology, and Social Medicine
Albert Einstein College of Medicine
Bronx, New York

DAVID R. GENS, M.D., F.A.C.S. [16]
Assistant Professor
Department of Surgery and Program in Trauma
University of Maryland School of Medicine
R. Adams Cowley Shock Trauma Center
University of Maryland Medical Center
Baltimore, Maryland

MAXIME ALIX GILLES, M.D. [60]
Clinical Faculty
Co-Director, Medical Students
Department of Emergency Medicine
Case Western Reserve University
MetroHealth Emergency Medicine
Cleveland, Ohio

LEWIS R. GOLDFRANK, M.D. [303]
Associate Professor of Clinical Medicine
New York University School of Medicine
Director of Emergency Medicine
Bellevue Hospital
Center and New York University Medical Center
New York, New York

BRIAN GOLDMAN, M.D., F.A.C.E.P. [223]
Assistant Professor
Department of Family and Community Medicine
University of Toronto
Staff Emergency Physician
Mount Sinai Hospital
Toronto, Ontario, Canada

ANTHONY GOMEZ, M.D. [94]
Attending Physician
Department of Emergency Medicine
St. Luke's-Roosevelt Hospital Center
New York, New York

HERMAN F. GOMEZ, M.D. [189]
Clinical Instructor
Division of Emergency Medicine
University of Michigan Medical Center
Ann Arbor, Michigan

PHILLIP V. GORDON, M.D., Ph.D. [4]
Fellow in Neonatal-Perinatal Medicine
Department of Pediatrics
University of North Carolina
Chapel Hill, North Carolina

SUSAN J. GOTTLIEB, M.D. [283]
Department of Psychiatry
William Beaumont Hospital
Royal Oak, Michigan

MICHELLE S. GRADY, R.N., B.S.N. [56]
Heart and Heart-Lung Transplant Coordinator
Heart and Heart-Lung Transplantation Program
University of North Carolina Hospitals
Chapel Hill, North Carolina

CHARLES S. GRAFFEO, M.D. [205]
Associate Professor and Assistant Residency Director
Department of Emergency Medicine
Eastern Virginia Medical School
Norfolk, Virginia

MATTHEW C. GRATTON, M.D. [73]
Associate Professor/EMS Medical Director
Department of Emergency Medicine
University of Missouri at Kansas City School of Medicine
Truman Medical Center
Kansas City, Missouri

GARY B. GREEN, M.D., M.P.H., .F.A.C.E.P. [45]
Assistant Professor
Director
Cardiac Evaluation Unit
Department of Emergency Medicine
Johns Hopkins University
Baltimore, Maryland

RACHELLE A. GREENMAN, M.D. [106]
Assistant Professor of Emergency Medicine
Department of Emergency Medicine
Cooper Hospital
University Medical Center
UMDNJ-Robert Wood Johnson Medical School at Camden
Camden, New Jersey

CHERYL H. HACK, M.D. [134]
Assistant Clinical Professor
Wayne State University School of Medicine
Medical Director, Myelomeningocele Care Center
Medical Director, Comprehensive Multi-Handicapped Team
Children's Hospital of Michigan
Detroit, Michigan

JASON B. HACK, M.D. [151]

THERESA A. HACKELING, M.D. [235, 236]
Attending Physician
Department of Emergency Medicine
WakeMed Center
Raleigh, North Carolina

PETER H. HACKETT, M.D., F.A.C.E.P. [191]
Affiliate Associate Professor
Department of Medicine
University of Washington School of Medicine
Seattle, Washington
Attending Physician
Emergency Department
St Mary's Hospital and Medical Center
Grand Junction, Colorado

PAUL R. HALLER, M.D. [267]
Assistant Professor
Emergency Medicine
Program University of Minnesota
Minneapolis, Minnesota

GLENN C. HAMILTON, M.D., M.S.M. [286]
Professor and Chair
Department of Emergency Medicine
Wright State University School of Medicine
Dayton, Ohio

MARK P. HAMLIN, M.D., M.S. [22]
Fellow
Critical Care Medicine
Department of Anesthesiology and Critical Care Medicine
Johns Hopkins University School of Medicine
Baltimore, Maryland

DANIEL G. HANKINS, M.D., F.A.C.E.P. [6]
Assistant Professor
Department of Emergency Medicine
Mayo Clinic
Medical Director
Mayo Medical Transport and Communications
Rochester, Minnesota

KAREN N. HANSEN, M.D. [163]
Assistant Professor
Department of Emergency Medicine
Johns Hopkins University Baltimore, Maryland

CHRISTINA E. HANTSCH, M.D. [99]
Medical Toxicology Fellow
Middle Tennessee Poison Center
Center for Clinical Toxicology
Vanderbilt University Medical Center
Nashville, Tennessee

FRED P. HARCHELROAD, JR., M.D. [195]
Director
Medical Toxicology Treatment Center
Associate Professor
Department of Emergency Medicine
MCP-Hahneman School of Medicine
Allegheny General Hospital
Pittsburgh, Pennsylvania

KAREN J. MORRILL HARDART, M.D. [108]
Attending Physician
Department of Obstetrics and Gynecology
Anne Arundel Medical Center
Annapolis, Maryland

RICHARD A. HARRIGAN, M.D., F.A.C.E.P. [155, 202]
Associate Professor of Medicine
Temple University School of Medicine
Acting Chief and Associate Research Director
Division of Emergency Medicine
Temple University Hospital
Philadelphia, Pennsylvania

ANN L. HARWOOD-NUSS, M.D., F.A.C.E.P. [138]
Professor and Assistant Dean for Educational Affairs
Department of Emergency Medicine
University of Florida Health Science Center-Jacksonville
Jacksonville, Florida

M. YOUSUF HASAN, M.D., F.A.A.P. [112]
Fellow
Critical Care Medicine
Department of Pediatrics
University of Florida Health Science Center-Jacksonville
The Nemours Children's Clinic and Wolfson Children's Hospital
Jacksonville, Florida

WILLIAM E. HAUDA II, M.D. [10, 127, 224]
Assistant Clinical Professor of Emergency Medicine
George Washington University School of Medicine
Washington, DC
Clinical Instructor of Pediatrics
University of Virginia School of Medicine
Charlottesville, Virginia
Co-Director
Pediatric Emergency Medicine
Fellowship
Inova Fairfax Hospital
Falls Church, Virginia

BRUCE E. HAYNES, M.D. [193]
Medical Director
Emergency Medical Services
County of Imperial
El Centro, California
County of Orange
Santa Ana, California

MICHAEL B. HELLER, M.D., F.A.C.E.P. [295]
Director
Emergency Medicine
Residency
St. Luke's Hospital
Bethlehem, Pennsylvania
Clinical Professor
Temple University School of Medicine
Philadelphia, Pennsylvania

WILMA V. HENDERSON, M.D., F.A.C.E.P. [160]
Assistant Professor
Medical Student Coordinator
Department of Emergency Medicine
Wayne State University
Detroit, Michigan

LEE U. HERFEL, M.D. [30]
Resident
Department of Emergency Medicine
University of Kentucky
Lexington, Kentucky

ROB HERFEL, M.D. [37]
Resident
Department of Emergency Medicine
University of Kentucky
Lexington, Kentucky

PATTI J. HERLING, M.D. [296]
Assistant Professor
Department of Radiology
Section of Emergency Radiology
University of Pennsylvania Health System
Philadelphia, Pennsylvania

PETER M. HILL, M.D., M.Sc. [45]
Instructor
Assistant Chief of Service
Department of Emergency Medicine
Johns Hopkins Bayview Medical Center
Johns Hopkins University
Baltimore, Maryland

JON MARK HIRSHON, M.D., M.P.H., F.A.C.E.P., F.A.A.E.M. [8]
Assistant Professor
Department of Emergency Medicine
Johns Hopkins University
Baltimore, Maryland

ROBERT S. HOFFMAN, M.D, F.A.C.E.P., F.A.A.C.T., F.A.C. M.T. [151, 162]
Assistant Professor of Clinical Surgery and Emergency Medicine
New York University School of Medicine
Director
New York City Poison Center
New York, New York

TERESITA M. HOGAN, M.D., F.A.C.E.P. [247]
Associate Professor
Department of Emergency Medicine
University of Illinois
Program Director
Resurrection Emergency Medicine
Residency Program
Resurrection Medical Center
Chicago, Illinois

JUDD E. HOLLANDER, M.D. [47, 48]
Associate Professor
Clinical Research Director
Department of Emergency Medicine
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania

JEREMY J. HOLLERMAN, M.D. [256]
Assistant Chief
Department of Medical Imaging
Hennepin County Medical Center
Minneapolis, Minnesota
Assistant Professor
Department of Radiology
University of Minnesota School of Medicine
Minneapolis, Minnesota

CHRISTOPHER M. HOLMES, M.D. [122]
Department of Pediatrics
University of Michigan Medical Center
Ann Arbor, Michigan

RONALD D. HOLMES, M.D. [122]
Clinical Professor

Division of Pediatric Gastroenterology
Department of Pediatrics and Communicable Diseases
University of Michigan Medical Center
Ann Arbor, Michigan

EDMOND A. HOOKER, M.D. [84, 85]
Assistant Clinical Instructor
Department of Emergency Medicine
University of Louisville
Louisville, Kentucky

MARK A. HOSTETLER, M.D., F.A.C.E.P. [201]
Assistant Professor
Associate Director
Pediatric Emergency Medicine
Departments of Emergency Medicine and Pediatrics
Vanderbilt University
Nashville, Tennessee

DAVID S. HOWES, M.D., F.A.C.E.P. [90, 93]
Program Director
University of Chicago Emergency Medicine
Residency
Associate Professor of Clinical Medicine
University of Chicago
Chicago, Illinois

J. STEPHEN HUFF, M.D., F.A.C.E.P. [221, 222]
Associate Professor of Emergency Medicine and Neurology
Department of Emergency Medicine
University of Virginia
Charlottesville, Virginia

ROGER LOYD HUMPHRIES, M.D. [62]
Assistant Professor
Department of Emergency Medicine
University of Kentucky
Lexington, Kentucky

OLIVER L. HUNG, M.D. [165]
Assistant Professor of Clinical Surgery and Emergency Medicine
Department of Emergency Medicine
Bellevue Hospital
Center and New York University Medical Center
New York, New York

D. MONTE HUNTER, M.D. [275]
Clinical Instructor Section of Sports Medicine
Department of Orthopaedics UCLA Medical Center
Los Angeles, California

JEFFERY C. HUTZLER, M.D. [281]

KENNETH G. JACKIMCZYK, M.D., F.A.C.E.P. [285]
Associate Chairman
Director of Academic Affairs
Department of Emergency Medicine
Maricopa Medical Center
Phoenix, Arizona

RAYMOND E. JACKSON, M.D., M.S. [29]
Clinical Associate Professor
Wayne State University School of Medicine
Department of Emergency Medicine
William Beaumont Hospital
Royal Oak, Michigan

DAVID M. JAFFE, M.D., F.A.A.P., F.A.C.E.P. [116]
Professor of Pediatrics
Director
Division of Emergency Medicine
Washington University School of Medicine
Director
Emergency Services
St. Louis Children's Hospital
St. Louis, Missouri

DAVID M. JANICKE, M.D. [100]
Associate Research Director Clinical Assistant Professor
Department of Emergency Medicine
State University of New York-Buffalo Millard Fillmore Hospital
Buffalo, New York

DIETRICH VON KUENSSBERG JEHLE, M.D., F.A.C.E.P. [109]
Director of Emergency Services Erie County Medical Center
Associate Professor and Vice Chairman
Department of Emergency Medicine
State University of New York at Buffalo Buffalo, New York

GARY A. JOHNSON, M.D., F.A.C.E.P. [54]
Associate Professor

Residency Program Director
Department of Emergency Medicine
State University of New York Health Sciences Center at Syracuse
Syracuse, New York

ELAINE B. JOSEPHSON, M.D., F.A.C.E.P. [94]
Attending Physician
Department of Emergency Medicine
St. Luke's-Roosevelt Hospital Center
New York, New York

JONATHAN JUI, M.D., M.P.H. [28, 149]
Associate Professor
EMS Medical Director, Multnomah County
Department of Emergency Medicine
Oregon Health Sciences University Portland, Oregon

LAWRENCE M. KATZ, M.D., F.A.C.E.P. [20]
Assistant Professor
Department of Emergency Medicine
University of North Carolina Chapel Hill School of Medicine
Chapel Hill, North Carolina

GABOR D. KELEN, M.D. [21, 23, 139, 251, 254]
Professor and Chair
Department of Emergency Medicine
Johns Hopkins University
Baltimore, Maryland

ARTHUR L. KELLERMANN, M.D., M.P.H., F.A.C.E.P. [258]
Professor and Chair
Department of Emergency Medicine
Emory University School of Medicine
Director
Center for Injury Control
Rollins School of Public Health
Emory University
Atlanta, Georgia

SCOTT S. KELLEY M.D. [272]
Vice-Chairman and Associate Professor
Department of Orthopaedic Surgery
University of North Carolina at Chapel Hill
Chapel Hill, North Carolina

WILLIAM P. KERNS II, M.D., F.A.C.E.P., A.C.M.T. [169]
Clinical Instructor
Department of Emergency Medicine
Carolinas Medical Center
Charlotte, North Carolina

SORABH KHANDELWAL, M.D. [64, 65]
Attending Physician
Department of Emergency Medicine
Assistant Professor
The Ohio State University College of Medicine
Columbus, Ohio

MARK A. KIRK, M.D. [168]
Medical Toxicology Fellowship Director
Indiana Poison Center and Emergency Medicine and Trauma Center at Methodist Hospital
Indiana University School of Medicine
Indianapolis, Indiana

THOMAS D. KIRSCH, M.D., M.P.H., F.A.C.E.P. [247]
Chairman
Department of Emergency Medicine
Resurrection Medical Center
Chicago, Illinois

NIRANJAN KISSOON, M.B.B.S., F.A.A.P., F.C.C.M., F.R.C.P.(C.) [112]
Professor and Chief Division of Critical Care Medicine
Department of Pediatrics
University of Florida Health Science Center-Jacksonville
The Nemours Children's Clinic and Wolfson Children's Hospital
Jacksonville, Florida

KENNETH W. KIZER, M.D., M.P.H. [192]
Department of Veterans Affairs
Under Secretary for Health
Washington, DC

JEFFREY A. KLINE, M.D. [170]
Assistant Director of Research
Department of Emergency Medicine
Carolinas Medical Center
Charlotte, North Carolina

SANFORD H. KOLTONOW, M.D., Psy.S., F.A.C.E.P. [288]
Attending Physician
Residency Faculty

Director of Physician Wellness Programs
Department of Emergency Medicine
William Beaumont Hospital
Royal Oak, Michigan

MAYBELLE KOU, M.D. [120, 133]

RONALD F. KOURY, D.O. [43]
Resident
Department of Emergency Medicine
University of Kentucky
Lexington, Kentucky

SHAHEED I. KOURY, M.D., F.A.C.E.P. [30]
Assistant Professor
Department of Emergency Medicine
University of Kentucky Lexington, Kentucky

ALAN J. KOZAK, M.D. [227]
Attending Physician
Division of Infectious Disease
Department of Medicine
Mary Imogene Bassett Hospital
Cooperstown, New York

DANIEL J. KRANITZ, D.O. [167]
Attending Staff
Department of Emergency Medicine
Cleveland Clinic Foundation Cleveland, Ohio

GARY S. KRAUSE, M.D., M.S., F.A.C.E.P. [19]
Professor
Department of Emergency Medicine
Wayne State University School of Medicine
Detroit, Michigan

RICHARD S. KRAUSE, M.D. [100]
Clinical Assistant Professor
Department of Emergency Medicine
Buffalo General Hospital
State University of New York at Buffalo
Buffalo, New York

STEVEN KRONICK, M.D., M.S. [86]
Lecturer
Department of Emergency Medicine
University of Michigan
Ann Arbor, Michigan

LOUIS J. KROOT, M.D., F.A.C.E.P. [35, 44]
Associate Professor
Department of Emergency Medicine
University of Kentucky
Chandler Medical Center
Lexington, Kentucky

GLORIA J. KUHN, D.O., Ph.D, F.A.C.E.P.
Associate Professor
Virginia Commonwealth University
Medical College of Virginia
Director of Faculty Development
Department of Emergency Medicine
Richmond, Virginia

ALLAN KUMAR, M.D. [255]

MYRON M. LABAN, M.D. [273, 274]
Director
Physical Medicine and Rehabilitation
William Beaumont Hospital
Royal Oak, Michigan

RICHARD L. LAMMERS, M.D., F.A.C.E.P. [42]
Research Director
Michigan State University and Kalamazoo Center for Medical Studies
Associate Professor of Emergency Medicine
Michigan State University
Kalamazoo, Michigan

JAMES L. LARSON, JR., M.D. [264]
Assistant Professor
Department of Emergency Medicine
University of North Carolina Chapel Hill School of Medicine
Chapel Hill, North Carolina

HARRISON A. LATIMER, M.D. [272]
Kinston Clinics
Kinston, North Carolina

FRANK W. LAVOIE, M.D. [76]
Chief

Department of Emergency Medicine
Southern Maine Medical Center
Biddeford, Maine

EDWARD LEE, M.D. [95]
Attending Physician
Department of Emergency Medicine
St. Luke's-Roosevelt Hospital Center
New York City, New York

NADINE LEVICK, M.D. [32, 130]
Assistant Professor
Division of Pediatric Emergency Medicine
Department of Pediatrics
Johns Hopkins University School of Medicine
Baltimore, Maryland

HORACE K. LIANG, M.D., M.A., F.A.C.E.P., F.A.A.E.M. |206, 207]
Assistant Professor of Emergency Medicine
Residency Director
Department of Emergency Medicine
Johns Hopkins University School of Medicine
Baltimore, Maryland

ERICA L. LIEBELT, M.D. [32, 130]
Assistant Professor
Division of Pediatric Emergency Medicine
Department of Pediatrics
Johns Hopkins University School of Medicine
Baltimore, Maryland

G. PATRICK LILJA, M.D. [1]
Clinical Professor
Department of Emergency Medicine
University of Minnesota School of Medicine
North Memorial Medical Center
Minneapolis, Minnesota

JOÃO A. C. LIMA, M.D. [57]

MICHAEL LONDNER, M.D. [23, 107]
Instructor
Department of Emergency Medicine
Johns Hopkins University School of Medicine
Baltimore, Maryland

KEITH E. LORING, M.D., M.P.H., F.A.C.E.P. [227]

Assistant Professor
Department of Emergency Medicine
Eastern Virginia Medical School
Norfolk, Virginia

JEFFREY S. MENKES, M.D. [259]
Attending Physician
Department of Traumatology and Emergency Medicine
Hartford Hospital
Hartford, Connecticut
Assistant Professor of Emergency Medicine
University of Connecticut School of Medicine
Farmington, Connecticut

JOHN T. MEREDITH, M.D., F.A.C.E.P. [145]
Assistant Professor
Department of Emergency Medicine
East Carolina University School of Medicine
Greenville, North Carolina

JOHN A. MICHAEL, M.D., F.R.C.P.C., F.A.A.E.M. [268, 269]
Attending Physician
The North Shore Medical Center
Salem, Massachusetts

HUBERT S. MICKEL, M.D., F.A.C.E.P. [218]
Assistant Professor
Department of Emergency Medicine
Johns Hopkins Bayview Medical Center
Johns Hopkins University
Baltimore, Maryland

SALVATORE A. MIGLIORE, M.D. [247]
Resident Physician
Resurrection Emergency Medicine
Residency Program
Resurrection Medical Center
Chicago, Illinois

MICHAEL R. MILL, M.D., F.A.C.S., F.A.C.C., F.C.C.P. [56]
Professor and Interim Chief
Division of Cardiothoracic Surgery
Director
Heart and Heart-Lung Transplantation Program
Director
University of North Carolina Comprehensive Transplantation Center
University of North Carolina at Chapel Hill School of Medicine
University of North Carolina Hospitals
Chapel Hill, North Carolina

KIRK C. MILLS, M.D., F.A.C.E.P. [152-154]
Medical Toxicologist
Assistant Clinical Professor
Department of Emergency Medicine
Detroit Receiving Hospital
Detroit, Michigan

JOHN D. MITCHELL, M.D. [230]
Program Director
Ophthalmology Residency
Washington National Eye Center/Washington Hospital Center
Washington, DC
Attending Physician, Emergency Medicine
Fair Oaks Hospital
Fairfax, Virginia

DONALD A. MOFFA, JR., M.D. [59]
Clinical Faculty
Department of Emergency Medicine
Case Western Reserve University
MetroHealth Emergency Medicine
Cleveland Clinic Foundation

Cleveland, Ohio

JOEL MOLL, M.D. [61, 92]
Senior Instructor
Case Western Reserve University
Department of Emergency Medicine
MetroHealth Medical Center
Cleveland, Ohio

GREGORY P. MOORE, M.D., F.A.C.E.P. [285]
Clinical Associate Professor
Department of Emergency Medicine
Indiana University School of Medicine
Attending Faculty
Methodist Hospital
Indianapolis, Indiana

DEXTER L. MORRIS, Ph.D., M.D., F.A.C.E.P. [137]
Vice-Chair
Associate Professor
Department of Emergency Medicine
University of North Carolina Chapel Hill School of Medicine
Chapel Hill, North Carolina

LAURIE MORRISON, M.D., F.R.C.P.C., A.B.E.M. [98]
Director
Division of Emergency Medicine
Assistant Professor
Department of Medicine
University of Toronto
Department of Emergency Services
Sunnybrook and Women's Health Sciences Center
Toronto, Ontario, Canada

ROBERT L. MUELLEMAN, M.D., F.A.C.E.P. [260]

Professor and Chairman
Department of Emergency Medicine
Virginia Commonwealth University's Medical College of Virginia
Richmond, Virginia

HAROLD H. OSBORN, M.D., F.A.C.E.P. [143, 172]
Professor and Chair
Department of Emergency Medicine
Long Island College Hospital
Brooklyn, New York

DAVID T. OVERTON, M.D., M.B.A., F.A.C.E.P., F.A.C.P. [70]
Emergency Medicine
Program Director
Michigan State University Kalamazoo Center for Medical Studies
Professor and Chairman of Emergency Medicine
Michigan State University College of Human Medicine
Kalamazoo, Michigan

JOSEPH PAGANE, M.D. [228]
Attending Physician
Department of Emergency Medicine
Orlando Regional Healthcare System
Orlando, Florida

PETER J. PAGANUSSI, M.D., F.A.C.E.P. [133]
Department of Emergency Medicine
Inova Fairfax Hospital
Falls Church, Virginia

ARTHUR M. PANCIOLI, M.D., F.A.C.E.P. [74]
Assistant Professor
Associate Residency Director
Department of Emergency Medicine
University of Cincinnati College of Medicine
Cincinnati, Ohio

WILLIAM FRANKLIN PEACOCK IV, M.D., F.A.C.E.P. [92, 232, 233]
Director of Clinical Operations
Department of Emergency Medicine
The Cleveland Clinic
Associate Professor
Department of Emergency Medicine
Ohio State University
Cleveland, Ohio

DEBRA G. PERINA, M.D. [204]
Associate Professor
Director
Prehospital Care Division
Medical Director
Pegasus Flight Operations
Department of Emergency Medicine
University of Virginia
Health Sciences Center
Charlottesville, Virginia

JEANMARIE PERRONE, M.D. [162]
Co-Director, Division of Toxicology
Assistant Professor
Department of Emergency Medicine
University of Pennsylvania School of Medicine
Attending Physician
Emergency Department
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania

SHAWNA J. PERRY, M.D. [138]
Department of Emergency Medicine
University of Florida Health Science Center-Jacksonville
Jacksonville, Florida

PAMELA L. PIGGOTT, M.D. [199]
Resident Physician
Department of Emergency Medicine
Pitt County Memorial Hospital
East Carolina University School of Medicine
Greenville, North Carolina

NANCY A. POOK, M.D. [126]
Assistant Clinical Professor
Department of Emergency Medicine
Kettering Medical Center

Dayton, Ohio

Bellevue Hospital
Center and New York University Medical Center
New York, New York

ROBERT F. REARDON, M.D. [109]
Assistant Professor of Clinical Emergency Medicine
University of Minnesota
Department of Emergency Medicine
Hennepin County Medical Center
Minneapolis, Minnesota

SEAN M. REES, M.D. [183]
Attending Physician
Bethesda and Good Samaritan Hospitals
Cincinnati, Ohio

EARL J. REISDORFF, M.D. [41]
Program Director
Department of Emergency Medicine
Inghram Regional Medical Center
Lansing, Michigan

NICHOLAS C. RELICH, M.D. [129]
Co-Director
Neonatal Intensive Care Unit
Department of Emergency Medicine
St. John Hospital and Medical Center
Detroit, Michigan

JOSEPH G. RELLA, M.D. [173, 184]
Clinical Instructor Surgery and Emergency Medicine
New York University School of Medicine
Fellowship in Medical Toxicology
New York City Poison Control Center
New York, New York

KATHY J. RINNERT, M.D., M.P.H. [148]
Instructor in Emergency Medicine
EMS Fellowship Director
Department of Surgery
Division of Emergency Medicine
University of Texas Southwestern Medical Center at Dallas
Parkland Health and Hospital Systems
Dallas, Texas

EMANUEL P. RIVERS, M.D., M.P.H. [26]
Assistant Professor of Emergency Medicine and Surgery
Director of Research
Department of Emergency Medicine
Associate Director of Hyperbaric Therapy
Department of Emergency Medicine
Henry Ford Health Systems
Case Western Reserve University
Detroit, Michigan

WALTER C. ROBEY III, M.D. [176]
Clinical Associate Professor of Emergency Medicine
Associate Director
Emergency Medicine
Residency Program
East Carolina University School of Medicine
Greenville, North Carolina

MARIBEL RODRIGUEZ, M.D., F.A.C.E.P. [124]
Department of Emergency Medicine
Inova Fairfax Hospital
Falls Church, Virginia

A. MICHAEL ROMAN, M.D., F.A.C.E.P. [14]
Assistant Professor
Department of Emergency Medicine
University of Arkansas Medical Sciences
Little Rock, Arkansas

C. RICHARD ROSS, M.D., Ph.D. [95]
Attending Physician
Department of Emergency Medicine
St. Luke's-Roosevelt Hospital Center
New York, New York

RICHARD E. ROTHMAN, M.D., Ph.D. [139]
Assistant Professor
Department of Emergency Medicine
Johns Hopkins University
Baltimore, Maryland

MARCIE RUBIN, M.D., F.A.C.E.P. [11]
Department of Emergency Medicine
Brigham and Women's Hospital
Boston, Massachusetts

JOHN P. RUDZINSKI, M.D. [263]
Department of Emergency Medicine
Rockford Memorial Hospital
Rockford, Illinois

ERNEST RUIZ, M.D. [267, 270]
Professor and Director
Emergency Medicine Program
University of Minnesota
Minneapolis, Minnesota

DOUGLAS A. RUND, M.D., F.A.C.E.P. [77, 280-282]
Professor and Chairman
Department of Emergency Medicine
Ohio State University
University Medical Center
Columbus, Ohio

MICHEAL D. RUSH, M.D. [209]
Assistant Program Director
Department of Emergency Medicine
University of Missouri-Kansas City School of Medicine
Truman Medical Center
Kansas City, Missouri

WILLIAM A. RUTALA, Ph.D., M.P.H. [141]
Professor of Medicine
Director, Occupational Health, Hospital Epidemiology, and

Environmental Health and Safety
University of North Carolina at Chapel Hill
University of North Carolina Hospitals
Chapel Hill, North Carolina

ALEXANDER H. SACKEYFIO, M.D. [283]

The Study Guide is the fifth edition to follow the first one published by the American College of Emergency Physicians in 1979. The increasing complexity of each edition has reflected the maturation of our practices over twenty years.

To prepare for this edition, we solicited written reviews of the fourth edition from emergency medicine residents, clinical practitioners, and academicians. We expanded the format of the Study Guide to incorporate evidence from the medical literature to support clinical practice. Chapter structure was improved, several new sections have been added, and many new emergency medicine authors were recruited. It is surprising how little of the practice of medicine is founded on the results of clinical investigation. We hope that our readers and users will be stimulated to design their own clinical investigations to help us improve our future practices.

We have incorporated the EMRA Antibiotic Handbook into the body of the Study Guide, to make this excellent resource more widely available.

The list of reviewers and authors for the Study Guide is impressive. We are especially proud of the many contributions by young emergency medicine faculty and practitioners. Their knowledge, clinical expertise, and commitment to emergency medicine reflect positively on our specialty.

Of the skills important for an emergency physician-knowledge, technical proficiency, compassion, and wisdom-this book can only provide the first, knowledge, to help us practice. Technical ability is learned at the bedside under the watchful eyes and hands of a teacher-a book cannot guide your hands through a difficult procedure. Compassion comes from the values and beliefs that we bring to our profession-a book cannot infuse us with compassion and advocacy for the patients we treat. And wisdom comes from awareness of your own strengths, weaknesses, abilities, and limitations. Our hope is that this text, containing the experience of hundreds of emergency physicians, will stimulate your own development as an emergency physician.

1 EMERGENCY MEDICAL SERVICES

G. Patrick Lilja
Robert A. Swor

Emergency medical services (EMS) constitute the extension of emergency medical care into the community. Strong emergency department leadership is absolutely essential to a safe and effective EMS system.

The 1966 National Highway Safety Act authorized the US Department of Transportation (DOT) to fund ambulances, communications, and training programs for prehospital medical services.[1] Coincidentally, in 1967 J. Frank Pantridge began using a mobile coronary care unit in Belfast, Northern Ireland, to extend coronary care into the prehospital setting.

In 1973, public law 93-154 defined a goal of improving emergency medical care and EMS on a national scale. Although much has changed in EMS since passage of that initial act, the original definition of EMS systems is useful for understanding their functions. This law identified 15 elements of an EMS system: (1) personnel, (2) training, (3) communications, (4) transportation, (5) facilities, (6) critical care units, (7) public safety agencies, (8) consumer participation, (9) access to care, (10) transfer of care, (11) standardization of patients' records, (12) public information and education, (13) independent review and evaluation, (14) disaster linkage, and (15) mutual aid agreements. Thus, an EMS system is the entire system in place to provide care to emergency patients, from the initial 911 call until definitive care is rendered.

State laws broadly outline what is safe and prudent for the public good. State EMS laws and regulations typically define levels of ambulance service capability, training requirements, equipment requirements, and requirements for physician leadership and accountability. In addition, the state health department may be the lead agency in promoting and funding EMS activity.

LOCAL ROLE IN EMERGENCY MEDICAL SERVICES

To be effective, an EMS system must be planned, organized, and operated at the local level. Any community contemplating an EMS system must identify its resources and needs and determine how much service its citizens are willing or able to afford. The 15 elements of an EMS system defined by public law 93-154 can provide guidance in this process. Each element is discussed below.

Personnel

In urban areas, public safety and ambulance personnel provide prehospital medical care, but in rural or wilderness areas, volunteers, park rangers, or ski patrols are commonly employed. Citizen volunteers should not be overlooked, especially in rural communities. Public interest and participation are key ingredients in any EMS system.

Training

Training begins with the education of the private citizen. Courses in EMS system access, cardiopulmonary resuscitation (CPR), and other forms of first aid are essential. Communications media can be utilized to reach large populations with the minimum information necessary to educate citizens to respond to emergencies.

Some communities use a dual-response system consisting of first responders (FRs) followed by ambulance personnel. The FRs may be firefighters, police, park rangers, or citizen volunteers. The DOT National Highway Traffic Safety Administration (NHTSA) was initially given the responsibility of developing training curricula for EMS providers. The use of these curricula was tied to receipt of federal EMS grants, and the training programs were widely accepted and utilized nationally. Although their use is no longer required, DOT training standards are the de facto national standard for EMS education. Training for FRs may include the DOT FR course (which encompasses 60 h of classroom training) or similar courses developed by the American Red Cross or American Heart Association. The training for ambulance personnel usually requires completion of an emergency medical technician (EMT) course. Although various levels of EMT training have evolved in various states, there are three nationally recognized levels of EMTs: EMT basic (EMT-B), EMT intermediate (EMT-I), and EMT paramedic (EMT-P). The EMT-Bs have the necessary first aid skills to take care of immediately life-threatening prehospital emergency conditions. These skills include CPR, use of an automated external defibrillator (AED), and safe extrication, immobilization, and transportation of emergency victims. EMT-Bs are now being trained to assist patients in using their own nitroglycerin, epinephrine, and inhalers. There is an optional module in the DOT EMT-B curriculum on advanced airway techniques; it teaches EMT-Bs to perform endotracheal intubation or to use an advanced airway adjunct, such as a Combitube (Sheridan Corp, Argyle, NY). The decision to teach the optional airway module is generally made by the state EMS agency. EMT-I training includes the additional skills of intravenous access, pneumatic antishock garment use, and advanced airway techniques. EMT-P training adds drug therapy for selected prehospital conditions, interpretation of electrocardiogram (ECG) rhythms, synchronized cardioversion, and manual defibrillation. Clearly, physicians need to be deeply involved in EMT training to ensure that knowledge and skills are being taught appropriately and safely.

Communications

The universal 911 emergency telephone number, available in most locations, has greatly facilitated citizens' access to emergency medical care. In many systems, 911 answering centers have enhanced 911 (E-911) equipment that provides automatic number and location identification as well as additional information to assist the responding personnel. However, the advent of cellular telephones has complicated this process. In some urban areas, up to 25 percent of all 911 calls are made from cellular phones. Technology is being developed to address this issue.

The call to 911 is the essential front door of the EMS system. The EMS system must assure that those answering the calls have the knowledge and training to

properly obtain initial medical information, dispatch appropriate personnel, and offer first aid information to the caller when appropriate. A variety of courses have been developed to train 911 dispatchers, those who answer calls and dispatch appropriate personnel and equipment. The 911 center must have adequate staff and equipment to ensure that calls are answered and responded to in a timely manner. The public should be encouraged to use the 911 number rather than call a hospital or physician when certain symptoms (e.g., acute chest pain, dyspnea, loss of consciousness, or focal weakness) occur.

Information can be collected and ambulances dispatched by the 911 center in many ways. The process known as priority dispatch utilizes structured information gathering by the 911 dispatcher, followed by direction concerning the most appropriate EMS response. Use of this procedure is on the rise. Many of the 911 dispatch protocols also contain first aid information that the dispatcher can give to the caller so that the caller can provide care until EMS arrives. Ambulance personnel must be able directly or indirectly to communicate with the hospital of destination. Most EMTs operate in the field under "off-line" medical control, according to standing orders and patient care protocols developed by physicians. However, there are times when EMS personnel may require "on-line" medical control, in which they talk directly with a physician for specific direction or orders. The communications system functions to provide public access, prompt dispatch of the appropriate vehicles and personnel, timely hospital notification, and on-line medical control.

Transportation

Ground ambulances have evolved from transport vehicles into sophisticated and efficient mobile patient care areas where lifesaving maneuvers can be performed. Federal standards provide specifications for ambulance construction, and vehicles that meet these specifications can display the "star of life" emblem. Nontransporting vehicles, such as rescue response units, carry personnel and equipment to the scene but cannot transport patients. Type I ambulances have a conventional cab and chassis fitted with a modular patient care compartment; there is no passageway between the driver's and the patient's compartments.Type II ambulances are van-type vehicles; the body and the cab form a single unit, and most models have a raised roof for extra stand-up space. Type III ambulances are larger units with a forward cab connected by a walk-through passage to the patient care compartment. The most important aspect of ambulance design is that the attendants must be able to provide airway and ventilatory support while safely transporting the patient. Basic life support (BLS) ambulances carry equipment appropriate for attendants trained at the EMT-B level. Advanced life support (ALS) ambulances are equipped for EMT-Ps or other health care personnel capable of providing drug therapy and performing other advanced medical procedures. Ground transportation is appropriate for the majority of ill or injured patients, especially in urban and suburban areas. Air transport should be considered if the time elapsed before definitive care is important and air transport would shorten that interval.

Facilities

In general, emergency patients should be transported to the closest appropriate hospital or, if there are multiple hospitals within the same transport time, to the hospital of the patient's choice. However, if the EMS system has identified a specific hospital with better resources to treat seriously ill or injured patients (e.g., a trauma center), the patient should be transported to that institution, bypassing closer hospitals. Several systems of categorizing hospitals exist, and this process should precede or coincide with the development of the EMS system. In a number of regions, the state has the statutory authority to designate certain specialty hospitals to receive a subset of patients (most commonly trauma patients), based on an objective review of the hospitals' capabilities. Some states and the American College of Surgeons have also developed a process to provide external verification of trauma centers. This process requires a review of hospital facilities, treatment processes, and patients' outcomes to confirm that quality trauma care is in place. Many EMS systems are now also identifying hospitals as specialized receiving facilities that can provide 24-h emergency angioplasty for patients with acute myocardial infarction (AMI) or that have special expertise with thrombolytic therapy for acute stroke patients.

Decisions to divert patients to specialty centers have substantial health care and commercial implications. These decisions should be made in a collaborative manner for the EMS region based on clearly defined criteria.

Critical Care Units

Tertiary care facilities should be identified by every EMS system to provide specialty care that is not available in typical community hospitals. These facilities may be either within the EMS service area or, more commonly, outside the area. Usually, patients are initially transported to a local hospital for assessment and treatment and then transferred to a tertiary center. In some EMS regions, it may be possible to develop criteria for the transport of patients requiring tertiary specialty care directly from the scene to these centers. The most common reasons for tertiary care emergency transfer are trauma, neonatal intensive care, high-risk obstetrics, burns, spinal cord injury, and neurosurgical and cardiac care. It is not cost effective or feasible for every community to support all of these specialty services.

Public Safety Agencies

The EMS system must have strong ties with police and fire departments. Public safety officials must have input into the decisions of EMS councils, and, conversely, EMS providers must have input into public safety decisions that affect emergency medical care. Public safety agencies provide first-response services because their personnel are often the first on the scene of an emergency, and they are vital links in the delivery of emergency care. For example, police in some municipalities have begun carrying automatic defibrillators in order to improve outcomes for patients suffering cardiac arrest. [2]

Consumer Participation

The public must have input into the governance of its EMS system. Laypersons should be represented on EMS councils. If the public does not understand what a good EMS system offers, public support for the system, including financial support, will dwindle. Two important components of a successful EMS system are lay public first aid training and the implementation of a 911 system.

Access to Care

A successful EMS system ensures that all individuals have access to emergency care regardless of their ability to pay or type of insurance coverage. Often the EMS system is a patient's only point of entry into the health care system. As pressure increases to control health care costs, patients may be discouraged by a variety of sources from accessing the EMS system for perceived emergencies. Emergency physicians must serve as patients' advocates on this issue to ensure that patients access the system in a timely fashion.

A more difficult problem exists when population densities or terrain dictate longer response times for some citizens than others. EMS councils must be able to handle such inequities, which are, both politically and economically, difficult to adjust. Typically, EMS councils are advisory bodies to county boards or other political entities. An informed, representative governing body ultimately makes the best decisions.

Transfer of Care

Patients must sometimes be transferred from one medical care facility to another either within or outside of the EMS service area. These transfers must be made with maximum safety for the patient. Many problems can be avoided if both the transferring and the receiving medical facilities develop transfer agreements in advance. For example, the prospective agreement to accept a trauma patient decreases the time spent arranging for the transfer of a critical patient when necessary. The referring physician should be assured of receiving follow-up information about the patient, and the receiving physician should be assured of receiving all important information about the patient on arrival. Proper medical support en route should be ensured by establishing contact with the receiving center as soon as possible and having appropriate medical personnel accompany the patient.

Standardization of Patients' Records

A patient's care depends on good medical records, and prehospital records are no exception. All ambulance services within a specific region should use a similar reporting form that can be quickly and easily interpreted by receiving nurses and physicians. It is more difficult to standardize emergency department records. However, flow sheets that are easily interpretable by receiving physicians and nurses can be used. Uniform data elements for EMS care have been developed by the NHTSA and are coming into common use.[3] Uniform data elements for emergency department care have also been developed by a cooperative effort among the NHTSA, the Centers for Disease Control, and many emergency medical organizations. It is wise to design record systems that facilitate data extraction for trauma

registries, severity scoring, and cardiac arrest outcome studies.

Public Information and Education

The public should be well informed on how to deal with medical emergencies. In designing a public information program, the EMS council should consider the following:

1. The public should understand how the community stands to benefit from an excellent EMS system.
2. The public should be prepared to render first aid care.
3. The public must know how to access the EMS system quickly.
4. The public should understand that patients may not be delivered to the hospital of their choice under life-threatening conditions.

Independent Review and Evaluation

Governing agencies should be assured that there is ongoing review of the EMS system. Monitoring of radio communications, review of response times, and review of patients' care records are relatively mechanical methods of quality control that are easily implemented. Outcome studies of such entities as cardiac arrest and multiple trauma require considerable physician input and cooperation. The system medical director should require that mechanisms be in place to ensure and improve the quality of EMS care. EMS system access to hospital charts should be a requirement for participating hospitals, with proper controls to ensure patients' confidentiality.

Disaster Linkage

The EMS system is an integral part of disaster preparedness and should be involved in planning and practice drills along with public safety agencies and others. Public safety agencies should keep the EMS system informed of potential disaster situations or hazards that may temporarily be present. Also, hospitals must be prepared to keep the EMS system informed of their capacity to receive certain kinds of patients under disaster conditions.

Mutual Aid Agreements

EMS services should develop mutual aid agreements with neighboring jurisdictions so that uninterrupted emergency care is available when local agencies are overwhelmed or unable to provide services.

MEDICAL CONTROL

A safe and effective EMS system requires considerable physician input and surveillance to provide the best possible care for patients. [4] Medical control can be either on line (immediate and direct) or off line (indirect).

On-line medical control is the provision of direct medical communication to personnel in the field either in person or by radio or phone communication. The EMS medical director delegates this authority to other physicians who understand the protocols under which paramedics administer care. Also, the medical director may allow ambulance personnel to carry out certain standing orders when timely contact with the controlling physician is not feasible.

Off-line medical control is the responsibility of the service medical director. Three main components of off-line medical control are (1) development of protocols, (2) development of medical accountability (quality assurance), and (3) development of ongoing education. Protocol development determines those treatment procedures that prehospital personnel may perform under the medical license of the medical director. Protocols should not only address care but should also specify the utilization of medical devices and equipment. It is the medical director's responsibility to approve the medical devices utilized by EMS personnel. The protocols must be reviewed and rewritten on a regular basis to keep pace with current medical knowledge. Quality assurance requires ongoing surveillance and study of the system. The medical director should enlist other physicians to review existing protocols and suggest improvement where deficiencies are noted. Finally, the medical director is responsible for the ongoing educational needs of the prehospital care providers under his or her direction. The medical director should direct the quality and content of the training. Physicians must remember that they have the ultimate responsibility for the overall quality of prehospital medical care.

MEDICAL BASIS FOR EMERGENCY MEDICAL SERVICES

While a relatively small number of emergency physicians are involved in the direction and control of an EMS system, virtually every emergency physician deals with prehospital care in day-to-day practice. This section reviews the medical basis for EMS care as well as common problems in medical practice in a prehospital setting.

Emergency Cardiac Care

While it is clear that ALS saves lives after sudden cardiac arrest, the number of lives saved and the cost are often debated. [5,6] Since sudden cardiac death (SCD) is the number one cause of out-of-hospital death in the United States, the potential benefit of treatment is enormous. Some have argued that the successful treatment of out-of-hospital cardiac arrest alone by EMS systems justifies their existence. [6] Population studies with an age distribution of the entire US population find that the annual incidence of out-of-hospital cardiac arrest is about 1 per 1000. [6] In regions with a higher concentration of elderly persons, the annual incidence is higher.

Without treatment at the scene, the survival rate of out-of-hospital cardiac arrest is virtually zero. Early studies by groups in Seattle and King County, Washington, have demonstrated that as many as 26 percent of patients may be successfully resuscitated from out-of-hospital cardiac arrest. [5] Resuscitation rates in other communities are not as high. The overwhelming majority of survivors of out-of-hospital sudden cardiac arrest were those whose cardiac arrests were witnessed and who had an initial cardiac rhythm of ventricular fibrillation (VF). Multiple studies have shown that survival is clearly related to the time from the collapse of the patient to the delivery of defibrillation and that survival rates decline dramatically with delays of only a few minutes. [7]

These findings have lead a number of physicians to train FRs or EMT-Bs, who usually arrive first at the scene of an emergency, to recognize and treat VF. Systems in King County, Washington, and in Iowa have documented that this approach improves survival from cardiac arrest if the interval between collapse and defibrillation is short. That observation has lead to the wide proliferation of automated external defibrillators (AEDs). The American Heart Association has identified AED defibrillation as the standard of care for vehicles that respond to emergencies and transport patients. However, there is conflicting evidence concerning whether equipping FRs or EMT-Bs with AEDs incrementally improves survival in an existing EMS system with paramedics. [2] Clearly, a cost-benefit analysis should be undertaken in individual systems, and, if implementation of AEDs by police or fire FRs can significantly decrease the time to defibrillation in a system, this modality should be part of the system. Automatic defibrillation is clearly efficacious, but for maximum benefit (more survivors in the community) the local system must optimize the "chain of survival": early access, early CPR, early defibrillation, and early ALS. [7] Citizen awareness of the signs of cardiac arrest, quick access to the system, and rapid and appropriate dispatch of units are all critical links to maximizing survival. Pilot programs are being conducted to test whether laypersons, or targeted FRs, such as casino security guards, can effectively utilize AEDs to treat SCD patients.

Despite the emphasis on cardiac arrest during the development of EMS systems, such cases make up less than 5 percent of the volume of an EMS system. The most common clinical entities seen in EMS systems are the manifestations of cardiac disease, usually ischemic chest pain and its complications. Common treatment includes relief of ischemic chest pain with nitrates and narcotic analgesics, control of cardiac arrhythmias with antiarrhythmics, treatment of symptomatic bradyarrhythmias with external pacemakers, and treatment of congestive failure with diuretics and, if necessary, endotracheal intubation. While most EMS authorities agree that such treatment to prevent a cardiac arrest is the true benefit of an ALS system, there is a lack of research to document this assertion.

Many EMS systems are now also facilitating emergency department care through the field use of 12-lead electrocardiography (ECG). Either paramedics interpret the initial rhythm or a computer-generated algorithm is used to diagnose an AMI and contact an intended receiving facility. Limited studies have found that field ECG decreases the time to initiate thrombolysis or to perform angioplasty in patients with AMI. Some EMS systems have used field 12-lead ECG to triage AMI patients to "cardiac centers" that have been prospectively identified to provide emergency angioplasty.

Early administration of thrombolytics has been shown to significantly reduce mortality and morbidity. Logistical obstacles to field thrombolytic therapy include the

difficulty in diagnosing myocardial infarction in the field, identification of contraindications by paramedics, and management of complications by the limited resources available in the field. Studies of field administration of thrombolytics by paramedics have identified that this therapeutic approach is feasible, but it does not improve outcome when compared to patients who are diagnosed in the field (by 12-lead ECG) and are treated promptly on arrival in the emergency department. [8]

Trauma Care

While the care of trauma patients is more controversial than cardiac care for EMS systems, there is widespread agreement that delivery of critically injured trauma patients to trauma centers saves lives.[9] Systems are designed to bypass certain hospitals under predetermined protocols based on the mechanism of injury or the patient's physiologic status.

There is less agreement on what therapy should be given by EMS providers to trauma victims in the field and en route. [10,11] Some early literature documented a decreased survival rate if patients received ALS (intravenous fluid administration and intubation) at the scene instead of immediate transport to the hospital; presumably this occurred because of the delay to definitive care. More recent studies have found that paramedics may secure an airway, establish an intravenous line, and infuse significant volumes of fluid rapidly without delaying transport of the patient. While the value of providing a secure airway is unarguable, the value of prehospital intravenous fluid administration has been challenged. Thought-provoking work from Houston found that, for hypotensive victims of penetrating truncal trauma who required surgical repair, withholding fluid and blood in both the prehospital and emergency department phases until arrival in the operating room improved survival rates, reduced the amount of blood loss, and shortened the overall hospital stay compared to patients who received fluid and blood in the field and emergency department.[12] Many questions concerning the value of prehospital fluid therapy for trauma victims remain. Until further studies are done, emphasis remains on rapid transport and airway support of the trauma victim, with intravenous fluid administration an unproven but commonly performed treatment.

Adult Medical Care

While much of the initial research in EMS has centered on cardiac and traumatic emergencies, interest has evolved in management of other emergencies by EMS providers as they have broadened their scope of practice. There is evidence that prehospital ALS care improves a patient's condition during transport. [13] However, it is not known whether the ultimate outcome is improved by such care.

The management of airway obstruction and respiratory arrest is an important function of the EMS system. Airway control by endotracheal and nasotracheal intubation is readily achieved by paramedics with a high success rate and an acceptable complication rate. Early advanced airway measures for upper airway obstruction from burns, trauma, foreign body, or allergic causes may be lifesaving. Some EMS systems have shown that neuromuscular paralytic agents, such as succinylcholine, may be safely used by paramedics in the field with appropriate instruction and close medical oversight.

Respiratory distress in patients with chronic obstructive pulmonary disease and asthma is a common clinical entity treated in EMS systems. b_2 agonists have been shown to be safe and effective bronchodilators for field use. Pulse oximetric studies for the evaluation of occult hypoxemia have become widely utilized.

Paramedics are commonly called to evaluate patients with altered mental status. Glucose is frequently given to hypoglycemic patients and naloxone to patients with suspected narcotic overdose. Similarly, control of seizures with diazepam and airway support for status epilepticus are important EMS functions.

Pediatric Care

With the development of pediatric emergency care as an area of interest, experts and organizations have started to review the care of children in EMS systems. [14] It is estimated that 5 to 10 percent of a system's volume consists of pediatric cases, and the most common pediatric emergencies are trauma, respiratory emergencies, and seizures.[15] Cardiac arrest in children is rare (approximately 1 per 10,000 children per year in the United States) usually with a dismal outcome. The ability of paramedics to perform procedures to treat pediatric cardiac arrest, respiratory emergencies, and trauma is extremely variable and age dependent. For most age groups, endotracheal intubation success rates are comparable to those for adults. As would be expected, endotracheal intubation and intravenous access are performed with poor success in infants. In a large regional study of pediatric intubation, Gausche and others have shown no change in patient outcome after field endotracheal intubation.[16] The Los Angeles County EMS system has withdrawn the use of pediatric intubation by paramedics, although it has greatly increased clinical education regarding field bag-valve-mask ventilation.

RURAL EMERGENCY MEDICAL SERVICES

Most EMS literature has been developed by urban and suburban systems, with little emphasis on rural EMS care. However, rural EMS systems are an integral part of health care for the ill and injured rural patient. The rural environment provides a number of unique challenges to providers of emergency care. [17] Long distances over which to reach and transport patients are a central issue. Specialized search and rescue capabilities may be needed for off-road and wilderness emergencies. Because of the low population density of rural areas, there is a decreased likelihood that an emergency will be witnessed and emergency aid summoned. Compared to urban and suburban populations, the population in rural areas tends to be less affluent, older, and less likely to request emergency aid unless it is truly needed.

The implementation of a 911 system has not occurred in many rural communities. Enhanced 911 services, which provide automatic location identifiers, may not be as useful in rural as in urban locations because there may not be addresses to guide emergency providers. The infrastructure for basic radio communications may not be as well developed or supported. The contraction of the health care system in the United States has caused the closure of a number of hospitals, most of them in rural areas. If an emergency facility exists, it may not have specialty or critical care services. Therefore, patients must have access to air or ground interfacility transport service. Fortunately, large tertiary care facilities can facilitate these transfers, and most rural facilities are able to prospectively develop the necessary relationships and transfer agreements.

The key component of any EMS system is its personnel. Rural EMS systems face particular challenges in maintaining a cadre of EMS personnel. The volume of EMS responses in most rural communities is too low to allow for the employment of full-time EMS providers; thus, rural EMS services often use volunteers or on-call part-time personnel who are paid only when called out. Volunteer and part-time personnel have limited time for initial training and continuing education and limited experience necessary for skill maintenance. Most, but not all, rural EMS services are provided at the EMT-B level. The recent revision of the model DOT EMT curriculum allows for an increased level of service by EMT-Bs that would be useful in rural areas. They can now assist patients with self-administration of some medications (e.g., nitroglycerin for angina or bronchodilators for asthma), use AEDs for cardiac arrest, and, with the optional 10-h training module, utilize advanced airway techniques. These modifications allow a higher level of basic EMT service without having to commit rural providers to the much longer time required to obtain a higher level of certification. Innovative approaches to continuing education are also needed, particularly in isolated areas. Distance learning approaches, often in collaboration with local schools, are invaluable. Videotape conferences, satellite transmission of lectures, and computer- and Internet-based education programs are all valuable adjuncts to rural EMS continuing education.

The provision of lifesaving services on a volunteer basis entails particular obstacles. Daytime coverage for service is a challenge because most volunteers or part-time personnel have other full-time employment. As a result, many services hire a cadre of full-time providers to respond during business hours. Dispatching volunteers from home or work directly to the scene may be one method of providing daytime coverage and reducing response times. [18] Recruitment and retention of providers is an ongoing problem. To address it, volunteer services may be able to provide incentives, such as retirement benefits, death benefits, and scholarships for volunteers and their children. Undoubtedly, the most powerful incentive for EMS volunteers is the fellowship bonds that develop within volunteer EMS agencies.

Medical leadership of any EMS system is crucial. Identification of a physician who is knowledgeable and experienced in emergency care and willing to take time away from his or her family and practice is a difficult problem for rural systems. Many systems depend on nonemergency physicians, such as family physicians with an interest in community health or general surgeons with an interest in acute surgical care, to provide medical leadership.

EMERGENCY MEDICAL SERVICES AGENDA FOR THE FUTURE

With wide input from the EMS community, NHTSA sponsored the development of a visionary planning document, "The EMS Agenda for the Future." [19] This document defines EMS as the "intersection of public safety, public health, and health care systems" and as an essential component of the emergency care safety net. It proposes that EMS systems and providers play a role in illness and injury prevention. As a result, EMS systems have become involved in drowning prevention for children, social service referral and fall prevention for the elderly, and immunization of adults and children for infectious disease. [20] This concept will evolve

significantly in the years ahead.

2 PREHOSPITAL EQUIPMENT AND ADJUNCTS

Daniel G. Hankins

Early emergency medical services (EMS) equipment began as hospital equipment that was extrapolated to the field. It soon became apparent that hospital equipment did not always perform under the more rigorous conditions of out-of-hospital care. Over the last 25 years, equipment has evolved specifically for EMS that is better adapted to field use in terms of size, weight, and durability. This equipment is designed for resuscitating and packaging the patient for transport to the hospital and for maintenance of stability during emergency or interfacility transport.

Much EMS equipment has been placed in vehicles without clear-cut proof of efficacy. More and more equipment will be scrutinized for effectiveness, with good equipment being kept and useless equipment being discarded.[1] Reimbursement for out-of-hospital transports is changing, and the cost-benefit ratio becomes important in the face of ever-tightening EMS budgets. The EMS medical director should be actively involved in evaluating and choosing equipment for use in the field. The nature of EMS equipment is changing due to the expanded scope of practice by paramedics and the blurring of care levels between basic and advanced life support personnel. Equipment once considered only for advanced level care (e.g., defibrillators) is now being carried routinely on basic life support ambulances. There are still differences in the equipment carried by providers of the two levels of care, primarily due to differences in the demographics of prehospital care. Advanced life support (ALS) services tend to be paid, full-time, and urban, while basic life support (BLS) services tend to be volunteer, part-time, and rural.

There are four basic questions that must be answered about EMS equipment: (1) Does it do the job?, (2) Is it safe?, (3) Does it do the job and is it safe in the field environment?, and (4) Does it do the job and is it safe in the field environment in the hands of field personnel?[2]

VEHICLES

The equipment used in out-of-hospital care includes the vehicles and everything on them. The two most common EMS vehicles are first-response units (fire engines, police cruisers, and rescue vehicles), which do not transport patients, and ground ambulances, which do transport patients. Ground ambulances come in three common varieties: type I, a standard pick-up chassis with a modular box to carry personnel, patient, and equipment; type II, an enlarged van-type vehicle; and type III, a van chassis with a modular box on the back.

Ground vehicles have warning devices (lights and siren) as part of their equipment. Unwarranted use of red lights and sirens is dangerous for the EMS crew, any patient on board, and the general public on the streets. Ambulance transport with lights and sirens does not save significant amounts of time in most urban and suburban transports.[3] Every EMS system must have protocols or guidelines written by the medical director to use these devices only at times when medically indicated when the crew is responding to the scene, transporting the patient back to the hospital, and during interfacility transports. [4]

UNIVERSAL PRECAUTIONS

Every EMS provider must be protected against exposure to blood and other body fluids from patients. This protection includes masks, goggles, and gloves for routine use. On occasion, more extensive protection may be needed, such as gowns or perhaps heavier gloves. This equipment must be carried on any EMS vehicle.

RESUSCITATION EQUIPMENT AND THERAPEUTIC MODALITIES

Defibrillators

Defibrillators have been an essential part of out-of-hospital care since Pantridge showed that defibrillation could be done in the field on the streets of Belfast in 1965. Early defibrillation is the most important factor in surviving an out-of-hospital cardiac arrest. To meet this need, defibrillators have become smaller, less expensive, and easier to use. Many BLS services carry automated external defibrillators (AEDs) (Fig. 2-1). These devices are more precisely called shock advisory defibrillators because they analyze the patient's rhythm, determine whether a defibrillatory shock is indicated, charge the capacitors, and then inform the operator that a shock is advised. The operator can press the appropriate button to deliver the defibrillatory shock. The arrhythmia recognition algorithm of the AED is designed to advise defibrillation only for ventricular fibrillation and very fast wide QRS complex tachycardias (usually over 180 beats per minute). Rhythm monitoring and defibrillation are performed with combination pads, one placed over the cardiac apex and the other placed over the left paraspinal area at approximately the T6 level. Automated external defibrillators are designed to be used only on pulseless and apneic patients. Because AEDs have become so easy to use and function almost always as designed, a debate is ongoing whether these devices should be available for public access defibrillation by laypersons. While layperson defibrillation is beyond the scope of this discussion, there is developing evidence that rapid first-response defibrillation before the ambulance arrives, (e.g., by law enforcement officers using an AED) results in improved survival rates.[5]

FIG. 2-1. Automated external defibrillators (AEDs).

Automated external defibrillators are priced at about $2500 to $3500 for a basic version without a rhythm monitor display, $5000 to $7000 for versions with monitor display screens, and $9000 to $10,000 for versions with full-function defibrillation, synchronized cardioversion, and external pacing capabilities. The AEDs without rhythm display monitors may actually function better because a displayed rhythm may only serve to distract a non-ALS operator. The event-recording capabilities of AEDs facilitate later review of the cardiac arrest for medical oversight and quality assurance reasons. The medical director must be involved in the selection of these

devices, the training of EMS personnel, and subsequent review of their use.

Defibrillators used by ALS personnel are more sophisticated, with monitoring screens, printout units, manual defibrillation ability, and synchronized cardioversion capability. Defibrillation is often done with combination pads (as with the AED) rather than with paddles. These pads provide better contact with the skin, resulting in decreased resistance and allowing for more current to be delivered with a higher success rate for conversion. Such pads are also safer for the operator, who does not have direct contact with the patient when the shock is delivered. The monitor screen is used by the paramedics for initial interpretation of rhythms, ongoing monitoring of patients' rhythms, synchronizing a countershock for rhythms other than ventricular fibrillation, and pacing bradycardiac rhythms. The ALS defibrillators will soon be equipped with the technology to monitor blood pressures, pulse oximetry, and end tidal CO_2. The ALS personnel will use these machines for monitoring very ill patients from emergent calls or interfacility transfers.

Airway and Ventilation Adjuncts

For patients with acute respiratory failure or arrest, airway and ventilation adjuncts are useful to maintain an airway that would otherwise require continuous bag-valve-mask (BVM) ventilation. In addition, some airway adjuncts aid in preventing gastric distention or aspiration (Fig. 2-2).
FIG. 2-2. Airway devices and adjuncts. A. Combitude. B. Pharyngeal tracheal lumen airway. C. Nasopharyngeal airway. D. Oropharyngeal airway. E. Tube exchanger. F. Laryngoscope. G. Magill forceps. H. Qualitative end expiratory CO_2 detector. I and J. Stylets for endotracheal intubation. K. Endotracheal tube.

The simplest devices for airway management used with BVM ventilation are the oropharyngeal and nasopharyngeal airways. These devices prevent obstruction of the upper airway so that externally applied positive-pressure ventilation can reach the trachea. Effective portable suction devices are available that can be carried to the patient's side to help clear the airway (Fig. 2-3).
FIG. 2-3. Suction devices. A. Yankauer rigid suction catheter. B. V-Vac (Laerdal Medical Corp., Wappingers Falls, NY) portable suction device. C Flexible suction catheter.

More advanced airway devices are required if the patient needs more prolonged airway management or is at risk for aspiration. At the BLS level, available options include the pharyngeal tracheal lumen (PTL) airway, the esophagotracheal double lumen tube (or, simply, Combitube), and the laryngeal mask airway (LMA). Each of these is used in conjunction with a bag-valve for ventilation. These devices are great improvement over the old esophageal obturator airway and esophageal gastric airway, both of which had unacceptably high complication rates and are no longer recommended for use. Both the PTL and the Combitube (Sheridan Corp.) are only for adult patients in full cardiac arrest. The PTL and Combitube provide a seal in the upper airway—to promote better ventilation than the BVM with oral airway—and a seal in the esophagus—to prevent gastric regurgitation and aspiration. Both devices are passed blindly, and the tube usually passes into the esophagus. A small percentage of the time, the device goes into the trachea, where it can function as an endotracheal tube. There is some evidence that the Combitube is an easier device to use than the PTL because the large PTL mouth balloon is more easily broken than the Combitube balloon. [6] The Combitube may be easier for basic emergency medical technicians (EMTs) to ventilate through. There are few data on usage of the LMA for out-of-hospital care. While the LMA provides a seal for ventilation, it does not prevent aspiration. One possible advantage of the LMA is that it is less expensive than the Combitube or the PTL. The PTL and/or Combitube is mostly used by BLS ambulance personnel but may be used by ALS personnel (or even by hospital personnel) for a patient with a difficult airway who cannot be intubated with an endotracheal tube. The disadvantages of the PTL, Combitube, or LMA is that it cannot be used in small adults, children, or patients who are somewhat responsive with a gag reflex.

Endotracheal intubation is the "gold standard" for airway management; it provides the best access for ventilation and the greatest protection against aspiration. The majority of ALS systems use endotracheal intubation as the airway of choice for the patient in respiratory failure or with an unprotected airway. Therefore, a number of different-sized endotracheal tubes, laryngoscope blades with handles, stylets, lubricants, and Magill forceps must be carried in the airway kit. Tube exchanger catheters or gum bougies can also aid with establishing a difficult endotracheal tube. Directors of EMS must ensure that ALS personnel maintain their intubation skills through field experience and practice.

The new basic EMT model curriculum has made endotracheal intubation an optional module. Therefore, intubation training may be provided to basic EMTs and intubation equipment may be placed on some BLS ambulances. Increasing the number of ambulance personnel in need of endotracheal intubation training in an EMS system may cause logistical problems for the medical director. It is sometimes difficult to obtain adequate live intubation opportunities for the personnel in an EMS system in order to develop and maintain skills. Some studies have found that basic EMTs do not maintain endotracheal intubation skills and have low rates of successful field intubations. [7,8] This would suggest that intubation will generally remain an ALS skill. [9]

Another intubation-related modality that has bearing on the equipment carried on the ambulance is rapid sequence intubation (RSI) using intravenous (IV) hypnotics and neuromuscular paralytic drugs. [10] Critical care transport services have been using RSI for more than a decade, but now a number of ALS systems are doing so, also with good success. The use of RSI raises the level of psychomotor and judgment skills required of the paramedic. While the use of RSI increases the amount of training needed, it enables paramedics to secure more difficult airways. In addition to the usual equipment required for intubation, these ALS services must carry the drugs needed for sedation and paralysis.

Vascular Access Equipment

The equipment used to establish IV access in the field is the same as at the hospital: tourniquets, cleaning agent, IV catheters, IV fluid bags, and IV tubing. In ALS

ambulances, IV access is used for fluid resuscitation and administration of drugs. In general, vascular access is obtained for drug administration as soon as possible after the patient is assessed and it is determined that pharmacologic intervention is required. Paramedics are very adept at rapid IV placement. [11] For fluid resuscitation, usually in trauma patients, vascular access is usually started en route to the hospital after the patient is immobilized, unless there is prolonged scene time due to extrication difficulties. Obtaining IV access should not prolong scene times in a trauma patient, especially when "LOAD AND GO" criteria are present. Prehospital fluid administration may make little difference in the patient's outcome. [12] First, the amount of fluid that can be administered during transport in most urban and suburban EMS systems is modest and may not be physiologically significant. Second, there is evidence that prehospital (and emergency department) fluid administration to hypotensive victims of penetrating truncal trauma does not improve survival and may even decrease survival in those patients who require surgery. [13] The medical director is responsible for developing protocols for prehospital IV access and monitoring their use in an ongoing manner.

Vascular access is also utilized by some BLS services, not for drug administration, but for fluid resuscitation. Since BLS services usually serve rural areas and have longer transport times, fluid resuscitation may be more beneficial (although this is unproven) for the hypovolemic trauma patient.

Pneumatic Antishock Garment

The military antishock trousers (MAST) garment is a one-piece layered device made of polyvinyl fabric that encircles the legs and lower abdomen and can be inflated to apply external pressure to enclosed body parts. The legs are enclosed separately from the inguinal crease to the ankle; the feet are exposed. The abdominal component encloses the body from the lower rib cage to the pelvis, with the perineal area exposed. Three compartments are fastened with Velcro (Velcro USA, Inc.). Most versions of the garment allow separate inflation and deflation of the three compartments. The MAST is inflated with a foot pump, and some units are equipped with inflation pressure monitoring gauges. Internal pressures of the suit are limited by pressure relief valves (set at 104 mmHg) and the ability of the Velcro fasteners to withstand stress.

The MAST is a old concept but was rediscovered in Vietnam when a commercially available "G-suit" inflated to a pressure of 30 to 40 cmH$_2$O was used during the transport of seriously injured soldiers from combat areas to the hospital. [14] The authors of this study felt that the device was beneficial because four soldiers survived while using it who otherwise would have died, a judgment based on the physician's previous experience with similar casualties. Since then, considerable study, thought, and opinion have been published concerning the utility of the MAST in civilian EMS. [15,16] Currently, the MAST has fallen into disfavor because there is little evidence that it improves survival rates for the condition for which it is most commonly used: hemorrhagic shock after trauma. In fact, there is evidence from the Houston EMS system that the MAST may be detrimental in cases of cardiac and thoracic trauma with short transport times. [17] It is not clear whether MAST may be useful in other situations or in disease entities other than trauma. For instance, there is theoretical and anecdotal evidence that the MAST may be useful in bluntly traumatized patients with long transport times, in ruptured abdominal aortic aneurysms (AAAs), or in pelvic fractures. A position paper from the National Association of EMS physicians attempts to bring a reasoned approach to the use of MAST by categorizing the possible indications into classes I, II-A, II-B, and III, based on possible efficacy or lack thereof. [15] Incidentally, the only class I intervention (usually indicated, useful, and effective) for MAST in that paper is ruptured AAA. It may be reasonable to keep MAST on ambulances for now, especially for rural services, to use it primarily for blunt trauma with long transport times and to avoid its use with penetrating thoracic injury.

The physiologic effects of the MAST are often misunderstood. [16] The MAST increases blood pressure primarily by increasing peripheral vascular resistance (afterload). The MAST does not reliably mobilize pooled blood (autotransfuse) from the legs or abdomen, especially in hypovolemic trauma patients. The MAST does decrease bleeding from vessels under the compartments by applying external pressure that decreases the pressure gradient for continued hemorrhage.

In practice, the MAST is applied as the patient is being immobilized on the long spine board. After physical assessment of the abdomen, pelvis, and legs, the three compartments are closed over the patient. If the patient is hypotensive, the garment is inflated sequentially, first the legs and then the abdomen. Inflation is done in stages until the desired response by the patient is seen—usually a systolic blood pressure greater than 90 mmHg—and the MAST is not inflated further. While the compartments have pressure relief valves set at 104 mmHg, the Velcro fasteners usually give way at pressures far less, usually around 60 mmHg; thus, it is difficult to achieve high MAST compartment pressures.

Once a patient has been placed in a MAST and the compartments have been inflated, their cardiovascular system responds and adapts to the increased afterload. If that external pressure is suddenly relieved, systolic blood pressure can fall precipitously, especially in a hypovolemic patient. Therefore, MAST deflation in the emergency department should be done slowly, with blood pressure monitoring and IV fluid administration in case of sudden hypotension.

Since the MAST increases afterload, pulmonary edema is the one absolute contraindication to its use. Contraindications for use of the abdominal compartment of the MAST (and relative contraindications to the use of the MAST in general) are pregnancy, the presence of impaled objects, evisceration of the abdominal contents, and thoracic and diaphragmatic injuries.

SPINAL IMMOBILIZATION

The preservation of integrity of the spinal column and the enclosed spinal cord is of paramount importance in the field. Cervical spine stabilization and airway assessment are performed simultaneously. Manual stabilization of the neck is not released until the patient has been transferred and securely strapped to a board. The length of boards used (whether short, long, or both) depends on the initial position in which the patient is found by the first responder or EMT.

Carrying boarded patients takes a heavy toll on the backs of EMTs and paramedics. Evaluation of the boarded patient is expensive and time-consuming in the emergency department because of the need to "clear the spine." Not all trauma victims require spinal immobilization for transport. The medical director should develop protocols or guidelines to avoid unnecessary field immobilization. [18] For example, a patient with no neck pain or tenderness (neck pain must be defined liberally and includes stiffness or "feels funny"), not in the extremes of age (below 10 or above 65), with no altered sensorium (no drugs or alcohol present and no head injury), and with no distracting injuries (e.g., long bone fracture or abdominal or chest injury) does not routinely require immobilization because there is an extraordinarily low probability of neck injury. Ideal guidelines for prehospital personnel necessarily would have virtually 100 percent sensitivity with acceptable specificity for cervical spine injuries.

Spinal Boards and Cervical Collars

Spine boards, either short or long, are made from plastic or wood to provide a rigid surface on which to bind the patient to ensure that no movement occurs in the cervical, thoracic, or lumbar spine during transportation. Straps with buckles or Velcro fasteners are used to secure the patient to the board. Some boards have attached firm head blocks for either side of the head and straps to go across these blocks to keep the head steady between them. Rolled up blankets ("blanket rolls") secured to the board with tape are also effective head blocks. A popular and effective variation of the short board is the Kendrick extrication device (KED) (Ferno, Wilmington, OH), which consists of slats of rigid material bound together by heavy cloth. The KED immobilizes the cervical spine, wraps partly around the patient, and is then strapped the rest of the way around the thorax and around the thighs for secure immobilization. The patient can be lifted using the KED straps, allowing for easier and safer extrication from a vehicle.

Rigid cervical collars are more accurately called cervical extrication devices. Multiple types are commercially available for use in the field: Philadelphia collar (Philadelphia Cervical Collar Co., Westville, NJ), the StifNeck (Laerdal Medical Corp., Wappingers Falls, NY), and the Neck-Loc (Un-I-Med, Louisville, KY). These collars come either as two asymmetric pieces, which are used and marked for back and front, or as a single piece that is folded into the correct shape. By themselves, collars are not adequate for complete cervical immobilization; additional lateral support is required to avoid lateral movement. For complete immobilization, the patient needs to be strapped on the backboard and secured with head blocks and head straps. Once the patient is well secured to the board, the collar does not add a significant amount of stabilization and can actually be removed without compromise of the spine. However, the collar is often left in place for added protection. Patients with mandible or soft tissue neck injuries should probably not have a collar applied because of the potential for airway compromise that could be masked by the collar. More recent designs have openings in the front to allow observation of the trachea and jugular veins, but this may not be adequate for observing other neck areas. Soft cervical collars are not adequate or appropriate for out-of-hospital care.

Sequence of Spinal Immobilization

Prehospital personnel are taught to have a high index of suspicion for spine trauma. If the patient is sitting in a car after an accident and is stable from respiratory and circulatory standpoints, the short spine board and rigid cervical collar or KED are first used to safely get the patient onto a long spine board and out of the vehicle in a

orderly manner. If time is critical because of the patient's condition or the threat of hazards such as chemicals, fire, or water, the patient can be extricated more rapidly without the short board or KED. The risk of rapid extrication must be weighed carefully but quickly against the benefit of getting out of the vehicle promptly.

At a noncritical scene, when the patient is still sitting in the vehicle upon EMS arrival, one EMT secures the neck with his or her hands and applies the necessary airway maneuvers while the second EMT secures the rigid cervical collar. The short board is then slid in behind the patient and the patient is strapped to the board while still seated (short boards are not used if the patient is not seated in a vehicle). The first EMT maintains manual stabilization of the neck until the patient is secured to the short board. The patient can then be rotated around and slid directly onto the long board positioned on the car seat or directly onto the ambulance stretcher. The MAST garment, if needed, is often already placed on the long board underneath the patient. The patient is then strapped to the long board. A properly secured patient can be turned on the board or even stood on end if necessary to move the patient to the ambulance. If the patient vomits, for instance, the board can be partly turned ("logrolled") to prevent aspiration.

Because of the difference in relative size and positions of head and body, adults and children need slightly different positioning on a backboard. An adult needs more padding under the head, while a child needs more padding under the body, to maintain neutral neck position.

In more dangerous situations where rapid extrication is required, the short board is omitted, but the rigid cervical collar should still be used. The patient is carefully rotated out and slid onto the waiting long board.

If a patient is walking at the scene when EMS personnel arrive but complains of neck pain, the patient should be boarded from a standing position. If the patient is lying on the ground when the EMTs arrive, the patient should be carefully logrolled by several attendants onto a long backboard.

Radiographs can be obtained without difficulty through short and long boards. In general, patients should not be removed from these devices until the spine has been "cleared" clinically or radiographically. If removal off the spine board is necessary before clearing, the patient should be logrolled or lifted off carefully.

EXTREMITY IMMOBILIZATION

Most fractures encountered in the field are splinted for the patient's comfort and ease of transport. Air splints, or circumferential bladders that are inflated by mouth, are adequate for most distal fractures of the upper and lower extremities. In hot weather, air splints can be difficult to remove when they stick to the skin. An air splint with a zipper and powder on the inside is easier to remove. The MAST garment can function as an air splint for one or both lower extremities. Other splinting possibilities include simple sling and swathe, tying the legs together with cravats to splint one injured leg with the other normal one, or using a pillow wrapped around an extremity and secured with tape. A pillow splint is comfortable and secure for the patient either out-of-hospital or in the emergency department. Other splints are available on the market, such as vacuum splints, but add cost with perhaps no clear-cut advantages over older cheaper splinting methods.

Traction Splints

Pelvic fractures and fractures of the femoral shaft are potentially life- and limb-threatening. Stabilization of pelvic fractures is difficult. Indeed, the only effective method in the field or in the emergency department is using the MAST garment with all compartments inflated. Radiographs can be performed through the garment.

Fractures of the femur can damage vessels and nerves from movement of bony fragments. Stabilization of femur fractures in the field is imperative to minimize blood loss and soft tissue damage. While MAST garments are often used to immobilize femur fractures, they do limit the assessment of the patient and cannot reduce the fracture. The femoral traction splint is the preferred device for femur fractures.

Several leg traction splint variations are commercially available. The two most commonly used types are the Hare splint (Dyna Med, Carlsbad, CA) and the Sager splint (Minto Research and Development, Inc.) (Fig. 2-4 and Fig. 2-5). Other traction splints (Thomas Ring, Donway, and Klippel) are less commonly used. The underlying principle is the application of traction by a hitch on the ankle against resistance when the splint impinges proximally on the pelvis. The padded proximal end of the Hare splint abuts the ischial tuberosity (Fig. 2-4). The proximal end of the Sager splint rests against the ischial tuberosity medial to the shaft of the femur (Fig. 2-5). These splints cannot be used if a pelvic fracture is suspected, since the pressure on the pelvis may further displace a fracture and cause more bleeding. Another contraindication to the use of femoral traction splints is a hip dislocation.
FIG. 2-4. Hare traction splint.
FIG. 2-5. Sager traction splint.

Leg traction splints may also be used for tibial shaft fractures. Traction splints should not be used for fractures near the knee; since longitudinal traction may damage the neurovascular structures in the popliteal area. Traction splints for the tibia should be reserved for angulated or displaced fractures; otherwise, an air splint or the MAST would suffice.

Before applying a femoral traction splint at the scene, enough clothing must be cut or removed so that the extremity can be assessed for injury and distal neurovascular function. If the Hare splint (Fig. 2-4) is used, the proximal half ring is placed in the crease of the buttocks against the ischial tuberosity. Traction is placed on the ankle with the padded ankle strap by one rescuer while the splint is strapped to the leg. The ankle strap is then attached to a ratcheting mechanism, and traction is applied. If a Sager splint (Fig. 2-5) is used, the splint is placed on the medial side of the limb up against the groin. The padded ankle hitch is applied, and traction-applied elastic straps are then secured to hold the splint to the leg. With both splints, traction is applied until malalignment is reduced and pain is

relieved. Overtraction can be harmful.

The Hare splint can be longer than an ambulance stretcher when fully extended, and care needs to be taken when closing the rear door of the ambulance. The Sager splint is shorter than the Hare splint, and one Sager splint can be used to splint both legs simultaneously. The Sager device is less bulky and therefore takes up less room in an ambulance or a helicopter, which can be very important in the latter.

PHARMACEUTICAL EQUIPMENT

Another area where practice is becoming blurred between BLS and ALS is in the realm of medications. The new basic EMT model curriculum has a module on certain classes of pharmaceuticals to prepare basic EMTs for helping the patient administer his or her medication in a limited fashion. This module includes nitroglycerin for chest pain, inhaled beta-adrenergic agonists for bronchospasm, glucagon for hypoglycemia, and epinephrine preloaded injections for anaphylaxis. The curriculum assumes that the patient already has the medication and the EMT is simply assisting; the drugs are not carried on the ambulance. Some states have gone beyond that and allowed limited carrying of medications on BLS ambulances.

Drugs carried by ALS services are more extensive, but it must be emphasized that out-of-hospital pharmaceutical interventions are limited to a few that will make a real difference before the patient gets to the hospital. The drugs that can make a real difference when administered by a paramedic include oxygen for hypoxia; glucose for hypoglycemia; nitroglycerin for chest pain and pulmonary edema; inhaled beta-adrenergic agonists for bronchospasm; naloxone for suspected narcotic overdose; morphine for pain; benzodiazepines for seizures, delirium, or intubation; furosemide for fluid overload; epinephrine for cardiac arrest and anaphylaxis; and lidocaine, magnesium, bretylium, and perhaps amiodarone for cardiac arrest. Adenosine and diltiazem are useful for rate control of tachycardia, but most patients would be able to wait until arrival in the emergency department for treatment. Sodium bicarbonate is helpful for suspected or known hyperkalemia but probably not for cardiac arrest. Calcium may also be of use in cardiac arrest, especially if hyperkalemia is suspected. In some systems, paralytic drugs (e.g., succinylcholine and vecuronium) are used along with the sedating agents for RSI. Out-of-hospital care providers do not need the whole spectrum of drugs found in the emergency department; drugs carried by ALS services should be restricted to those that improve patients' outcomes.

3 AIR MEDICAL TRANSPORT

C. Keith Stone
Stephen H. Thomas

Air medical transport is part of an integrated emergency medical services (EMS) system. Field EMS personnel or physicians transferring patients between hospitals should be able to select the proper mode of transportation for an individual patient, depending on the particular circumstances (Fig. 3-1). Effective implementation of all these EMS tools requires well-trained communications and dispatch personnel who can quickly assess the situation at hand and then institute the right EMS response. In addition, the entire out-of-hospital care system must be designed with and medically supervised by physicians well versed in EMS care.

FIG. 3-1. The patient transport guidelines pyramid. (From North Flight EMS: *J Emerg Med Serv,* 18:50, 1993. Used by permission.)

The terms *aeromedical* and *air medical* are not interchangeable: *air medical* refers to the use of aircraft for evacuation of patients, whereas *aeromedical* refers to the study of the medical effects of flight and altitude on humans.

HELICOPTER TRANSPORT

The history of air evacuation is closely connected to the history of warfare. Igor Sikorsky's invention, the helicopter, first flown on September 14, 1939, was used for the first rotor-wing medical evacuation in Burma in 1945. From this small start in World War II, helicopter usage blossomed extensively in the Korean war, when more aircraft of sturdier construction were available. About 20,000 patients were transported by helicopter in the Korean war. During the Vietnamese war, about 370,000 patients were carried by helicopter from 1965 to 1969.

The first hospital-based civilian program began in 1972 in Denver. Currently, there are 385 air medical service providers identified by the Association of Air Medical Services (AAMS), 362 domestic and 23 international.[1] Most of these programs are run by hospitals or groups of hospitals. Helicopters are expensive, ranging from $750,000 to $5 million. Because of the high cost of purchase, maintenance, and pilot training, most programs lease their helicopters from aircraft vendors. In this arrangement, the air medical program provides the medical personnel (paramedics, nurses, physicians, and dispatchers) and medical supplies, while the aircraft vendor supplies the helicopters, pilots, and maintenance personnel. The annual cost of operating a rotor-wing service typically exceeds $2 million.

For safety reasons, air medical services have increasingly moved toward using two-engine helicopters with instrument flight rating (IFR), rather than single-engine helicopters with visual flight rating (VFR).[2] Twin-engine helicopters have greater lifting capacity, range, and speed. They are also safer if one engine fails in flight; the helicopter can make a more controlled landing on the remaining engine. Under similar conditions, a single-engine helicopter must make an autorotation landing with a dead engine. A VFR aircraft can only fly with good visibility, whereas an IFR craft can fly under conditions of poorer visibility. Both VFR and IFR helicopters have strict visibility limitations imposed by the Federal Aviation Administration (FAA), but the IFR helicopter has fewer restrictions. If the pilot unexpectedly encounters bad weather during a flight, an IFR helicopter has a better chance of successfully (and safely) completing the mission than does a VFR helicopter.[3] In areas with frequent bad weather periods, some programs have elected to use two-pilot IFR.[2] The addition of more sophisticated equipment, a second pilot, and a second engine increases both initial and ongoing costs for a helicopter air medical program.

As technology becomes increasingly available to civilian aviation, air medical services often incorporate the newer avionics. A survey from 115 domestic air medical services found that 78 percent of services were using the gobal positioning system (GPS) in 1997.[2]

A survey of 126 United States air medical programs found that the mean number of patients transported in 1997 was 827 per program; this figure has been generally stable since 1992.[1] Programs that responded to this survey were generally the larger programs. Total estimates of annual air medical transports are in the range of 150,000 to 300,000 patients.

Crew Configuration and Training

The medical crew on a rotor-wing craft can be configured in multiple ways: nurse-paramedic, nurse-nurse, nurse-physician, or nurse-respiratory therapist. The literature suggests that the addition of a physician to the crew does not add a significantly higher level of care to that already rendered by a flight nurse or flight medic, although there is a minority view that on-board physicians do improve patient care.[4,5] The most frequently used crew is nurse-paramedic because of their complementary skills. Since rotor-wing missions vary on the spectrum between scene flights and interfacility transports, a broad skill basis is essential in the medical crew. A comprehensive curriculum guide developed by a number of national air medical organizations under contract from the U.S. Department of Transportation is available to use for training medical flight crews.[6] This curriculum covers all aspects of air medical care and is intended for use by paramedics, nurses, and physicians.

The medical flight crew needs to know how the environment on board an aircraft will affect the patient's illness and how to transport the patient safely in the relatively hostile environment of that aircraft.[7] Since helicopters generally transport patients at about 1000 to 3500 ft, low barometric pressure with barotrauma is usually not a factor; but it could become a consideration if transportation were to occur over mountains. The noise, close quarters, vibration, and temperature changes of the cabin of a rotor-wing craft can have a marked effect on the patient's condition. Likewise, these factors make assessment of the patient more difficult. For example, measurement of blood pressure or ausculation of the lungs with a stethoscope is generally impossible during flight due to the noise and vibration.

Clinical Use of Helicopters

Helicopters are fast ambulances, cruising at 125 to 175 mph, depending on the aircraft. They are not limited by traffic or road quality. The usual flight range for a helicopter is 150 to 200 mi. Helicopters bring sophisticated medical care to areas that otherwise might have only basic life support (BLS) ground ambulance service. The air medical crews bring tertiary critical care and transfer patients back to the tertiary center at two to three times the speed of a ground ambulance. The two major types of helicopter missions are trauma/medical scene responses and interfacility transfers. Mission patterns vary widely among flight programs, with the national average in 1997 for scene and interfacility flights being 30 and 70 percent, respectively. [1]

Scene Helicopter Response

There is evidence that helicopter scene response for victims of trauma decreases morbidity and mortality rates for critically ill and injured patients. [8,9,10,11 and 12] In spite of this, there is still a concern that air medical services are inappropriately overutilized for trauma scene responses. The appropriate use of helicopters at trauma scenes involves a complex interplay of factors: How far away is the scene from the helicopter base? What resources are already responding to the patient or patients? What is the distance from the scene to the local hospital or the trauma center? How many victims are there, and what is the severity of their injuries? Is there a significant amount of extrication needed before a patient can be moved to definitive care?

National guidelines (Table 3-1) have been developed to assist in making decisions for trauma scene responses. [13] Clinical information such as mechanism of injury, severity of injury, vital signs, and level of consciousness are one part of the equation. Emergency medical technicians on the scene are very accurate at defining which patients are critical and need air medical transport to the trauma center. [14]

TABLE 3-1   Air Medical Dispatch: Guidelines for Trauma Scene Response

There are also logistical and operational factors to be considered. If the patient is not accessible because of location (e.g., off-road or wilderness), traffic, road conditions, or weather, a helicopter dispatch may be appropriate. However, helicopters are much more weather-sensitive than ground ambulances; if the weather is bad for ambulances, it is probably worse for helicopters.

Time and distance play key roles in electing to send a helicopter. A severe trauma or medical situation in an urban area close to a trauma center does not have the implications for the patient that the same situation would in a rural area 100 mi from a major medical center. If the time for transport to the trauma center is greater than 15 min by ground ambulance, if the transport time to the local hospital by ground is greater than the time required for the helicopter to reach the trauma center, or if patient extrication will take longer than 20 min, then dispatch of the helicopter should be considered. In general, scene responses occur within 25 mi of the helicopter base, although this varies with local conditions and protocols. It is likely that at distances greater than 25 mi the patient will be transported to the local hospital first for stabilization and then a helicopter will transfer the patient to the trauma center. Sometimes, if the patient is extricated faster than initially thought, the ground EMS personnel communicate to the helicopter to divert to the local hospital rather than go to the scene.

There is one group of trauma patients for whom air medical scene response has a very low rate of resuscitation and essentially zero survival: traumatic cardiac arrest.[15] Some services have developed protocols that patients in traumatic cardiac arrest are not flown back to the trauma center, but instead the air medical crew assists the ground EMS service and transports the patient to the local hospital.

Scene responses for patients with medical conditions (as opposed to traumatic conditions) vary from program to program. [16,17] Especially in rural areas, it is common for helicopters to intercept BLS ambulances that are transporting deteriorating or unstable patients. Basic life support technicians may call for a helicopter if the patient could be transported faster to the tertiary center by air than the ground ambulance could get the patient to the local hospital. Medical scene responses have not received as much attention in the literature as have trauma scene responses, although criteria for medical scene responses have been developed. [18] The small number of medical scene responses reported in the literature makes it difficult to judge the utility of this mode of response and transport. However, if a patient is in cardiac arrest and the ground ambulance crew has a defibrillator and has secured the airway, it is unlikely that the arrival of the helicopter crew will result in any more successful resuscitation.[19] Such intercept situations must be dealt with on a local or regional level by guidelines and protocols, and they reinforce the importance of an integrated EMS system in which air and ground units work smoothly together under medical direction.

One important factor to be considered in initiating helicopter transport of a patient is whether ground transport of the patient by the local ambulance will deprive that community of vital EMS services. If the local ambulance is out of service for 5 to 6 h and emergency ambulance coverage in that area is compromised, then use of the helicopter should be strongly considered.

Another other important use for helicopters is in disaster situations. Rotor-wing craft can not only bring in sophisticated triage and treatment personnel for better medical care at the scene, but they can also give the incident commander a bird's-eye view of the events, which can assist in best distributing the available resources. These functions can be served in addition to the usual role of the helicopter in evacuating the most seriously ill and injured to the trauma center.

Interfacility Helicopter Transports

The majority of air medical transports are interfacility. It is surprising to note that there have been few studies on the benefit of interfacility air medical transports. A recent study from Norway on 370 interfacility helicopter transfers found that positive benefit could be judged in only 11 percent of patients, and almost all of the total additional life-years gained from such transport was confined to only 9 patients. [20] Benefits were most often seen in neonates, children with infection, and adults with cardiovascular disease. While some adults with trauma benefited from the interfacility helicopter transfer, the total additional life-years gained was very small. Published studies in the United States have usually focused on acute myocardial infarction and unstable angina. [21,22] These studies have not found a positive benefit of interfacility helicopter transfer over ground ambulance.

The Federal Emergency Medical Treatment and Active Labor Act (EMTALA), originally passed in 1985 as part of the Consolidated Omnibus Budget Reconciliation Act (COBRA) and strengthened through amendment in 1989, directed the Health Care Financing Administration (HCFA) to develop regulations concerning the examination, treatment, and transfer of individuals with emergency medical conditions. The final interim rule issued by the HCFA in 1994 contains a prohibition against the transferring physician's having a patient transported to a medical facility with a lesser or inadequate level of care en route. Thus, if the patient is unstable or requires intensive care during transport, then it is not appropriate to use a BLS ambulance. The position paper from the Air Medical Committee of the National Association of EMS Physicians states: "Reducing out-of-hospital time for these patients seems to be in their best interest. Ground-based out-of-hospital care providers, faced with a patient whose needs obviously exceed their abilities, may wish to access a rotor-wing air medical transport service, especially if they are distant from an appropriate medical facility." [16] This position is strengthened by the literature, which suggests that a tertiary center can extend its care out to several hundred miles via rotor- or fixed-wing aircraft with no change in mortality compared with patients transported locally to the same trauma center. [23] However, air medical services may violate certain EMTALA sections by transporting "unstable" patients (as defined by the regulations) and bypassing closer "appropriate" hospitals in order to return to their base hospital. [24] The issue is complex, the regulations are vague, and case law is limited to date.

In this regard, then, air medical care and transport protocols should operate to ensure that the patient is transported with the highest appropriate level of service and to the closest appropriate hospital.

Safety

Flight programs are exceedingly safety conscious. While it is true that EMS helicopters have a crash rate exceeding that of non-EMS helicopters, it is probably true that, per patient-mile, EMS helicopters are safer than ground ambulances. [3,25] Air medical programs must follow FAA rules. The industry itself has set forth additional stringent standards under the auspices of the AAMS and, more recently, the Commission on Accreditation of Air Medical Services (CAAMS). [26] On request, CAAMS performs site visits of air medical programs to certify that they comply with strict safety and operational standards.

On a mission, safety is the chief responsibility of the pilot. Because weather and collisions against ground obstacles are the leading hazards, in most programs, the pilot is not told the nature of the mission until a weather check is done and it is decided that the flight can be made safely. The pilot does not then feel pressured into flying a mission under borderline weather conditions because of the patient's condition. For helicopters, visibility, wind, and icing conditions are major limiting conditions.

The use of fire-resistant flight clothing, helmets, and emergency absorbing seats are felt to be effective in reducing preventable injuries to the medical crew in survivable crashes. [27]

Safety training must involve everybody in contact with the aircraft, including the communicators and dispatchers, aircraft mechanics, and especially on-scene EMS personnel. The latter must be taught to function around the helicopter at the scene.

Scene flights are inherently more dangerous than landing at a regular hospital landing zone. The unfamiliar landing area at a scene has more obstacles, such as wires and trees. More material may be scattered on the ground and blown around by the rotor wash from the helicopter. Scenes to which EMS has been called tend to be uncontrolled, with more bystanders who have the potential of walking into a tail or main rotor. A small helicopter needs a minimum of 60 ft by 60 ft for a landing zone, and a medium-sized or larger aircraft requires at least 100 ft by 100 ft. A landing zone of this size may be difficult to secure on a rural highway or at other accident scenes.

Several points are important for scene helicopter safety. First, the craft should always be approached from the front, where the pilot can see approaching personnel and can then acknowledge their presence and motion them into the helicopter. In general, a flight team member will guide ground personnel into the aircraft. Second, a rotor-wing aircraft should never be approached from the rear, since the tail rotor is going very fast and is virtually invisible. The tail rotor is the most dangerous area of a helicopter. Third, landings and takeoffs are the most likely times for adverse incidents to occur. Ground personnel need to stand well away as the helicopter lifts off.

Cost and Reimbursement

Helicopter transport is more expensive than ground transport, with an average helicopter transport charge in 1997 of $3882 for a medium-sized twin-engine helicopter and a 50-mi one-way patient transport. [1] The fees charged by almost all programs include a base fee for liftoff plus a fee for loaded (one-way) mileage. [1] Some programs charge for professional services and drugs or medical supplies used in flight.

Reimbursement issues are complex and vary between government (Medicare and Medicaid), private insurance, and managed care health insurance plans. One program found that, with an average flight charge of $2298 in 1991 through 1992, mean reimbursement was $991, or 43 percent of charges. [28] Reimbursement rates varied from nearly zero for Medicaid to 90 percent for commercial insurance.

The cost-versus-benefit analysis of air medical transport is not easy. It is not easy to predict how a patient might deteriorate if sent by ground rather than by air. It is not enough to ask the simple question: "Would the patient have died if not transported by helicopter?" Other medical factors, such as the number of days in intensive care, duration of rehabilitation, and quality of future life may be positively affected by air medical transport. Models have been developed to analyze the cost-effectiveness of using a helicopter to provide advanced life support (ALS) to local BLS ambulance services instead of placing additional ground ALS vehicles. A recent analysis found that a single helicopter could provide ALS backup over a 50 km radius replacing six ground ALS units at less annual operating cost. [29]

In summary, the determinants of helicopter usage must be medical and driven by national standards, as described above. Currently, there is inherent conflict between the requirements of EMTALA/COBRA for adequate transport and the frequent unwillingness of other federal programs (Medicare) and third parties to pay for the service rendered.

FIXED-WING AIR MEDICAL TRANSPORT

Fixed-wing aircraft can serve a wide variety of missions, from urgent to routine, over great distances. Since airplanes land only at airports, they cannot make scene flights, and they need ground ambulance connections at both ends of the flight to transport the patient between the hospital and airport. Because of this need, fixed-wing flights generally take longer to arrange and are not used for truly emergent patients.

In the United States, more fixed-wing than rotor-wing aircraft are used for air medical transport. Rotor craft are usually dedicated as air medical transport units, while planes are often multifunctional, used for charter flights or business. Unfortunately, this may sometimes lead to inadequate equipping and staffing of airplanes when used for air medical work. Medical fixed-wing craft need to have an adequate cargo-type door to allow access to a patient on a stretcher. Removeable medical equipment modules have been developed for airplanes to ensure the presence of adequate medical equipment when required.

Fixed-wing transports are less expensive per mile and usually more practical than helicopters at distances over 150 mi. On average, helicopter transport costs about three to four times more than fixed-wing transport per patient-loaded mile. [1] This estimate is rough because of the large number of variables involved in determining charges: distance, aircraft type and speed, crew configuration, and the nature of the patient's condition.

Airplanes vary in size and speed. Jet aircraft typically cruise at 400 to 500 mph, turboprop airplanes at 200 to 300 mph, and piston-driven airplanes at 120 to 150 mph. The appropriate aircraft to use for any one mission depends on many factors: distance, the nature of the airport at the patient's pick-up point, the condition of the patient, the amount of equipment, and the crew required in transport. The more critically ill the patient, the more equipment and crew may be needed and the larger the aircraft required. The choice of aircraft must also take into account the comfort of the crew and the patient for a trip of that distance. The cabins of fixed-wing aircraft are more spacious than those of rotor-wing craft. A larger plane that is able to be pressurized can fly above 10,000 ft, which means the plane can go faster, farther, and more comfortably.

Since airplanes can fly above bad weather and are less susceptible to icing conditions, fixed-wing craft can often fly when helicopters cannot. Fixed-wing planes can also fly under more difficult visibility circumstances than rotor craft because of on-board instrumentation and ground control from an airport.

All fixed-wing services must comply with FAA rules for airplanes. Standards have been developed for air medical fixed-wing aircraft by the Association of Air Medical Services and CAAMS, just as they have been developed for helicopters. [26] These standards deal with aircraft configuration, medical equipment requirements, medical crew configuration and training, and medical director qualifications.

MEDICAL DIRECTION OF AIR MEDICAL SERVICES

Medical direction may be even more important with rotor- and fixed-wing services than with ground services; it is certainly more complicated. Guidelines for the medical director of air medical transport programs has been developed by the National Association of EMS Physicians. [30] The medical director should be familiar with the physiology and stress of flight on the patient. A flight crew requires more initial training and more ongoing education than do ground EMS personnel because patients transported by air are generally sicker and require more advanced interventions than those transported by ground. Because flight crews are often far from

their base of operations and out of voice contact, they must act independently. Standing orders or protocols for complex procedures such as chest tube insertion or cricothyrotomy are needed. More intense review of transport records is needed for quality control.

4 NEONATAL AND PEDIATRIC TRANSPORT

Carl L. Bose
Phillip V. Gordon

Regionalized intensive care is a concept that has gained wide acceptance in many fields of medicine, including neonatology, pediatric intensive care, and emergency medicine. This concept mandates that expensive, high-technology, labor-intensive therapies be limited to a few regional centers. Because patients in need of these services may initially present to other hospitals, interfacility transport has developed as a complement to regionalized intensive care. [1]

Either the referring hospital or the regional center may assume the responsibility for the transport of a patient to a regional center. Because regional neonatal and pediatric intensive care centers often provide transport services and because community emergency medical services (EMS) systems are often not equipped to transport critically ill children, the interfacility transport of pediatric patients is often conducted by regional centers. Under these circumstances, the referring hospital still has important responsibilities related to transport. Emergency department personnel must often assume these responsibilities because the emergency department is the site of initial care. This chapter focuses on the stabilization and preparation of critically ill children for transport. Since some emergency departments are also responsible for operating transport services, a brief discussion of the organization and administration of a pediatric transport program is also included.

THE TRANSPORT ENVIRONMENT

Moving critically ill patients between hospitals or even within a hospital invariably adds to the risks of the illness or injury because of the hazards associated with the transport environment. Patient care can be influenced dramatically by the unique features of this environment and is particularly affected during the transport of neonatal and pediatric patients. [2] For this reason, an understanding of the transport environment is essential for individuals who participate in the preparation or transport of children.

Features

The features of the transport environment that may distinguish this environment from the inpatient setting and the effects of these features on patients and caretakers include the following:

1. *Excessive noise.* The acute effects of excessive noise on older pediatric and adult patients are probably minimal. By contrast, persistent sound in excess of 80 dB appears to dramatically increase the frequency of arterial oxygen desaturation in premature infants. In addition, excessive noise makes it virtually impossible to use the sense of hearing to evaluate patients during transport.
2. *Vibration.* The effects of vibration on patients are uncertain but are probably not of great significance. However, vibration may limit the reliability of transport equipment. Monitor artifact must be recognized, and alternative techniques for monitoring should be employed as needed.
3. *Inadequate lighting.* Inadequate lighting is rarely a problem during the transport of adult patients because EMS vehicles generally have lighting designed for adult patients on stretchers. However, task lighting for illuminating small areas and small patients is usually not available.
4. *Variable ambient temperature.* Although the range of ambient temperature encountered during transport rarely influences the body temperature of adult patients, environmental conditions can have a dramatic influence on the body temperature of neonates and small children.
5. *Changes in barometric pressure.* Changes in barometric pressure during ascent in nonpressurized aircraft cause expansion of gases in closed spaces (e.g., with endotracheal tube cuffs or pulmonary interstitial emphysema) and a fall in the partial pressure of oxygen. These changes are rarely of sufficient magnitude to influence physiologic characteristics unless the change in altitude is greater than approximately 1500 m.
6. *Confined space.* The confined space in transport vehicles is an obvious handicap because it limits the number of caretakers and the amount of support equipment.
7. *Limited support services and personnel.* Similarly, the extent and precision of care is limited during transport by the lack of support services (e.g., radiographic and laboratory services) and specialty personnel.
8. *Equipment failure.* Equipment failure during transport is common and is particularly problematic because replacement equipment is less likely to be available in the vehicle than in an inpatient setting. The most common problem is the unexpected exhaustion of an oxygen tank.
9. *Motion-induced illness.* Many medical personnel develop motion-induced illnesses during transport. Symptoms are often categorized into one of two syndromes: the sopite syndrome, which is characterized by drowsiness and inability to concentrate, and the nausea syndrome. Either syndrome may impair the ability of personnel to provide skilled care.

Precautions

Plans to minimize the impact of the handicaps inherent in a transport environment are essential. Suggested guidelines include the following:

1. *Stabilize the patient carefully prior to transport.* Unless the immediate needs of the patient can only be met in the receiving hospital (e.g., severe trauma), ample time should be devoted to stabilizing the patient in the referring hospital.
2. *Anticipate deterioration.* Preparation of the patient should include not only care for the identified problems but also anticipation of problems that may arise during transport.
3. *Monitor as many physiologic parameters as possible electronically.* Because physical examination is nearly impossible during transport and because pediatric patients are often transported during dynamic changes in their physiologic condition, electronic monitoring is essential.
4. *Prepare the transport vehicle.* If repeated transport of pediatric patients is anticipated, one or more vehicles should be prepared to meet the special needs of these patients (e.g., accessory lighting and a more precisely controlled thermal environment).

PREPARATION OF A PATIENT FOR TRANSPORT

Decision to Transport

The decision to transport should be based on a patient's needs at the time of presentation and anticipated needs during the evolution or treatment of the disease or injury. If the patient's needs will exceed the resources of the hospital at any time, then the patient should be transported as soon as possible.

Basic Preparation

When a critically ill child arrives in the emergency department and the decision is made to transport that child to another institution, extensive preparation of the child should occur. This preparation should be completed by the referring hospital personnel to the limits of their abilities and resources, regardless of whether they or a receiving hospital will perform the transport. Two aspects of care to which referring hospitals should direct immediate attention are airway management and vascular access.

AIRWAY MANAGEMENT   The decision to intubate and mechanically ventilate a patient is usually based on objective evidence of respiratory failure. This principle applies to both inpatients and those being prepared for transport. However, the threshold for intervention should be lowered for most patients requiring transport. For example, an infant with an arterial partial pressure of carbon dioxide (Pa_{CO_2}) of 50 mmHg might be observed without ventilatory support in the inpatient setting but probably should be intubated and ventilated in preparation for transport. In addition, children without respiratory failure but in whom deterioration is anticipated should be intubated in preparation for transport. This more aggressive approach to airway management is justified because the ability to identify respiratory failure and to intubate is often impaired during transport.[3]

All emergency departments should be supplied with equipment to intubate and ventilate patients of all sizes (Table 4-1). All nonneonatal patients should be medicated prior to intubation unless they are unconscious or in extreme distress. Neonatal patients should be premedicated only if they are alert and vigorous. An opiate analgesic (morphine or fentanyl) should be administered intravenously to patients less than approximately 3 months of age. Older children should be intubated following rapid-sequence anesthesia and paralysis.

Age, Weight	Laryngoscope Blade	Tube Size, mm[*]	Insertion Distance, cm[†]
<1 kg	Straight 0	2.5	6.6–7.0
<1 kg	Straight 0	2.5	6.6–7.0
1–2 kg	Straight 0	3.0	7.0–8.0
2–3 kg	Straight 0 or 1	3.0–3.5	8.0–9.0
2–3 kg	Straight 0 or 1	3.0–3.5	8.0–9.0
3–4 kg	Straight 1	3.5–4.0	9.0–9.5
0.5–1 years	Straight 1	4.0–4.5	‡
1–3 years	Straight or curved 2	4.5–5.5	‡
3–8 years	Straight or curved 2	5.5–6.5	‡
>8 years	Straight or curved 2 or 3	6.5–7.5	‡

*Cuffed endotracheal tubes should not be used in children <7 years of age.
†Insertion distance is the distance from the tip of the tube to the lip.
‡See Chap. 11 for more details.

TABLE 4-1   Intubation Guide for Pediatric Patients

Neonatal intubation may be challenging for personnel not experienced in airway management in this population.[4] Attention to the following problems may increase the likelihood of success:

1. A common mistake made during neonatal intubation is to insert the blade into the esophagus and then fail to withdraw it far enough to visualize the glottis.
2. The glottis is in a more ventral position in infants than in older children; therefore, it is more difficult to visualize. This problem can be minimized by avoiding overextension of the neck and by applying gentle pressure to the cricoid. Too much pressure should be avoided because it can occlude the airway and prevent intubation.
3. Premature infants have very small mouths and upper airways, making insertion of the endotracheal tube difficult. Gentle traction on the infant's right cheek by an assistant can usually provide sufficient opening to allow insertion of the endotracheal tube just to the right of the blade. This maneuver also helps preserve the intubator's field of view.
4. Because the skin of newborns is usually moist, extra care must be taken during taping of the endotracheal tube.

Because the distance between the thoracic inlet and the carina is extremely short in small children, the position of the tip of the endotracheal tube should be confirmed with a chest radiograph as soon after insertion as possible. A radiograph should be obtained even when reassuring signs of a successful intubation are present (condensation on the wall of the tube, symmetrical chest rise and breath sounds, and positive CO_2 detection). Right main-stem intubation is common in neonates. Prolonged right main-stem intubation increases the likelihood of pneumothorax and is particularly hazardous in premature infants. Soon after the initiation of mechanical ventilation, arterial blood gas analysis should be performed to ensure appropriate ventilator settings. Overventilation is a common error that may have serious consequences.

VASCULAR ACCESS   All patients should have intravascular access during transport. Critically ill children should have at least two lines in case one becomes dislodged or several drugs must be administered simultaneously. Access should be through a device that includes a nonmetallic intravascular component. The metal butterfly needles often used in pediatric inpatient units are not satisfactory during transport because they frequently perforate the vessel as a result of vibration and movement. Intraosseous cannulation is an alternative technique for fluid and drug administration when intravascular lines cannot be placed and the severity of illness demands immediate access.

In small children, intravenous lines should be infused with the use of pumps. Open "drips" should not be used, even with volumetric drip chambers, because of the risk of fluid intoxication from inadvertent administration of large boluses. The amount of fluid administered should be carefully monitored and recorded.

SPECIAL PROBLEMS OF THE NEONATE

The stabilization and transport of critically ill neonates is complicated by their dependence on extrinsic factors to maintain homeostasis. This is particularly true when birth occurs prior to term. In fact, the complexity of care is often inversely related to birth weight and gestational age. The following aspects of care deserve special consideration: thermal regulation, mechanical ventilation, glucose homeostasis, vascular access, risk of infection, and determining viability.

Thermal Regulation

Humans conserve body temperature by several mechanisms, including (1) shunting blood from the skin and periphery to the core, (2) increasing basal metabolic rate, (3) voluntary muscle activity, (4) shivering, and (5) nonshivering thermogenesis. With the exception of nonshivering thermogenesis, all of these mechanisms are less effective in the neonate. Although older children and adults can maintain normal core body temperature when subjected to a wide range of environmental conditions, neonates, particularly premature infants, are very limited in this regard. In addition, even under conditions in which a neonate can maintain normal body temperature, this is often accomplished at the expense of increased oxygen consumption and carbon dioxide production. These consequences are particularly onerous in infants with respiratory failure.

Neonates should be cared for in a neutral thermal environment in which core temperature remains normal and oxygen consumption is minimized. Such an environment is best provided by treating a neonate on or within a thermo-controlled bed specially designed for neonates. Thermo-controlled beds come in two varieties: an open platform heated with an overhead radiant heat source and a closed plastic incubator heated with a convection heater. Although not satisfactory for transport, open incubators with radiant heaters are ideal for the care of critically ill neonates in the emergency department because they permit access by several caretakers. An alternative is the use of a portable overhead heat lamp and a standard crib. These devices should be used with extreme caution because they do not

usually include a servo-control mechanism. The patient's body temperature should be monitored frequently to avoid hyperthermia. The neutral thermal environment is presumed when the infant's body temperature is normal and there is a minimal gradient between the core and the skin temperature.

Humans lose body heat in four ways: (1) evaporation, (2) conduction, (3) convection, and (4) radiation. Neonates, especially preterm infants, are particularly susceptible to heat loss because they have a relatively large surface–to–body mass ratio when compared to older patients. Also, their skin is more permeable to water vapor, and they may have a paucity of subcutaneous tissue. In addition to providing a heat source, attempts to create a neutral thermal environment should include provisions to minimize heat loss:

1. Infants should be thoroughly dried to avoid evaporative heat loss. This is critical after an emergent delivery. Drying should not be delayed under any circumstances. If emergent procedures are necessary, such as intubation, another caretaker should simultaneously dry the infant.
2. Whenever possible, infants should be placed on a pre-warmed surface to avoid conductive heat loss. The temperature of these surfaces or auxiliary heat sources (e.g., hot water bottles) should not exceed 104°F (40°C) because of the risk of thermal injury.
3. When treating an infant in an open crib or platform warmer, the room temperature should be increased to avoid convective heat loss. The infant should be located away from drafts (e.g., heat and/or air conditioning vents).
4. An infant should be clothed to the extent that it does not interfere with patient care and should not be placed near cold surfaces (e.g., exterior windows) to avoid radiant heat loss. At a minimum, a hat should be placed on the infant's head. [5]

Mechanical Ventilation

Most neonates are ventilated with time-cycled, pressure-limited ventilators using intermittent mandatory ventilation. As with volume ventilation, the clinician must determine the fraction of inspired oxygen (Fi$_{O_2}$) and ventilator rate. In contrast to volume ventilation, the tidal volume is not set, and in fact is not known with most infant ventilators. The volume of each breath is determined by setting a peak inspiratory pressure (PIP), a positive end-expiratory pressure (PEEP), and an inspiratory time (T$_i$) with suggested initial ventilator settings for infants that vary according to the severity of lung disease (Table 4-2).

Disease Severity	Mild	Moderate	Severe
PIP (cmH₂O)	18	24	28
PEEP (cmH₂O)	4	4	5
T$_i$, s	0.5	0.4	0.4
Rate, breaths/min	20	24	30

TABLE 4-2   Initial Ventilator Settings for Neonates

The adequacy of oxygenation and ventilation should be assessed immediately after initiation of ventilation by observing the degree of chest expansion and the change in the color of mucous membranes. Arterial blood is the most accurate source for blood gas analysis, but capillary or venous blood is acceptable for measurement of the partial pressure of carbon dioxide (P$_{CO_2}$) and pH in the absence of access to arterial blood. Adequacy of oxygenation can be assessed using pulse oximetric measurements. The target ranges for oxygenation and ventilation of neonates are somewhat different than those for older patients (Table 4-3). The blending of oxygen and air to deliver the minimum Fi$_{O_2}$ required to achieve adequate oxygenation is highly desirable, particularly in premature infants, in whom hyperoxia may result in retinal damage.

OXYGENATION		
Premature infant	Pao₂ 50–70 mmHg	Sao₂ 93–98%
Term infant	Pao₂ 60–100 mmHg	Sao₂ 96–100%
VENTILATION		
All infants	Paco₂ 35–50 mmHg	

Note: Pao₂ = partial pressure of arterial oxygen; Sao₂ = percent saturation of oxygen.

TABLE 4-3   Target Ranges for Oxygenation and Ventilation of Neonates

Glucose Homeostasis

During fetal life, the placenta and the maternal circulation closely regulate metabolic homeostasis. In healthy full-term neonates, homeostasis is maintained by the infant's autoregulatory mechanisms. Unfortunately, these mechanisms often fail during acute illness or after preterm birth. The result is increasing dependence on caretakers for normal metabolic function.

The most common metabolic abnormality in newborns is hypoglycemia. At birth, blood glucose in the neonate is approximately 60 to 70 percent of the maternal level. Within 1 to 2 h, the level falls to approximately 40 mg/dL. This decline may be accentuated in premature infants, acutely ill infants of any gestational age, and certain other high-risk infants (e.g., infants of diabetic mothers).

Because of the risk of hypoglycemia, all neonates should receive glucose containing fluids in preparation for and during transport. Ten-percent dextrose infused at a rate of 80 mL/kg/d should be used in infants with birth weight greater than 1000 g. Five-percent dextrose should be used in smaller infants because they are likely to develop hyperglycemia with high glucose intake. In these infants, the infusion rate should be increased to approximately 100 mL/kg/d because of excessive insensible water loss. In all infants at risk for hypoglycemia, measurement of blood sugar should be repeated at frequent intervals, at least every 2 h. [6]

Vascular Access

Peripheral venous access in the neonate may be technically challenging and is usually performed successfully only by caretakers skilled in this technique. Femoral line placement is difficult in neonates and should rarely be considered. Intravascular lines placed through the umbilicus are a simple and desirable alternative for both arterial and venous access in infants less than 1 week of age. The most rapid way to obtain vascular access is to temporarily place an umbilical venous catheter (UVC) 2 to 3 cm below the level of the skin. A UVC located in this position can be used to administer fluid, medications, and pressors in emergency situations, but it is not a sufficiently stable form of access during transport. By contrast, UVCs with the tip located near the junction of the inferior vena cava and the right atrium are ideal for all infusions, both during stabilization and transport. The position of the tip of the catheter should be determined radiographically prior to use to ensure that medications are not being infused into the liver. An umbilical artery catheter is desirable when frequent blood gas analysis is anticipated or central blood pressure

monitoring is crucial. However, umbilical artery catheters should not generally be used for the administration of pressors.

Risk of Infection

Signs and symptoms of infection in a neonate are often nonspecific and may be indistinguishable from those associated with other diseases. Therefore, infection should be presumed as a cause of illness in any sick neonate. Broad-spectrum antibiotics should be administered unless the signs and symptoms can be attributed with reasonable certainty to a cause other than infection. Antibiotics should also be administered to premature infants because uterine and placental infection is a common cause of preterm labor.

Antibiotics should be administered as soon as possible because early treatment decreases mortality and morbidity rates. It is preferable to collect a blood culture prior to the initiation of antibiotic therapy, but therapy should not be withheld because of difficulties in collecting a blood culture.

Determining Viability

Delivery of premature infants who are at the limits of viability is not an uncommon occurrence in the emergency department. Under these circumstances, the first priority of the physician caring for the infant is to determine whether resuscitation is justified. An infant born at a gestational age of less than 24 weeks, weighing less than 500 g, who has gelatinous skin and fused eyes should not, except under unusual circumstances, be resuscitated. By contrast, infants born at greater than 24 weeks are likely to have a relatively good outcome and should be supported aggressively after birth. The decision to initiate support must be made immediately. If the decision is not clear, proceed with resuscitation.

Death of an infant judged to be nonviable might not occur rapidly even in the absence of respiratory support. After a decision has been made to withhold aggressive care, it is important that the staff remain supportive and available to the parents. If the parents desire, the child can be held in a quiet place with a physician checking periodically to determine the time of death. This period, around the time of death, may be emotionally difficult for the staff as well as the family. However, families often recall these irreplaceable moments with fondness. Futile efforts at resuscitation or interfacility transport should not be a substitute for compassionate support without medical intervention.

MONITORING DURING TRANSPORT

One of the critical aspects of care during transport is electronic monitoring. At a minimum, the following monitors should be considered:

1. *Heart rate and respiratory monitor.* All transported patients should be monitored with impedance electrocardiogram (ECG) and respiratory monitoring. The selection of a monitor should be based on its size, weight, battery life, and resistance to motion artifact. The monitor should include a screen with a graphic display of ECG and respiratory tracings. Ideally, the monitor should display pressure waveforms and digital readings of systolic, diastolic, and mean blood pressures from transduced intravascular catheters. It is not essential that the monitoring system include the capability of electrical cardioversion or pacing. The need for such a device in the care of pediatric patients is extremely rare. However, this capability should be available during the transport of patients with known arrhythmias or patients at risk for such problems (e.g., tricyclic poisoning).
2. *Pulse oximetry.* Continuous pulse oximetry is essential in patients with cardiorespiratory illness. Devices that display a plethysmographic waveform are ideal because they assist in identifying motion artifact.
3. *Body temperature monitor.* Continuous temperature monitoring is helpful in neonates and small infants because of their predisposition to hypothermia.
4. *Carbon dioxide monitor.* Continuous estimation of Pa_{CO_2} is helpful in patients with respiratory failure. Transcutaneous carbon dioxide monitors may be useful in young infants, but their value in transport is limited because of the need for frequent calibration using special calibration gases. In addition, they cannot be relied on to provide accurate absolute measurements. Rather, they are valuable only for identifying trends. Capnography, utilizing continuous in-line infrared analysis to measure end-tidal carbon dioxide, is becoming increasingly popular as an alternative to transcutaneous carbon dioxide monitoring. As yet, capnography has not been widely used during transport.
5. *Blood pressure monitor.* Noninvasive blood pressure monitoring is advisable in children without indwelling arterial catheters. The cuff should cycle frequently enough to provide meaningful information about changes in hemodynamics. Arterial pressure can be monitored directly in patients with indwelling arterial catheters. Direct monitoring is preferable because it is more accurate and provides an alarm system in the event that arterial pressure suddenly falls (e.g., if the line becomes disconnected and the neonate suddenly has unimpeded arterial hemorrhage). Noninvasive blood pressure monitoring may also be useful in patients with direct monitoring to differentiate abnormal findings from technical artifacts.
6. *Portable blood analyzer.* Small, battery-powered devices are now available for the performance of blood gas analysis and measurement of selected blood chemistries (e.g., electrolytes and blood glucose). These devices may be valuable for monitoring patients with dynamic diseases, particularly when the transit time between hospitals is long.

CONDUCT OF A TRANSPORT

The transport of a critically ill child from the emergency department in a community hospital to a regional center is rarely a scheduled event. Nevertheless, the transfer should proceed in an orderly fashion if protocols exist within the emergency department for referral of critically ill children. These protocols should provide information about each regional center to which a patient might be referred, including (1) special services available; (2) criteria for referral; (3) telephone numbers for consultation, referral, and transport; (4) distance and usual response time; (5) type of transport personnel and their capabilities; (6) type of transport vehicles; and (7) protocols for preparation of patients. It is also advisable to establish formal agreements with regional centers that outline the circumstances under which patients can be transported without prior administrative approval.

Once the decision has been made to transport a child, the referring hospital has certain obligations in addition to medical care. [7] The Consolidated Omnibus Budget Reconciliation Acts of 1985 and 1989 mandate some of these responsibilities. The referring physician must contact the receiving hospital and secure a receiving physician. The choice of receiving institution is critical because the referring physician is liable for the adequacy of that facility.

In preparation for transport, the referring hospital should assemble all available information pertinent to the current illness. This generally includes a copy of the emergency department record, laboratory data, radiographs, and old medical records if available. The referring physician should inform the parents of the need for transfer and discuss the mechanism by which the child will be transferred. Consent to transport should be obtained from a parent or other responsible individual.

Receiving physicians often make recommendations regarding stabilization of the patient. This information should be requested if necessary. However, referring physicians are not obligated to follow these recommendations if they are considered to be medically inappropriate or beyond the capabilities of the referring hospital. Under these circumstances, it is advisable for the referring and receiving physicians to develop an alternative plan.

A collaborative decision must also be made regarding who will assume the responsibility for transporting the patient. There are usually four options: private automobile, local ambulance service, local ambulance with personnel from the referring hospital, or service provided by the receiving hospital. The selection should be based on the appropriate balance between the needs of the patient and the resources of each type of provider. Cost should be a consideration only when more than one provider can satisfy the patient's needs.

For most critically ill pediatric patients, ideal care is provided when the emergency department of the referring hospital devotes its energy to providing emergent short-term care and the responsibility for transport is left to the regional center. This is particularly true for neonatal patients because of the special equipment and expertise required for transport. It is rarely in the best interest of critically ill children to "pick them up and run." When transport services are not provided by the regional center or when time is critical, it may be appropriate for the referring hospital to provide transport. In these circumstances, it is the referring hospital's responsibility to ensure the adequacy of care during transport. The converse is true if transport is conducted by the receiving hospital.

In many areas, physicians also have a choice between air and ground transportation. Again, this decision should be made collaboratively. [8] Air transport should be reserved for situations in which reduction of a critical period of time during transport is likely to reduce morbidity or mortality. In some emergencies, the critical period ends with the arrival of the receiving hospital's transport team because the team is able to administer a definitive intervention. Under these circumstances, the advantage of air compared to ground transport is directly related to the reduction in time between the referral and the arrival of the team at the referring hospital. Air transport may offer the greatest advantage when the definitive therapy is available only in the receiving hospital (e.g., a surgical procedure) because the patient

benefits from the reduction in transit time for the round trip between the receiving and referring hospitals.

When the transport team arrives, the referring physician should be present to coordinate the transition of care. Under most circumstances, a transport team originating from a hospital other than the referring hospital does not receive a detailed history of the patient's illness prior to arrival. It is essential that the referring physician be available to provide this history and a brief review of recent events. In addition to the referring physician, one or two support personnel should also be available to aid the transport team with further stabilization.

ORGANIZATION OF A PEDIATRIC TRANSPORT PROGRAM

The administration and staffing of a neonatal transport program is rarely the responsibility of emergency department personnel, and therefore is not discussed in this chapter. However, programs responsible for transporting older pediatric patients often originate in the emergency department. While a detailed discussion of the conduct of a pediatric transport program is beyond the scope of this book, this section outlines the principles of the organization of a transport program with emphasis on pediatric transport. The focus is on interhospital transport, although many of the principles also apply to prehospital and intrahospital transport.

Administration

Components of a transport program can be divided into two general categories: medical and nonmedical components. [9] The medical components include medical personnel, equipment, and supplies. The nonmedical components include transportation, communications, billing, and marketing. A physician with training and expertise in pediatric intensive care or pediatric emergency medicine should supervise the medical components of a pediatric transport program. While this individual assumes overall responsibility for the program, many management decisions may be shared with or delegated to a nurse manager or other professional. Because of the time constraints on medical professionals and their usual lack of administrative expertise, the responsibility for direction of the nonmedical components of the program is often best assumed by a member of the hospital administration.

Transport Team Personnel

A variety of personnel might serve as attendants during pediatric transport including physicians, nurses, nurse practitioners, respiratory therapists, physician assistants, and paramedic-emergency medical technicians. [10] Practical issues such as availability, salary costs, and the requirement for training most often govern the selection of a particular professional group. Although it would be desirable to have a physician with expertise in pediatric emergency medicine in attendance during each transport, this is rarely practical. Utilizing physicians in training is an alternative, but the competition between transport activities and other aspects of their training often makes this an unattractive alternative. An increasing number of programs now utilize specially trained nonphysician personnel exclusively.

Ideally, pediatric transport personnel would have responsibility for pediatric patients only. Unfortunately, few centers have the volume of pediatric transports or the resources to support a stand-alone team for pediatric patients. More often, the responsibility for transporting infants and small children falls to teams who also transport neonatal patients, while another team transports older children and adults. The latter model of care can result in competent patient care if special effort is devoted to preparing personnel to manage pediatric emergencies.

Training requirements for team members may vary and depend on their designated responsibilities during transport. For example, programs that utilize physicians may not need to train nonphysicians in skills related to airway management. At least one member of the team attending every patient should include an individual who is experienced in diagnosing and managing virtually all life-threatening pediatric emergencies. It is helpful to cross-train if more than one discipline (e.g., respiratory therapy and nursing) is represented on the team. In addition, all team members should have a thorough understanding of the transport environment and should be familiar with all communication devices.

Many different training strategies have been utilized to prepare transport personnel. Common to most are didactic sessions during which cognitive knowledge is attained, laboratory sessions during which technical skills are taught, and supervised patient care (Table 4-4). This training is generally followed by participation in transport accompanied by an experienced team member.

TABLE 4-4   Training for Pediatric Critical Care Transport Team

Vehicles

Three types of vehicles are used during interhospital transport: ground ambulances, helicopters, and fixed-wing aircraft. The choice of a vehicle for a program is often dictated by the features of the anticipated population and the relative advantages and disadvantages of each mode of transportation.

AMBULANCES   Ground ambulances are available at most medical centers but may require modification for optimal transport of pediatric patients. Their disadvantage is excessive travel time between hospitals when distances are great or when terrain, road conditions, or traffic congestion require slow travel. Their advantage is relatively low operating costs compared to other forms of transportation.

HELICOPTERS   Helicopters provide the most rapid service when distances between hospitals are within approximately 150 mi. When landing facilities are available at both hospitals, helicopter transportation reduces transit time by at least two-thirds compared to ground ambulance. Noise and vibration levels are high, and it is rarely practical to stop the vehicle for the management of an emergency requiring a more stable environment. They also have a more confined patient care compartment compared to other vehicles. The impact of these problems can be minimized by extensive preparation of the patient prior to transport and sophisticated electronic monitoring. Because of their speed, helicopters are the vehicle of choice for programs transporting a high proportion of trauma patients for whom time to the receiving hospital is much more important than in-transit care. The major disadvantage of helicopters is the extremely high cost of operation. The purchase cost of a helicopter is usually in excess of $2,500,000; lease/operation contracts usually exceed $100,000 per month.

FIXED-WING AIRCRAFT   Fixed-wing aircraft also offer the advantage of speed, which is five to six times that of ground ambulances. This advantage is only appreciated when distances exceed approximately 120 mi because of the additional time needed to transfer the patient and medical personnel between airports and hospitals. Fixed-wing aircraft are also much less costly to operate than helicopters.

Equipment and Supplies

Equipment used to care for pediatric patients during transport is similar to that found in most emergency departments except that it is portable and reduced in size and weight. This is in contrast to equipment used during neonatal transport, which is usually specially designed for its unique function. The basic equipment required for pediatric transport includes a ventilator, a cardiorespiratory monitor with invasive pressure monitoring capability, a pulse oximeter, intravenous pumps, and a noninvasive blood pressure monitor. This equipment should be mounted to a stretcher or fitted with devices that can be secured to the vehicle or stretcher during

transport.

Supplies and small equipment should be preassembled in equipment packs. These supplies can be divided into separate packs based on those required for airway management and all other care. Suggested inventories for these packs are included in Table 4-5.

TABLE 4-5   Content of Equipment Packs for Pediatric Critical Care Transport

Communications

Reliable and rapid communication is essential for the efficient operation of a transport program. Communication systems that support transport programs are of three varieties: 911 emergency dispatch centers, communication centers within emergency departments, and communication centers dedicated solely to transport programs. Centers that support EMS as well as transport programs are generally more economical. This combined function also helps facilitate the integration of EMS and the transport program. However, 911 dispatch centers are usually governed by agencies other than hospitals and therefore may not be responsive to the needs of the transport program.

The dispatch center should have equipment capable of coordinating communications among referring and receiving medical personnel, transport attendants, vehicle operators, local EMS providers, and area air traffic controllers. Coordinating communications may require the integration of local and long-distance telephone lines, cellular telephones, UHF and VHF band radios, and radio pagers. Ideally, the dispatch center should also have a device for recording all communications.

Transport vehicles should be equipped to provide the same range of communications as the dispatch center. At a minimum, both UHF and VHF band radios are required. Cellular telephones should also be considered in regions where cellular coverage is extensive. Telephones offer the advantage of user friendliness and a style of communication with which more medical personnel are familiar.

Patient Care Protocols and Quality Assurance

The medical director of the program should develop patient care protocols. They should reflect the institutional standards of care for the full range of emergencies likely to be encountered. The program should also document the techniques for training personnel and certifying competency.

During the conduct of a transport, the team should be supervised by a physician with expertise in the care of pediatric emergencies. If such an individual is not in attendance, phone or radio communication with an appropriate physician is advisable at some point during the transport.

To ensure quality of care, the program should also have a systematic plan to review transports. This plan should involve all disciplines represented by the team.

5 DISASTER MEDICAL SERVICES

Eric K. Noji

Natural disasters, such as earthquakes, tornadoes, floods, and hurricanes, have claimed about 3 million lives worldwide during the past 25 years, adversely affecting the lives of at least 800 million more people, and have resulted in property damages exceeding $23 billion. While past disasters have produced their share of mass-casualty situations, the future appears to be even bleaker. [1] Increasing population density in flood plains and earthquake- and hurricane-prone areas, the development of thousands of toxic and hazardous materials and their transportation on public roads, the potential risks from incidents at fixed-site industrial facilities, and the catastrophic possibilities of nuclear, biological, and chemical terrorism all suggest the probability of major emergencies in the future. Recent significant disasters include massive summer flooding in the Midwest (1993); earthquakes in Northridge, California (1994), and Kobe, Japan (1995); the bombing of a federal office building in Oklahoma City (1995); a sarin chemical weapon attack on a Tokyo subway (1995); a bombing during the Olympic Games in Atlanta (1996); severe El Nino-related flooding in California (1997); and Hurricane Mitch (1998). [2,3 and 4]

This chapter discusses disaster planning and operations with particular emphasis on the emergency department and the role of the emergency physician. Emergency physicians have extensive responsibilities for community disaster preparedness and other disaster medical services. In several position papers, the American College of Emergency Physicians (ACEP) has outlined the scope of emergency physicians' involvement in disaster medical services and stated its belief that "emergency physicians should assume a primary role in the medical aspects of disaster planning, management, and patient care ... [and that] emergency physicians should pursue training that will enable them to fulfill this responsibility." [5,6 and 7] Despite efficient field management of disaster victims, a rapid flow of victims from a disaster scene can quickly overwhelm a hospital emergency department. Emergency departments must have a specific set of protocols that direct the mobilization of personnel and equipment outside of the emergency department and permit rapid assessment, stabilization, and triage to definitive care of victims of a mass-casualty incident. [8]

DEFINITION OF DISASTER

According to the World Health Organization, a disaster is a sudden ecological phenomenon of sufficient magnitude to require external assistance. [9] From the perspective of the emergency department, however, a disaster exists when the number of patients and/or the severity of illness or injury are such that normal daily emergency department operations are no longer possible. In other words, the number of patients presenting in a given time period are such that the emergency department cannot provide care for them without external assistance. [10] Disasters that cause large numbers of deaths and injuries are referred to as mass-casualty incidents. [11] However, disasters cannot be defined simply by a given number of victims. Large university hospitals with house staff may not have the facilities to manage even two chemically contaminated patients. [12,13] The arrival of one important political person or celebrity with severe injuries (e.g., the President of the United States, the Pope, or a rock star) completely disrupts the normal operations of even the most efficient emergency department. [14]

Regardless how a disaster is defined numerically or situationally for a given institution, it is imperative that the hospital and, more specifically, the emergency department institute preestablished protocols for effectively dealing with such extraordinary situations. These protocols (e.g., for chemically contaminated patients or for the mobilization of appropriate outside assistance) must be instituted rapidly in order to prevent death or severe complications.

In many hospitals in the United States, disasters are often divided into external and internal events. External disasters are events that occur physically outside the hospital (e.g., transportation accidents, terrorist actions, etc.). As a result of such an external event, patients are brought to the hospital from the outside, usually to the emergency department. Unless the outside disaster is a chemical accident with contaminated patients, the hospital and its staff, patients, and visitors are in no immediate physical danger.

Internal disasters are events that occur within the physical plant of the hospital itself (e.g., a fire or laboratory accident involving radioactive material) that severely compromise the ability of the hospital to function. [15] A disaster may be both internal and external, for example, an earthquake that severely damages the hospital. [16] Such an event may damage the structural integrity of the hospital, cause dangerous equipment or supplies to fall over, and injure or kill hospital staff, patients, and visitors.

EFFECT OF MASS-CASUALTY EVENTS ON AN EMERGENCY DEPARTMENT

Extensive social and organizational research on the management of mass-casualty events has shown that emergency departments experience great difficulty coping with even moderate numbers of patients following a disaster. [17] The reasons for this difficulty include confusion, lack of planning, and lack of training in the principles of disaster management. Hospitals are often not well integrated into the surrounding community's disaster planning efforts. [18] Hospital disaster plans often exist only on paper and are rarely referred to, let alone carried out, during a real disaster. Shortcomings of hospital disaster plans include (1) delayed or improper notification of hospital staff, (2) poor delineation of the command structure, (3) overloaded or broken communications networks, (4) improper or incomplete identification of patients and the dead, (5) lack of supplies, and (6) lack of public relations. [19]

When a disaster occurs, transportation of patients to emergency departments is usually uncoordinated, with no thought given to equitable distribution of patients among potential receiving medical facilities. [20] As a result, nearby hospitals are usually overwhelmed with the majority of severely injured patients, while those farther away see very few patients. [21] Most casualties are transported to a hospital over a relatively short period of time, with most patients arriving at an emergency department within $1\frac{1}{2}$ h after the disaster has occurred. [22] Most patients presenting to an emergency department in a disaster have minor injuries and do not require advanced trauma services. [21]

Victims of mass-casualty events may arrive at hospitals by a variety of means, including ambulances, private automobiles, police vehicles, taxis, and on foot. [23] Since hospitals may receive patients in all sorts of unplanned ways, the flow of patients is not under the control of the official or formal emergency medical services (EMS) system. [22] In addition, ambulatory patients and those with relatively minor injuries may arrive at the emergency department before patients with more serious injuries because they are able to leave the disaster site by their own devices, using taxis, buses, private cars, vans, and police vehicles. The more severely injured, who often need extrication (e.g., from collapsed buildings following earthquakes), arrive at a later stage. The result is that less severely injured patients often tend to be treated before the more seriously injured. The early arrival of a large number of ambulatory patients can create serious problems because the emergency department may become badly overcrowded early, resulting in confusion in the efforts to provide treatment. [24] Similarly, when attention is being paid to early arrivals at a hospital, it is easy for the more seriously injured patients brought in later not to be noticed immediately or to be given delayed treatment.

Rescuers, emergency medical technicians, and representatives of the media may rapidly converge on the emergency department and contribute to chaos.

DISASTER PLANNING

Overview

Roles, responsibilities, and working relationships among those responsible for disaster operations should be clarified in the planning process to lessen the confusion that invariably occurs during a disaster. [25] Selected protocols should require personnel to perform functions that are relatively similar to their day-to-day activities.

The disaster planning process should begin by answering the following questions:

1. What types of disasters are most likely to occur in the community (hazard analysis)?
2. What are the disaster planning requirements of the Joint Commission on the Accreditation of Healthcare Organizations (JCAHO), as well as local and state health agencies? [26]
3. What are the capabilities and responsibilities of the hospital?

Hazard Analysis

Hospital disaster planners must plan for those disasters most likely to occur in their community. [27] Hospitals in Hawaii and along the Gulf coast of the United States should plan for hurricanes, [28,29] those in California should plan for earthquakes, [30,31,32,33 and 34] and those near chemical industries should have facilities for decontamination. Hospitals located near facilities using large amounts of hazardous materials are required by Title III of the Superfund Amendments and Reauthorization Act to participate in local emergency planning committees. [35] Accidents at large transportation facilities, such as airports and harbors, and at festivals, stadiums, and amusement parks can generate large numbers of casualties. [36,37,38 and 39] Various types of disasters are characterized by specific morbidity and mortality rate patterns, and thus health care requirements. [40] Earthquakes cause many deaths and severe injuries. [41,42 and 43] Hurricanes cause primarily property damage, with low numbers of deaths and predominantly minor injuries. [28] Pulmonary irritation from fires or hazardous chemicals requires large supplies of oxygen, as the 1984 industrial accident in Bhopal, India, demonstrated. [44] The Tokyo sarin chemical weapon attack in 1995 required large quantities of the antidote atropine. [45] Fortunately, some disasters, such as hurricanes, may afford several days' lead time, and preparations for management can begin early.

JCAHO Requirements

JCAHO requires that member hospitals have a written plan for the timely care of casualties arising from both external and internal disasters, and the hospital must document the rehearsal of these plans. [26]

Hospital-Community Cooperation in Disaster Planning

Every hospital should integrate its own disaster plan with those of community disaster management agencies. [10,27] Such integration is especially important in the areas of disaster notification and communications, transportation of casualties, and provisions for dispatch of hospital medical teams to a disaster site. Strong relationships with community agencies, such as the fire department, the regional EMS system, the local emergency management agency, and the civil defense agency, are important to ensure a coordinated disaster response. Table 5-1 lists key members of the community disaster team.

Community Agency	Responsibilities
EMS service	Patient triage in the field, stabilization, transfer to definitive care facility
Fire service Police service	Overall scene command, victim rescue, hazard control, traffic management, scene security
Emergency manager	Communications, personnel and equipment support, liaison with state and federal agencies
Public works	Support equipment and personnel, structural safety expertise
Chief executive officer	Management of overall operation, assurance of public safety, communication with public, direction of requests for outside assistance to appropriate state and federal authorities

TABLE 5-1   Community Disaster Team

The hospital may also interact with utility companies, the military, the local American Red Cross, the Salvation Army, the Federal Emergency Management Agency (FEMA), the National Disaster Medical System, and the Centers for Disease Control and Prevention during a disaster.

Medical planning for disasters in the community is usually the responsibility of local EMS councils. [46] Such councils include representatives from the local ambulance services, the fire department, and other nonmedical and government agencies as well as the physician EMS director. Physicians involved in community disaster planning must be familiar with the local EMS communications and treatment protocols. [5]

The hospital must develop its external disaster plan in conjunction with other emergency facilities in the community. For example, prearranged mutual aid agreements with hospitals outside the immediate area ensure that patients are cared for when hospital capacities are exceeded. Plans should also be made for referral to area tertiary centers and special units (e.g., burn, spinal cord, and pediatric trauma centers).

Hospital disaster planners should anticipate that information about specific hazards (e.g., chemicals and radiation), expert personnel (e.g., poison control), and special supplies (e.g., antidotes) not readily available may be needed in a particular disaster situation. Plans should consider how to rapidly access these resources and how to obtain additional shelter, food, and water if necessary.

THE HOSPITAL DISASTER PLAN

Basic Requirements of Hospital Planning

Hospital disaster planning is the responsibility of the administration, the nursing staff, and the medical staff. A good hospital disaster plan should be coordinated with community organizations and should provide an organized response for the management of casualties transported to the hospital from the disaster site. Finally, it should take into account disasters arising within or near the hospital that require hospital evacuation.

Staff members perform most efficiently when they are performing relatively familiar tasks. The disaster plan should therefore rely on standard operating procedures as much as possible. Key functions of the hospital plan are listed in Table 5-2.

Activation of the plan

Assessment of the hospital's capacity

Establishment of a disaster command

Communications

Supplies

Hospital disaster administrative and treatment areas

Training and drills

TABLE 5-2   Key Functions of the Hospital Disaster Plan

Activating the Disaster Plan

The plan must designate an individual and alternate who have the responsibility of putting the hospital's disaster plan into effect. Situations that warrant activation of the plan should also be defined (see "Definition of Disaster," above). For example, the emergency department disaster manual must define how the on-duty physician and nurse determine when to mobilize staff from other departments and when to involve the hospital administrator and nursing supervisor.

Following activation of the plan, there must be immediate mobilization of anticipated disaster resources: personnel, supplies, equipment, communications, and transportation.

Assessment of the Hospital's Capacity

Before the hospital can receive casualties, it must be determined whether the hospital itself has sustained any structural damage or loss of utility as a result of a disaster. Such damage may include blocked passageways; inoperable elevators; potential for fire, explosion, or building collapse; failure of any utility; loss of equipment and/or supplies, including oxygen; contamination of water; and outside access problems. Damage assessment is usually the responsibility of the plant safety officer or hospital engineer. If the structural integrity of the hospital has been compromised, it may be necessary to evacuate staff and patients. [16]

Once it is ascertained that the hospital itself is safe, the hospital must determine how many casualties from the disaster site it can safely manage. This capacity may be limited by available personnel, beds, and supplies as well as by the type of disaster and the availability of other community resources. At the time of disaster notification, it is necessary to know the status of many of the hospital's capabilities, including how many beds are available, how much blood is available, how many personnel are on duty, what damage has been done, how many operating rooms are in use, and which doctors are present. Either someone must tour the hospital to accumulate this information or a form for reporting it must be available in each department ahead of time.

Establishment of Disaster Command

A predesignated command site within the hospital should be established. The command site should be able to communicate with the emergency department receiving and triage area, with patient care areas, and with regional EMS, police, fire, and governmental authorities. Provisions for multiple modes of communication should be made. The command personnel should include at least a physician, a nurse, and an administrator. [10]

Communication

Establishment of good communications is critical in any disaster or mass-casualty situation. Past experience, however, has shown that this essential function is difficult to achieve for a variety of reasons. Telephones frequently become inoperative due to switchboard overload and damage to telephone lines and other equipment. A major goal should be full utilization of all possible communications resources, including citizens' band groups, cellular phones, blackboards, E mail, intercoms, closed-circuit television, short-wave radio and radio-equipped individuals of all kinds, runners, and even messenger and courier services.

Interhospital communication may be necessary because of shortages of supplies, such as blood or intravenous fluids; certain equipment, such as incubators or surgical instruments; or personnel, such as nurses, x-ray technicians, respiratory therapists, or physicians. When a hospital is overloaded, it may be desirable to transfer patients to a prearranged receiving hospital. Unfortunately, interhospital communications may present a weak link in the community's disaster response. After one Los Angeles earthquake in 1971, 67 percent of hospitals had difficulty with interhospital communications. [46a]

Supplies

During a disaster, necessary supplies and equipment must be ready for immediate distribution to appropriate locations in the hospital (e.g., stretchers and wheelchairs to the receiving area). Each hospital must estimate the amount of disaster supplies that will be needed in addition to its regular stock. The trend toward last-minute inventories may exacerbate problems in this area.

Hospital Disaster Administrative and Treatment Areas

Specific areas of the hospital must be designated for specific functions (Table 5-3). Staffing requirements and basic supplies for each area should be defined.

Disaster command

Triage

Patient identification, registration, and documentation

Patient care stations

Presurgical holding

Surgery

Morgue

Decontamination

Psychiatry

Family waiting and discharge area

Public relations

TABLE 5-3   Hospital Disaster Areas

DISASTER COMMAND   Disaster command provides overall direction and coordination of the hospital disaster response activities. These activities include activation of the plan, coordination of hospital activities with those at the disaster site, opening up additional hospital wards or clinics, obtaining outside assistance, evacuation of endangered patients, assignment of staff to treatment areas, and adjustment of the plan as necessary. Good, reliable communication is essential.

TRIAGE   Entry of all patients should be restricted to one location: the triage area. The primary function of a disaster triage area is rapid assessment of all incoming casualties, assignment of priorities for management, and distribution of patients to various patient care areas in the hospital. A senior emergency physician or resident should be responsible for triage.

PATIENT IDENTIFICATION, REGISTRATION, AND DOCUMENTATION   Emergency department registration personnel are key components of the emergency department disaster response. Ideally, they should be part of the triage team. Prepared documents assigned to each patient should include a unique disaster number for each patient, the patient's name and key information if available, the triage designation, the patient's wristband identification and charting materials, and copies for postevent analysis. A system should be in place to quickly obtain more patient documents when the supply is depleted. A separate triage log should be maintained. Individuals must also be assigned to transfer registration information to the hospital computer system so that laboratory requests, admissions, blood for type and cross-match, and dispositions can be systematically recorded. Finally, if unique disaster numbers are used, a system for transferring to the hospital medical record number system should be in place.

PATIENT CARE STATIONS   One suggested method of organizing patient care stations includes division into resuscitation, major illness and injury, and minor trauma/primary care.

A resuscitation area should handle all life-threatening problems. Seriously injured patients who do not require immediate airway management or resuscitation are sent to the major illness or injury area, located in the emergency department.

In most disaster situations, the majority of patients are not seriously injured. Such patients can be sent to the minor trauma/primary care area for splinting of fractures, primary closure of lacerations, and tetanus prophylaxis. This area can be established in the hospital's outpatient clinics.

PRESURGICAL HOLDING   Most trauma patients stabilized in the major illness or injury area (emergency department) will be sent to the admission presurgical holding area.

SURGERY   The number of operating rooms that can be staffed is the main limiting factor in the provision of definitive care for a large number of severely injured casualties.[47] The most senior surgeon available must take the responsibility for prioritizing cases and assigning surgeons to them as rapidly as possible.

MORGUE   Many disasters can result in a large number of fatalities. Morgue capacities may need to be expanded or outside facilities, such as a church or stadium, temporarily utilized.[48]

DECONTAMINATION   JCAHO requires hospitals to have provisions for emergency treatment and decontamination of individuals who are radioactively or chemically contaminated.[13,49] Some basic requirements for hospitals are (1) a safe area for decontamination, (2) a means of washing external contamination from patients, (3) a method of containing contaminated materials, (4) adequate protection for persons handling patients and for other hospital personnel, and (5) disposable and/or cleanable medical equipment.

The goals are to reduce external contamination, contain the contamination that remains, and prevent further spread of potentially dangerous substances.[12,50] After being decontaminated, the patient can be treated as a "normal" accident victim. To accomplish this, three things must be achieved: (1) termination of exposure to toxic material, (2) stabilization of the patient, and (3) initiation of proper definitive care.

PSYCHIATRY   In the event of a disaster involving mass casualties and extensive property damage, it is common for patients to present with episodes of anxiety, depression, and psychosis. Hysterical persons, whether patients, visitors, or staff, can be extremely disruptive to hospital disaster operations. A separate, isolated area must be predesignated to receive individuals in need of psychological intervention.

FAMILY WAITING AND DISCHARGE AREA   Families and friends will converge on the hospital seeking information about victims. A separate area must be predesignated for family members seeking information. This area may also be utilized to discharge in-hospital patients and victims of the disaster. It may be staffed by volunteers, chaplains, and members of the public relations staff.

PUBLIC RELATIONS COMMAND   The medical disaster plan should include a section on the proper relationship with the media. Representatives of the media are present at all medical disasters. They may be a valuable resource for announcing hazards or the need for evacuation. In addition, they may be used to make a general announcement that hospital or rescue personnel should report to work. The plan should include a means of providing the media with adequate information both at the site and in the hospital. At the disaster site, regular briefings help prevent representatives of the media from becoming victims as they search for more information. At the hospital, regular briefings and a room with adequate telephone access will prevent members of the media from invading patient care areas. A hospital public relations officer should act as liaison to the media. His or her duties are to prepare the pressroom, hold regular briefings, and arrange appropriate photographic opportunities. These functions must be carried out while balancing the public's right to know with individual victims' rights to privacy.

Training and Drills

Regular training and drills help to familiarize staff with their disaster roles and responsibilities. They also serve to point out weaknesses or omissions in the plan that require additions or revisions. Drills can range from full-scale community-wide simulations with moulage victims to tabletop triage games to minidrills that test only certain components of the disaster plan, such as call-up of personnel and testing of communications. JCAHO requires two drills a year; the scenarios should reflect incidents that are likely to occur in the community.

FIELD DISASTER OPERATIONS

On-Site Medical Care

In the field, rescue personnel often use a simple triage and rapid treatment (START) technique that depends on a quick assessment of respiration, perfusion, and mental status.[51] Subsequently, determining how much and what type of care to administer at the disaster site depends on several factors. If the number of patients is small and sufficient prehospital personnel and transportation resources are available, on-site medical care can proceed in a fairly normal manner, with rapid stabilization and transportation to nearby hospitals. When extrication will be prolonged, potentially lifesaving interventions, such as crystalloid infusion for hypovolemic shock, should be instituted in the field.[52,53] On the other hand, early, rapid transportation with a minimum of treatment should be practiced when there is danger to rescuers and casualties from fire, explosion, falling buildings, hazardous materials, or extreme weather conditions.

When there is an overwhelming number of casualties that exceed transportation capacities, advanced field medical and surgical treatment may be beneficial, since it may be hours before seriously injured patients can be evacuated.[54] This may necessitate the establishment of field hospitals with operating-theater capabilities. Casualties are brought there from the disaster site for further assessment and initial treatment of their injuries. After a period of observation and stabilization, they are either sent home or transported to a hospital.

If evacuation of ambulatory victims and those with minor injuries rapidly overwhelm local hospitals prior to the arrival of the more severely injured, it may be better to

treat them locally. To address these considerations, the secondary assessment of victim endpoint (SAVE) system of triage has been proposed. [55] The SAVE triage system is designed to identify patients who are most likely to benefit from the care available under austere field conditions. When combined with the START protocol, the SAVE triage is useful for any scenario where multiple patients experience a prolonged delay to definitive care (Fig. 5-1). The SAVE triage method divides patients into three categories: (1) those who will die regardless of how much care they receive, (2) those who will survive whether or not they receive care, and (3) those who will benefit significantly from austere field interventions.

FIG. 5-1. Medical disaster response modified simple triage and rapid treatment (START). There are three SAVE triage categories: unsalvageable, immediate care, and delayed care. (Used with permission, copyright Medical Disaster Response Inc., Dana Point, CA, 1990.)

Incident Command System

The incident command system (ICS) is a standard emergency management system used throughout the United States to provide a flexible command and control structure upon which to organize a response. [56] The ICS is generally used when there is an identifiable single scene for a disaster event, such as the site of a plane crash. By standardizing an organizational structure and using common terminology, the ICS provides a management system that is adaptable to incidents involving a multiagency or multijurisdictional response. At the most basic level, the organizational structure has five main components: (1) incident command, (2) operations, (3) planning, (4) logistics, and (5) finance. The principles of a prehospital ICS can also be applied to the hospital setting. With this type of organizational infrastructure and the flexibility to expand and collapse as needed, an orderly and efficient response to any incident can theoretically be implemented.

Communication from Disaster Site to Hospital

The local emergency communications or disaster operations center should alert hospitals in the affected area of a possible mass- or multiple-casualty situation. Ideally, this report should include the number of injured divided into categories: serious injuries, minor injuries, and special patients (e.g., pregnant women). Hospitals should report to the local emergency communications center the following information: (1) bed availability, (2) number of casualties received thus far, (3) number of additional casualties that the hospital is prepared to accept, and (4) specific items in short supply.

Distribution of Casualties to Receiving Hospitals

Typically, in the past, the hospital closest to the disaster site received an inordinately large number of disaster victims as well as the most critically injured. It is important that the casualty load be distributed among available hospitals so that the injured receive prompt and appropriate treatment and individual hospitals do not become overwhelmed.

However, such a situation may be unavoidable due to large numbers of critically injured patients, blocked transportation routes, or weather conditions. Nevertheless, such problems can be minimized by maintaining good communications between hospitals and on-site EMS command. The on-scene incident commander should be alerted immediately by a potentially overloaded hospital so that less injured and more stable patients can be sent to other hospitals. Secondary triage from one hospital to another may also be necessary if the hospital's capability to handle victims has been exceeded.

Casualties with special problems, such as major burns, carbon monoxide poisoning, and spinal cord injuries, may need to be transferred directly to specialized units, although it may not be possible for these units to accept a large number of injured.

On-Site Disaster Medical Teams from Hospitals

On-site disaster medical teams dispatched from local hospitals may be of value if victims require prolonged extrication; transportation routes are blocked, preventing easy evacuation to hospitals; or the number of casualties exceeds transportation capacities. Such a team should be dispatched with great caution. Most physicians and nurses function well in an in-hospital setting, but few are prepared, either by training or experience, to work under austere field conditions. Such hospital-based teams should probably not come from the emergency department staff until backup staff has arrived to care for patients expected from the disaster site and those already in the emergency department. The resources for such teams should be carefully planned on a regional basis. The capability to send hospital teams to a disaster site can be developed in a number of ways. For example, an on-site triage team of physicians and nurses can come from teaching hospitals or be created from a pool of volunteer medical staff in office practice. Ideally, at least one institution from each region should maintain such a capability. The designated hospital should store disaster triage kits containing essential resuscitation and stabilization equipment in the emergency department for such circumstances.

EMERGENCY DEPARTMENT

The emergency department is the most critical part of a hospital's initial response to virtually any type of external disaster. It is the department of the hospital that usually receives first notification that a disaster has occurred, and it is usually the entry point for incoming victims.

Initial Response

When a call is made to a hospital about a disaster or a potentially mass-casualty-producing event, the recipient of the call must have a procedure to follow for verification of the incident. A disaster notification form is used by some facilities to remind the staff of the questions they are to ask the caller.

The appropriate hospital official or administrator on duty is then given this information. When the emergency department is notified by hospital administration (now Disaster Command) that the external disaster plan is in effect, it sets in motion a series of activities. The information obtained from the call is given to the charge nurse; the clerical, registration, nursing, and medical personnel in the department are notified of the impending arrival of casualties; and the emergency department plan for calling additional staff is activated.

An initial needs assessment is conducted by the nurse and physician in charge, given the information available. They must evaluate and prioritize the patients currently in the department and admit, discharge, or transfer them. All stable and nonurgent patients should be given plans for follow-up care and discharged from the emergency department with responsible individuals.

Based on this initial assessment, the number of patients that the department can receive is determined and communicated to the prehospital disaster communications center. The nurse and the physician in charge then determine whether more physician and nursing coverage is required in the emergency department and assign staff to those areas in the department to be used during the disaster. As patients begin to arrive, the charge nurse must be alert to signs of staff stress and work overload before the problem gets out of hand. Family members and representatives of the media should be directed away from the emergency department.

Personnel Notification

The director of the emergency department or a designee should have a phone list of appropriate personnel to be called in to work during a disaster. Lists of addresses and phone numbers of these individuals should be distributed to all key personnel. This information should be regularly updated.

If hospital telephone communications have been completely disrupted, emergency department personnel may have to be reached by cellular phone, E mail, or radio or television announcement. Alternatively, a telephone remote from the hospital, even at a personal residence, may be able to handle this extensive calling job.

Security and Traffic Control

Hospital security personnel play a key role in the emergency department by diverting nonessential vehicles and ensuring a smooth, one-way flow of traffic to the ambulance entrance.

Reception of Patients

Since many patients will arrive independently of the official or formal EMS system, reports from the field may greatly underestimate the total number of patients.

All available litters and wheelchairs should be taken to the ambulance ramp immediately on announcement of the disaster status. Patients from the disaster site are met at the receiving area by hospital escorts, who assist the emergency medical technicians in transferring patients to wheelchairs or stretchers.

Essential equipment, such as endotracheal tubes, intravenous solutions, cervical collars, splints, and bandages should be placed near the ambulance entrance to permit convenient restocking of the ambulance and rapid return to the disaster site.

Medical Care during Disaster Situations

PATIENT IDENTIFICATION, REGISTRATION, AND CHARTING   Documentation is limited to patient identification and charting of critical findings and treatments. Some plans call for the use of the prehospital disaster tag to record this limited information. Other plans include the preparation of kits containing the emergency department records, x-ray requests, laboratory slips and tubes, and wristbands, all prelabeled with a discrete disaster number. Medical records and laboratory computers accept these numbers, which are used for patient identification until full normal registration is possible. At that point the computer will search previous medical records to match disaster numbers with the records of victims who have been patients previously. Such a prelabeled kit system can be used during normal operations on unidentified critically ill or injured patients, so that all hospital departments are familiar with the concept. Admissions personnel are needed to log key information rapidly. Hours or days later they will be able to complete the registration process.

TRIAGE   Triage is the prioritization of care based on severity of injury or illness, prognosis, and availability of resources. The triage personnel determine to which predesignated patient care area a patient should be sent based on priorities for care. For example, patients needing immediate decontamination or resuscitation are taken to decontamination and resuscitation areas. The dead are moved directly to the morgue. The severely but less critically injured are taken to the major illness/injury area. The walking injured are directed to the minor injury/primary care treatment area, often located in outpatient clinic areas.

A team consisting of an emergency physician or a surgeon skilled in triage, an emergency department nurse, and a medical records or admitting clerk should assess every patient. In extraordinary situations, several triage teams may be required to handle the casualty load. The physician performing hospital triage should be acknowledged as being in command in the triage area, should be clearly identified by a specially colored vest or other garment, and must understand all triage options.

Even though patients may have been triaged at the scene, they should undergo a second triage upon arrival at the hospital at the ambulance/triage entrance to the emergency department. Triage teams must remain at triage and cannot be diverted for patient care. Another team should be called to triage if immediate life support is needed. Only the most basic steps, such as opening the airway and applying pressure to active bleeding, should be done.

The triage team may need to communicate information on the number of casualties, severity of injuries, and need for additional resources to both the emergency department and the hospital Disaster Command center. Likewise, triage personnel need to be informed about the capability of the various treatment areas (e.g., major and minor injury) to handle additional casualties or special problems, such as eye injuries or burns. They also need to know about the establishment and location of patient overflow areas.

The admitting clerk's role as part of the triage team is to complete triage tags, attach them to victims, retrieve valuables and clothing for bagging, and maintain the triage area casualty log.

The approach to patient evaluation and treatment is quite different under disaster situations resulting in large numbers of casualties. While some principles of medical care are unchanged in a mass-casualty incident, other principles must be altered to achieve the best outcome for the largest number of patients rather than concentrating resources on a single patient. There is no role for advanced life support resuscitation at triage; care should be limited to manual opening of airways and control of external hemorrhage. Routine emergency department care is also modified: patients in cardiac arrest do not usually receive advanced life support and cardiopulmonary resuscitation in order that other seriously injured patients with a better chance of survival can be treated with available resources; radiologic and laboratory studies are used only if they will provide critical information; patients are hospitalized only when necessary; nurses have increased autonomy; and paramedics operate under standing orders without the need for on-line medical control.

The most common triage classification involves assigning patients to one of four color-coded categories (red, yellow, green, or black) depending on injury severity and prognosis (Table 5-4). In addition to taking into account the nature and urgency of the patient's condition, triage decisions should be sensitive to such factors affecting prognosis as age, general health, and prior physical condition of the patient.

TABLE 5-4   Triage Categories

WOUND CARE AND CRUSH SYNDROME   This section addresses some concepts of care that are not found in the routine management of emergency patients.

Wound infections may occur in virtually all types of disasters. Infected wounds and gangrene were major problems following an earthquake in Armenia (1988) and tornadoes in Illinois (1991).[57,58] In hurricanes or tornadoes, persons may be cut by flying glass and other, potentially highly contaminated material. Because of this, all wounds should be copiously irrigated. Primary closure of heavily contaminated wounds may result in major complications, as was the case following the Armero

volcanic eruption in Colombia in 1985. [59] If lacerations are more than 6 to 12 h old or appear contaminated, they should be treated by debridement and left open for primary delayed closure. Tetanus prophylaxis and tetanus immunoglobulin should be administered if indicated.

Victims who have been trapped by rubble for several hours or days should be watched very closely for signs and symptoms of crush syndrome, such as cardiac arrhythmias, hyperkalemia, and renal failure. [60,61] Fulminant pulmonary edema or pneumonia from dust inhalation may also be a delayed cause of death for victims of building collapse.

RADIOGRAPHIC AND LABORATORY STUDIES   Radiographic and laboratory studies should be used only if test results will change therapeutic intervention. For example, x-rays of closed, nonangulated potential fractures can be safely delayed for 24 to 48 h, during which time effective splinting, elevation, and ice can be utilized. On the other hand, cervical spine, pelvic, and femur x-rays may be indicated, considering their potential complications. A chest radiograph is needed in patients complaining of chest pain, dyspnea, or abnormal chest wall motion.

Indications for clinical laboratory studies are minimal. In cases of hemorrhagic shock, a baseline hematocrit and type and cross-matching for blood should be obtained. A urine dipstick test for blood may be useful in detecting renal or urinary tract injuries. All other laboratory studies should be considered accessory and ordered only in specific circumstances (e.g., determination of serum carboxyhemoglobin levels in cases of smoke inhalation).

BLOOD BANK   In a disaster situation involving many casualties, it is recommended that the blood bank have as many as 50 units of blood available. [62] It is also important that the bank have ready access to a source of volunteer donors who can be rapidly mobilized. Other potential sources of blood include friends and family members of patients as well as those with minor injuries.

PATIENT IDENTIFICATION AND RECORD KEEPING   Emergency department records of disaster victims have usually been poor or nonexistent in past disasters. [63] The general absence of detailed and systematic record keeping in disasters, except for serious cases in which patients were admitted to hospitals for surgery or to intensive care units, has implications for reimbursement and quality improvement.

Documentation of the patient's hospital course starts in the triage area. Proper tagging with a triage tag is essential for patient identification, documentation of medical care rendered, and supplying information for relatives and the news media. Unfortunately, triage tags are frequently underutilized in actual disasters because they are a departure from normal emergency department routine.

One member of the triage team (admitting or medical records clerk) should be assigned to record the patient's name and triage destination. If identification of the patient is not available, race, gender, and approximate age should be noted on the tag. An initial diagnostic impression should also be registered on the tag. This information is entered in the triage area log.

MEDIA RELATIONS AND FAMILY   The hospital may become inundated by more members of the media than disaster victims. [64] Members of the news media should be directed to an area away from patient care. The pressroom should be closely supervised by a hospital administrator or public relations specialist who is in direct contact with the disaster command center. To ensure that consistent information is released by the hospital, the staff must leave all communications with the media to the public relations team.

Family members should not be allowed into patient care areas. Special policies should be developed for handling family members whose relatives are critically ill or who have died. The hospital operator will also be inundated with calls of inquiry. Such calls should be directed to a single predesignated desk or office.

Aftermath of Disaster

As soon as possible, efforts should be directed toward returning the hospital to normal operations. Besides restocking and cleaning, consideration must be given to the emotional stress experienced by both prehospital and hospital staff. Short- and long-term emotional problems, including posttraumatic stress disorder, particularly among rescuers, have been reported on numerous occasions. [65] A technique known as critical incident stress debriefing (CISD) was introduced in 1983, [66,67] and such an intervention can assist providers in maintaining job performance and satisfaction, resulting in improved patient care. [68]

Deficiencies in a hospital's disaster plan that are revealed during a disaster should be carefully recorded, reviewed, and criticized. Immediate steps should then be taken to correct these flaws in the plan.

MAJOR DISASTER RESPONSE ORGANIZATIONS IN THE UNITED STATES

Federal Emergency Management Agency

In the United States, the Federal Emergency Management Agency (FEMA) is the federal government agency responsible for emergency preparedness and response. FEMA helps state and local organizations prepare for, respond to, and recover from emergencies. Under the Robert T. Stafford Disaster Relief and Emergency Assistance Act, public law 93-288 (the Stafford Act, 1988), the President is authorized to direct federal agencies to provide emergency assistance to save lives and protect property, public health, and safety in emergencies. "The Federal Response Plan" developed by FEMA in the early 1990s is the operational blueprint for the implementation of the Stafford Act in responding to all disasters and emergencies. The plan is a cooperative agreement signed by all 26 federal agencies and the American Red Cross for providing services when there is a need for federal response assistance following any type of disaster or emergency. The plan outlines a problem-oriented or functional approach to identifying the types of federal assistance that a state is most likely to need following a major disaster. Emergency support functions are grouped into 12 categories, such as food, health and medical services, transportation, and communications. For each emergency support function, one agency is charged with being the major provider of the service, with several other agencies responsible for supporting the primary agency. For health and medical services, the primary agency is the US Department of Health and Human Services.

Disaster Medical Assistance Teams

The National Disaster Medical System (NDMS) is a federally coordinated initiative designed to augment the emergency medical response capability of the United States in the event of a catastrophic disaster. [69] This system is a cooperative program of four federal government agencies: the Department of Defense, the Department of Health and Human Services, FEMA, and the Department of Veterans Affairs. The NDMS provides an interstate medical mutual-aid system linking federal, state, and local agencies and private-sector institutions to address medical care needs in a catastrophic disaster. The program was designed to supplement the activities of state and local governments during a massive civil disaster and to supplement the military medical care system in the event of an overseas conventional conflict. The NDMS contains a medical response element to provide organized aid to a disaster-affected area, an evacuation system, and a network of precommitted hospital beds throughout the United States. Its medical response element includes dozens of volunteer civilian disaster medical assistance teams (DMATs), which (1) operate supplemental casualty clearing facilities for triage, stabilization, and holding care for disaster victims; and (2) operate evacuation facilities for patients in excess of local hospital capacity. DMATs have also been developed for specialized needs, such as quick response, preventive medicine, burn care, renal dialysis, mental health, intensive care, and mortuary services.

In a disaster, NDMS will be activated only when state resources have been overwhelmed and the governor has requested federal assistance. [70] The DMATs are designated by the Department of Health and Human Services and must meet specific NDMS standards. Although DMAT members are volunteers, they become temporary federal employees if they are activated and are paid a per diem rate.

Throughout the NDMS, emergency physicians play key roles in the definition of training standards, the deployment of clinical services, the administration of field operations, and the further development of the civilian-federal disaster response capacity during times of national emergency.

DISASTER MEDICINE

The field of disaster medicine has become an area of major interest within the specialty of emergency medicine. [71,72] A section for disaster medicine has been organized within the American College of Emergency Physicians. Several national and international forums present the results of disaster medical research (e.g.,

annual conferences sponsored by the Florida chapter of ACEP, World Congresses on Disaster and Emergency Medicine, and meetings of the International Society for Disaster Medicine).[73] Since ACEP first defined a disaster medicine curriculum for residencies and fellowships, a number of disaster medicine fellowships have been established in the United States.[74] Disaster medicine continues to develop as a professional discipline in the United States, and emergency physicians are becoming increasingly involved in the areas of disaster response and humanitarian medical relief.[56]

6 MASS GATHERINGS

Gregory D. Mears
Arthur H. Yancey II

Medical care for mass gatherings represents an intersection of emergency medicine with public health and public safety requiring working talents in business, logistics, disaster preparedness, telecommunications, and public relations. The ingredients for success lie in understanding the health and medical care of populations through systems.

Each year over 200,000,000 people show their support for their favorite sports team by attending an event affiliated with the National Basketball Association, the National Football League, major league baseball, the National Hockey League, National Collegiate Athletic Association division I college football and basketball, or National Association for Stock Car Auto Racing (NASCAR) (Table 6-1). Not included in these figures are the millions who attend high school athletics events, Olympic festivals, local and state fairs, music concerts, and religious, political, or professional gatherings.

Sport	No. of Events	Average Attendance per Event	Season Total Attendance
Major league baseball	2,430	28,000	68,048,000
National Basketball Association	1,189	17,135	20,373,079
National Football League	316	60,284	19,049,886
National Hockey League	1,066	16,196	17,264,678
National Association for Stock Car Auto Racing			
Winston Cup	32	190,335	6,090,356
All other series	233	46,223	10,769,935
National Collegiate Athletic Association			
Men's football division I	1,297	25,272	32,778,007
Men's basketball division I	4,265	5,459	23,282,774
Women's basketball division I	3,890	1,384	5,382,042
Totals	14,718		203,031,757

Source: Verbal communication with the individual organizations.

TABLE 6-1   Attendance at Major Sporting Events, 1997–1998 Season

A mass gathering is any collection of greater than 1000 people at one site or location. Although this definition specifies an exact number of people, many unique smaller gatherings have many of the same characteristics. Such gatherings include groups of people on commercial airliners, passenger trains, and offshore transportation modes, such as ferries or hydrofoils, and groups at other events that may be smaller but that create a situation where a large number of people are crowded into a limited area somewhat isolated from routine emergency medical services (EMS). The same treatment principles can often be applied in each of these settings. It is important for emergency physicians to understand the structure and organization of mass gatherings. It has been shown that these events are characterized by higher injury and illness rates than for the general population and create unique treatment and transportation dilemmas.

HISTORY

In 1965, two spectators collapsed and died in the University of Nebraska football stadium. Cardiopulmonary resuscitation (CPR) was not available. Based on the need to address this problem and the expanding philosophy at that time involving CPR, airway management and defibrillation were included in the emergency medical care provided for the stadium. In the 8 years that followed, 18 spectators developed a cardiac or pulmonary emergency. Of these, 9 experienced cardiac arrest. Eight of the 9 were successfully resuscitated and discharged from the hospital. Other specific experiences with medical care provided at mass gatherings have been reported by the Denver Mile High Stadium; the University of Arizona, Tucson; the 1984 Los Angeles and 1996 Atlanta Summer Olympic Games; the 1986 World's Exposition In Vancouver, British Columbia; the XV Winter Olympic Games in Calgary, Canada; the Indianapolis 500, the Carrier Dome at Syracuse University; and the 1982 US Rock Music Festival in Devore, California. Statistics generated from these events have shown an incidence of medical problems ranging from 0.12 to 6.00 per 1000 spectators and cardiac arrests ranging from 0.3 to 4.0 per 1,000,000 spectators. These numbers reflect the unique medical setting and indicate a need for a medical care plan and program in any mass gathering.

EVENT RECONNAISSANCE

Physical Setting

Preparation should begin with repeated reconnaissance of the event setting with respect to the event type and expected population. Will the participants be seated at a sports event in a stadium or a political rally at a convention center or arena, or will they be ambulatory at a golf or racecourse, an aviation exhibit, or a cross-country running, biking, or equestrian event? The mobility of the attendees has important implications for the population density and expected morbidity rate. At events where spectators are predominantly ambulatory, especially on irregular terrain, lower extremity trauma should be anticipated. Reports from both the 1984 Los Angeles and 1996 Atlanta Summer Olympics revealed the highest medical care use in venues where spectators moved about during the events.

Within the venue, the medical director must investigate the total geographic area of medical responsibility as well as the physical barriers to accessing potential patients. These factors can affect the ability to discover, locate, and extricate victims from a crowd as well as the ability to transport them to the most appropriate treatment site. Are there dedicated public safety ingress and egress routes adequate to handle anticipated medical needs? What is the estimated transport time to the nearest hospital for noncritical patients and the nearest appropriate facility for critical patients? These factors hold profound implications for both the number and expertise of medical care providers needed for the event as well as their mode of transportation within the venue.

Will the event be held indoors? Adequate ventilation and access to exits are important issues indoors and are usually specified by jurisdictional fire codes. If the event is outdoors, climatic exposure, access to shelter, and protection from indigenous species must be evaluated. In both settings, access to potable water, adequate numbers and distribution of restrooms, and the geographic range of the public address system must be investigated. The history of severe weather conditions during

the time of the event should be researched in anticipation of resultant illness or injury, such as heat syndromes or hypothermia and frostbite.

Expected Populations and Hazardous Exposures

The event attendance bears some relationship to the expected volume of patients and has implications for the numbers and type of medical personnel needed. However, retrospective research has not yielded any universally acceptable mathematical relationship, and the exposure of the crowd to hazards at an event bears a much greater relationship to the volume of patients than does crowd size. In studying Syracuse University's rock concert, basketball, and football events for 7 years, De Lorenzo found a correlation between crowd size and volume of patients only for the concerts. The duration of the event also correlates with the volume of patients through the duration of exposure to the event and population health risk factors. The 1982 US Rock Music Festival experienced a significant increase in the daily volume of patients on the second day of the 3-day event.

Therefore, investigating expected population characteristics and hazardous exposures is crucial to planning for their medical care. The expected density and range of ambulatory movement within a venue may foretell the risk of heat exhaustion. Will this event attract an older population at risk for sudden cerebrovascular and cardiovascular events or one in which a younger population will likely be exposed to street drugs? Children presenting the danger of separation from responsible adults can be tagged with identification upon entry to the event. Will alcohol be allowed and/or served, and, if so, what is the history of its effect on participants' behavior and health at previous and similar events? Will food be offered at the event, and, if so, what public health officials have responsibility for monitoring and enforcing its sanitation and disposal? Will VIPs (e.g., politicians, heads of state, diplomats, media personalities, corporate executives, etc.) participate, and, if so, what special health and medical care measures are planned? Who are the officials responsible for these measures?

INTERACTIONS

Plans for medical care must proceed simultaneously along interdisciplinary and intradisciplinary lines. Coordination with fire, rescue, and hazardous materials teams; public health departments; and law enforcement agencies and/or security providers is essential. What law enforcement agency and officials are responsible for precautions against terrorism and the coordinated response to it? What agency and officials are responsible for the jurisdictional disaster or multicasualty incident (MCI) plan? What is the communications path to officials responsible for initiating execution of the plan and what intravenue officials are in the decision tree to trigger the request?

Planning for mass gatherings must also consider the EMS services responsible for responding to 911 calls within the jurisdiction surrounding the venue. The patient transport capacity at which the service becomes saturated and needs to shift into an MCI mode of operation must be known or determined. The extra patient transport capacity afforded by any existing mutual aid agreements with other services should be examined. What potential patient capacities do the surrounding hospitals possess? Limited external medical facilities (e.g., in a rural setting) may force more advanced care to be performed on site, requiring more medical personnel at a higher level of expertise, more supplies, and intravenue facilities. Both the medical and administrative directors of potentially affected EMS and hospital emergency services should be repeatedly updated on medical care plans for the event.

RESPONSIBILITY FOR COVERAGE

The producer or promoter of any mass gathering has an obligation to provide for the safety and security of its participants, spectators, and workers. Few venues have enough regularly scheduled events to be able to provide medical care without assistance. This assistance is typically provided through an affiliation or contractual arrangement with an EMS system and/or a health care provider, such as a hospital. The goal of any venue should be to provide the same quality of health care and security one could reasonably expect as a normal citizen outside the venue.

The medical director plays a key role in the planning of the medical facility and the care it is to provide during a mass gathering. The medical director should be involved in the plan, setup, and maintenance of the medical facility and the selection, training, and function of each medical team member. This requires involvement not only in the event planning but, if possible, in the design and construction of the facility. The medical director's goal is to provide the best possible care within the constraints of the available resources. Early involvement of the medical director can only improve the amount and quality of the resources available at the event.

The licensing of all medical personnel is extremely important. Large events may be able to benefit from a "Good Samaritan law" permitting health care workers to practice outside their licensed state or jurisdiction. Such laws are typically useful only when the worker is practicing in a voluntary capacity. Any such legal ramifications should be investigated prior to the event. Unless a Good Samaritan law is in effect, all health care providers must be licensed to function as such during the event. Liability insurance is also extremely important to the medical director as well as the health care providers. The producer or promoter of an event may be able to obtain coverage for the medical care, or coverage may have to provided by the health care providers or their employers.

Several legal issues should be addressed in a contract with the producer of the event. A contract should allow the medical director to have the authority to obtain whatever supplies or resources are needed prior to and during the event. The contract should spell out who pays for the equipment, resources, and personnel. At a minimum, the contract should include start and end dates, fee structures, health department and medical license structures, equipment and personnel requirements, minimum medical care requirements, medical direction authority level, and emergency provisions for disasters or MCIs. As much detail as possible should be listed with respect to the size, location, and physical construction of the medical treatment facility; the transportation of patients and personnel; the lodging, parking, food, and hygiene provisions for personnel; and the communications system and devices.

ANATOMY OF A MEDICAL CARE SYSTEM

Planning

The first step in designing any medical care system is to determine the level of medical care that is needed or desired. Levels of care may be (1) transportation only, (2) basic life support (BLS) only, (3) treatment without transportation, (4) advanced life support (ALS), or (5) aggressive ALS care targeting cardiac arrest victims. The patient population must also be established; it may be participants or performers, spectators, or employees. As mentioned above, the goal of any medical care system should be the same as that of any EMS system: to provide the maximum care possible with the resources available. Spectators should receive the same quality of care that they would have received if they had not attended the event. This goal requires the system to be cooperative, adjustable, organized, intelligent, and prepared.

If possible, the design of a medical care system should be based on factors known to positively affect patients' outcomes. For instance, a response time of 3 to 5 min can positively influence the ability to successfully resuscitate a cardiac arrest victim. Rapid CPR (optimally, performed by a bystander) is the cornerstone of BLS care, and airway management and early defibrillation are the cornerstones of ALS care. These skills must be applied if positive outcomes are to be realized. Therefore, responders who are trained at least at a BLS level should be stationed within 5 min of anyone in the venue.

Medical personnel and supplies should be allocated based on the anticipated number of patients and the seriousness of the anticipated medical problems. As stated, a general estimate of patient volume is from 0.12 to 6.00 patients per 1000 spectators and 0.3 to 4.0 cardiac arrests per 1,000,000 spectators. The medical problems encountered at mass gatherings are often similar (Table 6-2). The volume of patients and the nature of their complaints can depend to a large degree on the variables previously discussed. If possible, it is helpful to obtain preevent medical intelligence from the records of previous and/or similar events or from law enforcement agencies with experience with the particular event. This investigation may give insight to the potential for violence, alcohol, and drug use.

TABLE 6-2 Common Presenting Complaints at Mass Gatherings

Patient Care Path

The medical care plan should address the entire flow of patients' care from the occurrence of the medical problem to definitive care. Ushers, volunteers, and security personnel should be equipped with adequate communications devices and trained to relay information concerning any individual in need of medical care. Those without communications devices should be informed of the location of the nearest security officer or device for contacting the command center. Training should include the ability to communicate the appropriate information in a clear, concise format. These individuals must also act as first responders in providing a path to the patient and, when necessary, providing bystander CPR.

The command center or dispatch center is responsible for coordinating the response to a medical incident. Provision of a clear, concise chief complaint to the center is vital to coordinating an appropriate response. The command center should provide all the necessary medical and security resources, including maintenance personnel to address plumbing and electrical mishaps. The command center is also responsible for the flexibility of personnel duties and the positioning of the response teams within the facility to provide the best response time.

Once a response team has been dispatched, they should respond and initiate patient care. This is best accomplished by the rapid extrication of the patient from the crowd to the nearest space (e.g., a tunnel or open entryway) isolated by security personnel. At this point, treatment can be initiated by protocol or with on-line medical direction. The amount of treatment provided at this time depends on the medical condition of the patient and the layout of the facility. Transport to a designated treatment site or ambulance should occur as soon as possible so that a specialist can provide care at the highest level appropriate to definitive treatment. Ideally, direct supervision by the medical director should be available. Staffing of the treatment facility can be variable, including nurses, physician assistants, emergency medical technicians, paramedics, Red Cross volunteers, medical students, or first responders.

Transportation from the event should be by the most efficient mode possible considering all factors. If no access roads are available, helicopter transport may be the most appropriate option. A medical care plan should integrate the local EMS system to allow for increased transport capabilities to external hospitals if needed. EMS units, in normal service within the community, can be dispatched to the designated sites of medical incidents at the facility or can replace a unit that is already transporting a patient to the hospital.

MEDICAL CARE RESOURCES

Personnel

Often events are staffed by a combination of paid personnel and volunteers. The number of personnel is based on the layout of the facility and the size and characteristics of the crowd, adequacy of EMS coverage, and proximity to adequate hospital facilities. These factors determine the level of intravenue care needed. Response teams should be located throughout the facility to keep response times within a 3- to 5-min time period. It is often very beneficial to couple security officers with medical personnel in order to provide a safer environment and quicker response. In special situations, it may be necessary to add others, such as firefighters or water rescuers, to the response team. Each response team should be efficiently staffed and equipped to easily transport a nonambulatory patient.

Treatment facilities should be staffed with personnel capable of delivering definitive emergency care. The number of patients and the medical complaint categories can be estimated based on the attributes previously discussed. It is the function of the medical director to determine how to best meet the demands of patient care within the budget of the facility. The expertise level of nonphysician personnel varies greatly. Their availability can have a direct impact on the number of physicians required. The number of physicians recommended for on-site care ranges from 1 for every 5000 to 1 for every 50,000 people. These staffing requirements should be part of a formal contract with the facility management.

Equipment

It is the responsibility of the medical director to determine the supply level and type of equipment to be used within the facility and to incorporate these specifications into both the contract and the medical care plan. Often this is dictated by the local EMS system, which provides equipment for the facility. Response teams should be equipped with basic airway and first aid equipment. The teams must also have adequate extrication and transportation devices based on the layout of the facility. In the event of a cardiac arrest, a defibrillator should be available to be sent to the location of the patient along with ALS personnel with advanced airway equipment. This may not be necessary if an intravenue treatment facility is within 3 to 5 min transport time under actual event conditions. The medical care system should have enough defibrillators to allow access to one from any location within the facility in 5 min or less.

Equipment within the treatment sites should be based on the level of care provided, the number of patients anticipated, and the length of time each patient would be required to stay at the site awaiting disposition or transportation. If not on-site, transportation should be established in the plan to have the capabilities of transporting the patient to a hospital within 30 min of the request.

Communications

Audio and visual communications represent the glue that joins not only the myriad medical care and surveillance components into an efficiently functioning system but also the venue health care system to the other systems vital to managing a mass gathering.

The spectator level presents the greatest challenge. The first "first responders" are always fellow performers or spectators. Upon entry to an event, they should be educated in how to communicate knowledge of an illness or injury to the venue's medical care system so that rapid assistance can be rendered. In preparation for the 1996 Olympics, health promotion brochures were mailed with ticket information. Concise information on ticket stubs accompanied by periodic public service announcements can serve the same purpose.

At the medical care system personnel level, every event official, from ushers, volunteers, security guards, and public relations personnel to the top rung of management, must be educated in and updated on the most expedient manner in which to obtain medical assistance. Because radios are expensive, for the most numerous event workers, usually ushers, alternatives such as flag systems have been devised. At the US Open tennis tournament, in New York, a flare system has been organized. All event personnel should know the venue location of the nearest official who has a radio.

Among those officials with radios, frequencies and/or "talk groups" (800 MHz trunking) can be organized to minimize interruptions and maximize effective radio traffic from incident discovery through responders to definitive care givers. At the most highly evolved events, discovery of a victim by the system usually proceeds from bystanders, ushers, or vendors to in-field security personnel to a central communications or command center where the event medical director is based. Venue surveillance cameras can augment verbal reports on the victim's location and can show the scope of the incident. The medical director can then select and radio-dispatch the nearest most appropriate responders with adequate security and/or public relations assistance. Event field providers must be able to communicate with dedicated event ambulance crews, venue medical facilities, and the medical director to coordinate the transportation of the patient from the incident site to the

next most appropriate level of care. Fixed facility providers must be on line with field providers, event ambulance crews, and the medical director. The medical director must be able to communicate with all venue-dedicated ambulances, the jurisdictional 911 public safety answering point for access to the public EMS system, and those officials responsible for the jurisdictional disaster plan. In addition, medical command should have voice access to all area hospital emergency departments.

RELATIONSHIP OF FUNCTIONAL AREAS

Optimally, a central location should be designated for stationing the directors of the following functions: medical emergencies, event management, logistics, facility maintenance, public relations, security and law enforcement, ushers, and event performers or athletes. If not within the immediate area, the fire-rescue, public health, and public transportation and parking directors must be easily and reliably accessible by telephone and/or radio. From the medical care perspective, the leadership's close physical proximity is especially important if on-site care is provided, since such an arrangement allows for efficient information exchange and problem solving among the directors whose functional areas are integral to medical care delivery. A less reliable alternative involves intravenue radio links among the directors of these functional areas.

Internally, event management has to mediate issues at the interface of one functional area with another. Externally, event management represents the window with a view to outside resources, a vital function in the management of MCIs. Whenever depletion of operational resources is threatened, logistics personnel must immediately access and deliver additional equipment and supplies as patient demand dictates. The medical director and logistics supervisor must prospectively determine a threshold level for each essential supply item below which resupply is undertaken. The facility maintenance department has a major public health role in providing and maintaining an adequate potable water supply, sanitary facilities, and the venue electrical system vital to operating the public address system, air conditioning and ventilation, and lighting. Public relations plays a crucial role in directing crowd control and informing the event population of preventive public health measures as well as the location of medical care. Security and/or law enforcement personnel serve the entire spectrum of illness and injury prevention. Their primary preventative role includes pedestrian safety through the regulation of the interface of vehicular and pedestrian traffic, clearance of emergency vehicle access routes and pedestrian entrances and exits of the venue, and surveillance for and investigation of terrorist threats. The discovery of the ill or injured by direct sight or television surveillance, subsequent dispatch of medical care providers, and clearance of the path through crowds to patients represents the secondary preventative role of security and law enforcement personnel. They play a part in definitive care (tertiary prevention) when administering CPR or using automatic external defibrillators (AEDs). Similarly, ushers play a crucial role in the direct-sight discovery of victims and must know how to inform the predesignated personnel responsible for dispatching medical response teams. As with security and law enforcement personnel, their ubiquitous positioning makes ushers invaluable in the delivery of response-time-sensitive CPR. Finally, the event performers, whether they are athletes, politicians, musicians, or animals, represent a separate and distinct population requiring medical care specifically geared to their performance. The care of event performers is best provided by personnel most familiar with the performers' specific health care needs. When affordable, a separate medical care system and separate resources should be provided to ensure that care for performers does not interfere with care for spectators and vice versa.

QUALITY MANAGEMENT

Documentation

A medical record should be generated for each medical encounter, with the type of record based on the severity of the complaint. An officially sanctioned event form should be used to record the encounter date and time, patient's name, sex, age, race, medical complaint, drug allergies, and relevant medical history and examination findings. The tentative diagnosis and treatment plan should be documented, complete with discharge instructions. Because all patients provided ALS care will be transported to a hospital, the transporting EMS patient care report form can conveniently document the continuum of care provided at the scene and in transit.

As with every quality medical care system, treatment at mass gatherings should be evaluated systematically to improve care at subsequent events. The medical director should review all medical records. If the patient volume was large or included a MCI, a multidisciplinary audit committee should perform the review.

Event Training

Event training represents prospective quality management and puts into operation the aforementioned planned relationship of functional areas. Optimally, a representative of each of the personnel functions described under "Relationship of Functional Areas" should be represented at event training sessions held on site. However, especially with public safety, health, and medical care personnel, their regularly scheduled duties can be an obstacle to training participation. Possible alternatives for addressing this problem include videoconferencing and virtual reality applications. However, both of these modes preclude a realistic grasp of time-space relationships (e.g., patient access obstacles) that are facilitated by drills at the venue.

A central goal of event briefings must include instruction in the following venue locations: the command-center, medical care facilities, ambulance and radio-equipped security postings, and emergency ingress and egress routes. All personnel must know their geographic postings and coverage areas, receive instruction in communications equipment use, and practice the appropriate communications pathways to be used for medical care. Instruction in filling out a standardized medical care report form must be included. Practice scenarios should include a mock MCI requiring designation of ambulance staging and contingent triage zones and a request for outside intervention. Contingency plans for critical incident stress debriefing should be made and explained. Difficult access extrication, hyper- and/or hypothermia prevention and treatment, cardiac arrest, event player or performer injury, and dignitary or VIP care must also be rehearsed. Within each of these scenarios, communication (radio and cell phone) and physical routes to optimal care (ambulance evacuation to venue facility care) should be tested. Event briefings and training sessions should translate into efficient medical care. The retrospective aspect of the quality management process should detect this through instruments that document the quality of care (patient care report forms) and gauge the public image of care rendered at the event (patient-targeted surveys) and through management's degree of satisfaction with the results.

SPECIAL CONSIDERATIONS

Cardiac Arrests

As mentioned previously, the incidence of cardiac arrests in mass gatherings is higher than that in the normal population. It has been postulated that, due to the natural excitement generated by competitive sports, individuals who have cardiac disease are more likely to become symptomatic. However, medical systems at mass gatherings have demonstrated much higher success rates than even the most advanced EMS systems, primarily due to the ability to provide early bystander CPR, airway control, defibrillation, and ALS care. Survival rates for hospital discharge have varied from 20 to 100 percent survival from documented cardiac arrest. This evidence also supports the use of AEDs in mass gatherings where ALS support is not available in less than 5 min.

Commercial Airline In-Flight Emergencies

All US-commercial airlines are classified by federal law as "common carriers," and, as such, the airlines are not required to provide passengers with emergency care that meets jurisdictional EMS standards. Because of the population density on airliners, many of the principles of mass gathering medical care apply.

The medical problems encountered on airlines occur with a frequency and in an organ system category type resembling those of populations at ground-level mass gatherings. For the calendar year 1996, an average of three in-flight medical emergencies per day occurred on one major US airline. An average of one life-threatening (i.e., asthma, choking, cardiac arrest, heart attack, loss of consciousness, or stroke) emergency occurred every 2.5 days. Nationally, data covering nine major US air carriers from 1991 to 1993 revealed that the most frequent (in decreasing order) complaints were neurologic, syncopal, cardiac, psychiatric, and respiratory. Intentional injury of crews by unruly passengers increased each year from 1993 to 1995, when 174 incidents were reported. The emergency rate (incidents per million enplanements) has increased each year from 1990 to 1993.

The airplane environment presents several unique aspects of medical emergencies and their treatment. Following discovery of a medical incident, the response time to on-board care is minimal. Care givers' access to victims is compromised by their seated position in a setting similar to that in a crowded stadium. The victim's safe, timely extraction to a secured space allowing the supine (left lateral decubitus for pregnant patients) position is a foremost priority but is a great challenge in such a confined environment not dedicated to even provisional medical care. Oxygen sources are plentiful, but their location is not configured for optimal care of patients. At cruising altitude, despite cabin pressurization, ambient air oxygen availability is below that at sea level (P_{O_2} 118 mmHg in flight versus 159 mmHg at sea level) and has the potential of causing respiratory problems in the marginally compensated. Flight attendants receive basic first aid training to a degree that varies among

airlines.

The uneven training of flight attendants leads to requests for emergency assistance from "educated bystanders." National survey data reveal that from 1986 to1988, when all medical kit usage on the major air carriers was monitored, physicians responded in 85 percent of the 2322 cases. The US Department of Transportation mandated the study at the inauguration of its medical kit placement on board all commercial aircraft (Table 6-3). This kit places priority on airway, breathing, and circulation problems. Noticeably absent are aerosolized bronchodilators, anticonvulsants, and AEDs, the latter currently being placed and studied on some airlines.

TABLE 6-3   Medical Equipment on US Commercial Aircraft

When addressing the most frequent types of medical emergencies referred to above, as well as any involving vital functions, the issue of plane diversion arises. The desire to divert the aircraft stems from either the recognition that a patient is in immediate need of care and that expertise is not available on board or by radio, or the need for further evaluation of that condition. The decision to divert a commercial aircraft rests ultimately with the pilot. However, in 2321 cases representing 10.7 percent of all US domestic air carrier activity between 1990 and 1993, the crews complied with a physician's recommendation to divert 97 percent of the time. In addition to the time sensitivity of the patient's condition, this strategic decision involves issues of proximity to an airport suitable for the aircraft versus the original destination port, availability of adequate EMS resources (ALS versus BLS) to meet the diverted craft, and proximity of appropriate hospital resources to the diversion airport. Many US air carriers contract with in-flight medical consultation companies to assist crews and on-board medical personnel in making an appropriate diversion decision.

If the incidence of medical emergencies continues to increase, as it has from 1991 to 1993, on-board medical personnel will be called upon more frequently to become involved in patient care in this unique environment. On a more global scale, emergency physicians, by virtue of their expertise, should collaborate with the airlines to ensure optimal in-flight patient care.

7 SUDDEN CARDIAC DEATH

Joseph P. Ornato

Sudden cardiac death (SCD) due to unexpected cardiac arrest claims the lives of an estimated 250,000 adult Americans each year. Despite advances in resuscitation and emergency medical services (EMS), only about 3 to 8 percent of all cardiac arrest victims survive to leave the hospital neurologically intact. However, there is substantial variability in the odds for survival among various geographic locations, with published survival to hospital discharge for patients with all initial rhythms ranging from 1 to 25 percent.[1,2 and 3] This chapter reviews the epidemiology and pathophysiology of SCD in adults and the strategies to prevent and treat the problem. Sudden infant death syndrome and cardiac arrest in children are discussed in Chap. 9 and Chap. 10, respectively.

EPIDEMIOLOGY

Most episodes of unexpected SCD in adults occur in the home.[4] The most common victim is a male who is 50 to 75 years of age. The majority of SCD victims have underlying structural heart disease, usually in the form of coronary atherosclerosis and/or cardiomegaly. Although 75 percent of SCD victims have significant atherosclerotic narrowing (greater than 75 percent) in one or more major coronary arteries, fewer than half of all sudden deaths occur *during* an acute myocardial infarction (AMI).

Epidemiologic studies have identified both a circadian and a seasonal pattern of SCD and AMI, suggesting the presence of underlying biological triggers of the onset of both disease processes.[5] Both SCD and AMI are most likely to occur within the first few hours after awakening from sleep, at a time when there is increased sympathetic stimulation. Beta blockade appears to protect against SCD, particularly in patients with known coronary artery disease who have had an AMI. In addition, both SCD and AMI are much more likely to occur during climatic winter rather than summer.[5,6] These and other epidemiologic and experimental findings suggest that neurophysiologic factors, such as autonomic tone, may alter the heart's propensity to develop and sustain a serious ventricular dysrhythmia. An alternative possibility is that there are factors external to the atherosclerotic plaque, such as triggers of plaque rupture or thrombus formation, which may affect the onset of ischemic cardiac events.

PATHOPHYSIOLOGY

Ventricular Tachyarrhythmias

Sudden cardiac death is usually caused by chance arrhythmic events that are triggered by an interaction between structural heart abnormalities and transient, functional electrophysiologic disturbances. In the majority of cases the initiating event is a ventricular tachyarrhythmia, either pulseless ventricular tachycardia (VT) that degenerates rapidly to ventricular fibrillation (VF) or "primary" VF.[7,8] From a public health standpoint, strategies for preventing and treating SCD in the community can be targeted primarily at VT and VF because these rhythms are not only the most frequent, but also the most potentially treatable, currently identified initiating event.

The mechanisms responsible for triggering fatal ventricular dysrhythmias are only partially understood. Frequent ventricular ectopy alone, in the absence of significant underlying structural heart disease, does not generally result in cardiac arrest. However, ventricular extrasystoles in the presence of transient myocardial ischemia, left ventricular dysfunction, and/or cardiomegaly often trigger runs of VT that may degenerate into pulseless VT or VF.

Many types of structural heart disease can predispose to SCD. One common denominator is dispersion of ventricular depolarization and/or repolarization, allowing "islands" of ventricular tissue to depolarize and repolarize at different rates. This lack of homogeneity in electrical activation and recovery fosters the development of circus movement reentry, which can initiate and sustain ventricular tachyarrhythmias. Myocardial ischemia and/or infarction can also transiently diminish the homogeniety of left ventricular depolarization and repolarization.

Left ventricular hypertrophy (often due to hypertension and/or valvular heart disease) or conduction disturbances (left or right bundle branch block or a nonspecific intraventricular conduction disturbance) can create similar functional disturbances on a more chronic basis. An example of this SCD mechanism is the mysterious illness that causes death during sleep in young Asian (especially Thai) men who have no evidence of structural heart disease.[9] Many of these men have an abnormal cardiac conduction system that can be diagnosed by electrophysiologic testing. It is interesting to note that many of these Asian men who are at risk of SCD can be identified from a standard electrocardiogram (ECG), which shows a characteristic pattern of right bundle branch block with ST-segment elevation in V_{1-3}.

The long QT syndrome, in which the corrected QT interval is pathologically prolonged, is also associated with SCD.[10] Prolongation of the corrected QT interval probably represents dispersion in ventricular repolarization and can be congenital (with or without nerve deafness) or acquired (due to hypokalemia, hypomagnesemia, hypocalcemia, anorexia, ischemia, central nervous system pathology, terfenadine-ketoconazole combinations, or certain antipsychotic or antiarrhythmic drugs). The "corrected QT interval" can be calculated easily by the following formula:

$$QT_c = \frac{QT_m}{\sqrt{R-R}}$$

where QT_c is the corrected QT interval in seconds, QT_m is the measured QT interval in seconds, and R–R is the interval between any two consecutive R waves on the ECG in seconds. This formula, known as Bazett's equation, while seeming to be complex, is actually quite simple and easy to remember. Since the QT interval is heart rate dependent, the formula "corrects" the measured QT interval to a heart rate of 60 beats per minute (at which the R–R interval is 1.0 s). Since the square root of 1 = 1, the QT_c equals the QT_m at a heart rate of 60 beats per minute (at which the normal QT interval limits are 0.35 to 0.44 s).

Most SCD victims have cardiac abnormalities on postmortem examination. The most common autopsy findings in SCD victims are evidence of coronary atherosclerosis and its complications, cardiomegaly with left ventricular hypertrophy and contraction band necrosis. The latter appears to be a marker for catecholamine stimulation and occurs with high frequency regardless of whether cardiopulmonary resuscitation (CPR) was performed.[11]

Factors affecting survival of out-of-hospital VF include witnessed collapse, prompt initiation of CPR, early defibrillation, younger age, and arrest occurring away from home.[12] Comorbid illnesses, such as a history of congestive heart failure, contribute to hospital mortality following successful resuscitation but only account for one-fourth of the variation in survival from SCD. Cardiac arrest during AMI is associated with a significantly *improved* outcome compared to cases not occuring in the setting of AMI.[13] Although the reason for improved long-term survival of AMI patients is not fully known, it is probably due to the fact that such patients have *transient*

electrical instability, unlike patients with chronic cardiomyopathy, in whom there is a persistent vulnerability to VT or VF.

The outcome of resuscitation is strongly influenced by the patient's initial cardiac rhythm. The likelihood of survival is relatively high (up to 40 to 60 percent) if the initial rhythm is VT or VF (particularly if the VF is "coarse," the arrest was witnessed, and prompt CPR and defibrillation are provided). If the initial rhythm is not VT or VF, survival is typically less than 5 percent in most reported series. Asystolic patients whose cardiac arrest was unwitnessed rarely survive neurologically intact to hospital discharge. The only common exceptions are witnessed cardiac arrest patients whose initial asystole is due to increased vagal tone or other relatively easily correctible factors, such as hypoxia of brief duration.

Bradyasystole

Although this chapter emphasizes VT and VF, an important minority of SCD events begin with a bradyarrhythmia [14] or an organized rhythm without a pulse (e.g., pulseless electrical activity, or PEA). Bradyasystole refers to a cardiac rhythm that has a ventricular rate below 60 beats per minute in adults and/or periods of absent heart rhythm (asystole). Bradyasystolic states are clinical situations during which bradyasystole is the dominant heart rhythm.

Bradyasystolic rhythms other than asystole can either be accompanied by a pulse or there can be no discernible pulse with each QRS (PEA). Bradyasystole with a pulse is often accompanied by a significant decrease in cardiac output, leading to hypotension and/or syncope. Bradycardia with or without a pulse occurs frequently during cardiac arrest, either as the initial rhythm, during the course of resuscitation, or following electrical defibrillation. Obviously, asystole occurs eventually in all dying patients.

Ewy et al.[15] have shown that electrically induced coarse VF in dogs can have a direction or vector. When recordings are made using an ECG lead perpendicular to the main axis of the coarse fibrillation in experimental models, tracings show what appears to be asystole or fine VF. To ensure that VF is not masquerading as asystole, the American Heart Association recommends confirmation of asystole by switching to another lead whenever a "flat line" is recorded on the ECG during resuscitation. Although there are anecdotal case reports in the literature suggesting that this phenomenon can occur in humans, "masquerading" VF probably occurs rarely during clinical resuscitation and is not responsible for the misdiagnosis of large numbers of cases of asystole. [16]

Bradyasystole can be either primary or secondary. Primary bradyasystole occurs when the heart's electrical system intrinsically fails to generate and/or propagate an adequate number of ventricular depolarizations per minute to sustain consciousness and other vital functions. Secondary bradyasystole is present when factors external to the heart's electrical system cause it to fail (e.g., hypoxia). It is unclear why conventional treatment of bradyasystolic cardiac arrest with atropine, epinephrine, or electrical pacemakers rarely results in survival to hospital discharge.

Cellular metabolic functions must be intact for normal electrical impulse generation and propagation to occur. Severe ischemia of the sinoatrial (SA) node can disable cellular metabolism, preventing pacemaker cells from actively transporting the ions necessary to control the transmembrane action potential. Proximal occlusion of the right coronary artery (RCA) can cause ischemia and/or infarction of both the SA and atrioventricular (AV) nodes, since the SA node is supplied by a branch from the proximal RCA 55 percent of the time and the AV node receives its nourishment from a branch of the distal RCA 90 percent of the time. Ischemia or infarction of the AV node can disrupt normal conduction, causing bradycardia due to AV block. Because the bundle branches receive their blood supply from multiple coronary arteries, bradycardia caused by ischemic bilateral bundle branch block is rare and generally only occurs when there is extensive myocardial infarction due to severe, multivessel coronary artery disease.

The spectrum of disorders affecting the heart's primary pacemaker, known as the sick sinus syndrome, can cause intermittent lightheadedness, syncope, or SCD. The disorder affects both men and women. Although it is more common with advancing age, primary electrical failure of the heart can even occur in infants and children. The precise cause of sick sinus syndrome is unknown. Pathologic studies usually reveal histologic degeneration of the SA node. In addition, the disorder often involves the AV node and the conduction tissue between the SA and AV nodes. Thus, sick sinus syndrome should be thought of as a diffuse degenerative disease of the heart's electrical generation and conduction system. Idiopathic sclerodegeneration of the AV node and the bundle branches (Lenegre's disease) or invasion of the conduction system by fibrosis or calcification spreading from adjacent cardiac structures (Lev's disease) can lead to bradyasystolic heart block with or without cardiac arrest. In rare cases, a clinical presentation resembling the sick sinus syndrome can occur when the heart's electrical system is affected by systemic disease, vascular compromise, or tumor (e.g., melanoma metastatic to the AV node).

Atropine, transcutaneous pacing, dopamine, or epinephrine can be used to treat acute, symptomatic bradyasystole (including cardiac arrest) that is due to the sick sinus syndrome. Permanent ventricular or AV sequential pacing is usually necessary for patients with persistent symptomatic bradycardia. Patients who manifest the tachycardia-bradycardia variant (periods of supraventricular tachycardia followed by prolonged sinus arrest or bradycardia) may also require antiarrhythmic therapy or radiofrequency ablation.

Pacemaker cells and conducting tissue can be affected by a variety of endogenous chemical, hormonal, pharmacologic, toxicologic, and neurogenic influences. Hypoxia and hypercarbia due to respiratory arrest cause bradyasystole frequently, due to both a direct depressant effect on cardiac pacemaker cells and increased parasympathetic discharge. Common clinical conditions that often cause bradyasystole include suffocation, near drowning, stroke, and opiate overdose. Beta-adrenergic blocking agents, calcium channel blockers, digitalis glycosides, parasympathomimetic agents (e.g., edrophonium), hypoxia, hypercarbia, adenosine, and adenosine triphosphate can also cause bradyasystole.

Endogenous adenosine that is released when there is myocardial hypoxia and ischemia relaxes vascular smooth muscle, decreases atrial and ventricular contractility, depresses pacemaker automaticity, and impairs AV conduction. During normal aerobic metabolism, adenosine is formed primarily by intracellular degradation of S-adenosylhomocysteine (SAH), catalyzed by the enzyme SAH hydrolase (SAH pathway). During myocardial ischemia, adenosine is formed primarily by dephosphorylation of adenosine monophosphate (AMP), catalyzed by the enzyme 5' nucleotidase (adenosine triphosphate [ATP] pathway).

The cellular electrophysiologic effects of adenosine can be antagonized competitively by methylxanthines but not by atropine. A specific adenosine antagonist (BW-A1433U) has been shown to reverse and prevent postdefibrillation bradyasystole and hemodynamic depression in a domestic pig model. In small pilot studies, aminophylline, a competitive nonspecific adenosine antagonist, restored cardiac electrical activity within 30 s in more than half of the bradyasystolic cardiac arrest patients who were refractory to atropine and epinephrine. [17,18]

Myocardial ischemia excites cardiac vagal and sympathetic afferents, leading to vagally mediated depressor reflexes and/or sympathetic reflex cardioexcitation. In addition, myocardial infarction can interrupt afferent and efferent neural transmission, potentially triggering dysrhythmias. Autonomic disturbances have been documented in the majority of AMI patients, especially during the first 30 to 60 min after coronary artery occlusion. Stimulation of afferent vagal cardiac receptors, particularly those located in the posterior left ventricle, during ischemia or infarction can trigger sympathetic inhibition, vasodilation, bradycardia, and hypotension (the Bezold-Jarisch reflex). Activation of this reflex may explain the higher incidence of nausea and vomiting in patients with inferior (69 percent) compared to anterior (29 percent) infarction. Bradyasystole triggered by the Bezold-Jarisch reflex is usually short-lived and often responds to atropine.

One of the most baffling mysteries of bradyasystolic cardiac arrest relates to myocardial mechanics. Bradyasystole, unlike ventricular fibrillation, is accompanied by very little myocardial oxygen consumption in animal models. Because of this, myocardial high-energy phosphate stores should decay relatively slowly during bradyasystole. This should theoretically result in a high incidence of return of spontaneous circulation following restoration of a more normal rhythm (e.g., with the early use of electrical pacing). However, return of spontaneous circulation is infrequent, and long-term neurologically intact survival is rare in bradyasystolic cardiac arrest.

These findings strongly suggest that other factors must play a determining role in the pathophysiology and subsequent outcome of bradyasystolic cardiac arrest. Bradyasystolic arrest is not just a disorder of rhythm generation or propagation: it is a perplexing syndrome characterized by such rhythm disturbances accompanied, in many cases, by profound depression of myocardial and vascular function. The causes of the latter derangements have yet to be elucidated. Suspected causes include endogenous myocardial depressants (including downregulation of catecholamine receptors and/or toxic influences of intense sympathetic stimulation), neurogenic influences, postischemic myocardial stunning, and/or free radical injury.

Pulseless Electrical Activity

Pulseless electrical activity can be caused by a variety of pathophysiologic conditions. The sine qua non of this syndrome is the presence of an organized rhythm without the presence of a detectable pulse in an individual who is clinically in cardiac arrest. The latter is important to differentiate conditions in which the rescuer is

unable to detect a pulse but there is unmistakable evidence that there is adequate blood pressure and cardiac output to maintain vital organ perfusion (e.g., a conscious patient with profound vasoconstriction due to hypothermia). There is evidence that PEA encompasses a spectrum of pathophysiologic effects ranging from good LV function with an empty ventrical or widely dilated arterial bed, to a stiff ventrical.

The underlying physiologic cause of PEA is a marked reduction in cardiac output that is due to either profound myocardial depression or mechanical factors that reduce venous return or impede the flow of blood through the cardiovascular system. Common conditions that can cause PEA are shown in Table 7-1. In one recent analysis, PEA was present initially during resuscitation in 22 percent of cardiac arrest cases.[19] Compared to other patients, individuals with PEA were more likely to be women whose cardiac arrest was unwitnessed, at night, and without bystander-initiated CPR. Only 2 percent of these patients survived to hospital discharge. The management of patients with PEA is directed at identifying and treating the underlying cause or causes.

SCD PREVENTION

Prediction of SCD

It is necessary to accurately predict who is at risk for SCD for any prevention strategy to be of value. Unfortunately, the majority of future SCD victims cannot be identified in advance. Prodromal symptoms in the days to weeks preceding cardiac arrest are common but usually too nonspecific to be of important predictive value. In one of the largest series in which survivors of SCD were questioned about events preceding their collapse, Goldstein et al.[20] found that 71 percent of SCD survivors reported no prodromal symptoms or symptoms of 1 h or less in duration. Prodromal symptoms were present for more than 1 h in only 29 percent of patients. The most common symptoms reported by SCD survivors or family members of SCD victims are chest pain, dyspnea, and palpitations.

Even aggressive attempts to predict SCD in high-risk patients, such as those who have suffered a prior AMI or those with a chronic cardiomyopathy, have been of limited value. Various diagnostic techniques have been used to try to "risk-stratify" these patients, including invasive and noninvasive assessment of left ventricular ejection fraction, coronary angiography, ambulatory ECG (Holter) monitoring, exercise testing, detection of ventricular late potentials using signal averaging, programmed ventricular stimulation of the heart to test the inducibility of ventricular tachydysrhythmias, and assessment of heart rate variability.[21] None of these tests, alone or in combination, has sufficient sensitivity and specificity to identify more than a small fraction of those who will develop SCD. For example, only 15 to 30 percent of even "high-risk" post-AMI patients identified by a variety of these screening tests will experience a sustained ventricular tachydysrhythmia over the next several years of follow-up.[22]

Antidysrhythmic Drug Therapy

Although both an underlying substrate (cardiac pathology) and a trigger (a ventricular extrasystole) are commonly needed to initiate VT or VF, recent results of large randomized, controlled, clinical trials of antidysrhythmic agents for primary and secondary prevention of VT and VF are changing traditional beliefs regarding the actions, efficacy, and risk of antidysrhythmic agents. For example, it once seemed reasonable to expect that class I sodium channel blocking drugs (e.g., quinidine, procainamide, encainide, flecainide, and moricizine) that effectively suppress premature ventricular beats should reduce the risk of SCD. To test this theory, the Cardiac Arrhythmia Suppression Trial (CAST) was conducted to determine whether potent class I sodium channel blocking antidysrhythmic drugs are effective in preventing SCD in post-AMI patients compared to placebo. The trial had to be terminated prematurely because each of the antidysrhythmic agents tested (encainide, flecainide, and moricizine) paradoxically *increased* the odds of developing SCD, compared to placebo, in patients at relatively low risk for death in the long term.[23] The excess mortality in this trial was due to proarrhythmic effects of the type I drugs, resulting in a *facilitation* of reentry, especially during acute ischemia.

Antidysrhythmic drugs with class III and/or beta-blocking activity may be of some value in protecting patients at high risk of SCD. In the randomized, double-blind, placebo-controlled European Myocardial Infarct Amiodarone Trial (EMIAT), the type III antidysrhythmic drug amiodarone reduced all-cause mortality (primary endpoint) and cardiac mortality/dysrhythmic death (secondary endpoints) in survivors of myocardial infarction who had a left ventricular ejection fraction of less than 40 percent.[24] The Cardiac Arrest in Seattle: Conventional Versus Amiodarone Drug Evaluation (CASCADE) study evaluated antidysrhythmic drug therapy in VT and VF survivors who were thought to be at high risk for VT or VF recurrence. Therapy with empirical amiodarone was compared to therapy with other antidysrhythmic agents as guided by electrophysiologic testing and/or Holter recording. Survival was better in patients treated with amiodarone than in patients treated with other antidysrhythmic agents. Patients treated with amiodarone were less likely to receive a shock from an implanted defibrillator, and syncope followed by a shock from a defibrillator was less common in patients treated with amiodarone. However, overall mortality was high, and side effects of therapy were common. Patients treated with amiodarone, even at the low doses used in the study, were still at risk for thyroid dysfunction (both hyperthyroidism and hypothyroidism) and for pulmonary toxicity. The combined class II/III agent sotalol has also been shown to be better at reducing VT and VF recurrence than are conventional class I antidysrhythmic agents.[25]

Class II (beta-blocking drugs) also appear to offer some protection against SCD, particularly in patients with myocardial ischemia or prior AMI.[26] These agents probably exert their protective effects by reducing the risk of VT and VF during myocardial ischemia and following AMI by direct suppression of adrenergic myocardial stimulation, decreasing the rate of atheroma formation, directly suppressing the influence of the central nervous system on ventricular tachydysrhythmias, and preventing or attenuating fracture of vulnerable atherosclerotic plaques. In addition, beta blockers reduce morbidity and may even lower mortality in patients suffering from moderate to severe heart failure.[27] In these patients, careful titration of the drug dosage may be necessary.

Implantable Cardioverter Defibrillator Therapy

The benefits of beta blockade, sotalol, and amiodarone in decreasing mortality from SCD pale in comparison to the protective effects of the implantable cardioverter defibrillator (ICD) on high-risk patients.[28] The results of recent studies indicate that treatment with an ICD is more effective than electrophysiologically guided treatment with antidysrhythmic agents.[29] Although these devices are expensive to insert, their effectiveness over conventional therapy results in a cost of less than $30,000 per year of life saved, which is highly cost-effective.[30] At present, these devices are indicated for preventing SCD in high-risk patients, particularly those with clinically significant coronary artery disease, depressed left ventricular function, and spontaneous life-threatening and/or inducible ventricular dysrhythmias. Further research is necessary to determine the value of ICD therapy in patients with nonischemic cardiomyopathy accompanied by reduced left ventricular function.

RESCUE FROM SCD

Emergency medical services and in-hospital resuscitation (also known as code blue or code 99) systems are the most effective means currently known to rescue patients from SCD. Survival from pulseless VT or VF is inversely related to the time interval between its onset and its termination. Each minute that a patient remains in VF, the odds of survival decrease by 7 to 10 percent. Survival is optimal when both CPR and advanced cardiac life support (ACLS), including defibrillation and drug therapy, are provided early.

The American Heart Association has introduced the "chain of survival" concept to represent a sequence of events that ideally should occur to maximize the odds of successful resuscitation from cardiac arrest.[8] The links in the chain include early access (recognition of the problem and activation of the EMS system by a bystander), early CPR, early defibrillation for patients who need it, and early advanced cardiac life support.

Early Access

Because most SCDs occur suddenly and without warning, the victim cannot activate the emergency response system prior to collapse. Bystanders who witness the event can improve a victim's chances for survival significantly by alerting the emergency response system promptly. All too often, the untrained citizen only further delays treatment by attempting to inform relatives, call the neighbors, or contact the patient's personal physician instead of calling the local community emergency telephone number (in most places, it is 911).

Early CPR

Public CPR education can improve the behavior of bystanders significantly when a cardiac emergency occurs in the community. Availability of the simple three-digit 911 emergency number in the United States can reduce confusion and decrease delay in activating the EMS system. There are a number of problems associated with training the public to perform CPR. For example, it can be argued that the wrong rescuers have been trained. The typical cardiac arrest victim is male, is 50 to 75 years old, and usually arrests at home, often in the presence of a spouse of similar age. Most citizens who have taken CPR training are under 30 years of age; typically, fewer than 10 percent live with family members known to have heart disease. Most citizens who have received CPR training never actually witness or participate in managing a cardiac arrest; conversely, bystanders who witness a cardiac arrest usually do not know how to perform CPR. The majority of laypersons who attempt to perform CPR out of hospital are actually employed or volunteer their services as health professionals. The best solution to the problem is to target CPR training to "high-risk" individuals, such as middle-aged persons, senior center residents and staff, and family members (particularly the spouse) of patients who are survivors of AMI or cardiac arrest or who have other risk factors for SCD.

Skill retention is also a problem because CPR is a psychomotor technique that deteriorates rapidly over time unless practiced or used. In Belgium, 46 percent of bystanders who performed CPR forgot to perform mouth-to-mouth breathing; chest compressions were not done 17 percent of the time.[31] It is important for laypersons or health care professionals who perform CPR infrequently to receive at least annual reinforcement. However, only about 20 percent of trainees return for annual training in the United States. Irrational fear of communicable disease, particularly infection with the human immunodeficiency virus (HIV), that is disproportionate to the known minimal risk of disease transmission may decrease the likelihood that trained rescuers will actually perform mouth-to-mouth ventilation on strangers.[32]

Although the value of bystander CPR was once debatable, virtually all recent studies have shown that early initiation of CPR by a bystander improves survival from cardiac arrest significantly, and it also results in improved neurologic outcome of survivors.[8] The presumed mechanism by which CPR by a bystander improves outcome is the preservation of flow to the heart, brain, and other vital organs, providing a "holding action" until other therapies (e.g., defibrillation) can result in restoration of spontaneous circulation.

Early Defibrillation

The rationale for the use of early defibrillation stems from four observations: (1) ventricular tachydysrhythmias are the most common cause of SCD in adults; (2) defibrillation is the most effective treatment for VT and VF; (3) the effectiveness of defibrillation diminishes rapidly over time; and (4) unless treated promptly, VF becomes less coarse and eventually converts to the less treatable rhythm of fine VF or asystole.

The best outcomes from VT and VF in adults occur regularly in the electrophysiology laboratories, where prompt defibrillation (typically within 20 to 30 s of dysrhythmia onset) from pulseless VT or VF results in virtually 100 percent survival. The next best outcomes have been noted in cardiac rehabilitation programs, where defibrillation can be performed within the first minute or two. In such "ideal" settings, as many as 85 to 90 percent of patients are resuscitated and return to their prearrest neurologic status. Survival from out-of-hospital VT and VF treated by police officers equipped with automatic external defibrillators (AEDs) in Rochester, Minnesota, has averaged 50 percent, with a median time from collapse to defibrillation of about 5 min. Outcomes in many locations with EMS systems that cannot provide defibrillation until 10 min or more after a patient's collapse typically yield survival rates of less than 10 percent.[8]

The best survival is attained in EMS systems that can provide early defibrillation to a large percentage of patients. In most cases, this is most cost-effectively accomplished by a tiered response system, in which large numbers of rapid first-response firefighters or emergency medical technicians (EMTs) are trained and equipped to provide first aid, CPR, and early defibrillation using an AED. Unfortunately, not all communities in the United States have yet implemented a comprehensive, tiered EMS system. Many systems, particularly in suburban or rural areas, have EMTs who are neither trained nor equipped to defibrillate. For such areas, adding rapid defibrillation capability offers a cost-effective alternative that can significantly improve survival from out-of-hospital VF or pulseless VT.

The American Heart Association advocates the widespread implementation of rapid defibrillation programs throughout the nation in its belief that "all emergency personnel should be trained and permitted to operate an appropriately maintained defibrillator if their professional activities require that they respond to persons experiencing cardiac arrest. This includes all first responding emergency personnel, both hospital and nonhospital (e.g., emergency medical technicians (EMTs), non-EMT first responders, fire fighters, volunteer emergency personnel, physicians, nurses, and paramedics). To further facilitate early defibrillation, it is essential that a defibrillator be immediately available to emergency personnel responding to a cardiac arrest. Therefore, all emergency ambulances and other emergency vehicles that respond to or transport cardiac patients should be equipped with a defibrillator."[33]

More novel strategies have also been tried to increase the availability of rapid defibrillation in the community. There are many densely populated public areas in which conventional EMS systems *cannot* respond within an acceptable response time interval. The most innovative idea is termed *public access defibrillation* (PAD), so named because the intent is to have citizens from outside the health care fields perform early defibrillation using AEDs.

There are four "levels" of PAD based on the type of potential first responder expected to use the AED (Table 7-2). There has been considerable experience demonstrating benefit with minimal risk for level I (firefighters) and level II (police officers and airline flight attendants) first responders.[34,35 and 36] Other experimental approaches to rapid defibrillation in the workplace include use in British rail stations, oil platforms in the North sea, electricity plants, passenger cruise ships, and merchant marine vessels.[8] There has been little experience thus far with level III PAD, and the few studies that have been reported have been somewhat disappointing. For example, Eisenberg et al. trained family members of 59 patients who had survived out-of-hospital cardiac arrest in King County, Washington.[37] Only 6 of the 10 cardiac arrests that occurred in these patients were defibrillated successfully, and only 1 patient survived for a few months and sustained new neurologic impairment. Since AEDs are currently approved for marketing in United States under prescription only, there has been no experience thus far with level IV PAD.

Level	Personnel
1	Traditional first responders who have a duty to respond (fire-fighters)
2	Nontraditional first responders who have a secondary duty to respond (police, lifeguards, security officers, flight attendants)
3	Trained citizen CPR providers who volunteer to be trained to respond (building supervisors, family members of high-risk individuals)
4	Minimally trained or untrained lay witnesses who may try to respond (laypersons in the right place at the right time)

TABLE 7-2   Levels of Public Access Defibrillation

Early ACLS

Physicians provide prehospital ACLS by staffing specially equipped ambulances in many countries (e.g., western Europe, Scandinavia, and Canada). In the United States, "intermediate"-level EMTs or paramedics provide most prehospital ACLS intervention (e.g., defibrillation or synchronized cardioversion, endotracheal intubation, intravenous fluid therapy, or drug administration). Intermediate EMTs (often called cardiac technicians) typically receive several hundred hours of training; paramedics usually receive 1000 or more hours. Adding field ACLS capability appears to affect survival from out-of-hospital cardiac arrest favorably, although the degree of benefit is relatively minimal compared to the powerful effect of early defibrillation. 8 CARDIOPULMONARY RESUSCITATION IN ADULTS

Jon Mark Hirshon

Cardiopulmonary resuscitation (CPR) is a key part of emergency medical care designed to resuscitate individuals in cardiac arrest. The purpose of cardiopulmonary resuscitation is to temporarily provide effective oxygenation of vital organs, especially the brain and heart, through artificial circulation of oxygenated blood until the restoration of normal cardiac and respiratory activity occurs. This is to stop the degenerative processes of ischemia and anoxia caused by inadequate circulation and inadequate oxygenation. Time to initiation of cardiopulmonary resuscitation is critical to improve likelihood of recovery; ideally, it should be started within 4 min of arrest, and advanced cardiac life support should be initiated within 8 min of arrest. While basic life support alone may be lifesaving in some instances, in most cases, advanced interventions such as the delivery of electric current for defibrillation and the addition of various pharmacologic therapies are required to maximize the likelihood of patient recovery. Without rhythm-specific interventions, recovery from cardiac arrest is highly unlikely.

This chapter reviews basic CPR for adults, including approach to an unresponsive patient, basic airway opening procedures including initial management of an obstructed airway, and the physiology and mechanics of closed-chest compression techniques.

BASIC CARDIOPULMONARY RESUSCITATION

Overview

As with all aspects of emergency medicine, it is important to approach basic CPR systematically. When someone is found unresponsive, the following should be performed rapidly and in sequence:

1. Assess responsiveness. If unresponsive, then
2. Obtain assistance/activate the local emergency medical service system.
3. Call for a defibrillator (if available).
4. Position the patient and open the airway (maintain cervical spine immobilization if trauma is potentially involved).
5. Assess breathing. If no breathing is noted, then
6. Give two slow breaths.
7. Assess circulation. If no pulse noted, then
8. Begin closed-chest compressions and continue ventilations. Use the defibrillator if available.

Initial Actions

Upon discovery of a collapsed individual, the first medical action should be to assess the victim and determine whether the person is in fact unresponsive. However, prior to approaching a collapsed individual, the scene needs to be fully assessed for dangers to providers. Potential risks, whether from hazardous materials, unstable physical environment, or violence, should be considered. Becoming an additional victim will not aid patients and only add to the work load of other care providers. Once the patient is reached, level of responsiveness can be determined quickly through the administration of various stimuli from mild through noxious. If the individual is not responding, this is the time to obtain help prior to starting ventilations and chest compressions. Within a hospital, this may mean calling for the arrest team and requesting the arrest cart; outside the hospital, this is likely to be activation of the local emergency medical services system. Additionally, efforts should be made to obtain a defibrillator. Time to rhythm-specific therapy, especially defibrillation for unstable ventricular tachycardia or ventricular fibrillation, is critical for the recovery of patients in cardiac arrest.

Open the Airway

Once unresponsiveness has been determined, assistance obtained, and a defibrillator requested, the next step is to assess the upper airway of the victim. This usually requires positioning the individual supine on a flat, firm surface with arms along the sides of the body, followed by opening the person's airway. Unless trauma can be definitely excluded, any movement of the victim must take into account the potential of a spine injury; as the patient is placed supine, stabilize the cervical spine by maintaining the head, neck, and trunk in a straight line. If for some reason the patient cannot be placed supine, consider using the jaw-thrust maneuver (see below) from a lateral position to open the airway. Properly opening the airway is a critical and potentially lifesaving step. Common causes for airway obstruction in an unconscious patient are occlusion of the oropharynx by the tongue and laxity of the epiglottis. With loss of muscle tone, the tongue or the epiglottis can be forced back into the oropharynx on inspiration. This can create the effect of a one-way valve at the entrance to the trachea, leading to airway obstruction manifesting as inspiratory stridor. After positioning the patient, the mouth and oropharynx should be inspected for secretions or foreign objects. If secretions are present, they can be removed with the use of oropharyngeal suction; a foreign body may be dislodged by use of a finger sweep and then manually removed (see below).

Once the oropharynx has been cleared, two basic maneuvers for opening the airway may be tried to relieve upper airway obstruction. These are the head tilt–chin lift and the jaw thrust. These maneuvers help to open the airway by mechanically displacing the mandible and the attached tongue out of the oropharynx.

HEAD TILT–CHIN LIFT MANEUVER   The head tilt–chin lift is usually the first maneuver attempted if there is no concern for cervical spine injury. The head tilt is performed by gently extending the neck. This is done by placing one hand under the patient's neck and the other on the forehead and extending the head in relation to the neck. This should place the patient's head in the "sniffing position" with the nose pointing up. In conjunction with the head tilt, the chin lift is performed. This is done by carefully placing the hand, which had been supporting the neck for the head tilt, under the symphysis of the mandible so as not to compress the soft tissues of the submental triangle and the base of the tongue. The mandible is then lifted forward and up until the teeth barely touch. This supports the jaw and helps tilt the head back.

JAW-THRUST MANEUVER   The jaw thrust is the safest method for opening the airway if there is the possibility of cervical spine injury. It helps to maintain the cervical spine in a neutral position during resuscitation. The rescuer, who is positioned at the head of the patient, places the hands at the sides of the victim's face, grasps the mandible at its angle, and lifts the mandible forward (Fig. 8-1). The rescuer's elbows may rest on the surface on which the victim lies. This lifts the jaw and opens the airway with minimal head movement.

FIG. 8-1. Jaw-thrust maneuver.

Assess Breathing and Initiate Ventilation

Once the airway has been opened, assessment of respiratory effort and air movement should occur. The care provider should look for chest expansions and listen and feel for airflow. The simple act of opening the airway may be adequate for the return of spontaneous respirations. However, if the victim remains without adequate respiratory effort, then further intervention is required. Two slow breaths of $1\frac{1}{2}$ to 2 s each should be given. At this point, a foreign body obstruction, as indicated by lack of chest rise or airflow on ventilation, may be noted, which would require efforts to relieve the obstruction (Fig. 8-2). Agonal respirations in an individual who has just suffered a cardiac arrest are not considered adequate. Intermittent positive-pressure ventilation, if possible with oxygen-enriched air, should be initiated.
FIG. 8-2. Determine breathlessness.

VENTILATION TECHNIQUES   There are a number of techniques for ventilating an individual, including mouth to mouth, mouth to nose, mouth to stoma, mouth to mask. Rescue breaths of an inspiratory time of $1\frac{1}{2}$ to 2 s each should be given at a rate of 10 to 12 per minute, with a volume adequate to make the chest rise—800 to 1200 mL in most adults. Too large a volume or too rapid an inspiratory flow rate will likely cause gastric distention, which can lead to regurgitation and aspiration. Expired air has an F_{O_2} of 16 to 17 percent. Supplemental oxygen should be delivered as soon as possible.

Mouth to Mouth   With the airway open, the patient's nose should be gently pinched shut with the rescuer's thumb and index finger (Fig. 8-3). This prevents air escape. After a deep breath, the rescuer places his or her lips around the patient's mouth, forming an airtight seal. The rescuer slowly exhales. Release the seal and allow adequate time for passive exhalation by the victim, and then repeat the procedure.

FIG. 8-3. Mouth-to-mouth rescue breathing.

Mouth to Nose   At times, as with severe maxillofacial trauma, mouth-to-nose ventilation may be more effective. With the airway open, the rescuer lifts the patient's jaw, closing the mouth. After a deep breath, the rescuer places his or her lips around the patient's nose, forming an airtight seal. The rescuer slowly exhales.

Mouth to Stoma or Tracheostomy   After laryngectomy or tracheotomy, the stoma or tracheostomy becomes the patient's airway. As with the previous techniques, a seal is made around the stoma or tracheostomy tube, and the rescuer slowly exhales.

Mouth to Mask   Placement of the mask properly and securely on a victim's face is important when using a mask for ventilation, either with a bag or via mouth to mask. The mask should be placed over the bridge of the patient's nose and around the mouth. The rescuer places the thumb on the part of the mask that is sitting on the patient's nose and places the index finger of the same hand on the part of the mask sitting on the patient's chin (Fig. 8-4). The three other fingers of the same hand are then placed along the bony margin of the jaw. The mask can then be firmly sealed to the patient's face. Two hands may be used for this technique if a second rescuer is available. Ventilations are then performed through the mask; some masks also allow for supplemental oxygenation.

FIG. 8-4. Mouth-to-mask rescue breathing with proper mask placement.

Foreign Body Obstruction

It is important to recognize and be able to assist someone with an airway obstruction from a foreign body. The National Safety Council reported that approximately 2900 deaths from foreign body airway obstruction occurred in 1993.[1] An individual in distress from a compromised airway is likely to use the universal sign for an airway obstruction, which is for the individual to grab his or her neck with both hands. Foreign bodies can cause partial or complete obstruction. With a partial airway obstruction, air exchange may be adequate or inadequate. If the victim is able to speak, cough, and exchange air, then he or she should be encouraged to continue spontaneous efforts. Assistance, such as activation of the local emergency medical services system, should be obtained. No interference should be made with the patient's attempts to cough or expel the foreign body. If air exchange becomes inadequate, indicated by increased difficulty breathing, weak and ineffective cough, worsening inspiratory stridor, or cyanosis, direct medical intervention should occur. Inadequate air exchange from either a severe partial or a complete airway obstruction should be managed the same. In an unconscious person, airway obstruction may be noted through inadequate airflow and poor chest rise on efforts to ventilate.

OBSTRUCTION-RELIEVING MANEUVERS   Maneuvers used to relieve foreign body obstructions include the Heimlich maneuver (subdiaphragmatic abdominal thrusts), chest thrusts, and the finger sweep. As a single method, back blows are no longer recommended to relieve obstructions in adults. In a conscious individual, the Heimlich maneuver is the recommended maneuver in most adults for relieving airway obstruction from a solid object. It is not useful for liquids. In an unconscious individual suspected of having an aspirated foreign body, the recommended first step is the finger sweep. Otherwise, in an unconscious patient the recommended sequence is the Heimlich maneuver up to five times, open mouth and perform a finger sweep, and then attempt to ventilate. This sequence may be repeated as long as needed until the patient recovers or additional assistance arrives.

Heimlich Maneuver (Fig. 8-5) Described by Dr. Heimlich in 1975, this maneuver creates an artificial cough through elevating the diaphragm and forcing air from the lungs.[2] It may be repeated multiple times; each individual thrust should be performed with the intent to relieve the obstruction. It can be performed with the victim standing, sitting, or lying down, or it can be self-administered. To perform with the patient standing or sitting, the rescuer stands behind the patient and places the thumb side of a fist against the victim's abdomen midline just above the navel and well below the xiphoid process. Grasping the fist with the other hand, the rescuer presses the fist into the victim's abdomen with a quick upward thrust. This is repeated until the item is dislodged or the patient becomes unconscious. For an unconscious patient, the individual is placed supine on a firm surface with the rescuer sitting astride the victim's thighs (Fig. 8-6). The heel of a hand is positioned midline just above the patient's umbilicus, and the second hand is placed directly on top of the first. The rescuer then delivers quick upward thrusts. To self-administer thrusts, the individual can either use his or her own fist to delivery the thrusts or lean against a firm object, such as a porch rail or back of a chair. Potential complications of the Heimlich maneuver include injury or rupture of abdominal or thoracic viscera or regurgitation of stomach contents.

FIG. 8-5. Standing Heimlich maneuver administered to conscious victim of foreign body airway obstruction.

FIG. 8-6. Prone Heimlich maneuver administered to unconscious victim of foreign body airway obstruction.

Chest Thrusts   This maneuver is used primarily if someone is morbidly obese or in the late stages of pregnancy and the rescuer cannot reach around the patient's abdomen to perform abdominal thrusts (Fig. 8-7). To perform chest thrusts with the patient standing or sitting, the rescuer stands behind the patient and places the thumb side of a fist against the victim's sternum, avoiding the costal margins and the xiphoid process. Grasping the fist with the other hand, the rescuer presses the fist into the victim's chest with a quick backward thrust. This is repeated until the item is dislodged or the patient becomes unconscious. For an unconscious patient, the individual is placed supine on a firm surface with the rescuer kneeling close to the victim's side. The hands are placed in the same position as for chest compression, i.e., the lower sternum, and quick thrusts are delivered.

FIG. 8-7. Standing chest-thrust maneuver administered to conscious victim of foreign body airway obstruction.

Finger Sweep   This maneuver is used only in unconscious patients (Fig. 8-8). Using the thumb and fingers of one hand, the rescuer grasps both the tongue and the mandible and lifts. This may partially relieve the obstruction by lifting the tongue away from the back of the throat. With the other hand, the rescuer then inserts his or her index finger into the back of the throat and uses a hooking action in an attempt to dislodge the foreign body to move it into the mouth for manual removal. Care must be used so as to not push the foreign object deeper into the throat.

FIG. 8-8. Finger-sweep maneuver administered to unconscious victim of foreign body airway obstruction.

Assess Circulation and Initiate Compressions

The carotid artery is generally the most reliable and accessible location to palpate a pulse. The artery can be located by placing two fingers on the trachea and then sliding them down to the groove between the trachea and the sternocleidomastoid muscle. Simultaneous palpation of both carotid arteries should not be performed because this could obstruct cerebral blood flow. In low-pressure states, forceful palpation may interfere with the ability to detect a pulse. The femoral artery may be used as an alternative site to palpate a pulse. This can be found just below the inguinal ligament approximately halfway between the anterosuperior iliac spine and the pubic tubercle. If no pulse is felt after 5 to 10 s, chest compressions should begin.

PHYSIOLOGY OF CLOSED-CHEST COMPRESSIONS   Since the technique of closed-chest compressions was put forth initially by Kouwenhoven and colleagues in the 1960s, there has been an active debate as to the mechanism of blood flow. [3,4] In a closed system, liquid flows when pressure gradients develop. There are two basic theories for how pressure gradients and flow are produced during closed-chest cardiac massage. [5] The conventional theory of blood flow during compressions is called the *cardiac pump theory*. This postulates that direct compression of the heart between the spine and the sternum leads to increased pressure in the ventricles. This causes closure of the mitral and tricuspid valves, leading to blood flow into the aorta and the pulmonary arteries. The *thoracic pump theory* postulates that compressions lead to an increase in pressure throughout the thoracic cavity, leading to a pressure gradient from intrathoracic to extrathoracic arteries. It is possible that both mechanisms produce blood flow to varying degrees during closed-chest cardiac massage in humans. However, regardless of mechanism, conventional chest compressions generate one-fourth to one-third of physiologic cardiac output. Lower ratios can be expected with delays in initiating compressions.

TECHNIQUE OF CLOSED-CHEST COMPRESSIONS   Upon confirmation that an individual is without a pulse, serial rhythmic closed-chest compressions should be initiated. The victim is placed supine on a firm surface with the rescuer at the side. The care provider places the heel of one hand midline on the lower half of the sternum, approximately 2 in cephalad of the xiphoid process (Fig. 8-9). The heel of the hand should be parallel with the long axis of the patient's body. The second hand is then placed on top of the first hand so that the hands are parallel with each other. The fingers of the two hands may be interlaced if desired. The arms should be straight and the elbows preferably locked. The vector of the compression force should start from the rescuer's shoulders and be directed downward; lateral forces will decrease efficiency of the compressions and increase the likelihood of complications. The sternum should be depressed $1\frac{1}{2}$ to 2 in (3.8 to 5.1 cm) in an adult at a minimum rate of 80 to 100 compressions per minute. Rates less than this are inadequate. The compression-release phases should be roughly equal. With a single rescuer, 2 ventilations should be given after every 15 compressions; with two rescuers, a ventilation should be given after every fifth compression.

FIG. 8-9. Proper hand and rescuer positioning for chest compression.

There are currently several experimental techniques for closed-chest cardiac massage. In one method, circumferential chest compressions are performed by a pneumatic vest CPR to more effectively increase intrathoracic pressure during chest compressions. [6] In interposed abdominal compression CPR, abdominal compression occurs during the relaxation phase of chest compression, causing increased aortic diastolic pressure and leading to improved blood flow to organs above the diaphragm. [7] In active compression-decompression CPR, a hand-held suction device is used to decrease intrathoracic pressure during the relaxation phase of chest compression and to improve ventricular filling. [8] Additionally, self-initiated cardiopulmonary resuscitation can be performed by forceful coughing. This increases intrathoracic pressure, leading to blood flow to the brain for as long as the patient remains conscious and able to cough. [9]

Complications of Cardiopulmonary Resuscitation

Ventilations can cause insufflation of the stomach, leading to regurgitation and possible aspiration or possibly to gastric rupture. Closed-chest compressions can lead to fractures of the sternum or the ribs, separation of the ribs from the sternum, pulmonary contusion, pneumothorax, myocardial contusion, hemorrhagic pericardial effusions, splenic laceration, or liver laceration. Proper techniques can minimize these complications but not totally prevent them. Late complications include pulmonary edema, gastrointestinal hemorrhage, pneumonia, and recurrent cardiopulmonary arrest. Anoxic brain injury can occur in a resuscitated individual who had suffered prolonged hypoxia; it is the most common cause of death in resuscitated patients.

Terminating Resuscitation

Efforts at resuscitation should be continued until the patient recovers spontaneous respirations and cardiac output, the rescuer becomes exhausted, or the patient is pronounced dead. Atraumatic individuals who recover spontaneous respirations and circulation should be placed on their sides—the *recovery position*. Recovery from cardiac arrest depends on time to CPR and rhythm-specific intervention. Resuscitation and long-term outcome in normothermic patients with arrest times of 20 min or more are very poor.

FUTURE DIRECTIONS

It should be noted that many of the current basic CPR guidelines are based on expert consensus derived from limited scientific studies and clinical experience, and much active research is currently occurring.[10] Well-designed and executed outcome-directed scientific research will help to further develop the quality and efficacy of basic CPR.

9 NEONATAL RESUSCITATION AND EMERGENCIES

Eugene E. Cepeda
Seetha Shankaran

NEONATAL RESUSCITATION

Approximately 6 percent of all newborns require life support in the delivery room or nursery, and in those neonates whose birth weights are less than 1500 g, the need for resuscitation rises to 60 percent. Personnel skilled in neonatal resuscitation should be available at every delivery. It is important to anticipate the delivery of high-risk neonates so that delivery room personnel may be alerted to the possible need for resuscitation.

There are no guidelines available to assist in making the decision to resuscitate extremely premature infants in the emergency department. When in doubt, resuscitate. At the present time, survival at 22 weeks of gestation or less is rare. However, a 20 to 30 percent survival rate is reported at 24 weeks' gestation, although often with severe resultant morbidity.

The following factors are associated with an increased risk for neonatal resuscitation:

Maternal factors
  Inadequate prenatal care
  Age <16 and >35 years
  History of previous perinatal morbidity or mortality
  Toxemia, hypertension
  Diabetes
  Chronic renal disease
  Anemia
  Drug therapy (e.g., reserpine, lithium, carbonate, magnesium, adrenergic-blocking agents)
  Substance abuse
  Blood type or group isoimmunization
  Oligohydramnios
Intrapartum factors
  Abnormal presentation
  Caesarean section
  Prolonged labor or precipitous delivery
  Prolonged rupture of membranes, chorioamnionitis
  Cephalopelvic disproportion
  Forceps delivery other than outlet or vacuum extraction
  Prolapsed cord
  Cord compression
  Maternal hypotension, shock
  Analgesic or sedative drugs given within 2 h of delivery
Fetal factors
  Prematurity
  Postmaturity
  Intrauterine growth failure
  Multiple gestation
  Acidosis per fetal scalp capillary monitoring
  Abnormal fetal heart rate per monitor
  Thick meconium in amniotic fluid
  Congenital infection
  Fetal malformation or edema diagnosed by ultrasound

The following conditions should alert nursery personnel to the possibility of apnea: previous need for resuscitation, prematurity, sepsis and/or meningitis, congenital abnormalities, respiratory distress, or seizures.

Normal newborns are equipped with physiologic, pharmacologic, and metabolic responses to enable them to survive the hypoxia that develops as a consequence of asphyxia. Generally, brain injury occurs only when the asphyxia is severe enough to impair cerebral blood flow. Initially the injury is reversible, and only longer periods of ischemia lead to permanent damage. The pattern of injury is strongly influenced by the distribution of blood flow. During asphyxia, blood flow is redirected to the heart, brain, and adrenals at the expense of other organs, such as the kidneys and the gastrointestinal tract. Within the brain, flow is directed to the brainstem at the expense of the high cerebral structures, such as the cortex. In the preterm neonate, the periventricular white matter is susceptible to injury. In the full-term or postterm neonate, the gray-matter regions, such as the overlying parasagittal "watershed" cortex, are more vulnerable to ischemic injury. When the asphyxial insult is severe or prolonged, hypoxic multiorgan dysfunction occurs because of the redistribution of organ blood flow and results in cardiopulmonary distress, renal failure, impaired hepatic function, seizures and encephalopathy, gastrotintestinal dysfunction, and coagulopathies.

Principles of Resuscitation

The Apgar score (Table 9-1) is assessed at 1 and 5 min of age for every newly delivered infant. Although the scoring system has been useful in evaluating the condition of the newborn, 1 min is too long to wait to make the decision to initiate resuscitation. If the 5-min score is less than 7, additional scores are obtained every 5 min for a total of 20 min.

Sign	0	1	2
Heart rate	Absent	<100/min	>100/min
Respiratory effort	Absent	Weak cry	Strong cry
Muscle tone	Limp	Some flexion	Good flexion
Reflex irritability (when feet stimulated)	No response	Some motion	Cry
Color	Blue, pale	Body pink, extremities blue	Pink

TABLE 9-1 Apgar Score

Perinatal asphyxia is currently defined as the presence of the following: umbilical artery acidemia (pH <7.00), 5-min Apgar score of 0 to 3, neonatal neurologic sequelae, and multiorgan dysfunction. Certain conditions require specific measures during resuscitation in addition to those outlined below. These conditions are discussed following the general principles.

Resuscitation should be continued for a maximum of 30 min. Neonatal morbidity and mortality rates are high after 20 to 30 min of cardiac asystole and resulting encephalopathy in term infants. Infants who were successfully resuscitated at birth should have continuous monitoring of vital signs, blood gases, hematocrit, dextrose levels, blood pressure, fluid status, and clinical condition. Complications associated with severe asphyxia are seizures, hypoxic-ischemic encephalopathy, intracranial hemorrhage, inappropriate antidiuretic hormone (ADH) secretion, hypocalcemia, persistent pulmonary hypertension, ischemic cardiomyopathy, hypovolemia or shock, necrotizing enterocolitis, renal failure, and coagulopathy.

EQUIPMENT   The following is a list of the equipment necessary for resuscitation.

1. Bag and mask with manometer attached, connected to a source of 100 percent oxygen (oxygen should be heated and humidified; bag should be a rubber anesthesia bag, a rebreathing bag of 500-mL capacity, or a self-inflating bag designed for newborns)
2. Rubber face masks of varying sizes, 1, 2, 3, and 4
3. Wall suction, sterile catheters, and bulb syringes
4. DeLee suction catheter with mucus trap
5. Laryngoscope with 0 and 1 blades
6. Oral endotracheal tubes with stylet, sizes 2.5, 3.0, 3.5, and 4.0 mm
7. Radiant heater with servomechanism
8. Sterile umbilical vessel catheterization tray
9. Glucose oxidase blood test strips
10. Heart rate monitor with easily applicable leads
11. Intravenous infusion equipment
12. Transcutaneous oxygen monitor or saturation pulse oximeter
13. Appropriate light
14. Infant stethoscope
15. Nasogastric tubes, 5F and 8F
16. Clock with sweep second hand

Resuscitation Steps

MAINTAIN BODY TEMPERATURE   Maintain the infant below the level of the placenta prior to clamping the cord. When the cord is clamped, blot the infant dry with a sterile towel and place the infant under a preheated radiant warmer on a sterile table. Neonates should be placed either on the back or the left side somewhat in the Trendelenburg position, with the neck in a neutral position.

CLEAR THE AIRWAY   Gently suction the nose and mouth with a bulb syringe, DeLee trap, or mechanical suction apparatus with an 8F suction catheter. A 5- to 10-s examination should be performed to determine the need for resuscitation. This examination should include an assessment of heart rate, respiratory effort, color, and muscular activity. If the infant has a lusty cry, is pink, has spontaneous respirations, and has a heart rate above 120 beats per minute (Apgar > 8), no further therapy is needed.

INITIATE BREATHING   If the infant is apneic or the heart rate is slow and irregular (<100 beats per minute) and the color is cyanotic (Apgar 4 to 7), administer positive-pressure ventilation with the mask over the infant's face and 100% oxygen. The respiratory rate should be maintained at 40 breaths per minute, with pressure applied to gently move the chest wall. In an infant who has not yet taken a breath, over 40 cmH$_2$O pressure may be necessary to expand the lungs. In mildly depressed infants, this will produce a prompt increase in heart rate and the onset of regular spontaneous respirations. If no improvement is noted in 15 to 30 s and the condition deteriorates (Apgar £ 4), the trachea should be intubated and assisted ventilation continued.

MECONIUM STAINING   Meconium staining of the amniotic fluid occurs in from 0.5 to 20 percent of all births. Aspiration of thick meconium carries a 20 to 50 percent mortality rate; however, with proper management it is almost entirely preventable. When gross meconium is noted at the time of delivery, the following procedure should be followed. After delivery of the infant's head (but before delivery of the shoulders), the nose, mouth, and pharynx should be thoroughly suctioned with a DeLee suction catheter. Repeat suctioning of the upper airway should be performed as the infant is placed under the radiant warmer. The trachea should then be visualized with a laryngoscope and meconium aspirated by direct suctioning through an endotracheal tube. Suctioning should be repeated until no more meconium is present in the trachea. The infant may then be ventilated with positive pressure as indicated. Failure to clear the trachea before assisted or spontaneous ventilation may result in dissemination of the meconium through the airways.

ENDOTRACHEAL INTUBATION

Indications

1. Mechanical ventilation
2. To clear the trachea of meconium

Equipment

Pediatric laryngoscope handle
Laryngoscope blade no 0 for infants < 2000 g
Laryngoscope blade no 1 for infants > 2000 g
Self-inflating bag and mask apparatus
Adapter
Scissors
Stylet
Tape
Suction apparatus
Tincture of benzoin

Procedure

1. Check that the light source on the laryngoscope blade is working. Place the infant supine and suction the mouth and oropharynx. Monitor the heart rate and color.
2. Hold the laryngoscope in the left hand and open the infant's mouth by sliding your right index finger between the infant's right upper and lower gums. Insert the laryngoscope into the infant's mouth by sliding the blade down against your right index finger. Push the tongue with the blade to the left.
3. Advance the blade and lift. You should be able to see the epiglottis. Remove your right index finger, holding the blade with left hand.
4. Pass the endotracheal tube along the right side of the mouth and advance it past the vocal cords. If a stylet is used, it should be gently removed while the tube is held firmly in place. The tip of the tube should not go past 2.5 cm beyond the cords.
5. Attach the resuscitation bag to the tube and listen for breath sounds, which should be equal on both the right and left chest. The infant's oxygen saturation should improve. A chest x-ray will confirm proper placement.
6. Paint the skin with tincture of benzoin and tape the tube securely.

CARDIAC MASSAGE   If the heart rate is below 50 beats per minute with assisted ventilation, cardiac massage should be initiated by placing both hands around the infant's chest with two thumbs over the midsternum so that the sternum will be depressed two-thirds of the distance to the vertebral column at 120 compressions per minute. Cardiac massage may be stopped periodically to assess improvement, and ventilation and cardiac massage should be synchronized (1:3 ratio). The chest should expand, bilateral breath sounds should be heard in the axilla, and heart rate should increase if the resuscitation is effective and the endotracheal tube is in good position. *In most instances* it is possible to obtain an adequate response with the use of external cardiac massage and assisted ventilation. If there is no response to these measures, drug therapy should be considered. Any route of access to the circulatory system is acceptable, including a peripheral vein, the umbilical vein, or an umbilical artery.

UMBILICAL ARTERY CATHETERIZATION

Indications

1. To measure arterial blood gases
2. To monitor continuous blood pressure
3. To infuse fluids

Equipment

2 × 2 sponges, 5
Curved hemostat
Medicine glasses, 2
Scalpel blade, no 11
Iris forceps, curved, serrated end, no teeth, 2
Lacrimal probe
Needle holder
Debriding scissors
Umbilical tape, 6 in
Knife handle
4-0 silk suture with needle
Three-way stopcock
10-mL syringes, 2
Iodine solution
3.5F catheter for infant < 1200 g
5.0F catheter for infant > 1200 g

Procedure

1. Immobilize the patient. Measure the distance between the umbilicus and the right shoulder.
2. Clean the umbilical stump and surrounding area with iodine solution. Drape the umbilical area, but leave the head and feet uncovered.
3. Tie the base of the cord with the umbilical tape to minimize blood loss.
4. Cut the cord cleanly across its length to 1 cm with the scalpel. The arteries are small and have pinpoint openings. The vein is larger and has thinner walls and a larger opening.
5. Grasp the edge of the cord with the forceps. Using the iris forceps, enlarge the opening of the umbilical artery first with the tip of one arm of the forceps.
6. Insert both arms of the forceps to dilate the artery so that it will accept the catheter.
7. The length of the catheter inserted for the low position is two-thirds of the distance from the umbilicus to the right shoulder and for the high position, the full measurement from the right shoulder to the umbilicus.
8. Attach the three-way stopcock and aspirate blood with a syringe. Clear the catheter with normal saline.
9. Anchor the catheter with silk suture to the umbilical stump.
10. Check the position of the catheter tip with an x-ray. It should be at the level of L4 for the low position, or between T6 and T9, which is above the diaphragm, for the high position.

Patency of the umbilical arterial line can be maintained by a continuous infusion of fluid. The catheter should be removed when the need for arterial blood gas monitoring is no longer necessary (oxygen requirement £ 80%) or complications occur.

Complications   Possible complications of umbilical artery catheterization are infection, thrombosis and vasospasm, and hemorrhage. Renal hypertension is a delayed complication.

UMBILICAL VEIN CATHETERIZATION   The most expedient procedure for obtaining vascular access is to insert the venous catheter through the umbilicus via the umbilical vein, and the ductus venosus into the inferior vena cava. The venous catheter should be inserted 10 to 12 cm and anchored to the abdominal wall. Obtain radiographs of chest and abdomen to rule out other abnormalities and evaluate the position of the catheters.

Drug Therapy in Resuscitation

There is a very minor role for drug therapy in resuscitation. Most resuscitative efforts in the delivery room respond to adequate support of ventilation and circulation without drug therapy (see Table 9-2).

TABLE 9-2   Neonatal Resuscitation Drug Chart

DEXTROSE   To provide metabolic substrate and expansion of plasma volume, 10 percent dextrose in water ($D_{10}W$) at 100 (mL/kg)/day or 6 to 8 (mg/kg)/min should be infused. If the Dextrostix is less than 45 mg/dL, 5 mL/kg of 10 or 15% glucose solution should be infused; 25% dextrose infusions should be avoided because of the risk of rebound hypoglycemia.

EPINEPHRINE   To stimulate heart rate if it is under 120 beats per minute, 0.1 mL/kg of a 1:10,000 solution may be given through the endotracheal tube or intravenously. Cardiac massage should continue following epinephrine administration.

NALOXONE   Use naloxone only to reverse narcotic respiratory depression, 0.01 mg/kg of a neonatal solution (0.2 mg/mL) may be administered intravenously, subcutaneously, or through the endotracheal tube. The time for peak concentration of transplacentally acquired narcotics in the fetus is 2 h following administration of medication to the mother; thus, delivery of the fetus at that time would predispose the fetus to maximal depression. Naloxone may precipitate withdrawal in infants whose mothers are addicted to narcotics.

ISOPROTERENOL   If epinephrine has failed to raise the heart rate to at least 120 beats per minute, 1:10,000 solution or 0.05 to 0.1 µg/min may be infused.

A delay in onset of spontaneous regular respiration of more than 30 min following birth has been associated with a poor prognosis. Attempts at resuscitation after 30 min of no response do not appear to be warranted.

BICARBONATE   In the presence of metabolic acidosis, 2 to 3 meq/kg of sodium bicarbonate should be administered as an intravenous infusion. A continuous infusion may be necessary [not to exceed 8 meq/kg/day] if acidosis is protracted.

DOPAMINE   Dopamine should be initiated to raise the blood pressure after adequate fluids have been administered. At low doses (2 to 5 µg/kg/min) dopamine preserves renal and mesenteric perfusion; at higher doses (10 to 20 mg/kg/min) it has both inotropic and vasoactive properties through a- and b-adrenergic effects.

NEONATAL EMERGENCIES

Neonatal Shock

The risk factors for shock and hypotension in newborn infants are low birth weight, maternal sepsis, prolapsed cord, and acute onset of maternal vaginal bleeding. Clinical signs of hypovolemia are pallor, tachycardia, grunting respirations in the absence of pulmonary disease, mottling of skin, poor capillary filling, thready pulse and hypotension (systolic < 45 mmHg in a 1000-g premature neonate or < 60 mmHg in a term infant), and persistent metabolic acidosis. A hematocrit should be obtained, and if anemia (hematocrit < 45 vol%) or hypotension is diagnosed, immediate plasma expansion in the form of packed red blood cells 5 mL/kg or whole blood, fresh-frozen plasma, Plasmanate, or 5% salt-poor albumin 10 to 20 mL/kg should be given intravenously over 10 min.

Seizures

Seizures in neonates are common, with an incidence of 1 in 200 live births, and may represent primary central nervous system (CNS) disease or a systemic or metabolic disorder. Recent data suggest that seizure activity itself may adversely affect the growing brain. It is important to distinguish seizures from tremors or jitteriness, which may be seen in infants who have hypocalcemia, hypoglycemia, drug withdrawal, or no identifiable disease. Tremors are uniform, fine movements that respond to sensory stimuli, stop with manual stabilization, and do not occur spontaneously. They are not accompanied by eye, oral, or lingual movements. The types of neonatal seizures include subtle seizures, tonic seizures, multifocal clonic seizures, focal clonic seizures, and myoclonic seizures.

Subtle seizures occur in both preterm and term neonates. These seizures consist of ocular, facial, oral, or lingual movements and respiratory manifestations, such as apnea or stertorous breathing.

Tonic seizures are characteristic of premature infants. The seizures appear as decerebrate or decorticate posturing. There are sustained deviation of the eyes and assymetric posturing of the limbs and trunk.

Multifocal clonic seizures are seen in term infants. These are initially noted in one limb and migrate to another part of the body. There are rhythmic and slow movements at one to six times per second.

Focal clonic seizures are well localized and are accompanied by specific sharp activity on the electroencephalogram (EEG). These seizures occur more commonly in full-term infants.

Myoclonic seizures are expressed as single or multiple jerks of flexion of the upper or lower extremities. They are rare and occur in both premature and full-term infants.

CLINICAL FEATURES   There are numerous causes of neonatal seizures. Hypoxic-ischemic encephalopathy is the most common cause of seizures. The seizures occur between 6 and 18 h of life. In full-term neonates, the hypoxic injury may result in a cerebral hemorrhage, watershed infarct, posterior fossa hematoma, or subarachnoid or subdural hemorrhage. In premature infants, hypoxic injury often results in periventricular-intraventricular hemorrhage. This type of seizure has a poor prognosis.

The metabolic disturbances associated with neonatal seizures include hypoglycemia, hypocalcemia, hypomagnesemia, hyperammonemia, hypernatremia, and hyponatremia. Hypoglycemia, hypocalcemia, and hypomagnesemia are often found in premature infants with perinatal asphyxia. Hypernatremia occurs in neonates with dehydration secondary to excessive fluid losses or treatment with large doses of sodium bicarbonate. Hyponatremia may be seen secondary to inappropriate ADH secretion or acute volume overload. Inborn errors of amino acid metabolism also may present as seizures.

Seizures can result from bacterial meningitis, and encephalitis associated with TORCH complex (toxoplasmosis, rubella, cytomegalovirus infection, and herpes simplex infection) or coxsackie B encephalitis. Developmental abnormalities including congenital hydrocephalus, microcephaly, and other congenital brain anomalies can cause seizures. Drug withdrawal from maternal use of methadone, barbiturates, alcohol, pentazocine (Talwin), and tripelannamine (Pyribenzamine) rarely presents as seizures. Pyridoxine dependence occurs rarely but must be considered in neonatal seizures unresponsive to standard therapy. A rare cause of neonatal seizures is inadvertent fetal scalp injection of maternal local anesthetic agents. Finally, neonatal stroke diagnosed by computed tomography (CT) has recently been described in term infants with focal motor seizures. Neonatal stroke may occur in the setting of diverse cerebrovascular disorders, such as hypoxic-ischemic encephalopathy, polycythemia, acute severe hypertension, and cocaine use.

A careful history, including intrapartum monitoring data and physical examination, is essential when considering drug withdrawal, birth asphyxia, or metabolic disorders as a cause of the seizures. A lumbar puncture with analysis of cell count, culture, and Gram stain along with blood specimens for culture and determinations of sugar, calcium, magnesium, and blood urea nitrogen (BUN) levels should be obtained. The skull x-ray, echoencephalogram, and EEG can be obtained after the seizures have been controlled. In a full-term infant, a CT scan of the head to look for ischemic injury may be necessary, since an echoencephalogram may not provide adequate visualization of the subarachnoid space or posterior fossa. Recently, positron emission tomography of the head has been utilized to evaluate the effects of asphyxia and seizures on cerebral blood flow.

TREATMENT   Repeated seizures in neonates may be accompanied by hypoventilation and apnea, resulting in hypercapnia and hypoxemia. Increases in cerebral blood flow and arterial hypertension occur with neonatal seizures. Treatment of seizures should be initiated while awaiting results of laboratory data. An intravenous access route should be established immediately and the airway maintained; assisted ventilation should be initiated if apnea persists. Hypoglycemia and hypocalcemia

should be treated as stated above. Hypomagnesemia is often associated with hypocalcemia and should be treated by intravenous administration of 2 to 4 mL of a 2 percent magnesium sulfate solution.

The anticonvulsant drugs used most frequently include phenobarbital and diphenylhydantoin. The loading dosage of phenobarbital is 20 mg/kg intravenously given slowly over 10 min, and the maintenance dose is 5 (mg/kg)/day intramuscularly or orally in two divided doses. If the initial 20 mg/kg dose of phenobarbital is not effective in controlling the seizures, additional doses of 5 mg/kg may be administered every 5 min until the seizures have ceased or the total dose of 40 mg/kg has been reached. In unresponsive cases, diphenylhydantoin may be administered with a similar loading dose followed by maintenance dose of 3 to 5 (mg/kg)/day by the intravenous route in only two divided doses 20 min apart to avoid disturbance of cardiac function. Lorazepam is recommended for status epilepticus as long as ventilation and blood pressure are supported. The dose of lorazepam is 0.01 mg/kg administered intravenously. Infants with pyridoxine dependence respond immediately to an intravenous injection of 50 to 100 mg of pyridoxine.

Diaphragmatic Hernia

A failure of development of the posterolateral parts of the diaphragm at the Bochdalek foramen or retrosternally at the Morgagni foramen allows herniation of the gut into the chest cavity. Left-sided Bochdalek hernias are more common than those on the right. The defect occurs in one out of 2200 births. Associated anomalies with diaphragmatic hernias include congenital heart diseases, genitourinary anomalies, gastrointestinal anomalies, hydronephrosis, and cystic kidneys. Frequently the lungs are hypoplastic bilaterally and have abdominal pulmonary vasculature, predisposing the infant to pulmonary hypertension.

Fifty percent of fetuses with diaphragmatic hernia have difficulty swallowing, and the condition is therefore associated with polyhydramnios. The diagnosis can often be made by prenatal ultrasonography.

CLINICAL FEATURES   The clinical findings are localized to the respiratory and digestive tracts. The chest is large, while the abdomen is scaphoid. Bowel sounds are heard in the left chest, and the heart is displaced to the right. Dyspnea, cyanosis, retractions, and vomiting are proportional to the amount of abdominal viscera herniated into the thorax. Radiologic study reveals air-filled loops of bowel in the chest cavity and an absent diaphragmatic margin. The heart is often displaced and the lungs are small in size.

TREATMENT   Immediate surgical repair is a method of treatment, and the neonate should be stabilized as much as possible prior to surgery. Alternatively, the neonate can be placed on extracorporeal membrane oxygenation (ECMO) prior to repair. The infant should be intubated immediately, and little or no attempt should be made to ventilate with a mask. The endotracheal tube should be positioned above the carina. Rapid ventilatory rates and low peak inspirator pressures are used to ventilate the infant and prevent reactive respiratory acidosis and hypercarbia, which are potentially conducive to the development of pulmonary hypertension. A large-caliber 10F tube should be placed in the stomach with low continuous suction applied. An umbilical artery catheter is useful to monitor blood gases and pH. Any acidemia should be corrected and the pH maintained in the alkalotic range (pH > 7.45) if possible. Intravenous fluids should be given and the patient kept warm.

The outcome of management of diaphragmatic hernia is dependent on pulmonary parenchymal and vascular hypoplasia, as well as the complex syndrome of persistent fetal circulation. The morbidity is higher when the symptoms present at birth and when the diaphragmatic hernia is detected prenatally. Morgagni hernias, if they do not affect cardiac output, generally have a better prognosis than do Bochdalek hernias. Common complications that occur pre- and postoperatively are pneumothorax, persistent fetal circulation, overdistension of hypoplastic lungs, and chylothorax. The recent introduction of the use of ECMO for infants with persistent pulmonary hypertension after hernia repair has made a minimal impact on prognosis.

Tracheoesophageal Fistula

A defect in the separation of the trachea from the esophagus results in a persistent channel connecting the trachea and the esophagus. There are five types of tracheoesophageal fistulas (TEFs) which are descriptive of the malformations possible: (1) esophageal atresia with a distal communication between the trachea and the esophagus, the most common presentation (85 percent), (2) isolated esophageal atresia occurs, less common, (3) isolated TEF or H type, (4) esophageal atresia with a proximal TEF, and (5) esophageal atresia with a double TEF.

Tracheoesophageal fistulas occur in one out of every 4500 births. One-third of the affected infants weigh less than 2500 g. The incidence of associated anomalies with TEF ranges from 40 to 55 percent. The smaller the infant with TEF, the greater the number of other associated anomalies. Congenital heart malformation, vertebral anomalies, imperforate anus, and radial aplasia are common associated anomalies.

The inability to pass a catheter more than 20 cm through the gastrointestinal tract is the hallmark of esophageal atresia. An x-ray may show the air-filled proximal pouch, and if the catheter is left in place, it may coil in the proximal esophagus. Recurrent pneumonias occur in infants with an H-type fistula.

It is important to provide respiratory support by assisted ventilation if needed to correct acidosis before any surgical repair can be undertaken. A plastic sump catheter should be left in the pouch and connected to constant, low-pressure suction. The patient should be maintained in the reverse Trendelenburg or semi-Fowler position to prevent further reflux of gastric secretions through the fistula into the trachea. Intravenous fluids and antibiotics are indicated. Other coexistent problems, such as a heart defect, should be evaluated. Primary anastomosis is done in cases of esophageal atresia with a distal tracheoesophageal fistula.

The majority (80 percent) of infants with TEF survive. Operative mortality is low. Complications of surgery are pneumonia, atelectasis, anastomotic leak, anastomotic strictures, and (rarely) recurrent fistulas.

Pulmonary Air Leaks

Pulmonary air leaks are a common occurrence in the neonatal intensive care unit. The air may present as pneumothorax, pulmonary interstitial emphysema, pneumomediastinum, pneumopericardium, or pneumoperitoneum.

CLINICAL FEATURES   Spontaneous pneumothorax can occur in term and postterm infants following intrapartum asphyxia and meconium aspiration. Currently, however, pneumothorax has increased in incidence with the use of continuous positive airway pressure, positive end-expiratory pressure, mechanical ventilation, and cardiopulmonary resuscitation. Uneven ventilation caused by aspirated blood, mucus, meconium, and amniotic fluid debris can also result in an air leak. Atelectasis, poor ventilation, and air trapping are common predisposing factors. Premature, low-birth-weight infants with surfactant deficiency have a high incidence of air leaks (30 percent), as do newborns with meconium aspiration syndrome (10 percent).

The signs and symptoms of an air leak are those of respiratory distress and often present as an acute clinical deterioration. Grunting respirations and intercostal, sternal, and subcostal retractions may be seen. Cyanosis, elevated respiratory rate, and elevated heart rate are common. Auscultation of the chest reveals decreased breath sounds on the affected side of a pneumothorax, distant heart sounds, and a shift of the mediastinum. Transillumination of the chest with a high-intensity lamp may aid in the diagnosis. A chest x-ray is diagnostic. The accuracy can be improved with a cross-table lateral film of the chest taken along with the anteroposterior and lateral views.

TREATMENT   An asymptomatic pneumothorax that is less than 20 percent of the volume of the affected side may be followed clinically with no therapy and with serial radiographic studies every 4 h. Any pneumothorax with severe respiratory distress and clinical deterioration needs emergency treatment. When there are mediastinal shift and cardiovascular collapse, rapid decompression at the fourth intercostal space with a 21-gauge needle attached to a three-way stopcock and a large syringe can be lifesaving.

Thoracostomy

INDICATIONS

1. To decompress tension pneumothorax, which results in decreased venous return, decreased cardiac output, and low blood pressure
2. To relieve respiratory compromise, in which there is decreased ventilation, increased work of breathing, as well as hypoxia and hypercarbia

3. To drain pleural fluid

EQUIPMENT

Sterile towels, 4
4 × 4 Sterile gauze pads, 6
Curved hemostat
Scalpel
Scalpel blade, no 15
Needle holder
000 silk suture
5-mL syringe
10F chest tube for infant <1500 g
12F chest tube for infant >1500 g
Stopcock
Chest tube drainage system
6 ft connecting tubing
Wall suction gauge
Iodine solution
Lidocaine, 1%

PROCEDURE

1. Restrain the patient in the supine position and extend the arm to 90° on the affected side. Monitor heart rate, respiratory rate, and oxygen saturation if possible.
2. Mark the site for placement of the tube. Placement of the tube is at the second or third intercostal space on the midclavicular line. Posterior placement of the chest tube is at the fifth or sixth intercostal space on the anterior axillary line.
3. Clean the area with iodine solution. Infiltrate the site of insertion with lidocaine, and then infiltrate the intercostal muscles and parietal pleura. Incise the skin over the rib, 1 to 1.5 cm.
4. Take the curved hemostat, and, with the tip in the incision, enter the chest cavity just above the rib. Avoid the intercostal nerve, artery, and vein, which run on the lower edge of the rib.
5. Spread the hemostat open and slide the chest tube between the blades of the hemostat to the point where the side holes on the tube are within the pleural cavity. Connect the tube to a water-sealed vacuum system and apply 5 to 10 cm of negative pressure.
6. Increase the pressure to reduce the pneumothorax, if necessary.
7. Close the skin wound and secure the chest tube with silk suture. Verify the position of the chest tube with a chest x-ray. The lung should reexpand promptly following evacuation of the air in the pleural space.

Gastroschisis and Omphalocele

An omphalocele is a defect in the umbilical ring that allows the intestines to protrude out of the abdominal cavity in a sac. A gastroschisis is a defect in the abdominal wall that allows the antenatal evisceration of abdominal structures without a sac being present. There is some controversy as to the exact embryology of the two conditions.

Omphaloceles are found in one out of 6000 to 10,000 births, while gastroschisis occurs twice as frequently in the newborn population. Omphaloceles have a higher (37 percent) incidence of associated anomalies, including chromosomal abnormalities. Three specific syndromes are associated with omphalocele: the upper midline pentalogy of Cantrell, Haller, and Ravitch (sternal, ventral, diaphragmatic, pericardial, and cardiac defects); the lower midline syndrome (vesicointestinal fissure); and the Beckwith-Wiedemann syndrome (macroglossia, visceromegaly, and hypoglycemia).

The emergency management of the two conditions is not different, especially when the sac in an omphalocele is ruptured. The eviscerated bowel should be wrapped in saline-soaked gauze and placed in a plastic bag to protect it from hypothermia and evaporative losses. A nasogastric tube should be inserted to decompress the intestines. Rapid infusion of 20 mL/kg of 5% Ringer's lactate may be necessary to restore vital signs, after which the infusion should be adjusted to maintain a urine output of at least 2 (mL/kg)/h. Intravenous antibiotics should be administered.

Primary fascial closure is the treatment of choice and is often accomplished within hours after birth. When the defect is large, a Silastic silo may be used, but survival nonetheless correlates with rapid closure and removal of the prosthesis.

Complications include gastroesophageal reflux, malabsorption, diarrhea, dehydration, and failure to thrive. The mortality of omphalocele is 25 to 30 percent, largely as a result of congenital heart disease and sepsis, while death in patients with gastroschisis is associated with intestinal atresia.

Necrotizing Enterocolitis

Necrotizing enterocolitis is a disease entity that affects the asphyxiated or stressed premature infant of less than 2000-g weight. Full-term newborns with polycythemia or congenital heart disease and those who have had umbilical arterial or venous catheters in situ have been reported to also be at risk for necrotizing enterocolitis.

The exact cause of necrotizing enterocolitis remains unknown, and it is likely that there are multiple factors that ultimately lead to stasis, ischemia, and infection of the bowel wall. The risk factors include hypertonic feeding solutions producing damage to mucosal epithelium of the intestine, patent ductus arteriosus and episodes of apnea diverting blood flow away from the gastrointestinal tract, ischemia following exchange transfusions, and infections with *Escherichia coli, Klebsiella pseudomonas, Clostridium* species, coronavirus, rotavirus, and other enteroviruses.

The signs and symptoms, seen in decreasing frequency, are abdominal distention, gastric distention, retention of gastric feeds, apnea, gastrointestinal bleeding, and lethargy. Other signs are abdominal tenderness, redness of abdominal wall, and the presence of reducing substances in the stool.

A supine anteroposterior and cross-table lateral and upright view will aid in the radiographic diagnosis. Nonspecific findings are distention, air-fluid levels, and separation of intestinal loops, suggesting mural edema. Pneumatosis intestinalis is the radiographic hallmark, and its presence indicates gas in the bowel wall. Portal venous gas is an ominous sign, and pneumoperitoneum indicates perforation of the bowel.

The medical management consists of bowel rest, with the infant receiving nothing by mouth, and gastric decompression with a nasogastric tube. Cultures of blood, urine, and cerebrospinal fluid should be obtained. Ampicillin and cefotaxime 100 mg/kg q 8 to 12 h should be administered. The blood pressure and hydration status should be maintained with liberal use of crystalloids and Plasmanate. Fluid intake may have to be increased to 200 (mL/kg)/24 h and inotropic agents used if needed. Thrombocytopenia, neutropenia, and disseminated intravascular coagulopathy are often seen in neonates who are deteriorating, and platelet transfusions should be administered if there is evidence of systemic or gastrointestinal bleeding. Respiratory support may be required, and any acidosis should be corrected. Patients with early necrotizing enterocolitis should have close clinical observations and serial x-rays to look for signs of gangrene or intestinal perforation. The medical treatment includes bowel rest for 2 weeks and nutritional support with parenteral alimentation. The complications of necrotizing enterocolitis are bowel stricture, fistula, abscess, malabsorption, and failure to thrive.

Pneumoperitoneum related to signs of necrotizing enterocolitis is an absolute indication for surgical repair. Recent data indicate that paracentesis indicative of intestinal gangrene prior to intestinal perforation may be an indication for surgery. Persistent acidosis, oliguria, abdominal wall erythema, and portal vein air are associated with advanced disease. The surgical repair consists of removal of the segment of involved bowel and an enterostomy. Reanastomosis is usually performed after 4 to 6 weeks of bowel rest.

Rectal Bleeding

The conditions most often associated with rectal blood or blood in the diaper are polyps (24 to 25 percent), swallowed maternal blood (12 percent), anal fissures (1 to 36 percent), intussusception (7 to 26 percent), Meckel diverticulum (6 percent), and unexplained causes (31 to 48 percent). In unstable patients, management requires volume replacement followed by evaluation, identification, and control of the bleeding. Swallowed maternal blood from the delivery or from nursing on a nipple with a fissure appears in the second or third day of life. The Apt test can identify blood that is maternal in origin. Anal fissures are readily diagnosed as hairline breaks in the epithelium of the anus. In both swallowed blood and anal fissures, small amounts of blood are passed. Diaper blood stains are rarely larger than the size of a 50-cent piece. Patients present with no other signs and are stable and well hydrated. Meckel diverticulum, colonic polyps, and rectal varices are rare in newborns. The history is that of painless, fresh bleeding but no loose and no hard stools. Meckel diverticulum is seen in infants less than 1 year old, while polyps and varices are seen in infants older than 1 year. Intussusception presents with intermittent cramping, abdominal pain, and vomiting. Blood in the stools ("currant-jelly stools") is a late sign. Radiographic studies with contrast confirm the diagnosis.

Sepsis

Sepsis occurs at a rate of about one case per 1000 live births, and one-third of septic newborn babies develop meningitis. Factors associated with perinatal infection are either maternal or perinatal. Premature rupture of membranes, prolonged rupture of membranes, and maternal infection presenting as chorioamnionitis or urinary tract infection increase the likelihood of newborn disease. Low birth weight is the single most important risk factor for the infant. Group B b-hemolytic *Streptococcus* most frequently causes newborn sepsis and meningitis. *E. coli* is second in prevalence, and *Lysteria monocytogenes* and *Haemophilus influenzae* are other pathogens.

Infants often present with subtle and nonspecific findings. Ninety percent of sepsis infants have respiratory distress in the form of apnea, rapid respirations, grunting, nasal flaring, and cyanosis. Temperature instability, decreased activity, metabolic acidosis, low blood pressure, bruising, abdominal distention, ileus, diarrhea, lethargy, and seizures alone or in combination are manifestations of newborn sepsis.

Blood and cerebrospinal fluid samples should be cultured and evaluated for total and differential white blood cell counts, serum glucose level, and cerebrospinal fluid protein. Urinalysis has not been helpful in the management of neonatal sepsis. All infants suspected of being septic should be admitted to the hospital. Ampicillin and cefotaxime concomitantly and each at a dose of 50 to 100 mg/kg q 8 to 12 h will provide the broadest coverage until the organism and antibiotic susceptibility have been determined.

Apnea

Apnea is the absence of respirations for a period of 20 s or if it is associated with a decrease in heart rate of 80 beats per minute and/or accompanied by cyanosis or pallor. Apnea is categorized as *central apnea* when it is of CNS origin. There are no respiratory efforts and no gas flow in central apnea. In *obstructive apnea,* there is impaired gas flow in the presence of respiratory effort. In *mixed apnea,* there are components of both of the above. *Periodic breathing* is apnea of a few seconds' duration in a 20-s span of otherwise normal breathing. In term infants, apnea is never physiologic and is usually secondary to a serious disorder.

PATHOPHYSIOLOGY   Apnea and periodic breathing are thought to arise from an immature respiratory center. There is an abnormal biphasic response to hypoxia with a period of tachypnea of several seconds followed by apnea. In premature babies, there is a shift in the carbon dioxide curve so that higher levels of CO_2 are required for respiration. Airway muscle weakness, as well as skeletal muscle weakness, probably contribute to the problem. Finally, the preterm infant may have problems during the sleep-waking states in much the same way as shifts from one sleep state to another are accompanied by respiratory instability in adults.

CLINICAL FEATURES   Apnea may occur during any time in the neonatal period. It is always abnormal in the first day of life. After the age of 3 days in a preterm neonate, if it is not associated with any pathologic condition, it may be called benign apnea of prematurity. Apnea is always abnormal in a term newborn. Siblings of children who have died of sudden infant death syndrome have periods of apnea. The pathologic conditions associated with apnea are as follows:

1. Central nervous system: asphyxia, cerebral infarction, hydrocephalus, intracranial hemorrhage, meningitis, and seizures
2. Cardiovascular: congestive heart failure, and patent ductus arteriosus
3. Respiratory: chronic lung disease, hypoxia, pneumonia, and obstruction
4. Digestive system: necrotizing enterocolitis, overfeeding, and vagal response to a nasogastric tube
5. Other causes: anemia, polycythemia, sepsis, temperature instability, hyponatremia, hyperkalemia, hypocalcemia, hypermagnesemia, and high serum levels of phenobarbital, diazepam, opiates, and chloral hydrate

A complete blood count, electrolytes, calcium, glucose, blood gases, drug screen, chest x-ray, electrocardiogram, lumbar puncture, EEG, and an abdominal flat-plate film may be indicated on admission. Further workup may be necessary.

TREATMENT   All infants who have benign apnea of prematurity respond to tactile stimulation. When apnea is recurrent and sustained, specific treatment is indicated. The infant who presents in the emergency department should be admitted for evaluation.

Theophylline, 5 to 6 mg/kg should be administered as an oral or intravenous loading dose, followed by 2 mg/kg q 2 h as maintenance. An alternative drug is oral or intravenous caffeine citrate, 20 to 40 mg/kg as loading dose, with 2.5 to 5 mg/kg as maintenance dose.

Continuous positive airway pressure at 2 to 4 cmH$_2$O may be applied if the above drugs do not resolve the problem.

Mechanical ventilation with endotracheal intubation should be initiated if there is prolonged apnea or repeated episodes are not responsive to the above medications.

Cyanotic Newborns

Cyanosis in neonates may be central or peripheral. Central cyanosis is defined as cyanosis of the tongue, mucous membranes, and peripheral skin and indicates the presence of 5 g or more of reduced hemoglobin. Peripheral cyanosis is defined as blue discoloration confined to the skin of the extremities; the arterial saturation is greater than 94 percent. Peripheral cyanosis is common in neonates and may persist for 2 to 3 days. It is usually due to vasomotor instability secondary to a cold environment.

Normal newborn infants have a P_{O_2} above 50 mmHg by 5 to 10 min of age; hence, it is pathologic for central cyanosis to persist beyond 20 min after birth. Diagnostic considerations in central cyanosis include right-to-left shunts, pulmonary disorders, CNS disorders, polycythemia, or shock or sepsis.

Congenital heart disease presenting with cyanosis secondary to intracardiac right-to-left shunt includes transposition of the great vessels, tricuspid atresia, truncus arteriosus, tetralogy of Fallot and total anomalous pulmonary venous return with obstruction, pulmonary atresia, and preductal coarctation.

These lung disorders associated with cyanosis include hyaline membrane disease, pneumonia, meconium aspiration syndrome, and persistent fetal circulation due to pneumonia or asphyxia. Mechanical interference with lung function by air leaks (pneumothorax), diaphragmatic hernia, lobar emphysema, or mucous plugs also causes cyanosis.

Intracerebral hemorrhage, when severe, may be associated with shock and cyanosis. The increased viscosity and stagnation of blood in polycythemia may produce cyanosis. Shock and sepsis result in alveolar hypoventilation, causing central cyanosis.

DIAGNOSTIC APPROACH TO CENTRAL CYANOSIS   Neonates with cyanosis secondary to cyanotic heart disease rarely have respiratory symptoms other than tachypnea. A murmur may be present. Neonates with lung disease producing cyanosis have respiratory distress, grunting, tachypnea, and sternal and intercostal retractions. Cyanotic infants with CNS disturbances or sepsis have apnea, bradycardia, lethargy, and seizures. Neonates with methemoglobinemia have minimal distress despite their cyanotic appearance.

The "hyperoxia test" (the Pa_{O_2} in response to breathing 100% oxygen) may be of use in distinguishing heart disease from other causes of cyanosis. Neonates with

cyanotic heart disease do not demonstrate any increase in Pa_{O_2} over 20 mmHg because of the right-to-left shunting of the circulation. Most neonates with lung disease, however, demonstrate an increase in Pa_{O_2} after breathing 100% oxygen for 20 min. The neonate with persistent fetal circulation, CNS disorders, polycythemia, sepsis, and shock also demonstrates an increase in Pa_{O_2}. There is no response elicited in the neonate with methemoglobinemia. When a blood specimen is exposed to air, it turns pink in all the conditions described above except in methemoglobinemia, where the blood remains chocolate colored.

The chest radiograph may demonstrate pulmonary oligemia with normal heart size in tetralogy of Fallot and pulmonary or tricuspid atresia, while pulmonary vascularity is increased in transposition of great vessels, truncus arteriosus, anomalous pulmonary venous return, and hypoplastic left heart. Neonates with lung disease have radiographs that are characteristic of the underlying disease. The electrocardiogram and echocardiogram are useful in diagnosing cyanotic heart disease. Right ventricular hypertrophy may be seen in lung disease with associated pulmonary hypertension.

TREATMENT   Most of the cyanotic heart diseases are amenable to palliative or corrective surgery. Infants with severe or complete right ventricular outflow obstruction are dependent on the postnatal patency of the ductus arteriosus for maintenance of adequate pulmonary blood flow and systemic oxygenation. Short-term infusions of prostaglandin E_1 0.05 to 0.1 (μg/kg)/min in these infants have allowed stabilization prior to surgery.

Congestive Cardiac Failure

Heart failure in newborn infants is caused not only by structural heart disease but also by other systemic disorders. Causes of congestive heart failure include (1) structural heart disease (most commonly transposition of the great vessels and hypoplastic left heart syndromes), (2) heart disease without structural abnormalities (myocarditis, cardiac dysrhythmias, glycogen storage disease, and endocardial fibroelastosis), (3) respiratory disease with patent ductus arteriosus with left-to-right shunt, (4) anemia (hemoglobin < 3.5 g/dL), (5) polycythemia, (6) cerebral or other arteriovenous malformation, and (7) sepsis.

The most frequent symptoms are feeding difficulties, tachypnea, increased sweating, tachycardia, rales and rhonchi, liver enlargement, and cardiomegaly. Less common signs and symptoms are ascites, gallop rhythm, pulsus alternans, and increase in central venous pressure. Peripheral edema is exceedingly rare. A clear distinction between right heart failure (characterized by liver enlargement, tachycardia, and dependent edema) and left heart failure (cardiomegaly, rales, tachypnea, and tachycardia) is not as obvious in the neonate as in the older child or adult.

TREATMENT   It is essential to monitor the heart and respiratory rates and blood pressure closely. Blood gas levels should be determined frequently to identify and treat hypoxemia or acidosis. Fluid intake should be restricted to 100 (mL/kg)/day and adjusted according to the weight, liver size, and urine output. Electrolyte levels should be monitored closely. Anemia should be corrected with packed red blood cell transfusions. The neonate should be on a 10 to 30° incline with the head elevated inside the incubator.

Infants with heart failure should receive digoxin unless the heart rate is below 100 beats per minute. The digitalizing oral dose of digoxin is 0.03 mg/kg for term neonates. For digitalization, half the calculated digitalizing dose should be given initially, a fourth in 8 h, and another fourth in 8 h, with maintenance started 12 h after the last digitalizing dose. The maintenance dose is one-fourth of the total digitalizing dose in two divided doses. Serum K^+ levels should be checked and monitored.

Furosemide (Lasix) is the drug of choice for a rapid response and should be used intravenously (1 to 3 mg/kg). Maintenance therapy with hydrochlorothiazide (Diuril) and spironolactone (Aldactone) to help conserve potassium may be necessary.

Neonates with severe heart failure from left-to-right shunts with cardiogenic shock and bradycardia may require b-adrenergic drugs for inotropic action. Isoproterenol (Isuprel) may be infused at 0.1 (μg/kg)/min, increased to 0.4 (μg/kg)/min until the heart rate is 140 beats per min. Dopamine is useful in hypotensive shock and should be infused at 5 to 15 (μg/kg)/min. Both medications should be discontinued slowly while heart rate and blood pressure are monitored.

10 PEDIATRIC CARDIOPULMONARY RESUSCITATION

William E. Hauda II

This chapter reviews cardiopulmonary resuscitation (CPR) in children and notes pertinent differences compared with adults. Perhaps the greatest difference between adult and pediatric arrest is etiology. The most common cause of primary cardiac arrest in adults is coronary artery disease. Children usually develop cardiac arrest secondary to respiratory arrest and shock syndromes. Children have very poor survival rates from cardiac arrest, because it is often associated with prolonged hypoxia or shock.[1,2] Following a cardiac arrest, the survival rate without devastating neurologic sequelae in children is only 2 percent. [3] The best chance for a good outcome is to recognize impending respiratory failure or shock and intervene to prevent the development of cardiopulmonary arrest.

Age-related differences must still be considered with the pediatric population. [4] An appropriate drug dose for a 6-month-old may be excessive for a 1-month-old and yet inadequate for a 5-year-old. Other aspects of resuscitation, such as endotracheal tube size, tidal volumes, cardiac compression rates, and respiratory rates, also vary with a child's age. All emergency medicine practitioners who treat children must be familiar with appropriate size of equipment and rapidly determine the correct dosage of medication for any given child.

The priorities of resuscitation are airway, oxygenation, ventilation, and shock management. These factors are easily compromised in children, but, with prompt intervention, cardiopulmonary arrest may be prevented. [4] International consensus guidelines for basic life support procedures [5] are listed in Table 10-1.

TABLE 10-1   Guidelines for Pediatric Basic Life Support

AIRWAY

Anatomy

A child's airway is much smaller than an adult's, and the size varies depending on age. The anatomic and functional differences are more pronounced in infants and young children. The airway is higher and more anterior in a child's neck than in the adult's. The tongue and epiglottis are relatively larger and, thus, more likely to be an obstructing element in a child's airway. Infants younger than 6 months of age are primarily nasal breathers. Thus, keeping the nasal passages clear is vital in a young, spontaneously breathing infant. When a child is supine, the prominent occiput causes flexion of the neck on the chest, occluding the airway. This can be corrected by mild extension of the neck to the sniffing position. Overextension or hyperextension, acceptable for adults, causes obstruction and may kink the trachea, since the cartilaginous support is poor.

Positioning

The sniffing position can be maintained by placing a towel or other object beneath the shoulders. Despite good head position, a child's hypotonic mandibular tissues may still allow the relatively large tongue to occlude the airway posteriorly. This can be relieved by a chin lift or jaw thrust that elevates the mandible anteriorly and separates the tongue from the posterior pharyngeal wall. The jaw-thrust technique is preferred in a child with a possible cervical spine injury, because it minimizes the movement of the neck while allowing maintenance of a neutral position of the cervical spine. If these maneuvers are unsuccessful, an oral airway or endotracheal tube should be considered.

NASOPHARYNGEAL AIRWAY   Nasopharyngeal airways tend to be less useful in children because of the small nasal passages and the presence of hypertrophic adenoid tissue in the posterior nasopharynx, which is easily traumatized when inserting a nasopharyngeal airway.

ORAL AIRWAY   Oral airways, which should be used only in unconscious children, are most useful in patients who require a continuous jaw thrust or chin lift to maintain airway patency. Oral airways are inserted with a tongue depressor to push the tongue into the mandible so that the airway can be inserted under direct

vision.

Intubation

Endotracheal intubation of infants and children is felt by many to be easier than the same procedure in adults. There are, however, some differences related to a child's anatomy and proper sizing of equipment. Pediatric airway management is discussed in detail in Chap. 11. A brief overview is provided here for perspective.

POSITIONING   Hyperextension of the neck must be avoided by placing the child in the sniffing position prior to intubation. Also, the stretcher should be raised so that the child's head is at least at the level of the intubator's waist. All equipment should be located within easy reach of the team, including the bag-valve mask, oxygen source, monitoring equipment, and, perhaps most importantly, the suction device.

LARYNGOSCOPE BLADES   For two reasons, the curved (MacIntosh) blade is rarely used in children who are younger than age 4. The relatively large and flaccid epiglottis is not effectively displaced by pulling on it indirectly from the vallecular space. Second, an exact-sized blade must be used to fit the curvature of the tongue. For these reasons, a straight (Miller) blade is preferred. The straight blade is inserted in the midline with the tip underneath the epiglottis such that the epiglottis is directly lifted up to allow tracheal visualization.

ENDOTRACHEAL TUBE   Tracheal tube sizes vary with a patient's age. An often-quoted rule is that the correct internal diameter tube size is approximately the same size as the end of the patient's little finger. However, this tenet has been shown to not hold true. [6,7] The age-based formula (age + 16)/4 is a good predictor of correct endotracheal tube size for children. Uncuffed tubes are used for children up to 7 or 8 years old (tube size, 2.5 to 5.5 mm). The subglottic trachea (unlike in adults) is the narrowest spot of the tracheal apparatus and forms an adequate seal around the endotracheal tube in this age group. After this age, the vocal cords become the narrowest part to the airway and a cuff is needed to provide an adequate seal for positive pressure ventilation. One can almost always intubate with a laryngoscope blade that is too large and with a tube that is too small, but not vice versa.

SECURING THE AIRWAY   Once a child has been intubated, one person should be assigned to hold the endotracheal tube in place until it is securely fastened. Confirmation of endotracheal intubation is similar to that in adults: adequate chest rise, symmetric breath sounds, capnographic or capnometric readings, [8] improved oxygenation, and clinical improvement. [4] Because a young child has a small chest, listening to breath sounds in each axilla as well as over the stomach will minimize the chance of hearing sounds transmitted from the other lung. [4] The tube should be taped to the upper lip and jaw, ideally from both sides of the face. Especially in small infants, small movements can easily displace the tube from the trachea into the esophagus. Tape or ties should not be wrapped around the head of a young child, because these can slide off the occiput and easily allow displacement of the tube. Mechanical ventilation is discussed in *Breathing,* which follows.

Foreign Body Management

Controversy exists as to the safest and most effective emergency maneuvers to use with a choking child. The American Heart Association specifically discourages two common maneuvers used with adult patients: (1) the Heimlich maneuver for patients younger than age 1, because of the potential for injury to abdominal organs, and (2) blind finger sweeps, because of the possibility of pushing the foreign body further into the airway. [4] Serious differences of opinion exist, but current recommendations rely on the back blow and chest thrust to clear an infant's airway.

CONSCIOUS CHILDREN   A child who is choking but is able to maintain some ventilation or vocalization should be allowed to clear her or his own airway by coughing. Once a child cannot cough, vocalize, or breathe, a sequence of steps must be immediately instituted. Choking infants are treated with an alternating sequence of five back blows and five chest thrusts. With the infant's torso positioned prone and head down along the rescuer's arm, or the older child draped prone and head down across the rescuer's knees, five blows are delivered to the interscapular area. The infant is then repositioned supinely along the rescuer's arm, or the larger infant can be placed on the floor as for external cardiac compression, and five chest thrusts (cardiac compressions) are delivered. These are continued until the child's airway obstruction is relieved or the child becomes unconscious. In older children, the Heimlich maneuver is used, with the rescuer kneeling or standing behind the child. The clenched fist is placed at the level of the umbilicus, and firm upward thrusts are continued until the obstruction is cleared or the child becomes unconscious.

UNCONSCIOUS CHILDREN   In all cases where a child becomes unconscious with the rescuer present, the rescuer should first attempt ventilation because the object may have become dislodged. If an obstruction is still present, then airway clearance maneuvers must be continued. For infants, the same sequence is used, but between each cycle of back blows and chest thrusts (the same technique as for CPR) an attempt at ventilation should be made. Before attempting a ventilation, the airway should be inspected to see whether an object is present. Only remove a visualized object, do not use blind finger sweeps. If the obstruction persists, the sequence is repeated. For children older than age 1, the Heimlich maneuver is performed with the child lying down and the rescuer straddling the child's thighs. Future investigation may well lead to revised recommendations.

The foregoing recommendations are directed primarily at a first responder who has neither access to, nor the skills to use, airway management equipment. For unconscious children in emergency departments, direct laryngoscopy, visualization, and removal of the foreign body with McGill forceps should be attempted rapidly. Until this equipment is ready, however, use the basic life support techniques.

BREATHING

Mouth to Mouth

Whether to employ mouth-to-mouth or mouth-to-mouth-and-nose ventilation depends on the size of the patient. The rate of ventilation is shown in Table 10-1. Ventilations are done slowly to avoid the generation of high airway pressures, which can overcome esophageal resistance and result in gastric distention.

Bag-Valve Mask

The self-inflating bag-valve mask system is most commonly used for ventilation. Ventilation bags used for infants and children should have a minimum volume of 450 mL. There is a common misconception that children are more susceptible to pneumothoraces at high inspiratory pressures. In fact, pediatric lung compliance is very good, and children can tolerate relatively high pressures. Pneumothoraces more commonly result from the administration of excessive tidal volume. The tidal volume necessary to ventilate children is the same as that for adults: 10 to 15 mL/kg. Since it is impractical to calculate the tidal volume in emergency situations, start ventilating with the smallest volume that causes adequate chest rise. Careful monitoring of the rate of ventilation is crucial to avoid excessive hyperventilation, a very common mistake.

Mechanical Ventilation

If an endotracheal tube is placed, then mechanical ventilation should soon be instituted. Determining appropriate initial settings for the mechanical ventilation of children can be difficult. For children weighing less than 10 kg, time-flow or pressure preset ventilators should be used. For time-flow ventilators, inspiratory and expiratory times are needed. Typical inspiratory times are $\frac{1}{2}$ to 1 s, depending on ventilation frequency. For pressure ventilators, inflating pressures are determined by using pressures necessary to inflate the lungs and cause the chest to rise. Pressures usually range from 15 to 40 mmHg. Excess pressures can cause barotrauma. For older children, volume ventilators can be used, starting with a tidal volume of 10 mL/kg, as for adults. If the lungs have normal compliance and the child does not require hyperventilation, then the respiratory rate should be started at $\frac{1}{2}$ the normal rate for age (20 breaths/min for infants, 15 breaths/min for young children, and 10 breaths/min for older children and adolescents). Children should be adequately sedated and paralyzed during mechanical ventilation until definitive care is started in a pediatric intensive care unit.

CIRCULATION

External Cardiac Compression

The brachial pulse is recommended for monitoring purposes for infants younger than age 1. Above this age, the femoral pulse is most easily accessible, but most

guidelines recommend assessment of the carotid pulse by laypersons. Absence of pulse, or poor perfusion with a heart rate of 60 bpm or less, mandates external cardiac compression. Most patients should be placed on a hard surface. With smaller infants, the wraparound two-thumb technique can be used.

Current standards advocate compressions over the lower sternum as opposed to midsternum.[5] Whether to use two fingers, two thumbs, three fingers, or the heel of the hand depends on the size of the child. Whichever method comfortably produces a compression depth of approximately one-third the anteroposterior diameter should be used. The rate of compressions is at least 100/min in infants and older children. The ratio of ventilations to compressions is 1:5 for both one-person CPR and two-person CPR. A pause of 1 to 1.5 s between ventilations should be allowed for adequate exhalation. To assess the adequacy of the compression depth and rate, the femoral or carotid artery should be palpated during compressions.

VASCULAR ACCESS

Difficulty in obtaining rapid intravenous (IV) access is certainly one of the major differences between adult and pediatric resuscitation (see Chap. 17, "Vascular Access"). Two important facts should be kept in mind. First, a significant portion of children respond to airway management alone, since most cardiac arrests in children are secondary to hypoxic respiratory arrest. Time spent securing vascular access at the expense of adequate airway management is a common mistake in dealing with children. Second, once a patient has been intubated, the tracheal route may be used to administer drugs such as lidocaine, epinephrine, atropine, and naloxone (mnemonic: LEAN). The dose of endotracheal epinephrine for symptomatic bradycardia or pulseless cardiac arrest is 0.1 mg/kg, 1:1000 concentration q 3 to 5 min. Although the ideal doses for other drugs have never been studied in children, current recommendations support the use of two to three times the IV dose. [4]

Although central access would be ideal for administration of drugs during CPR, many emergency medicine practitioners are not highly skilled in placing central lines in children. Therefore, the most frequently used sites are peripheral: scalp, arm, hand, or antecubital veins; the external jugular vein; femoral vein; or distal saphenous vein via cutdown. Intraosseous infusion is a quick, safe route for resuscitation drugs as well as fluid administration. This is discussed in Chap. 17, "Vascular Access." The general order of attempts during a resuscitation should be antecubital, hand, or foot and then intraosseous.

FLUIDS

In the face of hypotension due to volume depletion, isotonic fluid boluses of 20 mL/kg should be given as rapidly as possible and repeated, depending on response. [4] A syringe attached to a three-way stopcock and extension tubing can be used to deliver aliquots of fluid rapidly, until the entire bolus is administered. Do not depend on gravity or pressure bags. The bolus should be delivered in a maximum of 20 min, and then the child's condition should be reassessed. If volume depletion has been corrected (at most, three to four boluses) and hypotension persists, a pressor agent should be strongly considered, preferably with the aid of a central venous pressure catheter. In normotensive patients or when the IV line is being used for drug administration only, it should be maintained at the minimum rate that will keep the vein open (KVO). Fine fluid and electrolyte calculations and adjustments can be made after the emergency treatment has been completed. Overhydration, even when IV lines are set at KVO, is common when adult equipment is used in pediatric resuscitations. To enable easy monitoring of the total volume given, preventing accidental overhydration, a pediatric microdrip should always be used when resuscitating children.

PHARMACOLOGIC AGENTS

The indications for the use of specific drugs are essentially the same for children as for adults. Particular to pediatrics, however, is the problem of drug dosage. Proper dosage in children requires knowledge of the patient's weight (Table 10-2), knowledge of the dose (usually given in milligrams per kilogram), and error-free calculation and delivery. Problems may arise in remembering the correct dose, performing calculations in the crisis situation (a common error involves the misplacement of a decimal point and results in 10 times or one-tenth the correct dosage), and delivery of the correct dosage (because of an error in drawing up the correctly calculated amount). Use of a chart with precalculated drug doses can help reduce dosage errors (Table 10-3). However, estimating a child's weight accurately so that the proper dosage can be determined from the table is not easy, especially in a crisis situation. Choosing the proper sized equipment for pediatric patients is similarly difficult. Valuable time can be lost in weight estimation, dosage calculations, and equipment selection.

Age	Weight, kg	
Term infant	3.5	Birth weight (BW)
6 Months	7	2 × BW
1 Year	10	3 × BW
4 Years	16	¼ Adult weight of 70 kg
10 Years	35	½ Adult weight

TABLE 10-2   Body Weight Estimation Guidelines

Drug	Concentration	Dose
Epinephrine		
First dose	1:10,000 (0.1 mg/mL)	0.01–0.02 mg/kg
High dose	1:1000 (1 mg/mL)	0.1–0.2 mg/kg
Atropine	1:10,000 (0.1 mg/mL)	0.02 mg/kg*
Sodium bicarbonate	1 meq/mL	1.0 meq/kg

*Minimum dose is 0.1 mg regardless of weight.

TABLE 10-3   Essential Drugs

Recently, systems based on a direct measurement of a patient's length have been developed for estimating dosages and selecting equipment in pediatric emergencies (see Table 10-3).[9] In children, length has a direct correlation with weight. It has also been shown to be one of the most accurate predictors of correct equipment sizes for pediatric patients, especially endotracheal tube sizes. The use of a length-based system is currently included in the American Heart Association's Pediatric Advanced Life Support Course (PALS). These systems use a tape to assist making appropriate selections. Most tapes are two sided and display emergency resuscitation drug dosage and equipment selection based on length (see Fig. 10-1, Fig. 10-2 and Fig. 10-3). Fluid volumes for resuscitation as well as appropriate basic life support techniques are often also displayed. To make optimal use of these systems, emergency personnel must be able to find the proper equipment rapidly. Equipment can be stored in shelves or drawers labeled by age and weight, or a system of color codes can be used in which color-coded shelves, carts, or equipment organizers correspond to specific length categories.

FIG. 10-1. The Broselow Resuscitation Tape.

FIG. 10-2. Equipment side of the Broselow Resuscitation Tape. One of seven color equipment zones.

FIG. 10-3. Drug side of the Broselow Resuscitation Tape. One of 25 precalculated weight zones for resuscitation drugs.

The pharmacology of resuscitation drugs has been well described in other chapters (see Chap. 25), but a few peculiarities pertain to pediatric resuscitation drug use.

Epinephrine

Epinephrine is the one drug proven beneficial in cases of cardiac arrest. It is specifically indicated for hypoxia- or ischemia-induced slow rates that fail to respond to adequate oxygenation and ventilation and to pulseless arrest situations (i.e., asystole, pulseless electrical activity, and ventricular fibrillation). If the initial dose of epinephrine is not effective, 10 to 20 times that dose should be given subsequently. However, the use of high-dose epinephrine (0.1 mg/kg of the 1:1000 concentration) for resuscitation in infants and children has not been associated with increased survival rate in any controlled prospective studies. PALS has recommended,[4] and at the time of this writing continues to recommend, that high-dose epinephrine be used if there is no response to the initial standard dose. Studies addressing this issue that are currently concluding are not expected to show an increase in neurologically intact survival. Adverse effects associated with the use of high-dose epinephrine in the clinical setting include intracranial hypertension, myocardial hemorrhage, and myocardial necrosis. [5] Epinephrine, rather than dopamine, is the vasopressor infusion of choice in children, because dopamine requires release of endogenous norepinephrine. In children with cardiac arrest, norepinephrine stores may be low.

Atropine

Primary cardiac causes of slow rates are rare with the pediatric population and may also be treated with atropine. The recommended dose of atropine is 0.02 mg/kg IV. The minimum dose is 0.1 mg, with a maximum single dose of 0.5 mg for children and 1.0 mg for adolescents. The dose may be repeated once, with a maximum total dose of 1.0 mg for children and 2.0 mg for adolescents. There is no particular proscription against further doses, but the maximum dose is considered to be fully vagolytic. If no response to atropine is seen, then dosing beyond the vagolytic amount is unlikely to be effective. If an effect is seen, but not maintained, further doses may be tried.

Sodium Bicarbonate

Sodium bicarbonate is no longer a first-line drug, because it worsens acidosis when administered in the presence of inadequate ventilation and perfusion. It is administered only after epinephrine administration has not improved a clinical situation. An initial dose of 1 meq/kg IV is given only after the airway has been secured, the patient hyperventilated, and CPR initiated. An exception may be a situation where hyperkalemia is a factor, and where metabolic acidosis is severe. Resuscitation drugs are ineffective in the face of severe acidosis and severe alkalosis. In neonates or premature infants, sodium bicarbonate should be diluted 1:1 with sterile water, not saline. Indications for bicarbonate use are the same as for adults.

Calcium

Because of lack of proven efficacy and because of possible deleterious effects, calcium administration is no longer routinely recommended during resuscitation. Calcium should be used for documented hyperkalemia, hypocalcemia, and calcium-channel blocker overdose.

The Rule of 6

Often there is great confusion when attempting to calculate the dose of a medication to be delivered by constant infusion. The *rule of 6* can be used to avoid mistakes (Table 10-4). The Broselow tape (Armstrong Medical Industries) can be used to assist.

TABLE 10-4   Calculation for Dosage of Medications Delivered by Constant Infusion Using the Rule of 6

DYSRHYTHMIAS

Dysrhythmia management plays only a small role in the resuscitation of children. Since rhythm disturbances are usually secondary to hypoxia and not primary cardiac events, careful attention must be given to the correction of hypoxia, acidosis, and fluid balance. Ventilation and oxygenation must be accomplished first. Pulse oximetry, or arterial blood-gas analysis, should be performed to assess oxygen and blood-gas status. An IV of 0.9% NaCl or lactated Ringer solution should be established and the child placed on a cardiac monitor.

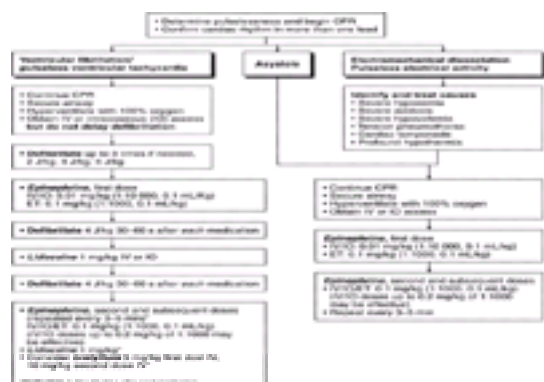
A patient with an abnormal cardiac rhythm or rate, coupled with evidence of poor end-organ perfusion (cyanosis, mottled skin, lethargy, etc.), has an unstable cardiac rhythm and requires immediate intervention. The parameters of clinical assessment and expression of instability vary with a child's age. In neonates, blood pressure measurement is difficult, and a heart rate of 80 bpm or less, coupled with evidence of poor end-organ perfusion, requires immediate intervention. In infants and children, variations in heart rate may be well tolerated clinically, and a blood pressure of 70 mmHg or less, coupled with evidence of poor end-organ perfusion, is used to define instability. Figure 10-4 and Figure 10-5 summarize electrical and drug therapy of unstable cardiac rhythms in children.


FIG. 10-4. Asystole and pulseless arrest decision tree. IV, intravenous/IO, intraosseous; ET, endotracheal.
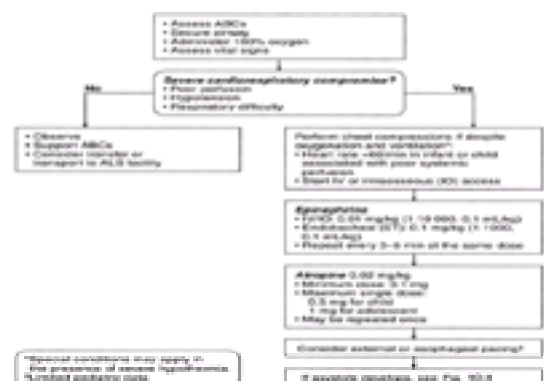

FIG. 10-5. Bradycardia decision tree. IV, intravenous; IO, intraosseous; ET, endotracheal.

The most common rhythms seen in pediatric arrest are the bradycardias, which lead to asystole if untreated. Treatment consists of maximizing oxygenation and ventilation. Chest compression should be started in children with a heart rate of less than 60 bpm and signs of poor perfusion.

Paroxysmal atrial tachycardia (supraventricular tachycardia, or SVT) is most commonly seen in infants and most often presents as a narrow complex tachycardia with rates usually between 250 and 350 bpm. Treatment of unstable patients consists of rapid synchronized cardioversion. Treatment of stable patients varies. Adenosine, vagal maneuvers, or cardioversion are used to treat stable SVT. Adenosine (0.1 mg/kg) is the current recommended drug for SVT in children. This dose can be doubled if the first dose is unsuccessful.

Differentiating a rapid secondary sinus tachycardia from a rapid primary cardiac tachycardia can be difficult. Although heart rates of 150 to 200 bpm in adults are usually cardiac in origin, young children not uncommonly have compensatory sinus tachycardias as fast as 200 to 220 bpm, especially small infants. Children can tolerate rapid primary cardiac heart rates for long periods before congestive heart failure or lethal dysrhythmias develop. Differentiating primary from secondary tachycardia is critical to patient management. However, an ECG may not be very helpful because, at very fast rates, in either sinus tachycardia or SVT, identifiable P waves may not be readily apparent. Historical features pointing to volume loss likely suggest sinus tachycardia. Evidence of congestive heart failure is more likely associated with a pathologic rhythm.

CARDIOVERSION, DEFIBRILLATION, AND PACING

Electric conversion is used on an emergency basis to treat ventricular fibrillation (defibrillation) and symptomatic tachydysrhythmias (cardioversion). Ventricular fibrillation as a cause of cardiac arrest is rare in children and even more rare in infants. [10]

Paddle Size

Paddle size is usually 4.5 cm for infants (who weigh less than 10 kg) and 8 cm for children. The paddle should be in contact with the chest wall over its entire surface area. The larger 8-cm paddles can be used for infants in the anteroposterior position.

Interface

Electrode cream, electrode paste, and saline-soaked gauze pads are all acceptable. Alcohol pads are to be discouraged, because serious burns may be produced.

Care must be taken so that the interface substance from one paddle does not come in contact with the substance from the other paddle. This creates a short circuit, and insufficient energy may be delivered to the heart.

Electrode Position

One paddle is placed on the right of the sternum at the second intercostal space. The other is placed in the left midclavicular line at the level of the xyphoid. The anteroposterior approach can be used as well. [4]

Defibrillation

Initially, 2 J/kg should be used. If that is unsuccessful, the amount should be doubled and performed twice at the higher energy level, if necessary. If the three attempts are unsuccessful, epinephrine should be given at the standard dose. The oxygenation and ventilation of the child should be maximized for 1 to 2 min before repeating a defibrillation attempt at the higher setting.

Cardioversion

Tachydysrhythmias are generally very sensitive to electric conversion. Initial dose is $\frac{1}{2}$ J/kg. The energy level is doubled if the first attempt is unsuccessful. If the device only has a few energy settings available, choose the one that is closest to the desired energy setting. All tachydysrhythmias should be treated with synchronized cardioversion. If synchronization in not possible (i.e., if the device cannot identify the QRS), then use the defibrillator in the unsynchronized mode.

Transcutaneous Pacing

Children with a severe bradycardia or asystole may respond to pacing. Because transvenous pacing requires central venous access with large tubing and proficient skill in placing the pacing electrodes, most emergency practitioners and prehospital providers should only attempt transcutaneous pacing. Adult patches should be used in children who weigh over 15 kg. [11] The negative electrode patch should be placed on the anterior chest at V_3, and the positive electrode patch is placed on the posterior chest between the shoulder blades at the T4 vertebral level. [12] Ventricular capture is determined by the palpation of a pulse or the appearance of an arterial waveform if an arterial pressure catheter is present. Begin with the maximal energy output. [12] If ventricular capture occurs, then decrease the energy setting progressively until the lowest setting is found that allows ventricular capture. The pacing rate should be set at a rate slightly higher than the normal rate for age. Transcutaneous pacing has not been associated with greatly improved survival rates, but it can be life-saving if applied quickly in a child with sudden asystole or bradycardia.

SUMMARY OF MANAGEMENT GUIDELINES

The age-related differences are difficult to remember and cause major problems in pediatric resuscitation. One should not have to memorize numbers such as drug doses, tube sizes, or cardiac compression ratios. The proper organization of equipment, the posting of pediatric CPR data and equipment sheets, and the use of a length-based system (Table 10-5) can eliminate the need to commit many variables to memory and can reduce the possibility of errors. This eliminates much of the general anxiety connected with pediatric resuscitation and leaves clinicians free to apply the principles of resuscitation to the children as presented.

TABLE 10-5   Length-Based Equipment Chart (Length, cm)

TERMINATION OF EFFORTS

Pediatric cardiopulmonary arrest of longer than 20 min or with no response to two doses of epinephrine has been associated with a dismal outcome. [1] Resuscitation should be continued until a core temperature of 30°C is reached if cardiac electrical activity is present in a child with hypothermia.

COPING WITH THE DEATH OF A CHILD

Both family members and the resuscitation team members will mourn the death of a child. Little attention has been focused on this issue for either the family or the emergency department staff. Several *tasks of mourning* have been described that must occur for successful resolution of grieving (Table 10-6). [13] Whether a child dies in the emergency department or after several days of hospitalization does not seem to affect the grieving process. [14] Pathologic grief reactions are often the result of fear that the child will be forgotten. Excessive focus of time, energy, and effort is spent on remembering the child without resolving the grief. Sharing feelings and memories about the child is crucial; persons who do not allow parents to express their feelings may mar the grieving process. [14]

1. Accept the reality of the loss

2. Work through painful grieving

3. Adjust to the life without the child

4. Emotional resolution and return to normal activities

TABLE 10-6   Tasks of Family Mourning a Lost Child

Physician and other health care providers can shape the way families remember the death of a child. Guidelines for communicating with parents are listed in Table 10-7. [14] Parents remember how compassionately the bad news is given, but most families still want the "bottom line" when they are first told of their child's death. They are waiting for it. Saying "I am very sorry, we did everything we could, but Sally died" is compassionate and direct. Most families do not want all the technical details about the resuscitation efforts. After delivering the bad news, have a chaplain or social worker stay with the family to allow the family time to deal initially with the

shocking news. The physician should remain quietly in the room or return after a few minutes (or later, if other duties require) to answer questions. This is also the time to ask whether the family would like to see the child and to prepare them for what they will see. This is also the time to inquire about organ or tissue donation, if a regional transplant consortium does not provide this service already. Although parents do not regret organ donation, donation is not associated with a higher likelihood of successful grieving. [14]

1. Utilize support staff such as chaplains and social workers

2. Early in your delivery of the news, let the family know the child died

3. Use simple, direct, understandable language

4. Speak with compassion and caring

5. Answer questions from any family members honestly

TABLE 10-7   Giving Bad News Effectively

Many hospitals have policies requiring that family wait outside the area where resuscitation efforts are being conducted, but family presence during resuscitation efforts is increasing in popularity. Both positive and negative family responses can occur during resuscitation. [15] Family presence during an attempted resuscitation may enable family members to begin appropriate grieving earlier. No studies have shown that the long-term effects on family grieving are beneficial, however. Some family members may become distressed or exceedingly emotional while care is being given to a loved one. Worries by emergency department staff members about the family's critiques of the resuscitation, or the family's unwillingness to terminate efforts, also contribute to the desire not to have the family present during resuscitation. However, the desire to have family members present during a resuscitation is a holistic approach to patient care with both the family's and the patient's needs addressed simultaneously. In general, the resistance of emergency department staff members to the presence of family members during a resuscitation has been diminishing. Policies are being created to train emergency department staff on how to assist family members and what to expect when families are present during a resuscitation.

11 PEDIATRIC AIRWAY MANAGEMENT

Marcie Rubin
Nicholas Sadovnikoff

As in all resuscitative efforts, the airway in pediatric patients has the highest priority. Skillful management of the pediatric airway requires a thorough familiarity with airway anatomy, an organized approach to the assessment of a compromised airway, and availability of the necessary tools for securing and maintaining a patent airway.

This chapter discusses the differences between adult and pediatric airways as well as causes for abnormal pediatric airways. It reviews the tools and techniques required for establishing and maintaining an airway and ventilation. It also addresses specific pathologic conditions leading to pediatric airway compromise and the appropriate interventions for such situations.

NORMAL PEDIATRIC AIRWAY ANATOMY

The normal airway of a pediatric patient has important anatomic differences from that of the adult. These differences are most apparent in infants and become relatively insignificant by age 8. They include the size of the occiput and the tongue in the infant, the high position of the larynx, the configuration of the larynx, and the position of the vocal cords.

The infant has a large occiput. Positioning of the head to obtain the optimum orientation for laryngoscopy, or the "sniffing position," is accomplished simply by rotating the head so that it rests on the occiput. Elevating the head with padding can lead to excessive flexion of the neck and may contribute to upper airway obstruction and difficulty during intubation. The infant's tongue is also relatively large, and this can impair laryngoscopy as well as contribute to upper airway obstruction. An infant's larynx is higher in the neck, located at the C3 level, than that of an adult, which is found at the C4 to C5 level. The larynx is also funnel-shaped in infants, with the narrowest portion at the subglottic area, rather than at the level of the vocal cords, as in an adult. Hence, in infants and small children, an endotracheal tube that passes easily through the vocal cords may encounter resistance more distally. Finally, infants' vocal cords are slanted anteriorly rather than being perpendicular to the trachea, as in an adult, and this characteristic, too, can result in more difficult visualization and intubation in the pediatric population. [1]

ABNORMAL PEDIATRIC AIRWAYS

Congenital

Numerous airway anomalies may be present at birth or develop over the first several months of life. While they rarely of themselves lead to the need for emergent airway control, their presence will complicate management of other emergencies requiring intubation.

Choanal atresia is the most common congenital anomaly of the nose. It may be unilateral or bilateral. Infants with this condition may not have difficulty breathing at birth if they can breathe orally, but they often present several months after birth when there is a concurrent problem, such as an upper respiratory infection. Maintaining an oral or tracheal airway overcomes the obstruction. Emergency department treatment is placement of oral airway, tube feedings, and admission for surgical repair.

Cystic hygroma is a benign congenital tumor of lymphatic origin. About 60 percent appear within the first year of life, and 80 to 90 percent occur before the second year. Cystic hygroma usually occurs in the neck or tongue but may also be found in the mediastinum. Progressive growth can lead to compromise of the structures of the pharynx and trachea, leading to airway obstruction and impairing or preventing laryngoscopy. The treatment is surgical resection. [2]

There are five types of tracheoesophageal fistulas, the most common defect consisting of a blind upper esophageal pouch and a fistula between the lower esophagus and the trachea. The diagnosis is usually made soon after birth when an infant becomes cyanotic and starts coughing after feeding or when a catheter cannot be passed into the stomach. Although most patients present soon after birth, a few with tracheoesophageal fistula with esophageal atresia present some time after discharge with pneumonia, and cyanosis with feeding. Placement of the endotracheal tube in patients with tracheoesophageal fistula is crucial to avoid gastric insufflation and resultant aspiration. The tube should be above the carina but below the fistula. This is often achieved by intubation of the right mainstem bronchus, then pulling back until breath sounds are heard bilaterally.

The common congenital syndrome of trisomy 21 (Down syndrome) may present significant difficulties in airway management. Characteristic of these patients are a short neck, small mouth, narrow nasopharynx, and large tongue; moreover, approximately 20 percent have asymptomatic dislocation of the atlas on the axis. [3] All of the potential difficulties must be considered prior to initiating intubation. Many congenital syndromes include airway abnormalities (Table 11-1). In controlled settings, management is preceded by careful evaluation and planning. Unfortunately, in the emergency department, this is rarely possible, and thus the approach to airway management must be mastered in all facets by those whose practice, even infrequently, involves pediatrics.

Prominent Airway Abnormality	Syndromes
Mandibular hypoplasia	Hallermann-Streiff-François Pierre-Robin Goldenhaber's Nager's Treacher Collins
Maxillary hypoplasia	Apert's Pfeiffer's Crouzon's
Macroglossia	Trisomy 21 Beckwith-Wiedemann Hurler's
Tracheomalacia	Apert's Crouzon's

Note: If patient has history of significant airway obstruction or apnea, premedication is best avoided or used with extreme caution.

TABLE 11-1   Pediatric Syndromes and Associated Airway Abnormalities

Acquired

Acquired abnormalities in pediatric airways can be subdivided into acute and chronic. Acute obstruction can result from foreign-body aspiration, infection such as laryngotracheobronchitis or epiglottitis, subglottic edema secondary to previous intubation or allergy, or internal or external airway trauma. Chronic obstruction can result from subglottic stenosis (posttraumatic or postsurgical), tumor, or abscess formation.

The management of an infant or child with airway obstruction depends on utilization of a safe, calculated approach to securing the airway. Such an approach requires a systematic evaluation of the pediatric airway, familiarity with pediatric airway equipment and pharmacologic agents, and recognition of a difficult airway and its appropriate management.

EVALUATION OF A PEDIATRIC AIRWAY

The first step in evaluating a pediatric airway is a directed history and physical examination. The time course of the present episode should be determined, as should a history of any recent fever, cough, or sore throat. Any history of previous airway problems should be elicited. If time permits, the history should include a review of the antenatal and perinatal periods, with an emphasis on feeding or sleeping difficulties. Any history of snoring or noisy breathing, recurrent croup or upper respiratory infections, or cyanosis or coughing during feedings should alert the clinician to the possibility of an abnormal airway.

The physical examination of a pediatric patient may be hindered by lack of cooperation, and care should be taken not to frighten the child. Visual signs of possible airway compromise include tachypnea, cyanosis, drooling, nasal flaring, and intercostal retractions. The child may assume a "tripod" position to enhance the use of accessory respiratory muscles. Auscultation may reveal stridor, wheezing, or grunting. Any change in the child's mental status, including agitation or somnolence, may further indicate airway difficulties. As in adults, features suggesting potentially difficult intubation include a small or recessed mandible, a prominent tongue, prominent upper incisors, and impairment of neck mobility.

Pediatric patients often have a period of compensated respiratory compromise prior to an arrest.[4] Pulse oximetric measurements should be continuously monitored, but adequate oxygen saturation should not be considered assurance of respiratory stability, since this measurement may not reflect declining ventilatory performance. All patients with potential airway compromise require attentive observation and frequent examination.

PEDIATRIC AIRWAY EQUIPMENT

Oropharyngeal and Nasopharyngeal Airways

Oropharyngeal airways are easy to use and available for pediatric patients of all ages. An oral airway should extend from the corner of the mouth to just cephalad to the angle of the mandible. To estimate the correct size, the airway can be placed next to the face. The oral airway should not be used in a conscious child because it may induce vomiting. The nasopharyngeal airway can be used in awake or semicomatose patients. The proper length is estimated by measuring the distance from the tip of the nose to the tragus of the ear. Complications include damage to adenoid tissue, epistaxis, and laryngospasm. Because the diameter of the nasal airways are so small in the pediatric population, they easily may become obstructed with blood, mucus, or vomitus and thus require frequent suctioning.

Bag-Valve-Mask Devices

The ideal pediatric mask should provide an airtight seal between the mask and the patient's face. A poor mask fit results in gas leaks, inability to maintain positive pressure, and potential compromise to ventilation and oxygenation. It has been found that child-size and adult-size self-inflating (Ambu, Inc., Linthicum, MD) bags may be utilized for the entire range of infants and children. Maximum oxygen delivery occurs at an oxygen flow of 15 L/min.[1]

Laryngoscope Blades

Two types of blades are most commonly available in emergency departments for pediatric intubation: curved (Macintosh) and straight (Miller). The tip of the Macintosh blade is inserted into the vallecula anterior to the epiglottis, and, as the blade is lifted, the epiglottis is elevated passively beneath the blade tip to expose the glottic opening. The tip of the Miller blade is placed beneath the epiglottis, which is directly elevated as the blade is lifted. A straight blade is superior to a curved blade in children under 2 years of age. Table 11-2 is a guide for laryngoscope selection in pediatric patients.

Age	SIZE	
	Miller	Macintosh
Premature	0	
Neonate	0 or 1	
1 month to 2 years	1	
2-6 years	*	2
6-12 years	2	2 or 3
12 or older	2 or 3	3

* If a straight blade is desired in this age group, a Wis-Hipple 1.5 may be used.

TABLE 11-2   Laryngoscope Blade Selection for Pediatric Patients

Endotracheal Tubes

There are numerous methods for selecting the correct endotracheal tube size for a given pediatric patient, including age, height, weight, and diameter of the fifth digit. Endotracheal tube size for premature and full-term infants is usually selected by weight, since, given the rapid growth during this period, age formulas become invalid. The rule usually employed is a 2.5-mm tube below 1.5 kg body weight, a 3.0-mm tube between 1.5 and 2.5 kg, and a 3.5-mm tube above 2.5 kg. The most commonly used formula for age determination of endotracheal tube size in children over 1 year of age is tube size (in millimeters) = 4 + age (in years)/4.[5] However, single-formula methods based on age have been shown to lead frequently to inappropriate tube selection.[6] Resuscitation measuring tapes have been found to be

more accurate than age-based formulas, which in turn are superior to the diameter of the fifth digit. [7,8] The tube should fit sufficiently snugly to prevent any leakage at pressures up to 10 cmH$_2$O but should leak at a pressure lower than 30 cmH$_2$O. An insufficiently snug fit will result in difficulty ventilating, compromised airway protection, and leakage of inhalational agents if the patient undergoes anesthesia. An overly tight-fitting tube risks endotracheal injury with the potential for development of subglottic stenosis due to the anatomic reasons noted above. For the same reason, cuffed tubes are generally avoided in patients 8 years old and under. Clearly, in the care of an unstable patient in the emergency department, a suboptimal tube that provides adequate ventilation is preferable to no airway at all, and exchange for a more appropriate tube can be deferred until the patient has been stabilized. The ideal depth of placement is midway between the glottis and the carina. Because of substantial variability in tracheal length, especially before the age of 1 year, formulas predicting the distance to the lips are unreliable. Since most pediatric tubes have a series of marks at the distal end, one technique is to simply advance the tube so that the second mark is just past the vocal cords. This results in a conservatively high tube that will not risk bronchial intubation. However, inadvertent dislodgement of the tube with head and neck manipulation may occur. A second technique is to initially deliberately perform a bronchial intubation, advancing the tube until breath sounds are heard only unilaterally, and then to back the tube up to a point 1 cm above where the breath sounds are again heard bilaterally. This method results in a conservatively low tube, but with little risk of inadvertent displacement out of the airway.

Laryngeal Mask Airway

The laryngeal mask airway (LMA) has been widely used in the pediatric population. [9] It has been found to be extremely useful in the management of difficult airways. It consists of a large-bore tube terminating in an ovoid, fenestrated cup with an inflatable rim that, when properly placed, forms a seal over the laryngeal orifice (Fig. 14-6). The result is an airway that is superior to a face mask in that it prevents supraglottic obstruction and greatly reduces the likelihood of gastric insufflation, but is less reliable at preventing aspiration than an endotracheal tube. Since it is placed blindly, it avoids the complications of endotracheal intubation that arise from the need to visualize and penetrate the glottic opening. It provides a useful rescue device in the event of a failed endotracheal intubation. Once in place, it can be used as a conduit for fiberoptically guided endotracheal intubation. Its applications and experience with its use continue to expand, and emergency physicians should be familiar with its insertion. LMAs can be sized from neonates to adults. Table 11-3 is a guideline of sizes according to weight.

Weight, kg	LMA Size
<5	1
5–10	1.5
10–20	2
20–30	2.5
30–50	3
50–70	4
>70	5

TABLE 11-3   Laryngeal Mask Airway Size Selection

RAPID-SEQUENCE INTUBATION OF THE PEDIATRIC PATIENT

Rapid-sequence intubation (RSI) is the nearly simultaneous administration of a potent intravenous anesthetic agent and a neuromuscular blocking agent to facilitate endotracheal intubation. The process involves preparation, preoxygenation, application of cricoid pressure (Sellick maneuver), induction of anesthesia, neuromuscular blockade, and intubation without attempting mask ventilation. While there remain advocates of other airway management methods, this technique provides unsurpassed airway access while minimizing complications. Its use in critically ill children is well described, and it is regarded as the first choice in the absence of contraindications (see below). [10,11]

Preparation

Prior to undertaking a RSI, all necessary tools and materials should be prepared. A well-functioning intravenous line must be in place, and all drugs to be used for the RSI should be predrawn in syringes and labeled. Laryngoscopes with blades of the appropriate sizes, with lights checked and working, should be within reach, as should suction equipment and a bag-mask-ventilation apparatus connected to oxygen. Any materials for rescue maneuvers following failed intubation, such as LMAs, jet ventilation devices, and cricothyrotomy trays, should be immediately available. An endotracheal tube of the estimated size should be styletted, with tubes a size larger and a size smaller present. At least one additional experienced provider should be present to apply cricoid pressure and provide assistance as needed. Continuous pulse oximetric monitoring is mandatory.

Preoxygenation

Due to their relatively high oxygen consumption, smaller children, and especially infants, undergo rapid desaturation with cessation of ventilation, even with normal lungs. Once drugs have been administered in RSI, patients rapidly become apneic. Positive-pressure mask ventilation is not performed at this point due to the risk of gastric insufflation and resultant regurgitation. Therefore, it is important to maximize the length of time that adequate saturation is maintained by maximizing the reservoir of oxygen in the lungs. The lung volume remaining at end-expiration, or functional residual capacity (FRC), contains less than 20% oxygen in a patient breathing room air, with nearly 80% occupied by nitrogen. Preoxygenation is effectively denitrogenation of FRC, and it increases by roughly fivefold the oxygen reservoir in the lungs once apnea occurs. Effective denitrogenation is ideally accomplished by having a patient breathe 100% oxygen from a tight-fitting mask for 2 min or for four vital capacity breaths. This is often not possible with a critically ill prediatric patient, but as long a period of preoxygenation as circumstances permit should be provided prior to RSI.

Cricoid Pressure

Application of cricoid pressure entails the manual application of firm pressure at the level of the cricoid cartilage anteroposteriorly to occlude the esophagus and minimize the risk of aspiration. It should not be applied over the thyroid cartilage or over the entire larynx. It should be initiated immediately prior to the administration of the RSI drugs and not released until correct endotracheal tube position is confirmed. The amount of pressure should be graded according to the size of the patient. In smaller patients, the person applying cricoid pressure may wish to use the other hand under the neck to avoid altering the neck position.

Induction of Anesthesia

Laryngoscopy and endotracheal intubation are extremely stimulating events that are powerfully resisted by the unanesthetized patient. The goal of RSI is to overcome this resistance while preserving hemodynamic stability. The term *induction of anesthesia* is used here rather than *sedation* because, while the distinction between the two is somewhat indistinct, performance of laryngoscopy and intubation without causing major hemodynamic perturbations requires a deep state of anesthesia, for which the term *sedation* is inappropriate. The drugs commonly used for induction of anesthesia and their pediatric doses are listed in Table 11-4. Note the absence of opioid agents, which do not reliably induce rapid hypnosis. These doses are appropriate for healthy, well-hydrated patients. The dose for critically ill patients, as well as for those who have received other agents, such as opioid analgesics, should be adjusted downward accordingly. All of these drugs are appropriate for this indication; however, the profiles and side effects of each differ somewhat, as discussed below.

Drug	Usual Dilution	IV Induction Dose	Duration of Action After an Induction Dose	Advantages	Disadvantages
Sodium thiopental	25 mg/mL	1–4 mg/kg	5–10 min	Safe with ICP; Possibly cardioprotective; Inexpensive	Hypotension; Extravasation; Histamine release
Propofol	10 mg/mL	2–3 mg/kg	4–6 min	Safe with ICP; Possibly cardioprotective; Not toxic resin	Pain on injection; Expensive; Short life when mixed
Ketamine	10 or 100 mg/mL	2–3 mg/kg	10–15 min	Supports blood pressure; In023 side; Can be given IM; Bronchodilator; Sedation; Potent analgesic	Raises ICP; Emergence hallucinations; Increases respiratory tract secretions
Midazolam	1 mg/mL	0.2–0.3 mg/kg	20–30 min	Cardiostable; Reversible	Slow onset; Long recovery time; Expensive
Etomidate	2 mg/mL	0.2–0.3 mg/kg	5–10 min	Cardiostable; Safe with ICP; Normal immune status	No analgesic effect; Pain on injection

Abbreviation: ICP, intracranial pressure; IM, intramuscular; IV, intravenous.

SODIUM THIOPENTAL   Sodium thiopental is the most commonly employed drug for induction of anesthesia and has been in use for some five decades. It is very inexpensive and provides reliable induction of anesthesia within 1 min. It causes significant venodilation and moderate direct myocardial suppression, which result in decreases in blood pressure and cardiac output in spite of an increase in heart rate mediated by a minimally suppressed baroreceptor reflex. It lowers intracranial and intraocular pressures and has long been the drug of choice where elevations of these pressures are a concern. Only barbiturates, of all the pharmacologic interventions studied, have been shown to provide cerebroprotection in acute brain injury, leading to the preference for this drug in the setting of intracranial mass lesions or head trauma. Its side effects include histamine release, which may manifest as flushing, exaggerated hypotension, and wheezing in patients with reactive airways. Neuroexcitatory effects during induction, such as twitching, cough, and hiccups, are relatively common. It can cause extensive tissue necrosis if extravasated.

PROPOFOL   Since its release in the United States in 1989, this drug has enjoyed increasing popularity, particularly in elective settings. Its onset of action is similar to that of thiopental, and it produces comparable decreases in blood pressure and cardiac output. Unlike thiopental, there is no reflex increase in heart rate. Propofol appears to be superior to thiopental at suppressing pharyngeal and laryngeal reflexes and for this reason is usually chosen for insertion of an LMA without paralysis. Like thiopental, it lowers intracranial and intraocular pressures, and, while experience with propofol is less extensive, it is probably as good a choice as thiopental in similar settings. It does not cause histamine release or stimulate bronchospasm, and extravasation has not been reported to cause significant tissue injury. It is notorious for causing pain on injection, which may be markedly attenuated by preadministration of a small dose of lidocaine. It is significantly more expensive than thiopental, and, given the overall similarity of their profiles, propofol has not been widely adopted for use in RSI due to this factor. Because it is prepared as an emulsion that readily supports bacterial growth, propofol must either be administered on discarded within 6 h of opening its container.

KETAMINE   Unlike any of the other induction agents, ketamine tends to increase heart rate, blood pressure, and cardiac output. These effects appear to be mediated through central sympathetic stimulation, since ketamine appears to be a weak myocardial depressant in isolated heart preparations. Such effects enhance its attractiveness in settings such as trauma with hypovolemia. It is also a bronchodilator with no suppression of ventilatory drive, making it an excellent choice for patients with known reactive airway disease. In addition, it has significant analgesic and amnestic properties. It can be given intramuscularly in a dose of 4 to 6 mg/kg with onset of anesthesia within 5 min. This may be desirable in the combative patient in whom intravenous access has not been secured. Unfortunately, it also carries a number of undesirable side effects. Despite the bronchodilatation, there are marked increases in upper airway secretions, which can occur briskly and complicate airway management. It increases cerebral blood flow, intracranial pressure, and intraocular pressure and should not be used in patients in whom these effects are a concern. Finally, it is associated with a significant incidence of emergence hallucinations, particularly in patients with a known history of psychosis, although this reaction is less common in children than in adults. This response can be attenuated by coadministration of benzodiazepines.

MIDAZOLAM   Of the benzodiazepines, midazolam is the most popular for induction of anesthesia due to its rapid onset time and lack of venous irritation. The doses required for induction are much larger than those used for sedation. The onset of action is still somewhat slower than with the other induction agents discussed here. As a consequence of the large dose, the time to recovery is prolonged compared to that for the other induction agents. Unlike the other induction agents, however, midazolam can be reversed by the benzodiazepine antagonist flumazenil, although this should be done with caution due to the risk of seizures. Remarkably little hemodynamic perturbation occurs with an induction dose, although significant hypotension may occur in a hypovolemic or critically ill patient. Apnea is common, and coadministration of opioids markedly potentiates respiratory suppression. Amnesia is most reliably accomplished with this induction agent. While expensive compared to thiopental, it is commonly used in the emergency department due to its stable hemodynamic profile.

ETOMIDATE   Etomidate is worthy of discussion due to its stable hemodynamic profile. An induction dose results in almost no change in heart rate, blood pressure, or cardiac output, since it appears to affect neither vascular tone nor baroreceptor reflex. It has little effect on ventilatory drive and none on airway smooth muscle. It lowers cerebral blood flow, intracranial pressure, and intraocular pressure much to the same degree as do thiopental and propofol. It completely lacks any analgesic properties and may require a low (2- to 4-μg/kg) dose of fentanyl to fully suppress the response to intubation. Side effects include pain on injection, myoclonic movements on induction, and a high incidence of subsequent nausea and vomiting. Reports suggesting adrenal suppression occurring with only an induction dose of the drug decreased its popularity, but evidence of the clinical significance of this observation has not been reported.

CHOICE OF AGENTS   The choice of agent should be dictated by the specifics of the patient's physiologic status as well as by the experience of the emergency physician. Factors such as cost and convenience of storage and administration affect a department's choice of options. Specific scenarios for which pharmacologic management may be tailored are discussed below.

Neuromuscular Blockade

The goal of neuromuscular blockade in RSI is to obtain the optimal conditions for laryngoscopy as quickly as possible. The neuromuscular-blocking drug (NMB) is thus injected immediately after the injection of the induction agent. Complete neuromuscular blockade enables maximal laryngoscopic displacement of the tongue and mandible to optimize the view of the glottic aperture. In most children without anatomic deformities, glottic visualization is relatively simple once neuromuscular blockade is accomplished. Neuromuscular blockade also ensures that the vocal cords will be open, facilitating atraumatic passage of the endotracheal tube. There are many NMBs available, but only those with the most rapid times of onset can be recommended for RSI. These include the depolarizing NMB succinylcholine and two nondepolarizing NMBs, vecuronium and rocuronium.

While many practitioners may be more familiar with pancuronium which is inexpensive and has a long history of use in the emergency department, its long time of onset and very long duration of action make it a suboptimal choice for RSI.

SUCCINYLCHOLINE   Succinylcholine, the only depolarizing NMB available in the United States, remains the drug of choice for RSI. While the US Food and Drug Administration has issued an advisory against its elective use in children, it continues to be approved for emergency airway management. The reason for the limitation of its use is that it has been associated with hyperkalemic arrest in children subsequently found to have underlying but undiagnosed myopathies (see below).

The advantages of succinylcholine include its extremely reliable and rapid time to onset of action; intubating conditions are obtained generally within 45 s. As noted, children become hypoxemic with apnea more rapidly than do adults, and even a 15-s advantage can be meaningful. Unlike nondepolarizing NMBs, duration of action is short. Spontaneous ventilation usually returns within 3 to 5 min. This is particularly important when ongoing neurologic assessment is desired, or when a difficult airway is anticipated or encountered, as options are preserved in the case of a failed intubation.

Unfortunately, the disadvantages of the drug are relatively numerous:

1. Hyperkalemia, with resultant cardiac arrest, is the most severe disadvantage. All patients experience a small rise, on the order of 0.5 meq/L, in their serum potassium following administration of succinylcholine. However, in certain subsets of patients, this rise is greatly exaggerated. Most of these are not likely to be a factor in an emergency department setting given the short time proximity of the injury or illness event to the need for intervention. In addition to myopathies, as mentioned above, other conditions that predispose to this occurrence include chronic immobilization, denervation lesions, spinal cord injuries, burns, crush injuries, and extensive necrotic soft tissue infections. The exaggerated response is due to unregulated proliferation of acetylcholine receptors on the muscle

membrane. This response takes 2 to 3 days to occur after burns and neurologic injuries; thus, succinylcholine is safe to use in the immediate postinjury period in such patients.

2. Malignant hyperthermia can be triggered by succinylcholine in susceptible individuals. Since the lesion causing this disease is hereditary, patients known to have a history *or a family history* of malignant hyperthermia should not receive this agent.

3. Fasciculations precede the onset of neuromuscular blockade as the depolarization of the muscle membranes occurs. These uncontrolled muscle contractions are not inherently dangerous as long as the patient is protected from involuntary physical injury. Thought to increase the occurrence of myalgias, they can be prevented by preadministration of a small "defasciculating" dose (10 percent of an intubating dose) of a nondepolarizing NMB 2 min before succinylcholine is given.

4. Elevations in intracranial, intraocular, and intragastric pressures have been documented. Such rises are not reliably prevented by defasciculating premedication. However, they are transient, and their clinical importance is largely theoretical. In a patient in whom elevated intracranial pressure is a concern, securing the airway and providing ventilation (and thus controlling P $_{CO_2}$) are of primary importance.

5. Bradycardia occurs unpredictably in some patients receiving succinylcholine and is more common after a second dose. When it does occur, hypoxia, rather than drug effect, should be the first consideration. This is of particular concern in small children and neonates, whose cardiac output is directly dependent on heart rate. Premedication with atropine 0.15 to 0.20 mg/kg is advisable in children under five years old or in any child with a heart rate less than 120 bpm.

6. Prolonged blockade, lasting hours instead of minutes, occurs in a small subset of patients who have decreased activity of plasma cholinesterase, the enzyme responsible for the inactivation of succinylcholine. This may be due either to a defective enzyme or to diminished levels of normal enzyme. The frequency of clinically significant prolongation in the population is roughly 1:3000. This condition is not inherently dangerous in and of itself. The implication is that occasionally a patient has a prolonged apparent absence of neurologic function that could be mistaken for central nervous system injury. Train-of-four monitoring, the elicitation of muscular response following a standardized series of four electrical pulses stimulating a particular nerve, is used primarily in the operating room and intensive care unit settings. Absence of any twitch response to train-of-four muscular stimulation 10 min after a dose of succinylcholine reflects prolonged neuromuscular blockade.

7. A small subset of patients develop masseter spasm on receiving succinylcholine, making intubation more difficult. These patients are at increased risk of developing myoglobinuria and have a higher propensity for developing malignant hyperthermia. Fewer than 1 percent of patients manifest this complication.

In the event that succinylcholine is contraindicated, a fast-acting nondepolarizing NMB may be chosen with the knowledge that the onset will be slightly slower and the duration of action substantially longer.

VECURONIUM Vecuronium was the first nondepolarizing NMB to be recommended for use in RSI. In order to obtain intubating conditions in 60 to 90 s, a dose of 0.3 to 0.4 mg/kg is given. This results in a duration of action of 90 to 150 min. Alternatively, if time permits, a "priming" dose of 0.01 mg/kg should be given 2 to 3 min before an intubating dose of 0.15 to 0.2 mg/kg. The priming technique entails no clinically significant issues, but it speeds the onset of intubating conditions after the intubating dose and shortens the duration of action to 60 to 75 min. Vecuronium is essentially devoid of hemodynamic effects and does not cause histamine release. It is stored as a powder that is easily diluted for use.

ROCURONIUM Rocuronium is similar to vecuronium in its lack of hemodynamic effects. It is somewhat less potent, giving it a more rapid time to onset of intubating conditions, sufficiently so that priming is not considered necessary. Doses of 0.9 and 1.2 mg/kg have been shown in adults to result in times to intubating conditions of 75 and 55 s, respectively, approaching the 45 s typical of succinylcholine. [12] The duration of action is comparable to that of vecuronium 0.1 mg/kg at the 0.9 mg/kg dose and somewhat longer at the 1.2 mg/kg dose. Rocuronium is supplied as a solution that requires refrigeration, making it slightly less convenient to stock and store than vecuronium.

Contraindications

There are few contraindications to RSI. A known difficult airway requires an alternative approach. A variety of other approaches may be considered in a patient known to have experienced failed laryngoscopic intubation in the past or whose anatomy or injuries preclude direct laryngoscopy. These approaches include blind techniques, fiberoptically assisted techniques, and techniques employing an LMA. (These are detailed in Chap. 15.) Invasive emergency airway management approaches are discussed below. Patients who are judged to be too ill to receive anesthetic drugs, such as those comatose, profoundly hypotensive, or without circulation, may be intubated without pharmacologic assistance. Cricoid pressure should nonetheless be applied, since regurgitation and aspiration may still occur in these patients.

INVASIVE AIRWAY TECHNIQUES

Needle Cricothyroidotomy

Emergency surgical airways are often difficult to establish in children and have high complication rates. Hence, needle cricothyroidotomy has been advocated as the preferred airway access technique in the pediatric population. Needle cricothyroidotomy is performed by first identifying the cricothyroid membrane. A large-bore (14-gauge) intravenous catheter is passed through the membrane into the airway at a 45-degree caudad angle. The needle is removed, and an adapter is placed on the catheter so a standard bag-valve mask can be connected for oxygenation. This system has been shown to provide adequate oxygenation for prolonged periods of time. It cannot, however, provide adequate ventilation. [13]

Transtracheal jet ventilation allows ventilation and oxygenation through a catheter. Ventilation is provided with short, intermittent bursts of oxygen. This requires high-pressure (50 psi) oxygen-delivery systems. The system of choice is a jet injector regulated by a flow meter attached to a wall or tank unit. The less optimal choice is an unregulated wall or tank system. A 1-s jet of oxygen followed by a 4-s expiratory phase achieves satisfactory ventilation. [14]

Complications of needle cricothyroidotomy include bleeding, infection, esophageal perforation, breakage or bending of the needle, subcutaneous emphysema, pneumothorax, pneumomediastinum, and pneumopericardium.

Surgical Cricothyroidotomy and Tracheostomy

Emergency surgical cricothyroidotomy and tracheostomy in pediatric patients is much more difficult than in adults due to the smaller dimensions of the structures and the relatively higher position of the larynx in the neck. Sufficient literature documenting the true complication rates of these procedures in the pediatric population is not available, but the procedures should be undertaken only as measures of last resort.

SPECIAL CONSIDERATIONS

Head Trauma or Intracranial Mass Lesion

Securing the airway in a pediatric patient with head trauma or an intracranial mass lesion plays an important role by correcting or preventing hypercarbia and hypoxemia, factors that can cause increases in intracranial pressure. Since endotracheal intubation itself is inherently stimulating to intracranial pressure, as noted above, all possible precautions should be taken to suppress this response. In addition, in the setting of head trauma, RSI should be undertaken with strict head and neck immobilization due to the potential for concomitant cervical spine injuries.

RSI is the preferred method of intubation in pediatric patients with suspected or known intracranial hypertension. In addition to the agents previously discussed, lidocaine at a dose of 1.5 mg/kg intravenously should be given prior to laryngoscopy. [15] This intervention blocks the rise in intracranial pressure that commonly accompanies endotracheal intubation. It is important to remember that in pediatric patients, as in adults, head injuries can also be associated with intraoral and intratracheal injuries. When managing the airway of a head-injured patient, one must always be prepared for invasive airway management.

Epiglottis and Croup

For a detailed discussion of pediatric upper airway obstruction, see Chap. 129. Optimal airway management for pediatric patients with epiglottitis is in the operating room. If the patient is stable, he or she should be transported to the operating room accompanied by a skilled airway manager and the proper equipment. A patient with complete airway obstruction can often be ventilated until an airway can be established. If this is unsuccessful, emergent orotracheal intubation should be

attempted. If this fails, invasive airway techniques should be utilized.

Uncommonly, a child with croup may be unresponsive to medical management and may require an artificial airway. An endotracheal tube is optimally placed in the operating room allowing for inhalation induction of anesthesia. Intubation, however, may have to be performed in the emergency department if the patient is in extremis.

Airway Foreign Bodies

Management of an unstable patient with acute airway obstruction requires immediate attention to the airway. In the prehospital setting, the American Heart Association recommends a series of five back blows and five chest thrusts in a child under the age of 1 (see Chap. 10). The child should have the oropharynx examined between each series. In a child older than 1, the recommendation is a series of abdominal thrusts in either the upright or the supine position.

In the emergency department, the child with a partially obstructed airway should be rapidly assessed. If the child will tolerate it, a visual inspection of the hypopharyngeal and laryngeal areas should be attempted. Commonly, a child will tolerate this procedure poorly and thus should be taken to the operating room for general anesthesia and removal of the foreign body. In an unstable or completely obstructed patient, orotracheal intubation may dislodge the foreign body, and this should be attempted prior to needle cricothyroidotomy.

12 RESUSCITATION ISSUES IN PREGNANCY

Elizabeth M. Datner
Susan B. Promes

ETIOLOGY OF MATERNAL DEATH

Although cardiac arrest in pregnant patients is rare—it is estimated to occur once in every 30,000 deliveries—the incidence of maternal death has been increasing recently. From 1987 to 1990, the overall pregnancy-related mortality ratio was 9.2 deaths per 100,000 live births. However, the National Health Promotion and Disease Prevention Objectives of Healthy People 2000 identifies a rate of no more than 3.3 maternal deaths per 100,000 live births as a national goal. Because critically ill obstetric patients are uncommon, optimal care is sometimes jeopardized. Many maternal deaths may be preventable if managed appropriately. Some of the factors associated with a higher risk of pregnancy-related death include increasing maternal age, race, increasing live birth order, lack of prenatal care, and unwed mothers.[1]

The leading causes of maternal death are pulmonary embolism, trauma, hemorrhage, and maternal cardiac disease (Table 12-1). While pulmonary embolism is considered the most common medical cause of death in pregnant women, several studies indicate that injury is the most common etiology of maternal death and homicide the most common form of injury.[2,3] Domestic violence and its relationship to pregnancy and homicide is poorly understood, but domestic violence indicators should be examined in all newly diagnosed pregnancies as a preventive measure.

TABLE 12-1   Common Etiologies of Maternal Cardiopulmonary Arrest

MATERNAL AND FETAL PHYSIOLOGIC CHANGES THAT AFFECT CARDIAC ARREST

Uteroplacental blood flow is directly related to maternal blood volume and arterial pressure. Support of maternal blood volume and oxygenation is the best way to prevent fetal hypoxia. With this principle in mind, a detailed understanding of cardiac arrest physiology is important. A full discussion of fetomaternal physiology can be found in Chap. 99, but several points are discussed and put in perspective here.

The maternal cardiovascular system undergoes dramatic changes. Cardiac output increases to 30 to 45 percent above baseline levels by the twentieth week of gestation and remains at that level until delivery. In addition, the mean arterial blood pressure gradually falls throughout the first two trimesters of pregnancy and returns to baseline levels by term. This change is a result of decreased resistance in the pulmonary and uteroplacental circulations. The uteroplacental mass increases and requires 10 percent of systemic blood volume by term, compared to a baseline 2 percent. By the second half of pregnancy, the uteroplacental vascular bed functions as a passive low-resistance system, with flow determined by maternal perfusion pressure. Thus, in a state of cardiac compromise, uterine blood flow is greatly diminished. The addition of vasopressors with a- and b-adrenergic effects can cause significant vasoconstriction, decreasing uterine blood flow even further.

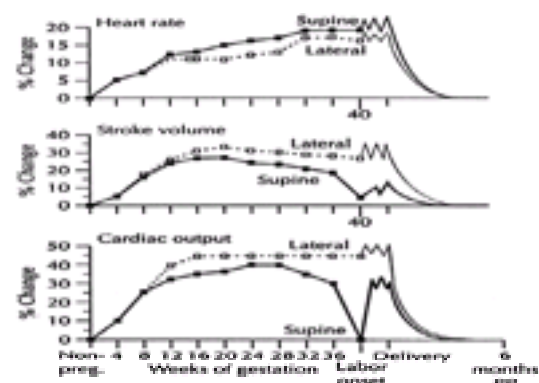
By the twentieth week of pregnancy, the enlarged uterus mechanically compresses the great vessels in the pelvis, particularly when the patient is in the supine position. As a result of decreased venous return from compression of the inferior vena cava, cardiac output is reduced 10 to 30 percent during spontaneous circulation (Fig. 12-1). Administration of medications through intravenous sites in the infradiaphragmatic vessels, such as the femoral or saphenous veins, is also compromised because of poor venous flow. These vascular sites are therefore not recommended for intravenous access in the resuscitation of a pregnant patient greater than 20 weeks' gestation. Aortal compression also occurs, causing diminished distal blood flow. The untoward effects of great vessel compression are worsened in the setting of maternal hypotension and uterine contractions, leading to an even more pronounced decrease in uteroplacental blood flow.


FIG. 12-1. Changes in maternal heart rate, stroke volume, and cardiac output during pregnancy with the gravida in the supine and lateral positions. (From Barclay ML, in Pearlman MD, Tintinalli JE (eds): *Emergency Care of the Woman,* McGraw-Hill, 1998.)

Pregnancy also alters the respiratory system. A state of partially compensated respiratory acidosis develops during the first trimester of pregnancy due to progesterone-stimulated hyperventilation. The resulting decrease in serum bicarbonate levels and P_{CO_2} makes the woman less able to buffer a state of acidosis from hypotension or cardiac arrest. In addition, the decreased functional residual capacity (FRC) and increased maternal oxygen consumption and basal metabolic rate during pregnancy, results in more rapid onset of anoxia with respiratory arrest. Arterial oxygen content drops three times more quickly in pregnant than in nonpregnant

patients.[4] Rapid resumption of respiration, whether mechanical or spontaneous, is essential to minimize hypoxic damage. Progesterone also increases gastric emptying time and decreases lower esophageal sphincter tone, making the gravid patient prone to aspiration. This is another reason to initiate endotracheal intubation early.

Fetal physiology appears to be protective of severe hypoxia. There are several reports of fetal survival when delivery occurred more than 20 min after maternal cardiac arrest in patients receiving cardiopulmonary resuscitation (CPR). The trauma literature indicates that absence of maternal vital signs for greater than 20 min renders emergency cesarean section futile. It is unclear whether CPR plays a role in potential fetal survival beyond 20 min. The fetal oxyhemoglobin dissociation curve is shifted to the left relative to the maternal oxyhemoglobin dissociation curve because of the greater affinity of hemoglobin F for oxygen. Thus, at any partial pressure of oxygen, fetal hemoglobin will bind oxygen more strongly, resulting in greater saturation. Fetal P_{O_2} does not fall significantly unless maternal P_{O_2} falls below 60 mmHg.[5] Below this level, only slight decreases in maternal P_{O_2} will result in significant decreases in fetal P_{O_2}. In addition, there is a higher concentration of fetal hemoglobin in fetal erythrocytes than maternal hemoglobin in maternal erythrocytes, and the fetus exists in a physiologically acidemic state relative to the mother, which allows preferential oxygen transfer at the fetal tissue level. Acidemia favors a rightward shift of the oxyhemoglobin dissociation curve. Thus, a greater amount of oxygen is supplied to fetal tissues.

Fetal cardiac output protects against hypoxia with increases in umbilical blood flow and placental gas exchange. Fetal blood flow is then preferentially redistributed to vital tissues. As a result, fetuses exposed to short periods of maternal hypoxia may not suffer neurologic damage.

Resuscitation of a pregnant patient can become a chaotic event. Particularly in major centers, there may be other specialists involved, including pediatricians, neonatologists, anesthesiologists, obstetricians, and possibly others. These specialists have unique skills and experience that will help in the resuscitation. However, many of the specialists are poorly versed in emergency medicine and advanced cardiac life support (ACLS) protocols. It is particularly important that the team leader of the resuscitation take strict control of the events and the order in which they occur. The other specialists involved should not be allowed to deviate from the proper process. The team leader for such resuscitations may be decided by hospital policy. If such a policy does not exist, then typically the emergency physician must be the director of the resuscitation and take firm control.

AIRWAY ISSUES

The airway presents special concerns in obstetric patients. Attention to a few details, particularly in the setting of maternal cardiac arrest, may reduce morbidity and mortality. Airway management and its associated problems represent the greatest risk factor for anesthetic-related maternal deaths, the majority of which occur in the setting of an emergent cesarean section. Maternal death related to anesthesia most commonly results from aspiration of gastric contents or failure to intubate the trachea, resulting in hypoxia, which ultimately can result in cardiac arrest.[6] Mask ventilation can be difficult and ineffectual in obstetric patients because of low FRC, elevated diaphragms, and raised intraabdominal pressure. The incidence of failed intubations in pregnant patients is approximately 1 in 300 to 500 patients undergoing general anesthesia.[7] Complicating the fact that pregnant patients develop hypoxia more quickly and are less tolerant of apneic periods, the airway poses more difficulties than in the general population. The potential factors accounting for these difficulties should be assessed prior to attempting an intubation.

Parturients in general are in an edematous state, which effects the tongue and supraglottic soft tissues.[8] The edema may compromise the airway lumen, making mask ventilation, laryngoscopy, and endotracheal intubation more challenging. Smaller endotracheal tubes may be needed to achieve a successful intubation and should be readily available. Mucosal engorgement and increased friability make the airway more likely to bleed and swell. This in itself can cause rapid deterioration. Decreased gastric emptying and diminished lower esophageal sphincter tone allow for increased gastric insufflation and result in a higher risk of aspiration during intubation. The intubating physician should make as few attempts as possible, to avoid making a difficult airway worse. Blind nasotracheal intubation is relatively contraindicated, and nasogastric tubes should generally be avoided, given the engorgement and friability of the mucosa in pregnant patients. Orogastric tubes may be used with caution in pregnant patients in cardiac arrest.

Several other physical conditions should be considered prior to intubating a parturient. Pregnant patients are likely to have full and intact dentition, and there may be little interdental distance in which to maneuver a laryngoscope. Obesity is relatively common in pregnant patients, causing relative neck extension when patients are supine, which results in greater anterior placement of the larynx. The neck is foreshortened, and there are often redundant pharyngeal and palatal folds in the airways of obese gravid women. In addition, enlarged and engorged breasts may obstruct placement of the laryngoscope in the mouth and the hand of an assistant attempting to maintain cricoid pressure.

The technique for intubating pregnant patients may require several modifications. As in any intubation, adjunctive equipment, including small endotracheal tubes, short laryngoscope handles, and stylets, should be readily available and familiar to the physician managing the airway. The patient should be placed in the supine position with the right hip elevated 10 to 12 cm to minimize aortocaval compression. The head and shoulders can be elevated with a pillow or folded sheets to achieve the sniffing position. This maneuver is particularly important in obese patients.

Use of rapid-sequence induction with cricoid pressure has become the standard of care for intubating pregnant women, particularly unstable patients with airway compromise. Administration of an induction agent, such as thiopental or etomidate, is followed by administration of succinylcholine, the muscle relaxant of choice, unless there is a contraindication to its use. It is helpful to allow a sufficient amount of time for muscle relaxants to take effect and for adequate preoxygenation prior to attempting laryngoscopy, given its potential hazards in pregnant patients. Preoxygenation prior to intubation is important because of the parturient's decreased FRC. However, hyperventilation may lead to respiratory alkalosis, which, in addition to shifting the oxyhemoglobin dissociation curve to the left, causes decreased uterine blood flow. Cricoid pressure must be carefully applied throughout the intubation procedure. In the case of failed intubation, more invasive maneuvers, such as percutaneous transtracheal jet ventilation or cricothyrotomy, may need to be performed in order to maintain oxygenation and prevent hypercarbia. Ventilator settings for pregnant patients are similar to those for nonpregnant patients, with minor modifications. Minute ventilation should aim to maintain a P_{CO_2} of approximately 30 mmHg. Significant respiratory alkalosis must be avoided to prevent decreased uterine blood flow.

MODIFICATIONS OF CARDIOPULMONARY RESUSCITATION

The etiology of cardiac arrest in pregnant patients is different from that in nonpregnant patients and includes pulmonary embolism, amniotic fluid embolism, eclampsia, drug toxicity (e.g., magnesium sulfate or epidural anesthetics), cardiomyopathy, aortic dissection, trauma, and hemorrhage. As always, one should address the potential underlying etiology as well as the cardiovascular collapse.

Cardiopulmonary arrest in a pregnant patient must be considered under two scenarios: prior to fetal viability and after fetal viability. The accepted age of fetal viability may vary among institutions, but 24 to 26 weeks is generally considered the age of viability. The uterine fundus is palpable at the umbilicus at 20 weeks. After 20 weeks, the gestational age of the fetus can be estimated by measuring the fundus from the pubic symphysis to the top of the fundus. The fundal height in centimeters corresponds roughly to the gestational age in weeks. Prior to 24 weeks' gestation, all efforts should focus on the mother, with no modifications to CPR. However, early intubation and resumption of respirations and circulation is essential in all gravid arrests for the reasons mentioned earlier. Beyond 20 weeks or if the gravid uterus can be palpated above the umbilicus, several modifications of CPR should be instituted: (1) the patient should be positioned to minimize aortocaval compression, and (2) an emergency cesarean section should be considered.

Aortocaval compression must be limited in all patients beyond the twentieth week of gestation. This can be achieved by (1) having someone manually displace the uterus to the left, (2) tilting the patient 15 to 30° on a tiltable table, or (3) placement of a roll or a Cardiff wedge, if available, under the patient's right hip and flank. The Cardiff wedge provides a tilt of 27 percent, allowing 80 pecent of perfusion compared with CPR in the supine position.[9] Even this is minimal blood flow, considering that correctly performed CPR maintains 30 percent or less of normal cardiac output in nonpregnant adults.[10,11] The "human wedge" has been advocated for bystander CPR. In this technique, the patient lies across the thighs of the rescuer, who is in a kneeling position. Despite relatively clear current recommendations regarding resuscitation in pregnancy, summarized in Table 12-2, there remains a paucity of research in this area.[6]

TABLE 12-2 Algorithm for Cardiopulmonary Resuscitation in Pregnant Patients

Five factors have been suggested as important to improving the chance of fetal survival when the mother suffers cardiac arrest: gestational age greater than 28 weeks or fetal weight greater than 1 kg, short interval between maternal death and delivery, a cause of maternal death not related to chronic hypoxia, fetal status before maternal death, availability of neonatal intensive care facilities, and quality of maternal resuscitation. [12],[13]

The role of open chest cardiopulmonary resuscitation (OCCPR) remains unclear. There is some evidence that early thoracotomy and open chest cardiac massage may improve both maternal and fetal outcome. If, after several minutes of external CPR (15 min has been suggested), a pregnant woman has failed to achieve return of spontaneous circulation, OCCPR should be considered.

DEFIBRILLATION AND MEDICATIONS

Pregnant patients who experience cardiac arrest should be treated using current ACLS guidelines. Defibrillation has never been found to have adverse effects on the fetus and thus is not contraindicated. The patient should be placed in the left lateral tilt position if possible prior to defibrillation or cardioversion. Large-bore intravenous lines should be placed, preferably above the diaphragm, and lactated Ringer's or normal saline solution infused. Supplemental oxygen should be given. APGAR scores and fetal outcome are positively affected by greater fetal oxygen reserves. [14] In limited published reports, the standard medications used in ACLS have not been demonstrated to have adverse effects on the fetus and thus are recommended in the setting of cardiac arrest. [15] See Table 12-3 for details regarding ACLS medications. Vasopressors, such as epinephrine and dopamine, may be detrimental in the setting of maternal hypotension, since they cause uteroplacental vasoconstriction, but should be used as needed during cardiac arrest. In the setting of hypotension alone without cardiac arrest, ephedrine, in standard doses, is the preferred pressor when fluids fail to restore adequate blood pressure. (The dose is 5 mg IV q 5 min until a response is seen.) The use of sodium bicarbonate is not well studied. Sodium bicarbonate crosses the placenta slowly and can potentially be problematic for the fetus for the following reason. Rapid correction of maternal metabolic acidosis will decrease maternal respiratory compensation and lead to a rise in or normalization of maternal P_{CO_2}. As maternal P_{CO_2} increases, the concomitant rise in fetal P_{CO_2} occurs at a faster rate than does the rise in HCO_3^-, causing the fetus to become more acidotic.

TABLE 12-3 Medications Used During Cardiopulmonary Resuscitation—Considerations in Pregnancy*

COMPLICATIONS FROM CARDIOPULMONARY RESUSCITATION

Complications may occur from standard resuscitation. Maternal problems secondary to CPR include liver lacerations, uterine rupture, hemothorax, and hemopericardium. Fetal complications include cardiac dysrhythmias from maternal defibrillation and ACLS drugs, central nervous system toxicity from ACLS drugs, and altered uteroplacental blood flow from maternal hypoxia, acidosis, and vasoconstriction. Despite all of the aforementioned problems, standard ACLS protocols, with the addition of a pelvic tilt, are still the standard of care in resuscitating pregnant patients. The ultimate goal is to oxygenate the mother, and in turn the fetus, and achieve return of spontaneous circulation as soon as possible.

CARDIAC ISCHEMIA

Pregnant women thought to be experiencing cardiac ischemia are treated the same as nonpregnant patients, with the exception of thrombolytic therapy. Pregnancy is considered a relative contraindication to thrombolytic therapy by the American College of Cardiology/American Heart Association. [16] No controlled trials using thrombolytic agents, such as streptokinase, urokinase, or tissue plasminogen activator, have been performed on pregnant women or are currently feasible. Patients with suspected myocardial infarction should be evaluated for emergent percutaneous interventional therapy or medical management.

PULMONARY EMBOLISM

Thromboembolic disease is increased in pregnancy. Anticoagulation with heparin is currently the treatment of choice for a pulmonary embolism, along with ensuring adequate oxygenation and treating hypotension. Both unfractionated and low-molecular-weight heparin are acceptable treatment regimens. When a pulmonary embolism is suspected, empiric treatment with heparin should be started immediately, especially if the patient is hypoxic or hemodynamically unstable. Once treatment has begun, a Doppler ultrasound or ventilation-perfusion scan should be obtained to confirm the diagnosis. Traditionally, thrombolytic therapy for pulmonary embolism has been considered relatively contraindicated in pregnant patients. However, pregnant women have been treated successfully with thrombolytics with no untoward complications. [17] The use of thrombolytics should be reserved for patients in extremis.

AMNIOTIC FLUID EMBOLISM

The classic presentation of amniotic fluid embolism is the development of dyspnea and hypotension in association with labor or an abortion. Milder forms can present with sudden onset of shortness of breath and air hunger along with a decreased oxygen saturation that resolves spontaneously. Amniotic fluid embolism can be difficult to distinguish from pulmonary embolism. Patients can develop cardiac arrest within minutes, and if they survive they will go on to develop disseminated intravascular coagulation. Treatment is primarily supportive care along with invasive cardiac monitoring and correction of the coagulopathy. The use of cardiopulmonary bypass and open pulmonary artery thromboembolectomy has been used with success in a moribund patient with AFE. [18]

PERIMORTEM CESAREAN SECTION

Perimortem cesarean section must be considered as part of any resuscitation in the case of maternal cardiac arrest and a viable fetus. Prognosis for intact survival of the infant is excellent if delivery occurs within 5 min of maternal arrest and initiation of CPR. If the 5-min time frame has been exceeded, it is still recommended to perform a perimortem cesarean section. One case has been reported of a perimortem cesarean section performed 22 min after maternal cardiac arrest that resulted in a normal living infant.[19] No cases have been reported of live births by perimortem cesarean section beyond 25 min after maternal arrest. Ideally, an obstetrician and a pediatrician or neonatologist are present at the time of a perimortem cesarean section. In the absence of these specialists, the emergency physician must be prepared to perform the procedure. It is not necessary and only delays a potentially lifesaving procedure to evaluate fetal viability prior to initiation of the cesarean section. For the same reasons, the patient should not be moved to an operating suite, since this only wastes time. The decision to perform a perimortem cesarean section should be made by 4 min after cardiac arrest, with delivery of the fetus by 5 min postarrest.

Maternal CPR should be continued throughout the procedure and for a brief time afterward, since a few cases of successful resuscitation following such a procedure have been reported. Necessary equipment includes a scalpel, bandage scissors, Mayo scissors, toothed forceps, Richardson retractors, needle drivers, and suture material ([Table 12-4](#)). The goal of this procedure is to remove and resuscitate the fetus.

Scalpel
Mayo scissors
Bandage scissors
Toothed forceps
Needle holders
0 chromic sutures on a CT 1 needle
Richardson retractors
10 U/mL oxytocin vials
10 mL normal saline solution vials
10 mL syringe with intramuscular needles

TABLE 12-4 Equipment Required for Emergency Cesarean Section

Abdominal preparation and insertion of a Foley catheter to decompress the bladder may be performed prior to initial incision if time allows but should not delay the procedure. No anesthesia is required, since the mother is in cardiac arrest. A vertical midline (classical) incision is made from 4 to 5 cm below the xiphoid process to the pubic symphysis through the abdominal wall. The rectus muscles may be separated by blunt dissection, and the peritoneum is entered with a midline incision that is continued superiorly and inferiorly to allow visualization of the uterus. A vertical uterine incision is made from the fundus to the point at which the opaque bladder is adherent to the uterus. An initial small inferior incision may be made until amniotic fluid is obtained and then extended with scissors using the free hand to elevate the uterus, avoiding injury to the fetus. An anterior placenta should be incised in order to reach the fetus. The fetus is then delivered and resuscitated. The placenta is then manually removed from the uterus, and the uterus is wiped clean of membranes with a sponge or towel. The uterus is closed with one or two layers with a locked running stitch using number 0 or number 1 semipermanent suture and a large needle. The fascia and peritoneum may be closed with a permanent or semipermanent number 0 or number 1 suture with a running stitch. Finally the skin is closed. Closure of the abdomen may be delayed until maternal pulse and blood pressure are restored, to allow direct observation of the uterus for ongoing bleeding. Uterine atony after perimortem cesarean section is common and may lead to significant blood loss when the uterus fails to contract after delivery. Because maternal blood circulation may not be sufficient to deliver intravenously administered medication, dilute oxytocin (10 U in 9 mL normal saline solution) may be injected directly into the myometrium in divided doses until contraction occurs. Other possible therapeutic medications include ergometrine (intravenous or intramuscular) or prostaglandin F$_{2a}$ into the uterus.

Informed consent for perimortem cesarean section is not necessary. The procedure needs to be performed expediently and should be considered part of the resuscitation. The performance of a non-life-threatening operation in the setting of cardiac arrest abides by the ethics of absence of malfeasance and beneficence for both the mother and the fetus. The question of when emergent cesarean section should be performed in critically ill, prearrest patients has not been adequately addressed in the literature. In addition, the recommendations for perimortem cesarean section are based on multiple case reports. No experimental studies have been done to evaluate this procedure.

DISPOSITION

The presence of experienced obstetricians, anesthesiologists, and pediatricians or neonatologists will facilitate the care of pregnant patients with cardiac arrest. However, none of the required care and procedures should be delayed if these specialists are not available. When trained staff are available to perform external fetal tococardiography without diverting care from the mother, it should be provided for pregnancies beyond 20 weeks' gestation. If this technology is not available or personnel are limited, the often-quoted maxim "Maternal resuscitation is the best fetal resuscitation" should be kept in mind. The closest center providing neonatal services should be contacted as soon as possible to facilitate rapid transport of the newly delivered infant.

13 ETHICAL ISSUES OF RESUSCITATION

Catherine A. Marco

GENERAL PRINCIPLES OF MEDICAL ETHICS

The study of ethics has been defined as the way of *understanding and examining the moral life* (Beauchamp and Childress, *Principles of Biomedical Ethics*, 4th ed., 1994), and as the study of standards of conduct and moral judgment (*Webster's Dictionary*). The Hippocratic Oath has been revered as one of the oldest codes of medical ethics. More recently, the American Medical Association (AMA) Code of Ethics (earliest version from 1847) and American College of Emergency Physicians (ACEP) Code of Ethics (1997) have provided guidance to emergency physicians in application of ethical principles to clinical practice. Most ethical codes address common features, such as beneficence (doing good), nonmalfeasance (primum non nocere, or "do no harm"), respect for patient autonomy, confidentiality, honesty, distributive justice, and respect for the law. Ethical dilemmas may arise when there is a seeming conflict between two ethical principles or values. Ethical dilemmas may be resolved by various means, including individual physician judgment, additional information gathering, meetings with health care professionals, patients, and families. In some circumstances, the involvement of the institutional ethics committee or the judicial system may be sought. Several ethical situations related to emergency medicine are explored in this chapter.

CARDIAC RESUSCITATION AND OUTCOMES

There are an estimated 750,000 sudden deaths in the United States annually. The outcome of resuscitative efforts for victims of cardiac arrest is uniformly poor, but varies, dependent on a variety of factors. The most important factor determining outcome is the time elapsed since arrest ("downtime"). One study showed a 27 percent resuscitation rate for patients who received advanced cardiac life support (ACLS) within 8 min of arrest, and a dismal outcome if more than 20 min elapses. [1] Improved outcomes have been demonstrated for witnessed arrests, who received early cardiopulmonary resuscitation (CPR) and advanced life support (ALS). Another important prognostic factor is the presenting rhythm. Previous studies have demonstrated improved survival rates for patients with presenting rhythms of ventricular fibrillation or ventricular tachycardia, and reduced survival rates for patients with asystole or pulseless electrical activity. The underlying medical condition of the patient is another important factor affecting outcome.

A potentially poor response to resuscitation can be expected for patients with metastatic disease, acute cerebrovascular accident, sepsis, renal failure, or pneumonia. Failure to respond to prehospital ALS protocols leads to a survival rate of less than 2 percent. The age of the patient also affects predicted survival rate, with a 0 percent survival rate for unwitnessed arrests of elderly patients [2] and for long-term care patients. [3] Overall survival of victims of cardiac arrests, to hospital discharge, has been estimated to be between 0 and 16 percent.

Based on such data, several authors have suggested proposed criteria for withholding resuscitative efforts for patients in certain clinical settings with low likelihood of successful resuscitation (e.g., apneic, pulseless for longer than 10 min prior to Emergency Medical Service arrival, no response to ACLS, and preexisting terminal disease). [4,5] Knowledge of data regarding resuscitation outcomes in various clinical settings is crucial when making evidence-based decisions regarding the risks and benefits of attempting cardiopulmonary resuscitation and the duration of the resuscitation attempt.

RISKS AND BENEFITS OF RESUSCITATIVE EFFORTS

When considering offering or withholding resuscitative efforts, risks and benefits of resuscitative efforts should be carefully considered. The goal of resuscitative efforts is to restore circulation, and life to the patient. Other less tangible benefits may include such entities as resolution of guilt of the survivors, and the additional time for acceptance of bad news for survivors.

However, often resuscitative measures are undertaken in clinical situations in which physiologic survival is very unlikely. In some situations, there is a substantial risk that, if circulation is restored, significant anoxic brain injury will result, possibly resulting in impairment of quality of life (dementia, persistent vegetative state, or other cognitive impairments). Additionally, substantial resources (supply costs, as well as personnel) are often invested in this clinical setting of low likelihood of benefit, while the care of many other patients is delayed (distributive justice). Another consideration for limiting resuscitative efforts is the potentially increased human resources that could be available for family counseling, rather than investing such resources in resuscitative efforts unlikely to be successful.

"FUTILITY" AND NONBENEFICIAL INTERVENTIONS

The term *futility* is fraught with difficulties in definition and interpretation. Health care professionals may interpret futile interventions as those that carry an absolute impossibility of successful outcome, a low likelihood of success, a low likelihood of survival to discharge from the hospital, or a low likelihood of restoration of meaningful quality of life. Schneiderman and colleagues defined "futility" as "any effort to achieve a result that is possible but that reasoning or experience suggests is highly improbable and that cannot be systematically produced." [6] Several authors have demonstrated that there is no consensus among physicians about the meaning of futility. [7,8] Because of these difficulties, it is probably more accurate to use the appropriate terminology, such as "nonbeneficial," "ineffectual," or "low likelihood of success."

The withholding or limitation of medical interventions that have a predicted low likelihood of producing a successful outcome can be a difficult and far-reaching decision. Many emergency physicians continue to attempt resuscitation on patients in cardiac arrest, in situations considered nonbeneficial, often because of fears of litigation or criticism. [9] Medical ethicists have stated widely variable opinions regarding rendering treatments considered futile or of low likelihood of benefit. The AMA Council on Ethical and Judicial Affairs stated that "the social commitment of the physician is to sustain life and relieve suffering. Where the performance of one duty conflicts with the other, the choice of the patient should prevail." [10] One extreme viewpoint is that even the irrational choices of a competent patient must be respected if the patient cannot be persuaded to change them. [11] However, most ethicists agree that physicians are under no obligation to render treatments that they deem of little or no benefit to the patient. ACEP has a policy which states that "physicians are under no ethical obligation to render treatments that they judge have no realistic likelihood of medical benefit to the patient." [12]

There have been numerous ethical opinions supportive of the position of offering only those treatments judged to be of likely medical benefit. The Hastings Center concluded, "if a treatment is clearly futile ... there is no obligation to provide the treatment." [13] The AMA Council on Ethical and Judicial Affairs holds that CPR may be withheld, even if requested by the patient, "when efforts to resuscitate a patient are judged by the treating physician to be futile." [14] Blackhall stated that in cases of low likelihood of successful resuscitation, "the issue of patient autonomy is irrelevant." [15] Tomlinson and Brody stated that "physicians have no obligation to provide, and patients and families have no right to demand, medical treatment that is of no demonstrable benefit." [16] Hackler and Hiller believe that "respect for patient autonomy does not require that the physician initiate decisions of medically pointless procedures." [17] Schneiderman and colleagues wrote that "futility is a professional judgement that takes precedence over patient autonomy and permits physicians to withhold or withdraw care deemed to be inappropriate without subjecting such a decision to patient approval." [6] Jecker and Schneiderman also stated that physicians have no ordinary ethical obligation to offer futile interventions. [18] Paris and Reardon wrote that "physicians as moral agents should exercise professional judgment in assessing patient requests. If the request goes beyond well-established criteria of reasonableness, the physician ought not feel obliged to provide it." [19]

Ultimately, the decision regarding CPR, its likelihood of benefit to the patient, and decisions to provide, limit, or withhold resuscitative efforts are to be made by the emergency physician in the context of well-established research results, patient and family wishes, and professional judgment. Individual bias regarding quality of life

or other related issues should be avoided. There are many cases where dying should be accepted as a natural process, even in an emergency setting. Perhaps palliative care, communication, and counseling with the patient, family, and friends may be of greater benefit then technology of unlikely benefit.

ADVANCE DIRECTIVES

The *living wil*, which was adopted by many states in 1990. The treating physician abides by the providions when an ill individual can no longer make competent decisions regarding their medical care. Many living wills are created to ensure that no high-technology life support be used in cases where meaningful recovery will not occur. *Durable power of attorney* specifies a surrogate decision maker in the event the patient no longer has the capacity to make medical decisions. An *advance directive* refers to any document stating the patient's wishes in various situations, should the patient be unable to state them in an actual clinical encounter. In 1991, the Federal Patient Self-Determination Act mandated the opportunity to sign an advance directive, for all patients admitted to a hospital. In many cases, the existence of an advance directive can facilitate the implementation of the patient's specific wishes. However, there still exist numerous problems with the widespread implementation of advance directives in the emergency setting, including the fact that very few patients compose them, the designated decision maker may be unavailable, or the advance directive may not reflect a changed opinion. State law often limits advance directives, and patients may lack understanding of decisions and ramifications of the advance directive. Even when an advance directive exists, compliance may be variable, dependent on the clinical circumstances. [20] When an advance directive exists, but is unavailable, the emergency physician must make a decision regarding the reliability of the information available and make every attempt to offer treatment congruent with the patient's previously stated wishes. In the absence of an advance directive, a surrogate may be consulted to aid in the determination of the most appropriate course of action. Decision-making authorities may be a court-appointed guardian, patient-designated decision maker, spouse, adult child (or majority of children available), parents, or the nearest living relative.

PROCEDURES ON RECENTLY DECEASED PATIENTS

The practices of teaching and performing procedures on recently deceased patients are controversial. The most important benefit of these practices is the fulfillment of the recognized need for hands-on practice for students and housestaff, as well as experienced physicians. [21] The setting of the recently deceased patient provides a unique clinical setting with literally *no* tangible risk to the patient. Following this rationale, physicians so inclined are able to perform these procedures competently on future, living patients, resulting in overall benefit to society. However, informed consent is rarely obtained or available in these settings. Some consider performing procedures without informed consent to be disrespectful, deceptive, or unethical. [22]

Until formal policies are developed by governing organizations in emergency medicine, emergency physicians must make the choices they judge most appropriate in the specific clinical situations encountered. Factors to be considered, when making such decisions, include the teaching benefit, to the student and his/her future patients, the overall benefit to society, invasiveness and disfigurement produced by the procedure(s), availability of the family and feasibility of informed consent, potential distress to the family, other potential avenues for teaching procedures, and any institutional policies on this issue.

RESUSCITATION RESEARCH

Research on resuscitation techniques and pharmaceuticals has been problematic, due to the frequent inability to obtain informed consent and the constraints of the decision-making process. Ordinarily, the process of obtaining informed consent for human subject research is designed to assure protection and autonomy of the subject. However, the process of obtaining informed consent is time consuming and requires competence of the subject. Because of these difficulties, the Food and Drug Administration recently issued guidelines under which resuscitation research may be performed, with a waiver of informed consent, under certain conditions. [23] When designing such research protocols, factors to be considered include the patient's wishes (if known), expected safety of the study protocol, expected benefit of the therapeutic intervention, overall expected benefit to society by improved knowledge regarding resuscitation, related animal data, feasibility of surrogate consent, local Institutional Review Board opinion, and local general public opinion, if available.

COMMUNICATION AND COUNSELING FOR SURVIVORS

In many cases, the communication, care, and counseling provided for survivors (family, friends, and the like) of victims of cardiac arrest will have more impact than the actual resuscitative efforts. A majority of emergency physicians find the notification of death to survivors emotionally difficult. [24] Optimum care should be provided for families and friends of victims of cardiac arrest, regardless of the level of treatment rendered and outcome. Some general guidelines for such support might include the following: [25,26]

1. Give advance warning, if possible. During the resuscitative efforts, a member of the health care team should communicate the gravity of the patient's condition.
2. Provide a private, quiet location for communications.
3. Spend adequate time in counseling and in answering questions.
4. Use clear and succinct language. Often medical jargon is not accurately understood. It is generally appropriate to use straightforward language, such as "died" and "death," rather than "didn't make it," "passed on," and the like.
5. Use proper names of the deceased and family members.
6. Accept any reaction as normal. Even unexpected reactions, such as apathy, anger, and hysteria may not be inappropriate.
7. Don't hesitate to show emotion. Families may benefit from sharing emotions.
8. Reassure loved ones that the patient likely did not suffer.
9. Attempt to absolve any guilt feelings. It is generally inappropriate to suggest that a different course of action (calling 911 sooner, different actions by prehospital personnel, and so on) may have changed the outcome.
10. When appropriate, discuss organ donation. Many families find organ donation a positive experience.
11. Allow the family to view the body. This may provide some closure and aid in their acceptance of the death.
12. Utilize additional resources when appropriate. These may include social work, nursing, psychiatry, clergy, or other ancillary and support staff.
13. Invite further questioning. The emergency physician may serve as an important resource for future concerns or questions that may arise.

Recently, some facilities have allowed family members to be present during the resuscitative phase of a dying child or adult. The practice is growing but remains controversial.

14 NONINVASIVE AIRWAY MANAGEMENT

A. Michael Roman

The principal goal of this chapter is to familiarize the physician with upper airway control by presenting alternatives to tracheal intubation. Reviewed is a brief anatomic and pathophysiologic description of the upper airway, the (oral, nasal) airway management, bag-valve mask, esophageal airway devices, and noninvasive pressure support ventilation techniques.

ANATOMY AND PATHOPHYSIOLOGY

Prior to airway management procedures, when there is sufficient time, the physician should:

1. Inspect the patient's mouth for size of teeth and size and mobility of the jaw.
2. Open the patient's mouth and observe the palate, tongue, and oropharynx.
3. Flex the stable neck (in the absence of trauma), and assess mobility, and place in the sniffing position.
4. Examine the size and alignment of the neck.
5. Inspect the nasal openings for patency.
6. Ask the patient's history, if possible.
7. Listen for abnormal airway sounds like stridor, hoarseness, or gurgling.
8. Be sure to have suction available at all times, especially during any procedures.

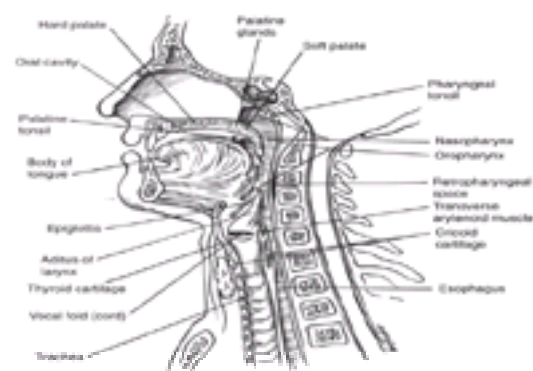
The anatomic airway (Fig. 14-1) begins at the oral/nasal cavities and continues posteriorly to the tongue/turbinates; the tonsils/adenoids; past the palate; through the oropharynx; across the epiglottis, which protects the glottis (the narrowest portion of the airway); past the false and true vocal cords; and into the larynx. Surrounding the larynx is the thyroid cartilage, cricoid cartilage, and thyroid gland. The upper airway ends here; the lower airway then continues to the trachea and into the lungs. Potential obstruction may develop anywhere along this route. In infants and small children, the anatomy is somewhat different than in the adult. The tongue is relatively larger in relation to the mandible. The glottis is higher and more anterior and the vocal cords are angled more anteriorly and inferiorly. The epiglottis is large and floppy and may lie against the posterior wall of the pharynx.


FIG. 14-1. The anatomic airway.

AIRWAY OBSTRUCTION

Potential causes of upper airway obstruction are shown in Table 14-1. Basic management of the obstructed airway is discussed in Chap. 8. Most of these entities cause soft tissue swelling or themselves are soft tissue masses that compromise the upper airway, but a few need mentioning. Certain medical diseases like respiratory syncytial virus (RSV) and cystic fibrosis produce copious secretions in the upper airway that can lead to partial or complete occlusion. Angioedema may present with soft tissue swelling sufficient to preclude an oral airway, requiring a nasal pharyngeal airway, nasotracheal intubation, or surgical intervention to reestablish patency. Laryngospasm, the feared complication of any invasive airway technique, needs to be considered in any patient with a compromised airway, especially in children. It is defined as closure of the glottis by the constriction of intrinsic/extrinsic laryngeal muscles, which can completely restrict ventilation. This pathophysiologic state often persists long after the stimulus has ceased. Laryngospasm may occur secondary to contact with the upper airway receptors on the tongue, palate, and oropharynx. Light touch to the upper airway, anal stretch, traction on the pelvic/abdominal viscera, chemical irritation, secretions, blood, water, and vomitus may all cause laryngospasm. Hypoxia and hypercapnea depress the activity of laryngeal adductor neurons, so laryngospasm is somewhat self-limited. Laryngospasm and bronchospasm occur more frequently in children and particularly following a recent respiratory tract infection.

Congenital/ Genetic	Infectious	Medical	Trauma/ Tumor
Large tonsils	Tonsillitis	Cystic fibrosis	Laryngeal trauma
Macroglossia	Peritonsillar abscess	Angioedema	Hematoma/ masses
Micrognathia	Retropharyngeal abscess	Laryngospasm	Smoke inhalation
Neck masses	Pretracheal abscess	Airway muscle relaxation	Thermal injuries
Large adenoids	Epiglottitis	Inflammatory	Foreign body
	Laryngitis/RSV*	Asthma	
	Ludwig angina		

*Respiratory syncytial virus.

TABLE 14-1   Causes of Upper Airway Obstruction

Altered mental status, somnolence, or even sleep can depress the intrinsic and extrinsic muscle tone of the airway and produce obstruction. Some authors question the long-standing belief that the tongue falling back and occluding the lower pharynx is the major cause of airway obstruction in the somnolent or comatose patient. In a supine individual, the degree of extension of the head required to open the airway depends on elevation of the occiput above the horizontal plane. Relative to the neck, the more the occiput is elevated, the less extension is required to open the airway, which explains why patients with airway compromise need to have their heads in the "sniffing" position. One can place a folded towel or foam rubber device behind the patient's occiput (not neck) to create this position. Flexion of the neck has a marked effect of closing the airway, specifically the oropharynx. Recently, it has been shown that during anesthesia in the supine patient, the tongue does in fact displace posteriorly, but it does not appear to occlude the pharynx. Upper airway obstruction in the unconscious patient occurs primarily because the epiglottis occludes the laryngeal inlet due to intrinsic muscle relaxation, which can be relieved simply by extending the neck. Extension of the neck and anterior displacement of the mandible moves the hyoid bone anteriorly and, in turn, lifts the epiglottis away from the laryngeal inlet. Recent magnetic resonance imaging (MRI) studies show that the soft palate also relaxes significantly during sedation, partially occluding the nasopharynx and causing complete obstruction when the patient is fully anesthetized. Moreover, retraction of the anterior tongue does not appear to relieve this obstruction. [1]

Esophageal foreign bodies can also obstruct the airway. They can impinge upon the larynx or trachea, causing either acute or subacute obstruction. Some foreign bodies, such as large fruit pits, may have been present for some time; thus there may not be a history of swallowing an object.

ORAL/NASAL AIRWAYS

The oral airway (Fig. 14-2) is an "S"-shaped, rigid instrument used to prevent the base of the tongue from occluding the hypopharynx. It should be used to maintain the airway only in a patient with an absent gag reflex. It can also be used as a bite block during orotracheal intubation. The operator places the oral airway over the tongue, being careful not to push it further into the hypopharynx. A tongue blade can be used to aid insertion. The concave portion is placed cephalad, rotated 180°, or aimed toward the ear and rotated 90° inferiorly to hold the tongue away from the pharyngeal wall.

FIG. 14-2. An oral airway.

A nasal airway (nasopharyngeal tube) (Fig. 14-3) is made of a pliable (latex) material that allows it to be placed into the nostril of a somnolent patient with an intact gag reflex. The nasal airway is a wonderful tool that can be quickly placed in a sonorous patient who may have decreased pharyngeal muscle tone and an obstructing soft palate and tongue. It allows air to bypass such obstructions, and if topical anesthesia was used as a lubricant, may ease subsequent passage of a nasogastric tube. The nasopharyngeal tube should be inserted into the most patent nostril (with the tip lubricated, ideally with a topical anesthetic such as lidocaine jelly) horizontal to the palate, and advanced until maximal airflow is heard. It is important to use the correct size tube and to avoid inserting it far enough to stimulate the gag reflex.

FIG. 14-3. Nasal airways.

THE BAG-VALVE-MASK UNIT

The bag-valve-mask (BVM) unit (Fig. 14-4) is a self-inflating bag with a nonrebreathing valve that can be attached to a face mask. This design allows room air or oxygenated air to be manually delivered into the victim's lungs after any obstruction has been eliminated. This apparatus can be used initially while preparing for definitive airway maintenance. After the mask is placed, the handler clamps it snugly to the face. The thumb and index finger grasp the mask while the other fingers grasp the chin and pull it forward to hyperextend the stable neck. The other hand compresses the bag, expelling air into the patient's respiratory tree. This procedure can be used to manage respiratory failure temporarily, to assist poor inspiratory effort, or to temporize respiratory fatigue. The most common problem with a one-person operation is air leaks around the mask. A two-person operation employs two hands to hold the mask flush and has been shown to result in more effective ventilation.[2] After an intubation, the BVM unit can be attached to the proximal end of the endotracheal tube. Placement of an oral or nasal airway further facilitates airflow. The BVM unit may also be used prior to rapid-sequence intubation (RSI) to quickly assess the ease of BVM ventilation in cases where oral intubation fails.

FIG. 14-4. Bag-valve-mask unit.

To deliver 100% oxygen, there must be a reservoir with the same volume as the bag and an oxygen flow rate equal to the respiratory minute volume of the patient. By using a 2.5-L reservoir bag with an oxygen flow of 15 L/min, 100% oxygen can be delivered. Similarly, a demand valve attached to the reservoir port of the ventilation bag will deliver a high concentration of oxygen.

ESOPHAGEAL AIRWAYS

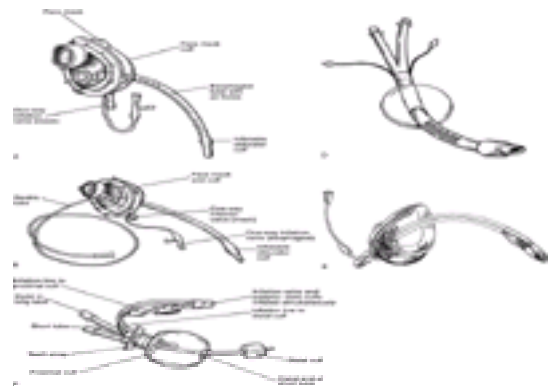
Esophageal obturator airways (EOAs) (Fig. 14-5)—the pharyngotracheal lumen airway, and the esophageal tracheal Combitube—are all devices used in the prehospital setting when oral endotracheal intubation is not a viable option. These devices are designed to be placed in apneic, unconscious adults only.


FIG. 14-5. *A.* Esophageal obturator airway. *B.* Esophageal gastric tube airway. *C.* Pharyngotracheal lumen airway. *D.* Esophageal tracheal Combitube. *E.* Tracheoesophageal airway. (Used with permission.)

Esophageal Obturator Airway/Esophageal Gastric Tube Airway (EOA/EGTA)

The EOA, a 34-cm tube (Fig. 14-5*A*), is placed by flexing the neck and blindly inserting the device into the esophagus. The closed-tube distal cuff is inflated and the more proximal holes allow pressurized air to enter the hypopharyngeal area for ventilation. The EOA has a proximal face mask that requires a good seal to ensure adequate ventilation. The primary benefit is placement without direct laryngeal visualization. The secondary benefits are prevention of gastric distention, regurgitation, and aspiration. The esophageal gastric tube airway (EGTA) (Fig. 14-5*B*), a modification of the EOA, has an open distal tube containing a valve that allows passage of a nasogastric tube.

Once placed, the EOA is left alone until definitive oral endotracheal intubation is performed, at which point the EOA tube is pulled. EOAs have been shown to be more effective in oxygenation than mask ventilation, but the potential complications are the main reason this tool is used only when endotracheal intubation is not an option. Inadvertent tracheal intubation occurs in approximately 4 to 10 percent of cases. Esophageal injury, including laceration, occurs in up to 10 percent and perforation in approximately 2 percent. Related mortality is 10 to 15 percent. Other considerations include the possibility of vomitus with aspiration and difficulty in maintaining a good seal with the face mask.

Since airway management in the prehospital setting is now more sophisticated in most jurisdictions than it was in the past, the use of EOAs has become quite uncommon. One study showed that some physicians had never seen an EOA, and unfamiliarity is reason enough to avoid using this tool.

Pharyngotracheal Lumen Airway

The pharyngotracheal lumen airway (PTLA) (Fig. 14-5*C*) is another two-tubed, cuffed airway that seals the oropharynx proximally and allows ventilation below the cuff. If the trachea is intubated, no complication arises because the open lumen allows ventilation to occur. This design was the first to offer an esophageal airway without the need for a face-to-mask seal.

Esophageal Tracheal Combitube

The esophageal tracheal Combitube (ETC) (Sheridan Catheter Corp.) (Fig. 14-5*D*) is a plastic twin-lumen tube with a proximal low-pressure cuff that seals the pharyngeal area and a distal cuff that seals the esophagus, allowing ventilation between the cuffs. The proximal seal also removes the need for a facemask and, as compared with the PTLA, minimizes dental damage to the cuff. The distal cuff is similar to an ETT and serves to seal either the esophagus or the trachea when inflated. If the distal tube enters the esophagus, perforations in the esophageal lumen serve to ventilate the patient. If the trachea is intubated, the patient is ventilated directly, as with the cuffed ETT.

Studies show that by comparison to the simple oral airway, the EOAs are superior in preventing regurgitation and thus aspiration. Compared with the ETT, ventilation and oxygenation studies reveal varying results but suggest that the EOAs are adequate during cardiac arrest. [3] However, the method of choice for airway management for both hospital and prehospital therapy remains direct oral endotracheal intubation.

Tracheoesophageal Airway

Another modification of the EOA is the tracheoesophageal airway (TEA) (Fig. 14-5*E*). It has a standard endotracheal tube (ETT) with two openings, one for the ETT and the other for oropharyngeal ventilation. It is designed to function equally well if inserted into the trachea or the esophagus. Tracheal intubation is facilitated by using cricoid pressure and extending the neck. While the tube is in the trachea, the cuff is inflated and the patient is ventilated normally. While the tube is in the esophagus, the patient is ventilated through the mask and the ETT allows for gastric venting or decompression.

Laryngeal Mask Airway

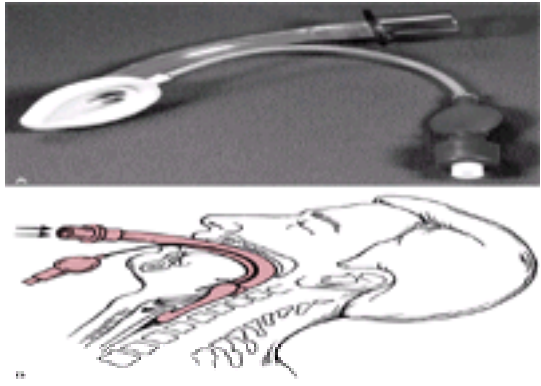
The laryngeal mask airway (LMA) (Intavent, Ltd.) (Fig. 14-6) was developed by Brain in 1983 as another artificial airway that can be placed blindly yet can provide a positive-pressure airway. The LMA consists of a tubular oropharyngeal airway similar to the ETT, but it is shorter and has a distal silicone laryngeal mask (balloon-type bulb) that inflates and provides a seal around the larynx. The LMA, when placed, is similar to other esophageal airways in that it can be inserted without manipulation of the patient's head. Because of its large diameter and short length, intubation of the bronchi or esophagus is circumvented. The hypopharynx, which is adapted to the passage of food, is less sensitive to a foreign body than the larynx and vocal cords, which have sensitive, protective reflexes. Many published cases show the LMA to be an effective alternative when the ETT fails because of nonvisualization of the cords secondary to ETT difficulty, airway masses, or cervical pathology.[4] Studies of LMA use by nonphysician emergency personnel in fasting patients found it easier to place than the ETT. The LMA never failed, versus 21 percent of failures for the ETT, required only half as many attempts and one-fifth the time to perform, and was rated equal to the ETT as an airway by anesthesiologists.[5] Some of the complications included partial or complete respiratory obstruction (3 percent). In general, failure to protect against aspiration of gastric contents was noted. The LMA was also inadequate in severe chronic obstructive pulmonary disease (COPD) because of the high pressure requirement.[6] Applying cricoid pressure in the acute setting almost always impedes insertion of the LMA and therefore reduces the chance of successful ventilation of the patient.[7] Therefore the LMA seems an effective alternative to the ETT when endotracheal intubation fails or when cervical pathology exists.


FIG. 14-6. *A.* Laryngeal mask airway (LMA). *B.* LMA diagram showing placement at the larynx. (Used with permission.)

NONINVASIVE POSITIVE-PRESSURE VENTILATION

The widespread use of noninvasive positive-pressure ventilation (NIPPV) for chronic sleep apnea in the 1980s has prompted investigators to look at NIPPV in the acute setting today. NIPPV can be described as an application of a preset volume/pressure of inspiratory air through a face or nasal mask.

Inspiratory muscle fatigue is the final phase of ventilatory failure in patients with severe reactive airway disease, COPD, and end-state pulmonary edema/pneumonia. The airway resistance overcomes the patient's muscular ability to ventilate. Another noninvasive technique used as an effective alternative to the traditional ETT, with its potential complications, is noninvasive, mechanically assisted ventilation with continuous positive pressure (CPAP) or bilevel positive pressure (Bi-PAP). CPAP applied through a face or nasal mask has recently received renewed application in the treatment of patients with *acute* hypoxemic respiratory failure.[8] NIPPV has been used to support patients with acute respiratory failure but has been primarily studied in the intensive care setting. Patient diagnostic categories individually studied in the emergency department (ED) include those with COPD, status asthmaticus, adult respiratory distress syndrome (ARDS), those who have been intubated, and those with pulmonary edema, pneumonia, or traumatic respiratory insufficiency. In early published and unpublished studies, CPAP used in the hospital and prehospital settings showed potential improvement of vital signs (heart rate, respiratory rate, and blood pressure) and oxygen saturation. In the pediatric patient population, BiPAP appears to improve respiratory rate, heart rate, Pa_{CO_2}, and O_2 saturation; it also decreases the need for intubation in obstructive apnea. The use of face-mask positive-pressure ventilation with acute exacerbation of COPD has been shown to avoid intubation up to 76 percent of the time.[9] It has been proven to decrease the requirement for mechanical support and to lower the average stay in the intensive care unit.[10] The patients studied all had impending respiratory failure but were hemodynamically stable. Studies showed arterial blood gas improvement (85 percent), intubation avoidance (72 to 76 percent), decreased respiratory rates (31 percent), with low complication risk.[8,11] In the elderly, where the decision to intubate is more complex (because of age, illness, or cancer), nasal-mask ventilation yielded improvements in Pa_{O_2} similar to those of other studies (60 percent), but hypercarbia improved more slowly.[12]

Trauma patients frequently have a significant loss of functional residual capacity (FRC) that often leads to mild to moderate respiratory insufficiency. In such instances, CPAP has been used to improve respiratory function and reduce hypoxemia.[13] CPAP is helpful in decreasing the work of breathing and improving FRC, thus preventing hypoxemia, hypocarbia, and tachypnea. Criteria for NIPPV have included spontaneous respirations, absence of respiratory acidemia/hypercarbia, intact mental status, a Pa_{O_2} above 65 torr, presence of a functioning nasogastric tube, and absence of severe maxillofacial injury. Improvement may be seen starting at 5 cm of H_2O. Studies have shown a mean CPAP of 8.6 cmH_2O meets therapeutic goals. Duration of therapy may range from a few hours to 2 days. Trauma conditions that have been studied include pulmonary contusion, flail chest, pneumothorax, hemopneumothorax, and multiple chest and abdominal gunshot/stab wounds. In this setting, a functioning nasogastric tube and respective chest tube placement, when indicated, are extremely important. Patients suffering high esophageal or tracheal injuries should not be supported with a CPAP mask. Maxillofacial and basilar skull fractures are also contraindications to CPAP ventilation by face mask. Since many traumatized patients exhibit a remarkable capacity to breathe spontaneously and improvements in hemodynamics have been shown to be one of the benefits of using spontaneous ventilation versus mechanical ventilation, CPAP is an appropriate adjunct for managing the airway in the trauma patient.

Technique

Nasal-mask or facial-mask ventilation employs a tight-fitting mask that allows for a CPAP or BiPAP support system. The patient with impending respiratory failure receives either continuous pressure or inspiratory/expiratory (bilevel) support, thus allowing a decrease in inspiratory effort, rest for respiratory and accessory muscles, improvement of gas exchange, avoidance of intubation, and improved comfort.[9,14] A nasal-mask protocol with BiPAP appears to be the most advanced protocol and appears to allow more sensitive changes during the course of treatment (Fig. 14-7). The nasal mask allows the patient to eat, drink, and converse with the emergency staff. However, the nasal positive-pressure ventilation (NPPV) does allow for air leaks through the mouth.

FIG. 14-7. A patient with severe COPD on nasal BiPAP. (Used with permission.)

The ventilatory support system frequently preferred is the BiPAP ventilator (Respironics, Murraysville, PA). It is small, relatively inexpensive, very mobile, and tolerates leaks better than other systems. It is possible to set the inspiratory positive airway pressure (IPAP) and the expiratory positive airway pressure (EPAP/PEEP) independently. Three modes of ventilatory triggering are available: spontaneous, combined spontaneous/timed, and timed. The proper-size mask should be chosen (allowing no mouth coverage) and tight enough to allow a good, comfortable seal. Settings should include spontaneous mode, IPAP set at 10, EPAP set at 3 cmH$_2$O initially and increasing IPAP by 3-cm increments and EPAP slowly. Continuing hypercarbic failure is treated by increasing IPAP alone by 3-cm increments.[15]

Complications

Some of the complications described include difficulty with mask seal requiring multiple readjustments, gastric distention, aspiration (rare), intolerance of the positive pressure, and facial skin breakdown (with long-term use). These complications appear to occur infrequently, but the most common intolerance was excessive respiratory secretions, which, in fact, may be a relative contraindication to NPPV. Other contraindications to NPPV are severe maxillofacial trauma and potential basilar skull fracture where pneumocephalus may occur. Another problem with *mask* ventilation is that using a conventional ventilator can be difficult or even counterproductive because of the inadvertent triggering of alarms in systems that are not designed for this use. The BiPAP ventilatory system, which has been used with success, may not be readily available in the ED, and respiratory services may have to be contacted for this setup.

Application of NPPV provides ventilatory support for impending respiratory failure and has been shown to decrease the workload of the respiratory muscles. Oxygen saturation, Pa_{CO_2}, and pH remain stable or improve as compared with unassisted ventilation. Therefore this technique may prove useful in respiratory failure when intubation is questionable. Facial/nasal-mask–assisted ventilation is a simple, noninvasive method that has few complications, and is shown to be well tolerated over

long periods of time. It also decreases negative intrathoracic pressure but needs to be studied more fully for situations where suppression of inspiratory effort is desired, as in flail chest.

This modality may decrease long-term hospital admissions, prevent unwanted intubations in the elderly or severely ill, and circumvent borderline respiratory failure intubations. Each patient must be closely monitored for tolerance of upper airway positive pressure. Multiple mask/ventilator adjustments may be required. Finally, any instability in ventilation or oxygenation requires close monitoring in case a more invasive intervention is required.

Patients who receive NIPPV need to be cooperative and should not have life-threatening cardiac ischemia, dysrhythmias, or hypotension. NIPPV is inappropriate in patients who have absent respiratory effort, who are agonal, or who produce excessive airway secretions. Airway management and apparatus associated with NIPPV can be distracting. However, medical treatment, such as in-line nebulized updrafts, anticholinergics, steroids, and respiratory hygiene must proceed as appropriate simultaneous with NIPPV.

15 TRACHEAL INTUBATION AND MECHANICAL VENTILATION

Daniel F. Danzl

Airway integrity, assurance of oxygenation, ventilation, and prevention of aspiration are the mainstays of emergency airway management. The indications for tracheal intubation in the emergency setting most commonly include correction of hypoxia or hypercarbia, prevention of impending hypoventilation, and assuring maintenance of a patent airway. Secondary indications include provision of a route for resuscitative medication administration and to permit temporizing paralysis during diagnostic testing. This chapter reviews tracheal intubation techniques to establish an airway and ventilate a patient after basic maneuvers have been utilized.

OROTRACHEAL INTUBATION

The most reliable means to ensure a patent airway, provide oxygenation and ventilation, and prevent aspiration is endotracheal intubation. Many unconscious and even conscious patients may be unable to spontaneously clear the airway of secretions, may require mechanical ventilation, may have aspirated, or may lack protective airway reflexes.

The clinical assessment of oxygenation and ventilation is often unreliable in a chaotic ED. Continuous noninvasive bedside monitoring of arterial oxygen saturation by oximetry is helpful. Isolated oximetry, however, does not assess the status of alveolar ventilation. Capnography does allow estimation of the Pa_{CO_2} based on the waveform display of the end-tidal Pa_{CO_2}. *Capnometry* refers to the numerical display. In combination, both of these noninvasive modalities affect decisions regarding tracheal intubation.

One should take the time to evaluate the upper airway anatomy. Examination of the teeth, size of the oral cavity, thyromental distance, mobility and posterior depth of the mandible, and neck mobility may point to a difficult airway. The normal adult mouth opening measures three finger breadths. The alert, sober patient may be asked to open the mouth as widely as possible and point the tongue in the examiner's direction. The ease of laryngoscopy correlates well with the examiner's ability to visualize the soft palate, uvula, and faucial pillars (see " Difficult Airway," below).

While calling for an assistant, check and arrange the necessary equipment. The appropriate-size tube and an additional tube (0.5 to 1 mm in size smaller) should be selected and the cuff checked for air leaks with a 10-mL syringe. Selecting a tube of the proper diameter is essential (Table 15-1). The second hole at the end of the tube above the bevel is called Murphy's eye. This permits some uninterrupted airflow if the tip is occluded.

Patient	Endotracheal Tube Inner Diameter, mm*	Suction Catheter Size (French) Outer Diameter
Adult Female	7.5-8.0	12-14
Adult Male	8.0-8.5	14

*Tubes of 0.5 to 1 mm smaller inner diameter are used for nasotracheal intubation.

TABLE 15-1   Approximate Adult Sizes for Endotracheal Tubes and Suction Catheters

Endotracheal tubes (ET) tubes with high-volume, low-pressure cuffs are the best design for adults. When properly inflated, thin-walled cuffs prevent aspiration better than medium-walled cuffs. The operator should test the light on the laryngoscope and then pick an appropriate sized blade. The straight Magill blade physically lifts the epiglottis. The curved Macintosh blade rests in the vallecula above the epiglottis and indirectly lifts the epiglottis off the larynx owing to the traction on the frenulum.

The development of expertise with both blades is desirable, since they offer differing advantages, depending on the clinical setting and the patient's body habitus. The curved blade may cause less trauma and be less likely to stimulate an airway reflex since it does not directly touch the larynx. It also allows more room for adequate visualization during tube placement and is helpful in the obese patient. The straight blade is mechanically easier to insert in many patients who do not have large central incisors. Simply point the tip of the blade directly at the epiglottis and aim for it. Selecting the proper-size blade greatly facilitates intubation. In adults, the curved Macintosh no. 3 is the most popular, or no. 4 for large patients. The straight Miller no. 2 or 3 is similarly most often ideal.

When all equipment is in order, the patient should be placed in the sniffing position. Flexion of the lower neck with extension at the atlantooccipital joint (sniffing position) aligns the oropharyngeolaryngeal axis, allowing a direct view of the larynx. Placing a folded towel or small pillow under the occiput is often helpful (Fig. 15-1). The inexperienced laryngoscopist's most common reasons for failure—inadequate equipment preparation and poor patient positioning—arise prior to the use of the laryngoscope.
FIG. 15-1. *A.* Oral pharyngeal laryngeal axes. *B.* Sniffing position.

The patient should be thoroughly preoxygenated prior to intubation if time permits. Begin with the laryngoscope in the left hand and an ET tube or suction apparatus in the right hand. After dentures and any obscuring blood, secretions, or vomitus are removed, the suction is exchanged for the ET tube and inserted during the same laryngoscopy.

The blade is inserted into the right corner of the patient's mouth. If a curved Macintosh blade is used, the flange will push the tongue toward the left side of the oropharynx. If the blade is inserted directly down the middle, the tongue can force the line of sight posteriorly—which is a common reason for the putative "anterior larynx." After visualization of the arytenoids, lift the epiglottis directly with the straight blade or indirectly with the curved blade. The larynx is exposed by pulling the handle in the direction that it points, that is, 90° to the blade. Cocking the handle back, especially with the straight blade, risks fracturing central incisors and is ineffective at revealing the cords.

There are a variety of other straight and curved blades available. To mention a few, the Guedel blade is a straight blade with an acute 72° angle to the handle. The Schapira straight blade has a side concavity that helps cradle the large tongue and push it toward the left side of the mouth. The CLM curved laryngoscope blade has a hinged tip. This permits elevation of the epiglottis with minimal force, since the fulcrum is repositioned down within the pharynx.

One technique to avoid the most common error, overly deep insertion of the blade, is to look for the arytenoid cartilages. If only the posterior commissure is visible, have an assistant apply more pressure on the cricoid (Sellick maneuver) or perform the laryngeal lift. Another option is the "BURP" technique. [1] The larynx is manually displaced posteriorly (backward) against the cervical vertebrae, superiorly (upward), and laterally to the right (rightward pressure). To avoid error, the cuff must be seen passing completely through the cords. Last-ditch attempts at blind passage will only invite anoxia. The intubator should never be reluctant to abort the attempt if visualization of the larynx is not successful. Whenever feasible, have an assistant apply steady cricoid pressure with the thumb and index finger during the intubation to help prevent aspiration.

With proper technique and practice, semirigid, malleable, blunt-tipped metal or plastic stylets are not usually necessary for most patients. Should the patient's anatomy call for them, a selection of proper-sized stylets must be available. The tip of the stylet should not extend beyond the end of the ET tube or exit Murphy's eye.

One aid to intubation with direct vision is the use of a thin, flexible intubation stylet. This type of stylet can be inserted blindly around the epiglottis into the trachea. The ET tube is then threaded over it into the trachea and the stylet is removed. The Eschmann tracheal tube introducer or stylet, also known as the "gum elastic bougie," is a valuable aid for difficult oral intubations. Another option is to use the tip on the laryngeal tracheal anesthesia kit. With either stylet, orient the tube so that Murphy's eye is at 12 o'clock.

The tube should never be forced through the vocal cords. Forced insertion can result in avulsion of the arytenoid cartilages or laceration of the vocal cords. Usually, any difficulty in passing the tube is a result of either the tube being too large or too soft and flexible. Directed transoral or translaryngeal anesthesia with lidocaine can help relax the cords. If this fails, sometimes lining up the bevel with the glottic opening will also be successful.

The tube should be advanced until the cuff disappears below the cords. Correct tube placement is about 2 cm above the carina. From the corner of the mouth, this is approximately 23 cm in men and 21 cm in women. The base of the pilot tube is usually at teeth level. The tube is also positioned by palpating its tip at the suprasternal notch and advancing it 2 to 3 cm. To avoid ischemia of the tracheal mucosa, keep the cuff pressure below 40 cmH$_2$O. The minimal intracuff pressure to prevent aspiration is 25 cmH$_2$O.[2]

After cuff inflation, auscultate to verify bilateral lung expansion and if satisfied insert an oropharyngeal airway or bite block. Some advocate first listening over the stomach, since the early detection of errant esophageal intubation is desirable to minimize insufflation of the stomach with subsequent regurgitation. Inadvertent endobronchial intubation is usually on the right side. The operator should secure the tube, being careful not to impede cervical venous return with the umbilical tape or fixator. The use of a modified clove-hitch knot or a commercial fixator is ideal and also helps avoid kinking the pilot tube. Ventilation should be initiated using 100% oxygen with a tidal volume of 10 to 15 mL/kg at a rate of 10 to 15 breaths per minute.

Confirmation and Complications of Intubation

Endobronchial or esophageal intubation will result in hypoxia or hypercarbia. There is no clinically reliable substitute for direct visualization of the tube passing through the vocal cords. Hence the adage, "when in doubt, take it out." Nevertheless, there are a number of options to help confirm intratracheal tube positioning. Clinical assessments—including chest and epigastric auscultation, tube condensation, and symmetrical chest wall expansion—are not infallible in the ED. "Breath sounds" from the stomach can be transmitted through the chest following gastric insufflation.

The two basic categories of adjuncts include end-tidal CO$_2$ detectors or monitors and esophageal detection devices (EDDs). Both have advantages provided that the operator remains cognizant of the sources of interpretation error. Capnometers are the devices that measure CO$_2$ in the expired air. The most commonly used capnometric devices used in the ED are colorimetric, with a pH-sensitive purple-colored filter paper. When in contact with CO$_2$, hydrogen ions are formed resulting in color changes depending upon the concentration of CO$_2$. For example, with the Nellcor Easy Cap II, a yellow color develops on exposure to 2 to 5% ET$_{CO_2}$, equivalent to 15 to 38 mmHg CO$_2$. There is no color change, that is the filter paper remains purple, with an ET$_{CO_2}$ of <0.5%, equivalent to <4 mmHg CO$_2$. An intermediate color results with an ET$_{CO_2}$ of 0.5% to 2%, corresponding to 4 to 15 mmHg CO$_2$. Generally these readings are accurate within +/- 3 mmHg. While capnometers are useful for general readings, as in assessing proper ETT placement, they are not accurate enough when precise determinations are necessary. Capnography is the real-time display of characteristic CO$_2$ waveforms.

The use of end-tidal CO$_2$ pressure (Pet$_{CO_2}$) monitoring can help confirm endotracheal intubation.[3] A color change to yellow indicates endotracheal placement. Colorimetric or infrared detection of Pet$_{CO_2}$, however, may not occur even with proper ETT placement, during states of low pulmonary perfusion such as during cardiac arrest, inadequate chest compressions during CPR, or massive pulmonary embolism. Other causes of false-negative interpretations include massive obesity. Severe pulmonary edema may obstruct the ET$_{CO_2}$ monitor with secretions. On the other hand, there may be an initial false-positive detection of CO$_2$ following esophageal intubation if carbonated beverages have been ingested by the patient, or for a few minutes after bolus sodium bicarbonate administration. Another cause is gastric distention resulting from bag-valve-mask ventilation. A heated humidifier or nebulizer or epinephrine instilled via the ET tube can also cause false-positive interpretations.

Correct technique is essential for accurate interpretation. After intubation and cuff inflation, attach the capnometer to the ET tube. Then attach a bag-valve-mask unit to the detector and ventilate the patient with about six ventilations to wash out residual CO$_2$. Then check for the Pet$_{CO_2}$-induced color changes. If capnography is also available, a persistent positive capnograph formation after clear and direct visualization of tube placement approaches certainty. On rare occasion, misplacement of the hypopharyngeal glottic tube tip may result in misleadingly normal oximetry and capnography. This error can be recognized by the inadequate depth of tube insertion, ventilatory volumes, or on chest x-ray.

Esophageal detection devices also offer the potential to accurately determine tube location. The various designs all depend on their proper function as in-line aspirators of the ET tube. The device adaptors fit over the 15-mm ET tube connector. One of the advantages of the EDD is that accuracy does not depend on adequate cardiac output and pulmonary perfusion. Instead, proper functioning is predicated on the anatomic differences between the esophagus and the trachea. When the ET tube is in the esophagus, the soft, noncartilagenous walls will collapse and air cannot be aspirated easily. [4]

To perform the syringe aspiration technique, attach the device after intubation but before ventilation. Then attempt to retract the syringe plunger. Resistance to aspiration reflects occlusion from esophageal collapse. If there is no resistance during aspiration, one assumes that the tube is in the trachea. If a self-inflating bulb is used, first compress the bulb and then attach it to the ET tube. One advantage of the bulb is that it requires only a single hand.

As expected, these devices are also not infallible. When the seal with the device leaks, there may be an erroneous assumption of intratracheal tube placement. In the prehospital setting, some studies report that the EDDs demonstrate poor sensitivity for esophageal intubations. On the other hand, the EDDs have a potential advantage over Petco$_2$ in cardiac arrest patients.[4]

The emergency physician should never assume that continued airway patency is assured after ET tube insertion. Repeated suctioning is necessary to prevent thrombotic or inspissated secretions from obstructing the tube. Endobronchial ball-valve obstruction can also occur with a clot. This will impair ventilation and produce hyperinflation of individual lobes.

Cuff displacement or overinflation can result in ball-valve obstruction of the airway. Cuffs inflated in the field during frigid conditions will expand with warming. Deflate the cuff when tracheal ball-valve obstruction is suspected. If the tube is blocked, deflation will allow exhalation.

There are a variety of other correctable intubation complications that should be kept in mind. If the ET tube cuff leaks after the intubation, first check for a defective inflation valve. One simple fix is to attach a three-way stopcock to the valve and reinflate the cuff. Then turn the stopcock off. If the cuff itself seems to be leaking slowly, it may be sealable. An option is to instill an aspirable mixture of normal saline and 2% lidocaine jelly into the cuff in a 3:1 ratio.

If the ET tube needs to be replaced, consider the use of a tube changer. A classic technique is to use nasogastric tubing at least three times longer than the ET tube. Standard room-temperature tubing, however, may not be a sufficiently rigid guide. There are a number of commercially available semirigid catheters that include 15-mm adaptors or connectors to permit ventilation during the tube exchange. These devices have quick-connect adapters that incorporate through-lumen designs to ensure adequate airflow during the procedure.

If the ET tube is inserted too deeply, carinal stimulation can cause bronchospasm. Unilateral pulmonary edema is also reported. The ET tube may be obstructed by a bulging cuff, secretions, kinking, or biting. The cuff may simply be overinflated. If the cuff was inflated with frigid air in the field, it may expand and compress the tube after warming.

Although uncommon, morbidity related to emergent endotracheal intubation does occur and may be quite debilitating. Arytenoid cartilage avulsion or displacement, usually on the right, prevents the patient from phonating properly. Intubation of the pyriform sinus and pharyngeal-esophageal perforation has been reported. Chordal synechiae may develop anteriorly or commissural stenosis posteriorly.

Subglottic stenosis is the most disastrous sequela. The physician should avoid cuff overinflation and attempt to minimize tube motion in the larynx and trachea. This usually occurs in patients with poorly secured tubes who are combative or on ventilators. Gastric rupture with tension pneumoperitoneum can occur after a difficult intubation.

NASOTRACHEAL INTUBATION

Nasotracheal intubation (NTI) is an essential psychomotor skill that may be useful in many difficult situations. Operators adept at both NTI and rapid-sequence intubation (RSI) are in the best position to assess and act on the following two prime considerations. What are the potential risk-benefits to having spontaneous respirations preserved versus ablated? Is there a safe alternative in this patient that may avoid precipitating the need for a potentially unnecessary surgical airway? [5]

Nasal intubation is helpful in situations where laryngoscopy or cricothyrotomy may be difficult and neuromuscular blockade hazardous. Severely dyspneic patients with congestive heart failure (CHF), chronic obstructive pulmonary disease (COPD), or asthma who are awake often cannot remain supine but do tolerate nasotracheal intubation in the sitting position. Nasotracheal tubes are better tolerated by some patients than oral tubes. There is often less intratracheal tube movement against the tracheal muscosa with head motion.

It may be impossible to align the oropharyngeolaryngeal axis in patients with arthritis, masseter spasm, temporomandibular dislocation, or recent oral surgical procedures. Patients with a peculiar body habitus may be difficult to intubate orally. Other considerations for NTI include trismus from seizures, facial trauma, infection, tetanus, or decorticate-decerebrate rigidity.

To minimize epistaxis, spray both nares with a topical vasoconstrictor anesthetic. While waiting briefly, select a cuffed ET tube 0.5 to 1 mm smaller than optimal for oral intubation. Check the integrity of the cuff and ensure snug fitting of the tube adapter. Since secretions and blood may be expelled into the air and onto the intubator's face, observe universal precautions. An option in addition to a face shield includes the use of a protective filtering adapter such as the Humid-Vent 1, which can be attached to the proximal end of the ET tube (Gibeck Respiration, Sweden).

Advance the tube, lubricated with a water-soluble (2% lidocaine or K-Y) jelly along the nasal floor on the more patent side. If the nares appear equal, initially try the right side. It helps to prevent abrasions of the Kiesselbach plexus by having the bevel face the septum. Steady, gentle pressure or slow rotation of the tube usually bypasses small obstructions. Passage of the tube is straight back toward the occiput. If the right side is not passable, try the other side before resorting to a smaller tube.

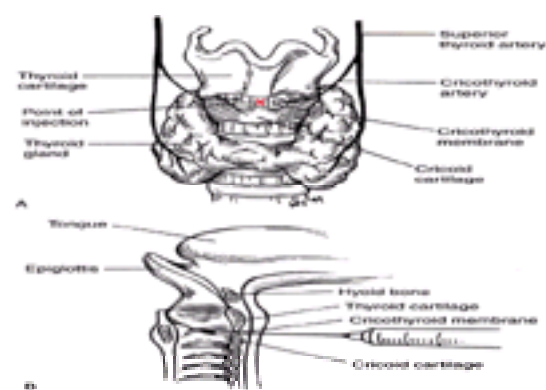
In patients with intact protective airway reflexes, directed transoral or translaryngeal anesthesia often facilitates intubation. Translaryngeal anesthesia, although not widely utilized in the ED, should be considered when the initial intubation attempt is unsuccessful. After palpating the superior border of the cricoid cartilage in the midline, puncture the cricothyroid membrane with a 22- to 25-gauge 0.5- to 1-in. needle (Fig. 15-2). The needle should be perpendicular to the membrane in the midline, with the point of injection just cephalad to the cricoid cartilage. Aspirate air, then swiftly inject 1.5 to 2.0 mL of 4% lidocaine (sterile for injection) and press the site firmly with a finger for a few seconds. This prevents small degrees of subcutaneous emphysema that would erroneously suggest a laryngeal injury.


FIG. 15-2. Translaryngeal anesthesia via cricothyroid puncture. *A.* Anatomy—anterior view. *B.* Anatomy—cross-sectional view.

The literature would suggest a complication rate of less than 0.5 per 1000 procedures. Translaryngeal anesthesia is contraindicated if the landmarks are obscured by thyroid or tumor impingement on the cricothyroid membrane and in obese or combative patients.

An assistant should immobilize the patient's head and initially maintain it in a neutral or slightly extended position ("sniffing position"). Stand to the side of the patient, with one hand on the tube and with the thumb and index finger of the other hand straddling the larynx. Advance the tube while rotating it medially 15 to 30° until you hear maximal airflow through the tube. Then gently but swiftly advance the tube. The best time for advancement is at the initiation of inspiration. Entrance into the larynx may initiate a cough, and most expired air should exit through the tube even though the cuff is uninflated. "Fogging" of the tube, while not foolproof, is usually a good sign. The presence of any vocal sounds indicates a failed attempt.

The advancement of the tube toward the carina can be observed externally. The normal distance from the external nares to the carina is 32 cm in the adult male and 27 to 28 cm in the adult female. Therefore, prior to obtaining a chest x-ray, the optimal initial depth of tube placement in NTI of adults, measured at the naris, is 28 cm in men and 26 cm in women.[6] Preformed nasal tracheal tubes are also available, with an acute angle bent at the 29-cm mark. Auscultate to verify bilateral lung expansion and cuff inflation and perform tube confirmation techniques. Secretions or blood in the tube should be removed prior to initiating positive-pressure ventilation.

If intubation is unsuccessful, carefully inspect the neck to determine malposition of the tube. Most commonly, the tube is in the pyriform fossa on the same side as the nostril used. A bulge will be seen and can be palpated laterally. Withdraw the tube into the retropharynx until breath sounds are again heard. Then redirect while manually displacing the larynx toward the bulge. If there is no contraindication, flexion and rotation of the neck to the ipsilateral side while the tube is rotated medially will often help.

The other most common tube misplacement is posteriorly in the esophagus. There will be no breath sounds through the tube, and the trachea will be slightly elevated. The intubator should attempt redirection after extending the patient's head and performing a Sellick maneuver. When cervical spine pathology is suspected, consider the use of a directional tip control tube (Endotrol) or a fiberoptic laryngoscope. Endotrol tubes smaller than 7.5 mm (ID) tend to soften and obstruct and can be difficult to suction. The use of these directional-tip tubes may improve the success rate of the first attempt at NTI. [7]

When the tube hangs up on the vocal cords, shrill, turbulent air noises will be heard. Rotate the tube slightly to realign the bevel with the cords or squirt 2 mL of 4% lidocaine (80 mg) down the tube onto the cords if transoral or translaryngeal anesthesia was omitted. There have been anecdotal reports that if NTI is unsuccessful with passage of the tube into the esophagus, leaving the original tube in place may facilitate passage of the tube using the other nostril. This technique may also afford some protection from aspiration.

Nasal intubation with a fiberoptic laryngoscope may be required when neoplastic lesions, lymphoid tissue, Ludwig angina, peritonsillar abscess, or epiglottitis obstructs the pharynx.

The presence of facial trauma does not appear to be a contraindication to NTI intubation. [8] Complex nasal and massive midfacial fractures as well as bleeding disorders are relative contraindications to NTI. Oral intubation, on the other hand, can impede prompt reduction and stabilization of some maxillary fractures. Since a LeFort I fracture does not extend to the cribriform plate, this is not a contraindication. Fiberoptic guidance or RSI is preferable for LeFort II and III fractures.

The risk of inadvertent intracranial passage of a nasotracheal tube is extremely low, unlike nasogastric tube insertion. Very poor technique in the setting of obvious massive head trauma would be required. Severe traumatic nasal or pharyngeal hemorrhage may necessitate orotracheal intubation or cricothyrotomy. Contamination of the spinal fluid is a hazard with some basilar skull fractures.

Serious complications of nasotracheal intubation are rare. In a number of large series, there was no permanent laryngeal damage. Epistaxis will occur with inadequate topical vasoconstriction, excessive tube size, poor technique, or anatomic defects. Excessive force can damage the nasal septum or turbinates.

Frequent suctioning, especially if epistaxis or other upper airway hemorrhage is present, will help to prevent thrombotic occlusion of the tube or a mainstem bronchus. Retropharyngeal lacerations, abscesses, and nasal necrosis are reported.

Paranasal sinusitis, especially occurring with prolonged nasotracheal intubation or severe cranial trauma, can be an unrecognized source of sepsis. The risk of postintubation sinusitis correlates with the duration of intubation, which often reflects the neurologic insult. In the setting of craniofacial trauma, any subsequent computed tomography (CT) scans should include views of the paranasal sinuses. Other factors causing sinusitis include presence of a nasogastric tube, sinus hemorrhage or fracture, and administration of glucocorticoids.

DIGITAL INTUBATION

Digital intubation is an underutilized noninvasive technique for ET tube insertion. The performance of this maneuver requires tactile recognition of the epiglottis. Visual landmarks may be impossible to identify with a laryngoscope because of patient positioning, anatomic disruption, or significant hemorrhage. Tactile digital intubation can avert cricothyrotomy when direct laryngoscopy has failed following neuromuscular blockade. Patients with micrognathia or temporomandibular immobility are poor candidates for the technique.

The patient must be deeply comatose, in cardiac arrest, or in a state of adequate neuromuscular blockade. Prior to insertion, shape the well-lubricated ET tube with a stylet into a J configuration. Then, unless the operator is quite confident, a bite block should be inserted in the opposite side of the mouth. Lift the tongue and pull the mandible forward with your gloved dominant hand. Then insert the lubricated middle and index fingers of the gloved nondominant hand down the middle of the tongue and palpate the cartilaginous epiglottis with the middle finger.

While palpating the epiglottis, insert the well-lubricated J-shaped tube with stylet and slide it along your middle finger. The path from the corner of the mouth opposite the bite block to the epiglottis is the shortest distance. The index finger can help guide the tube from behind. As the larynx is entered, resistance will be encountered. At this point, it is essential to partially withdraw the stylet. Otherwise, the tube will lodge against the anterior wall of the trachea and be difficult to advance. Left mainstem intubation is the unusual complication reported with this technique.

Transillumination

Transillumination with a lighted stylet can facilitate oral or nasal intubation and help to confirm ET tube placement and positioning. This technique is of particular assistance when direct laryngoscopy is anatomically impossible. Oral intubation is easiest with a semirigid stylet. Prior to insertion, transilluminate the patient's cheek. This serves as a check of the ambient light and will predict the laryngeal light intensity. It may be necessary to dim or shield bright ambient light from the neck. Obese patients who do not transilluminate buccally may not do so laryngeally.

For oral insertion, insert the lubricated ET tube with lighted stylet after pulling the tongue forward with a 4- by 4-in. gauze pad. The tube should initially be directed into the ipsilateral pyriform fossa, thus establishing the depth of the epiglottis. Then the tube is slightly withdrawn, and the tip directed toward the midline. The intubator must discriminate between the light emanating from the larynx and the much dimmer light transmitted from the esophagus. Usually the "jack-o-lantern" glow arising from the larynx or trachea is not appreciated when the light source is misplaced in the esophagus. Some manufacturers incorporate timed blinking lights that suggest when it is time for reoxygenation.

For nasal intubation, the flexible stylet or wand instrument is inserted into a directional tip ET tube (Endotrol). After positioning the tube in the retropharynx, very gentle traction is applied on the ring to achieve slight flexion of the tip of the ET tube. Standard training programs for transillumination-guided ET intubation may require didactic, video, and repeated demonstration and practice sessions. [9]

FIBEROPTIC ASSISTANCE

The flexible fiberoptic laryngoscope or bronchoscope can be a valuable adjunct when there are anatomic or traumatic limitations that prevent visualization of the vocal cords. Clinical examples include conditions that prevent opening or movement of the mandible, congenital anatomic abnormalities, and cervical spine immobility. These instruments allow visualization of laryngeal structures and can enable difficult intubations, including those around expanding hematomas (Fig. 15-3). Patients in need of an immediate airway or those with ongoing hemorrhage or copious secretions are poor candidates.

FIG. 15-3. Fiberoptic laryngoscope. An ET tube covers the shaft; suction or oxygen tubing is attached.

Directed transoral or transnasal and translaryngeal topical anesthesia is essential. The nasal mucosa should be sprayed with a vasoconstrictor. Dual suctioning capability is needed; a suction port should be attached to a suction apparatus for oral blood and secretions. Tongue extrusion and anterior mandibular displacement will be helpful if the oral route is chosen. Fragile equipment is more frequently damaged transorally. The nasal route is better also because the optic tip can enter the glottis at a less acute angle.

Begin by focusing the eyepiece and lubricating the flexible shaft. Then immerse the lens at the tip of the laryngoscope in warm water to prevent fogging. The intubator should continuously monitor pulse oximetry and assure that the gag reflex is not present. After attachment of oxygen tubing to the suction port, intermittent insufflation of oxygen at 10 to 15 L/min to keep the optic tip clear should be considered. Insufflation is usually superior to suction for clearing secretions.

Initially remove the adapter from an ET tube that is at least 7.0 mm (ID) in size. To prevent barotrauma when high-flow oxygen is insufflated, use at least a 7.5-mm (ID) tube. Then slip the lubricated ET tube over the shaft up to the handle. The distal end of the laryngoscope must extend beyond the end of the ET tube. The laryngoscope is held with your left hand, and tip deflection is controlled while advancing it through the cords. The laryngoscope will function as a stylet for the tube. After the laryngoscope is in the trachea, advance the ET tube and remove the laryngoscope.

Another option is to insert a nasotracheal tube blindly into the posterior pharynx and stop about 1 to 2 cm proximal to the epiglottis. The scope is then inserted through this hollow conduit and the fiberoptic tip can be directed into the glottis. Be careful not to pass the lubricated scope through Murphy's eye. If this occurs, it will be impossible to advance the ET tube.

The fiberoptic scope cannot be used as a stylet to guide the ET tube into the trachea. The stiffer ET tube will often deflect the thin scope tip posteriorly into the esophagus. In addition, this keeps the concavity of the ET tube anterior toward 12 o'clock and places the tube tip and Murphy's eye at 3 o'clock (90° to the right). The tip will then often hit the right arytenoid cartilage. Rotating the tube 90° counterclockwise lines up the tip with the upper triangular entrance into the trachea.

Fiberoptic ET tubes are also commercially available. Direct line of sight can improve visualization in many difficult intubations. The advantages of direct vision include verification of tube positioning, identification of the right- or left-sided source of pulmonary hemorrhage, and inspection of tracheal injury.

RETROGRADE TRACHEAL INTUBATION

Retrograde tracheal intubation (RTI) is another viable option when conventional airway approaches fail. This skill can be taught in a variety of ways, including the use of a mannequin.[10] The landmarks are the same as for cricothyroid puncture (Fig. 15-2). Severe maxillofacial trauma, cervical or mandibular ankylosis, and upper airway masses are some of the potential conditions in which RTI may help. Another advantage of RTI is that it is not impeded by the blood that obscures fiberoptically guided intubation.

The insertion of a retrograde translaryngeal catheter is a less invasive option than cricothyrotomy. This technique can be time-consuming and will not be quick enough for apneic patients. Before beginning the procedure the patient should be preoxygenated. Bag-valve-mask ventilation can continue to be performed without interrupting this technique. Then consider administering translaryngeal anesthesia via an 18-gauge needle through the caudal aspect of the membrane.

Alignment of the needle bevel with the syringe markings will help determine the bevel direction after puncture of the cricothyroid membrane. The initial angle of the needle should be 30 to 45° cephalad, and a 70- to 75-cm flexible-tip guidewire is advanced through the needle. The wire is then grasped in the oropharynx or nares with Magill forceps. Occasionally the wire will exit spontaneously.

Another option when hemorrhage is present is to insert a 75-cm CVP catheter and insufflate. To locate the tip, observe for bubbles and use forceps. J wire, which can be slowly twisted once it arrives at the oropharynx, can also be easier to locate than a straight guidewire. Most central line kits will have 60- to 80-cm wires. Use of a multilumen catheter is yet another option.

The next step is to clasp the guidewire securely with a hemostat at the neck. Then the proximal end of the guidewire is threaded through the Murphy's eye on the ET tube. This allows more of the ET tube to enter the trachea before the guidewire is removed. With both hands, tighten the wire like a tightrope and advance the tube. When the ET tube will pass no further, cut the guidewire or catheter flush with the cricothyroid membrane to minimize soft tissue contamination.

If the tube will not pass through the cords, try a 90° counterclockwise tube rotation to bring the Murphy's eye anterior; this realigns the bevel. Another technique is to insert the guidewire end that exits the mouth into the suction port of a fiberoptic scope. The scope is then inserted over the retrograde guidewire and functions as an antegrade guide.

RAPID-SEQUENCE INTUBATION

The term *induction* refers to the production of a deep level of unconsciousness. *Rapid-sequence induction* is the classic anesthesia term pertaining to the induction of anesthesia. In emergency medicine parlance, rapid sequence intubation (RSI) most commonly involves the combined administration of a sedative and a neuromuscular blocking agent to facilitate tracheal intubation (Table 15-2). This technique is a component of standard airway management in the emergency department.[11] Tracheal intubation follows laryngoscopy, while cricoid pressure is maintained to prevent aspiration. The principal contraindication is any condition preventing mask ventilation or intubation, since this may be the only way to ventilate a patient once the patient is paralyzed.

1. Set up IV × 2; cardiac monitor; oximetry, and capnography.
2. Check equipment: suction, airway devices; translaryngeal ventilation and cricothyrotomy tray.
3. Explain procedure, document neurologic status.
4. Preoxygenate (100% F_{IO_2}); no positive-pressure ventilation.
5. Consider sedation, analgesia, adjunctive lidocaine and/or atropine.
6. Defasciculation agent if necessary.
7. Induce with sedative agent.
8. Do Sellick maneuver.
9. Give neuromuscular blocking agent.
10. Intubate trachea and release Sellick maneuver.

TABLE 15-2   Rapid-Sequence Intubation

Patient care is optimized if emergency physicians are adept with all methods for managing standard and difficult airways in nonfasting patients. Otherwise, the incidence of cricothyrotomy will exceed the current 1 to 2 percent of patients when RSI is selected and fails. [12] The prime goal is to avoid placing the breathing patient in the "can't ventilate, can't intubate" predicament.

Topical laryngeal and intravenous lidocaine (1.5 mg/kg) is a useful adjunct during RSI. Lidocaine suppresses coughing, and adverse airway reflexes. The efficacy of pretreatment with intravenous lidocaine during tracheal intubation of patients with reactive airway disease is unclear. Lidocaine levels achieved through an ET tube side port designed to administer medication may not be therapeutic, and will be lower than than those achievable intravenously or via the ET tube's main lumen.

There is no single initial agent of choice for achieving hypnosis and sedation during rapid-sequence induction in the ED. Pharmacotherapy must be tailored to the patient's unique circumstances. All of the commonly used agents offer distinct advantages in specific clinical conditions. Each agent, however, also has signifcant potential side effects, and specific contraindications (Table 15-3).

TABLE 15-3   Sedative Induction Agents

Thiopental (Pentothal) is a short-acting barbiturate sedative. An intravenous dose of 3.0 to 5.0 mg/kg will induce unconsciousness in 30 to 60 s and last 10 to 30 min. It is a widely used induction agent. Hypotension is commonly observed because of myocardial depression and venous dilatation. An ultra-short-acting barbiturate option is methohexital (Brevital). It is twice as potent as thiopental with onset of action in 60 s, and a duration of action of 5 to 7 min. These cerebroprotective agents should be avoided if systemic hypotension is a problem. This is a major consideration in the multiple trauma patient. Thiopental and methohexital can cause laryngospasm. A more feared but very rare complication is trismus, or masseter muscle spasm, which has also been reported with fentanyl and propofol, often with rapid bolus administration. Methohexital reduces the seizure threshold.

Another pharmacologic alternative is a short-acting benzodiazepine, such as midazolam (Versed) at a dose of 0.1 mg/kg. This drug has valuable amnesic and anticonvulsant properties and is reversible with the antagonist flumazenil. One disadvantage is that it has a wide therapeutic index.

Some agitated and combative patients can be reasoned with only by using rapid-acting major tranquilization. The combative multiple trauma patient is the most common example. Repeated intravenous aliquots of haloperidol (Haldol) 5 to 10 mg will eventually control severe agitation. Another butyrophenone, droperidol (Inapsine), titrated with aliquots of 2.5 to 5.0 mg IV, is a more potent and rapid-onset agent. Droperidol can blunt the cardiovascular response to intubation. Hypotension is rare, and there are fewer dystonic reactions than with haloperidol. Since it is a potent antiemetic, it is an ideal option as a premedication or for neuroleptanalgesia.

Ketamine, a phencyclidine derivative, is a potent bronchodilator to be considered particularly in difficult hypotensive or bronchospastic patients. This agent is indicated for refractory status asthmaticus. Since ketamine increases the blood pressure, it is an appropriate choice in hypovolemic patients. It can, however, increase the intracranial pressure (ICP) in patients with head injuries. Owing to its inotropic and chronotropic cardiac effects, it should be used with caution in the elderly. As ketamine wears off and consciousness returns, the patient may experience "emergence phenomenon" in the form of nightmares, visual hallucinations, and dissociative sensations. Benzodiazepines (e.g., midazolam 0.5 mg aliquots limited to a maximum of 4 mg) may attenuate this phenomenon.

Etomidate is a nonbarbiturate nonreceptor hypnotic. It significantly inhibits adrenocortical function with continuous infusion. For single administration as an induction agent, however, this is not a major concern. The advantages of etomidate in the ED include protection from myocardial and cerebral ischemia, minimal histamine release, a stable hemodynamic profile, and short duration of action. This is another drug to consider if patients are hypovolemic or with closed head injury. Myoclonus, nausea, and vomiting do occur, and seizure foci may be stimulated. The incidence of severe etomidate-induced myoclonus can be decreased by pretreatment with diazepam or fentanyl. Etomidate lacks analgesic efficacy and does not blunt the sympathetic response to intubation.

Another option is propofol, a highly lipophilic, rapid-acting sedative. During RSI, this agent provides effective hypnosis. Propofol has a more rapid onset of action than etomidate and a shorter duration of action. Some of the pharmacologic advantages include its anticonvulsant and antiemetic properties and its ability to lower intracranial pressure.

While not first-line selections, opioids are also potent reversible induction agents. Fentanyl has an onset of action of less than 2 min. The ideal dose is highly variable (Table 15-3). Fentanyl is popular because of its sedative and analgesic properties. This agent provided the most neutral hemodynamic profile during RSI in a randomized double-blind study on sedatives and hemodynamics in the ED. [13] Rapid injection of high doses may cause chest wall rigidity. A related compound, alfentanil, is more potent and has a more immediate onset of action.

NEUROMUSCULAR BLOCKADE

Neuromuscular blocking agents facilitate airway management of selected patients in the emergency department. There are two major classes of drugs, depolarizing and nondepolarizing. Depolarizing neuromuscular blocking agents have high affinity for cholinergic receptors of the motor end plate, and are resistant to acetylcholinesterase. Initially they produce transient muscle fasciculations, followed by paralysis. This type of blockade is not antagonized, and may be enhanced, by anticholinesterase agents. Nondepolarizing neuromuscular blocking agents compete with acetylcholine for the cholinergic receptors, and can usually be antagonized by anticholinesterase agents. Succinylcholine, a depolarizing agent, inhibits neuromuscular transmission as long as an adequate concentration remains at one receptor site. However, succinylcholine is rapidly hydrolyzed by plasma cholinesterase. Potential adverse effects are listed in   Table 15-4. In contrast, pancuronium, vecuronium, atracurium, cisatracurium, rocuronium, and mivacurium are nondepolarizing agents (Table 15-5).

Adult Dose	Onset	Duration	Benefits
1.0–1.5 mg/kg	30–60 s	3–8 min	Rapid onset Short duration

Complications	
Bradyarrhythmias	Masseter spasm
Increased intragastric, intraocular, and intracranial pressure	Malignant hyperthermia Prolonged apnea with pseudocholinesterase deficiency
Hyperkalemia	
Fasciculation-induced musculoskeletal trauma	Histamine release
	Cardiac arrest

TABLE 15-4   Succinylcholine

Agent	Adult Induction Dose IV	Onset	Duration	Complications
Vecuronium (intermediate/long)	0.8–0.15 mg/kg; 0.15–0.25 mg/kg (high-dose protocol)	2–4 min	25–40 min; 60–120 min	Prolonged recovery time in obese or elderly, or if there is hepatorenal dysfunction
Pancuronium (long)	0.1–0.15 mg/kg	3–5 min	60–100 min	Vagolytic tachyarrhythmias. Prolonged recovery in elderly or if there is hepatorenal dysfunction
Doxacurium (long)	0.05–0.08 mg/kg	3–5 min	60–100 min	Prolonged block
Atracurium (intermediate)	0.4–0.5 mg/kg	2–3 min	25–45 min	Histamine release; Hypotension; Bronchospasm
Cisatracurium (intermediate)	0.15–0.20 mg/kg	2–3 min	30–60 min	Cardiovascular
Rocuronium (intermediate)	0.6–1.0 mg/kg	1–3 min	30–45 min	Tachycardia
Mivacurium (short)	0.15–0.20 mg/kg	2–3 min	10–20 min	Histamine release

TABLE 15-5   Nondepolarizing Neuromuscular Relaxants

In the ED, neuromuscular blockade can facilitate tracheal intubation, improve mechanical ventilation, and help control intracranial hypertension. Paralysis improves oxygenation and decreases peak airway pressures in a variety of disorders, including refractory pulmonary edema and the respiratory distress syndrome. Patients with refractory status asthmaticus, status epilepticus, or tetanic spasms resulting from clostridial infections or a variety of toxins, including strychnine, may improve with blockade.

In addition, extremely violent, agitated patients who jeopardize aeromedical personnel or their own airway security, spinal cord integrity, or fracture stability may require the ultimate pharmacologic restraint.

For the conditions mentioned above, nondepolarizing agents are preferable to succinylcholine. Although the onset of action is delayed, nondepolarizing agents have fewer adverse cardiovascular and histaminic effects coupled with a longer duration of paralysis. The delayed onset (1 to 5 min) and prolonged duration of action (25 to 120 min) require that the patient be ventilated with a bag-mask unit or other alternative, should intubation fail.

After documentation of the neurologic examination, including pupil size, presedation with an induction agent is advised unless there are other mitigating circumstances such as significant head injury or overdose. Neuromuscular blockers (NMBs) are neither anxiolytics nor analgesics. Omission of sedation is a common error in patients who remain aware of their paralysis. The resultant increased sympathetic tone can also exacerbate dysrhythmias.

The normal sequence in RSI is to induce sedation prior to administration of the depolarizing NMB agent. If a nondepolarizing agent is selected, some physicians reverse the sequence of administration, giving the nondepolarizing agent first because of its longer onset of action. Giving a rapid-acting hypnotic agent seconds later results in both medications having a synchronized peak effect.

Succinylcholine

When the indication for neuromuscular blockade is tracheal intubation, succinylcholine is the most commonly used agent. It has a more rapid onset (30 to 60 s) and shorter duration of action (average 5 to 6 min) than do the nondepolarizing agents. After a brief fasciculation, complete relaxation occurs at 60 s, with maximal paralysis at 2 to 3 min.

The dosage of succinylcholine is 1.0 to 1.5 mg/kg IV for adults. Succinylcholine can result in excellent intubation conditions in the ED. There are some significant potential complications.

Before injection of succinylcholine, atropine 0.01 mg/kg IV may attenuate the muscarinic vagal effects, especially in vagotonic adults and adolescents. An additional pretreatment to consider is a subparalytic dose of 0.01 mg/kg vecuronium or another nondepolarizing agent of similar duration to prevent the initial muscle fasciculations, which may cause long bone fractures to become displaced. Such fasiculations are most pronounced in muscular adolescents.

Succinylcholine increases intraocular pressure. In addition, the increased intragastric pressure will predispose to aspiration, hence the importance of cricoid pressure. Another concern with succinylcholine is its potential to increase the ICP. This increase in ICP is greater in patients with central nervous system (CNS) neoplasms and may not be clinically significant in those with acute CNS hemorrhage or trauma.

There are other, less preventable side effects of succinylcholine. The serum potassium will transiently rise an average of 0.5 meq/L with succinylcholine. A clinically significant hyperkalemic response following succinylcholine administration in prescreened ED patients is uncommon. [14] Nevertheless, hyperkalemia may be pronounced hours after muscle trauma or burns. It should not be a factor in the immediate aftermath of such injury. Still, it is advisable to avoid depolarizing agents in patients with burns, muscle trauma, crush injuries, myopathies, rhabdomyolysis, narrow-angle glaucoma, renal failure, or neurologic disorders. Any patient with "denervated musculature" (e.g., Guillain-Barré syndrome or spinal cord injury) is particularly at risk. Genetically susceptible individuals may develop acute malignant hyperthermia.

Dantrolene sodium should always be available. Patients with an atypical pseudocholinesterase will require prolonged ventilatory support, as will those with burns, cirrhosis, or carcinomas who have low plasma pseudocholinesterase levels.

Also, patients recently abusing cocaine may have a prolonged duration of neuromuscular blockade, since cocaine is metabolized by plasma cholinesterase, reducing the amount of enzyme available for succinylcholine metabolism.

Nondepolarizing Agents

Pancuronium is a nondepolarizing agent which is less likely than most others to cause histamine release. However, it more commonly results in tachycardia, so should be avoided in patients with underlying cardiac disease. While still commonly used, agents with a shorter duration of action and fewer cardiac effects have supplanted its use in some institutions.

Vecuronium bromide is an intermediate- to long-acting nondepolarizing agent. This drug is approximately one-third more potent than pancuronium. The duration of action is one-third to one-half as long. The usual dose of vecuronium is 0.08 to 0.15 mg/kg IV. Maximal paralysis occurs within 2 to 4 min, with full blockade lasting for 25 to 40 min. Vecuronium does not cause the degree of tachycardia commonly seen after pancuronium, since it has one-twentieth of the vagolytic effect. This simplifies interpretation of a tachycardia developing in the trauma patient.

A major advantage is the lack of hemodynamic alterations. Hypersensitivity reactions are rare, doses are only minimally cumulative, and excretion is biliary. Despite the lack of histamine release, hypotension may occur through two other mechanisms. Blockage of sympathetic ganglia occurs, and venous return is decreased from both absent muscle tone and the positive-pressure ventilation.

Doxacurium chloride is a long-acting nondepolarizing NMB used to facilitate prolonged mechanical ventilation after tracheal intubation. It provides skeletal muscle relaxation with no dose-related cardiovascular effects.

Atracurium is an agent well suited for patients with hepatic or renal failure. Elimination is via ester hydrolysis and Hoffman degradation, a nonenzymatic process. This nondepolarizing agent's elimination half-life is approximately 20 min, versus 65 to 75 min for vecuronium. Recovery time is consistent and unaffected by anticonvulsants. Consider this agent for intubated patients requiring brief diagnostic or therapeutic procedures.

Atracurium also offers advantages when continuous infusion is essential to maintain a precise, required level of neuromuscular blockade. A disadvantage is that histamine release can cause bronchospasm and hypotension. The risk with prolonged infusion is accumulation of laudanosine, a neuroexcitatory metabolic by-product.

Other nondepolarizing options include cisatracurium, rocuronium, and mivacurium. Cisatracurium is an intermediate-duration NMB agent. None of the metabolites have NMB activity, and excretion is independent of hepatorenal function. Rocuronium also has an intermediate duration of action, but the onset of action is much faster. Excretion is predominantly hepatic. Mivacurium is the nondepolarizing agent with the shortest duration of action. Histamine release can be minimized by slow infusion.

The reversal of nondepolarizing muscle relaxants is rarely necessary in the ED. Reversal should not be attempted prior to some sign of motion or spontaneous recovery. Reversal requires atropine 0.01 mg/kg IV to prevent muscarinic side effects, followed by edrophonium 0.5 to 1.0 mg/kg IV. The onset of action is 30 to 60 s, with a duration of 10 to 30 min. This reversal may be shorter than the duration of the muscle relaxant. Edrophonium is an acetylcholinesterase inhibitor with a faster onset and fewer muscarinic side effects than the longer-acting neostigmine.

Strategies

DIFFICULT AIRWAY   The management of the difficult airway in the ED is, in many regards, more challenging than in the controlled setting of the operating room. The patient generally has not been fasting and is not premedicated. There is rarely time for a leisurely evaluation of the "airway history" and "airway physical examination." The difficult airway constitutes the clinical scenario in which mask ventilation or tracheal intubation is challenging. Approximately 2 to 3 percent of tracheal intubations prove impossible with standard techniques. Difficult mask ventilation is defined as the inability to maintain the Sa $_{O_2}$ above 90 percent. Intubation is defined as difficult if more than three attempts are necessary or if conventional laryngoscopy requires more than 10 min. Many emergency physicians prefer to assure the availability of the appropriate airway equipment by customizing the contents of a portable airway kit (Table 15-6).

ET tubes: assorted sizes, designs, tip control, fiberoptic

Laryngoscope blades: alternate sizes and designs, fiberoptic

Stylets: Eschmann bougie, semirigid, hollow, light wand

Syringes, fixators, and Magill forceps

4% lidocaine and laryngotracheal anesthesia kit

1% phenylephrine (Neo-Synephrine)-lidocaine jelly

Tube changers

Emergency ventilation option:
 Laryngeal-mask airway
 Translaryngeal ventilation equipment
 Esophageal tracheal Combitube

Retrograde tracheal intubation equipment

Cricothyrotomy equipment: dilators, #4 Shiley

TABLE 15-6   "Difficult Airway" Kit

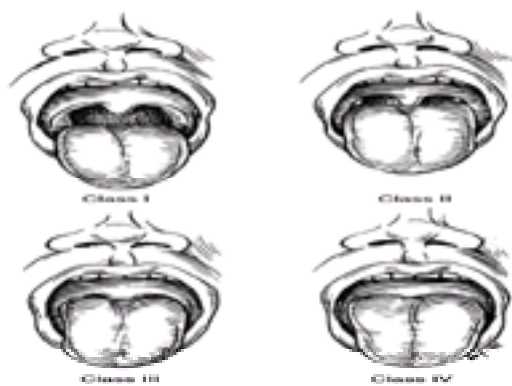
In some stable ED patients, it may be feasible to screen for those physical findings that might suggest a difficult laryngoscopy. The three most predictive tests include assessments of atlantooccipital extension, thyromental distance, and the Mallampati criteria [15] (Fig. 15-4).


FIG. 15-4. The classification of tongue size relative to the size of the oral cavity as described by Mallampati and colleagues. [15] Class I: faucial pillars, soft palate, and uvula can be visualized. Class II: faucial pillars and soft palate can be visualized, but the uvula is masked by the base of the tongue. Class III: only the base of the uvula can be visualized. Class IV: none of the three structures can be visualized.

Proper visualization of the larynx requires flexion of the lower cervical vertebrae coupled with extension at the atlantooccipital joint (the "sniffing position"). In addition, the mandibular opening in a normal adult should be at least 4 cm or two to three finger breadths. A thyromental distance less than 6 cm or a mandibular length less than 9 cm correlates with difficulties. Finally, the size of the tongue relative to the oral cavity affects visualization of the glottis. The Mallampati criteria (Fig. 15-4) help predict the degree of difficulty in visualizing the vocal cords. [15] The ability to visualize the faucial pillars, base of the uvula, and the soft palate predicts the degree of difficulty in laryngeal exposure.

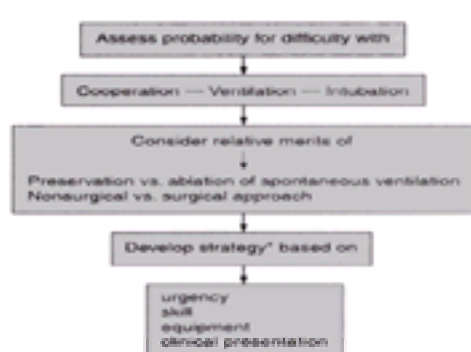
These clinical findings should affect the judgment of the emergency physician who is considering the feasibility of the various approaches to airway management. The decision is basically centered on two initial considerations: will a nonsurgical approach succeed, and is preservation versus ablation of spontaneous ventilation wise (Fig. 15-5).


FIG. 15-5. Difficult airway algorithm.
* Options include bag-valve-mask intubation, endotracheal intubation, nasotracheal intubation, rapid-sequence intubation, digital intubation, fiberoptic

transillumination, laryngeal mask airway, Combitube, retrograde tracheal intubation, translaryngeal ventilation, and cricothyrotomy. (Adapted from American Society of Anesthesiologists,[5] with permission.)

CEREBRAL RESUSCITATION   Patients with suspected acute intracranial hypertension require aggressive airway management. Direct laryngoscopy can elevate the ICP. Prior to oral or nasal intubation, pretreatment with intravenous lidocaine may help blunt this deleterious cardiovascular response. Fentanyl will also blunt the hemodynamic changes.

Since in certain situations succinylcholine may also increase ICP, the intubator should consider prior use of a defasciculating dose of a nondepolarizing NMB agent. If one is selected, the use of a priming dose will shorten the onset of action. However, a significantly prolonged duration of action may be the result, extending the risks if a difficult airway is encountered. Another consideration is the use of a short-acting sedative induction agent. Several of these drugs, including thiopental, fentanyl, and etomidate, directly decrease the ICP.

Effective oxygenation and ventilation during cerebral resuscitation often requires prolonged neuromuscular blockade. Autoregulation of cerebral blood flow (CBF) over a range of perfusion pressures may be impaired. As a result, CBF becomes pressure-dependent (*CBF = CPF/CVR,* where *CPF* is cerebral perfusion pressure and *CVR* is cerebral vascular resistance). Autoregulation is usually intact when the CPP ranges between 50 and 130 mmHg. The CPP equals the mean arterial pressure minus the ICP.

In traumatic brain injury, the goal is therefore to maintain the mean arterial pressures over 90 mmHg throughout the patient's course; this will usually maintain the CPP over 70 mmHg. Other treatment modalities, such as mannitol administration and hyperventilation, do have the potential for exacerbation of intracranial ischemia. Therefore, prophylactic hyperventilation therapy (P_{CO_2} less than 35 mmHg) should be avoided during the first 24 h after injury.[16]

On the other hand, brief hyperventilation therapy should rapidly be initiated in the ED in patients with definite acute signs of intracranial hypertension. If the intracranial hypertension does not respond to adjunctive osmotic diuretics, sedation, neuromuscular blockade, and neurosurgical drainage of cerebrospinal fluid, protracted hyperventilation may be necessary.

After blockade, select the Fi_{O_2} sufficient to maintain an arterial P_{O_2} of 100 mmHg, fully saturating hemoglobin. Positive end-expiratory pressure (PEEP) of up to 5 cmH_2O may help prevent atelectasis. Higher levels will impair cerebral venous drainage because of the elevated intrathoracic pressure. Avoid other modalities that also increase the ICP, including excessively tight ET tube straps, tight cervical collars, or Trendelenburg positioning.

CARDIOPULMONARY DISEASE   Tracheal intubation and mechanical ventilation can also have other significant physiologic consequences. In a prospective investigation of 297 tracheal intubations in an intensive care unit setting, there were 7 deaths.[17] These occurred predominantly among those requiring emergent tracheal intubation. Mortality risk, however, was greatest among those receiving prior vasopressor therapy. Any conditions that result in the cardiovascular system's reliance on preload to maintain perfusion will predispose to hypotension and cardiac decompensation. Particular caution is needed when intubating previously hypotensive patients who require vasopressor support. In addition, patients with hypercarbia and chronic obstructive pulmonary disease (COPD) require special consideration. As mentioned, mechanical ventilation increases the positive intrathoracic pressure. This decreases the preload by decreasing venous return. Hypotension may be anticipated. Additional physiologic considerations include the decreased left ventricular compliance and the fact that most of the medications useful in RSI decrease the sympathetic tone.

INTUBATION IN CERVICAL SPINE INJURY

Airway management of patients with the potential to have an unstable injury of the cervical spine challenges clinical judgment. There is no single best algorithm. Cervical spine radiography without a thorough and reliable neurologic examination does not "clear the neck." From 20 to 30 percent of cervical spine injuries are not appreciated on a single cross-table lateral view. In addition, patients with blunt major trauma requiring tracheal intubation have associated unstable cervical spine injuries that range from 1 to 12 percent. Spinal cord injury without radiographic abnormality (SCIWORA), is an important consideration, especially in adolescents and children.

The initial decision is to determine whether immediate airway intervention is really needed. Patients not in urgent need of an airway should be neurologically and radiographically evaluated as thoroughly as is practical given their condition. The need for in-line cervical stabilization should not be considered a license for axial in-line traction. For example, attempting to visualize C7 radiographically by countertracting on the head and shoulders of the near-hanging patient is counterintuitive.

There is a large selection of airway options to consider while attempting to maintain cervical spine immobilization. The selection is far less critical than the timing. Nasotracheal intubation, transillumination, fiberoptic laryngoscopy, and RTI are commonly selected options. Oral intubation appears safe when achieved without hyperdistraction, flexion, or extension of the neck. Maintenance of cervical spine immobilization is the paramount issue—not the approach to secure the airway. Careful endotracheal intubation (ETI) causes less cervical spine motion than bag-valve-mask (BVM) ventilation.

Visualization of the larynx prior to cervical spine clearance is difficult, since alignment of the oropharyngeolaryngeal axis is not possible. One method to move the tip of the tube anteriorly is to use a slightly flexed directional-tip tube (Endotrol) coupled with the Sellick maneuver. Another is to use a flexible stylet, such as the Flexiguide, which passes through the tube and has a trigger similar to the Endotrol. Another option is to aim the tip of the tube anteriorly with Magill forceps while an assistant advances the tube.

There are several new commercially available laryngoscope blade designs that allow vocal cord visualization without manipulation of the neck. Most designs have fiberoptic attachments to the blade. This allows elevation of the tongue to avoid the blood or secretions. Technically, these blades may prove simpler to use than conventional fiberoptic laryngoscopes.

The Bullard blade incorporates a fiberoptic bundle along the posterior aspect of the straight blade. After visualization, a stylet carries the ET tube, which is advanced through the vocal cords. The Direct View blade incorporates fiberoptics with a curved MacIntosh-style blade. A nonfiberoptic design is the Bainton blade; this has a tubular, square design to facilitate visualization when there is significant soft tissue swelling. This design helps displace tissue circumferentially.

SUCTIONING

A variety of conditions render patients unable to clear their own secretions. Aspiration usually occurs when the tone of the lower esophageal sphincter is insufficient to deal with the increased intragastric pressure and the protective laryngeal airway reflexes are depressed. The common iatrogenic causes include BVM ventilation, the presence of nasogastric tubes, and pharmacologic neuromuscular paralysis. Some common predisposing conditions include trauma, bowel obstruction, obesity, overdose, pregnancy, hiatus hernia and seizures.

Aspiration after urgent ET intubation occurs infrequently in ED patients if there is inattention to technique.[18] The intubator should consider using large-diameter suction systems or tubing for the removal of particulate matter or clots that are larger than the standard Yankauer tip can handle.[19] The rigid-tip plastic tonsil suction catheter can remove large quantities of oropharyngeal secretions.

When necessary, place the patient in a left lateral Trendelenburg position. This helps get the tongue out of the laryngoscopist's way and will facilitate immediate endotracheal suctioning.

To suction the nasopharynx and tracheobronchial tree, use a well-lubricated, soft, curved-tip catheter. Straight catheters will usually pass into the right mainstem bronchus. If a curved-tip catheter is available, turning the head to the right in addition to catheter rotation will often facilitate passage into the left bronchus.

A suction catheter of a size no larger than half the diameter of the tube to be suctioned should be selected. This will prevent pulmonic collapse from insufficient

ventilation during suctioning. Then oxygenate the patient before and after suctioning to avoid transient desaturation. The catheter is inserted without suctioning and then slowly removed, suctioning with rotation over 10 to 15 s.

Some of the complications of suctioning include hypoxia, cardiac dysrhythmias, hypotension, pulmonic collapse, and direct mucosal injury. The magnitude of the ICP increase during endotracheal suctioning may be related to the increase in intrathoracic pressure with coughing if lidocaine has been omitted.

MECHANICAL VENTILATORY SUPPORT

The knowledge of the pathophysiology of acute respiratory failure and the changes in lung physiology during positive-pressure ventilation will aid in the selection of an appropriate ventilatory modality and in the selection of the initial settings. [20] Ventilators are pressure- or volume-cycled. Volume-cycled ventilators are used routinely in EDs. Other decisions regarding mechanical ventilatory support in the ED include the rate, mode, F_{O_2}, minute ventilation, and use of positive end-expiratory pressure (PEEP) or continuous positive airway pressure (CPAP).

There are three common ventilator modes or methods for providing the tidal volume: controlled mechanical ventilation (CMV), assist-control (A/C), and intermittent mandatory ventilation (IMV). Use the control mode for apneic patients. The A/C mode allows the patient to trigger a cycle by inhaling and lowering the air pressure, which can be adjusted by the ventilator's trigger "sensitivity" (1 to 3 cmH_2O). The ventilator will provide an untriggered "controlled" breath unless one is triggered during the selected time cycle. Finally, a predetermined number of ventilator-generated tidal volumes can be assured either unsynchronized (IMV) or more commonly synchronized (to patient effort) intermittent mandatory ventilation (SIMV). In the ED, the A/C or SIMV is the preferred initial mode except with an apneic patient.

The initial Fi_{O_2} should be guided by the oximetry. Set the tidal volume at 10 to 15 mL/kg ideal body weight and adjust the rate accordingly. Allow sufficient time for expiration. Maintain the *peak* airway pressure (PAP) below 35 to 45 cmH_2O to prevent barotrauma. The PAP appears to be related to barotrauma more than the level of CPAP. The tidal volume can be increased up to 15 mL/kg to adjust the Pa_{CO_2} unless it elevates the PAP excessively.

To reclaim lung volumes, PEEP or CPAP should be considered if the decreased pulmonary compliance prevents delivery of an adequate tidal volume or if hypoxemia persists despite 100% Fi_{O_2}. Even low levels (3 to 5 cmH_2O) of PEEP/CPAP usually render ventilator "sighs" (1.5 × tidal volume) unnecessary. If hypotension develops, adjust the respiratory rate and PEEP to lower the *mean* airway pressure.

Some alert patients with mild respiratory insufficiency who do not meet intubation criteria can be temporarily managed with continuous positive airway pressure (CPAP) through a snug-fitting face mask. This reduces the functional residual capacity and the work of breathing. Mask CPAP may thus delay or reduce the need for intubation. In patients with severe maxillofacial trauma and potential basilar skull fractures, pneumocephalus is a hazard. Noninvasive positive-pressure ventilation delivered through a face mask has been compared to conventional mechanical ventilation and is an effective option for many types of acute respiratory failure. [21]

Face-mask CPAP may also prove to be a valuable initial adjunct in some patients with pulmonary edema. The pressure can be maintained below 18 cmH_2O if it is intermittently released. This decreases the potential for gastric insufflation and subsequent aspiration.

Patients who require prolonged CPAP to maintain oxygenation and adequate alveolar ventilation may subsequently benefit from airway pressure release ventilation (APRV). APRV is basically a CPAP system for spontaneously breathing patients who cannot maintain adequate alveolar ventilation on their own and who also require an increased functional residual capacity. This technique attempts to ventilate the lungs while avoiding higher PAPs by releasing the level of CPAP to a lower pressure. These ventilators incorporate a second relief valve that allows for the cyclical release of CPAP to the desired lower level. Inverse ratio ventilation (IRV), in contrast, is the technique to completely control ventilation and the PAP following NMB. In other words, APRV and IMV allow unrestricted spontaneous ventilation, while IRV and CMV do not.

EXTUBATION

Inherently more relaxing than intubation, extubation is nevertheless potentially hazardous. It should rarely occur in the ED. Patients who are recovering their protective airway reflexes may "fight" the tube yet still need to remain intubated. Instillation of 1 to 2 mL of 4% lidocaine (sterile for injection) down the ET tube will decrease bucking. The absorption of lidocaine via the airway yields a maximum serum level that is only slightly lower than that from an equivalent intravenous dose.

Prior to extubation, consider the impact of metabolic or circulatory abnormalities. The patient should be checked for respiratory insufficiency, and nasogastric decompression is advised. On command, the patient should have an inspiratory capacity of at least 15 mL/kg. Ideally there should be no intercostal or suprasternal reactions, and the patient's grip should be firm.

After suctioning secretions, assure adequate oxygenation and explain the procedure to the patient. Positive-pressure ventilation using a mask will help to exsufflate secretions while the cuff is deflated. At the end of a deep inspiration, to prevent secretory reaccumulation, remove the tube and oxygenate by mask.

Closely observe the patient for stridor. Postextubation laryngospasm is initially treated with oxygen by positive pressure. If necessary, nebulized racemic epinephrine (0.5 mL of 2.25% epinephrine in 4-mL saline) often helps.

16 SURGICAL AIRWAY MANAGEMENT

David R. Gens

Surgical airway management is an important skill for all medical personnel treating patients with potentially life-threatening airway emergencies. Up to 2 percent of emergency department intubations have been reported to result in a cricothyroidotomy, but the actual rate is certainly considerably lower. [1] It is probably underutilized as a technique.

The term *cricothyroidotomy* technically means vertically incising (splitting) both the cricoid and thyroid cartilages, and *coniotomy* means incising the cricothyroid (conic) ligament, which runs from the cricoid to the thyroid cartilage. Although *coniotomy* is the correct term for incising between these two cartilages, the term *cricothyroidotomy* is now commonly used to denote this procedure and is used throughout this chapter.

CLINICAL FEATURES

The indications for an emergency surgical airway are several; however, the majority are due to an inability to establish an orotracheal or nasopharyngeal airway. This may be due to anatomy (short, obese neck), a disease state (epiglottis, laryngeal edema, paralyzed vocal cords, or retropharyngeal abscess), trauma from distortion of the neck by hematoma (cervical fracture or major vessel injury), aspiration of blood (facial trauma), or loss of supporting structures (mandibular fractures). Clinical manifestations of acute airway obstruction are stridor (in a patient who is still able to breath) or cyanosis. Clinical signs and symptoms are listed in Table 16-1.

Etiology	Manifestation
Vascular	Hematoma
	External hemorrhage
	Hypotension
	Hemoptysis
Laryngotracheal	Stridor
	Subcutaneous air (massive)
	Hoarseness
	Dysphonia
	Hemoptysis
Pharyngeal and/or hypopharyngeal	Subcutaneous air
	Hematemesis
	Dysphagia
	Sucking wound

TABLE 16-1   Clinical Manifestations Associated with Acute Airway Obstruction

SPECIFIC ISSUES THAT AFFECT EVALUATION AND TREATMENT

Age

Needle cricothyroidotomy is the preferred emergency surgical airway in children under the age of approximately 12 years who cannot be intubated orotracheally or nasotracheally. A 12- or 14-gauge catheter over a needle will support ventilation and oxygenation in a child until a tracheostomy can be performed in the operating room by a surgeon familiar with the anatomy of a child's neck. Surgical cricothyroidotomy should not be considered. The larynx is easily damaged by surgical cricothyroidotomy, and younger individuals have a higher incidence of late airway complications. [2]

Associated Injuries

The standard indications for an airway in emergency patients are mentioned below; however, some specific types of trauma usually have a greater need for a surgical airway.

Penetrating trauma to the neck (gunshot or stab wound) that injures a major artery (carotid, vertebral, or thyroid) demonstrates an expanding hematoma around the injured artery and may cause obstruction of the airway by pressure. The need for a surgical airway should be anticipated. Infrequently, free blood from concomitant vascular and pharyngeal or tracheal injuries spills into the oro- or hypopharynx and causes severe aspiration of blood; in such cases a cuffed tube (surgical cricothyroidotomy, not needle cricothyroidotomy) is needed. Difficulty in establishing an airway occurs in approximately 10 percent of penetrating cervical trauma cases.[3]

Blunt trauma to the neck or face may cause hemorrhage of the soft tissues or injury to the trachea or larynx itself. The trachea may become detached from the larynx at the level of the first tracheal ring, and the larynx or the trachea itself may become ruptured. In either of these rare circumstances, an emergency tracheostomy is required. This procedure should be performed by someone with experience in surgery of the neck. It is difficult to perform as an emergency tracheostomy, especially with an awake patient who is becoming hypoxic and combative. Severe edema of the larynx or, rarely, fracture of the cartilages of the larynx may obstruct the airway.

In blunt facial trauma, the principal cause of death is obstruction of the airway. This occurs for several reasons. In patients with mandibular fractures, the loss of supporting structure for the tongue allows the base of the tongue to fall back into the hypopharynx and obstruct the airway. Also, these patients, placed supine and with major facial bleeding, will aspirate blood continuously.

Type of Emergency Airway and Tube Selection

Surgical cricothyroidotomy is always preferred over needle cricothyroidotomy (except for children under 12 years of age, as noted above) simply because of the larger diameter of the 6-mm (internal diameter) endotracheal or tracheostomy tube compared to the needle cricothyroidotomy catheter. Adequate ventilation is crucial in the early prevention of cerebral edema after brain injury. Ventilation is practically impossible through a 14- or 12-gauge catheter. Emergency tracheostomy is rarely indicated and extremely difficult to perform. This procedure should be performed only by physicians who are familiar with surgical anatomy and skilled with the procedure.

A tracheostomy tube is preferred to an endotracheal tube for several reasons. A tracheostomy tube has an obturator, which makes entry through the narrow cricothyroid membrane easier. The tracheostomy tube is shorter and therefore easier to suction through. Most important, it has phalanges on each side that allow it to be sutured to the neck and secured with a cloth ribbon around the neck (Fig. 16-1). The endotracheal tube (when used for cricothyroidotomy) is very difficult to affix to the neck and moves easily no matter how well secured with adhesive tape. Unfortunately, many emergency departments are not stocked with tracheostomy tubes

because of their infrequent need, or when they are stocked, they may not be readily available. Therefore, an endotracheal tube is most commonly used and is readily available. When a tracheostomy tube becomes available, a tube change can be made using the Seldinger technique; a suction catheter with the suction vent cut off at one end is readily available and easy to use.[7]
FIG. 16-1. Tracheostomy tube with obturator.

The diameter of the tube inserted is crucial. A 6-mm tracheostomy or 6-mm endotracheal tube is preferred (never larger than 7 mm in either case). Tubes with diameters larger than 7 mm are difficult to insert in the narrow space between the cricoid and thyroid cartilages. If airway pressures are high with the small-diameter tube, the cricothyroidotomy tube may be changed to a tracheostomy or endotracheal tube with a larger diameter at a later, convenient time.

Conversion from Cricothyroidotomy to Tracheostomy

The question frequently arises as to how long to leave a cricothyroidotomy tube in place in the larynx. A tube left in the narrow space between the cricoid and thyroid cartilages can erode both cartilages, and a bacterial chondritis may occur. The cartilages will be destroyed and eventually scar, leading to stenosis and loss of the function of the larynx. Because cricothyroidotomy has a higher incidence of airway stenosis, a cricothyroidotomy should be converted to a tracheostomy.[4] As a rule of thumb, if the airway will be needed for more than 2 to 3 days, the cricothyroidotomy should be changed to a tracheostomy. Otherwise, the cricothyroid tube may stay in place.

PROCEDURE

Surgical Cricothyroidotomy

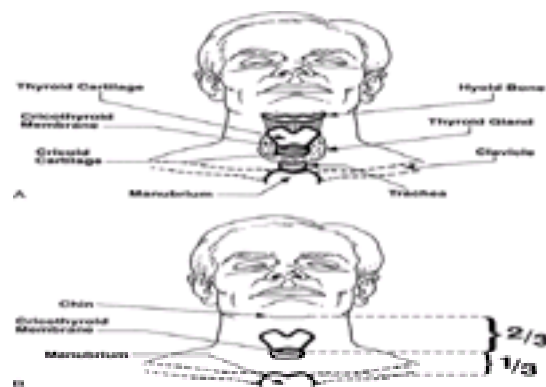
ANATOMY   The cricothyroid membrane is located between the thyroid and cricoid cartilages (Fig. 16-2A). Both of these structures are easily palpated. The cricothyroid membrane can be found approximately one-third the distance from the manubrium to the chin in the midline in patients with normal habitus (Fig. 16-2B). In a patient with a short, obese neck, the membrane may be hidden at the level of the manubrium, while in a patient with a thin, long neck, it may be midway between the chin and the manubrium. The thyroid gland overlies the trachea; both of these structures are difficult to palpate.


FIG. 16-2. A. Anatomy of the neck. **B.** Location of the cricothyroid membrane.

The only vascular structure that may be injured during the course of a properly performed cricothyroidotomy is the thyroid ima artery, a branch of the aorta that runs up to the thyroid gland in the midline and infrequently reaches the level of the cricothyroid membrane. When injured, it needs to be surgically ligated to control the hemorrhage.

INDICATIONS AND CONTRAINDICATIONS   Inability to orotracheally intubate an emergency patient is the prime indication for surgical or needle cricothyroidotomy. Orotracheal (or nasotracheal) intubation should be attempted first. In-line cervical stabilization must be maintained in trauma patients. If orotracheal intubation is unsuccessful, then cricothyroidotomy should be performed.

As mentioned earlier, surgical cricothyroidotomy is reserved for patients over the age of 12 years and is contraindicated in patients under the age of 12. Needle cricothyroidotomy is the procedure of choice in this age group.

COMPLICATIONS   Acute complications following emergency cricothyroidotomy occur in up to approximately 10 percent of cases.[5] Such complications include

1. *Bleeding from the insertion site.* Venous bleeding is almost always from small veins and usually stops (using a vertical neck incision decreases the chance of bleeding). Arterial bleeding can be from the thyroid ima artery or from a small artery at the base of the cricothyroid membrane. Apply gentle pressure to stop the bleeding. If bleeding persists, surgical control may be necessary in the operating room.
2. *Misplacement of the tube.* In an obese neck, it is possible to place the tube anterior to the larynx and trachea into the mediastinum. Ventilation is not possible. Manifestations of an incorrectly positioned tube are high airway pressures, absent breath sounds, and massive subcutaneous emphysema. The tube should be removed and a second attempt should be made.
3. *Laceration of the structures of the neck.* Laceration of the trachea, esophagus, or recurrent laryngeal nerves is extremely rare and is due to inadequate knowledge of the anatomy of the neck.
4. *Pneumothorax.* This complication is probably secondary to barotrauma caused by ventilation initiated immediately after tube placement.

Late airway complications may occur in up to 52 percent of cases. These complications include voice changes and laryngeal and/or tracheal stenosis.[6,7 and 8]

EQUIPMENT NEEDED

1. Personal protective equipment
2. Scalpel with number-10 blade (preferable due to its greater width) or a number-11 blade
3. A 6-mm endotracheal tube or 6-mm tracheostomy tube (preferred) (Do not use a tube that is larger than 6 mm. A larger size is difficult to place through the cricothyroid membrane.)

4. Tape to secure the endotracheal tube in place; cloth ribbon and sutures to secure tracheostomy tube in place
5. Bag-valve-mask device and oxygen source

PATIENT PREPARATION AND POSITIONING   The patient should be placed supine with the neck positioned in the midline. Povidone iodine solution should be quickly applied to the skin if time permits. If the patient still has a patent airway (albeit minimal), oxygen should be administered by mask.

STEPS OF PROCEDURE

1. Stand to one side of the patient at the level of the neck. A right-handed practitioner should stand on the right side, and a left-handed practitioner on the left side.
2. Locate the cricoid ring. Place the index finger at the sternal notch and palpate cephalad until the first rigid structure is felt (cricoid ring). Roll the index finger one finger breadth above to locate the "hollow" between the cricoid and thyroid cartilages. This is the cricothyroid membrane (Fig. 16-3).

FIG. 16-3. Surgical cricothyroidotomy: palpating the cricothyroid membrane.

3. Using the thumb and middle finger of the nondominant hand, stabilize the two cartilages.
4. Use the scalpel to make a vertical incision in the midline between the two cartilages. The incision should go through the skin and subcutaneous tissues. The structures are superficial, and care should be taken not to incise deeper, since this may result in damage to the cricoid or thyroid cartilage or vascular structures.
5. With the scalpel blade positioned horizontally, perforate the cricothyroid membrane so that the blade goes in approximately half its length (Fig. 16-4).

FIG. 16-4. Surgical cricothyroidotomy: puncturing the cricothyroid membrane with a scalpel blade.

6. Place the back end of the scalpel handle into the incision in the cricothyroid membrane to widen the opening (Fig. 16-5).

FIG. 16-5. Surgical cricothyroidotomy: placing the scalpel handle to widen the hole in cricothyroid membrane.

7. Place the endotracheal tube (or tracheostomy tube) in the opening (Fig. 16-6).

FIG. 16-6. Surgical cricothyroidotomy: endotracheal tube in place.

8. Secure the tube carefully with a ribbon and/or adhesive tape. If using an endotracheal tube, take special care that the tube is in no more than 2 to 3 cm; otherwise, the tube will slip down the right main-stem bronchus with even minimal movement.
9. Connect to a bag-valve-mask device for ventilation. Check for breath sounds for ventilation. If no ventilation is heard bilaterally, then pull the tube out and reinsert it. Constantly recheck for breath sounds to ensure that the endotracheal tube is correctly positioned. If breath sounds are absent only on the left side, then the tube has been inserted down the right main-stem bronchus and needs to be pulled back a few centimeters. This usually occurs with the use of an endotracheal tube.

DRESSING AND STABILIZATION   If a tracheostomy tube has been used, a simple dressing may be fashioned by cutting a slit halfway down the middle of a 4-by-4 cm dressing and placing it under the tracheostomy tube. This tube may be secured with a ribbon placed through the phalanges of the tracheostomy tube. For added security, 2-0 nylon sutures may be used to fix the tube to the skin. Endotracheal tubes are extremely difficult to secure properly to the neck and should be changed to

tracheostomy tubes whenever possible.

DEVICE REMOVAL   The cricothyroidotomy tube may be removed once the patient has a patent airway, or has been changed to a tracheostomy tube, as mentioned above. Patency may be evaluated by deflating the cuff of the tube and assessing airflow by breathing or by speech.

Needle Cricothyroidotomy

Needle cricothyroidotomy entails insertion of a catheter (generally an intravenous catheter) through the cricothyroid membrane. Although this procedure is easier to perform than surgical cricothyroidotomy, it is greatly inferior in providing adequate ventilation. The diameter of the catheter used is the limiting factor for airflow.

ANATOMY   See the discussion under "Surgical Cricothyroidotomy."

INDICATIONS AND CONTRAINDICATIONS   The general indications are listed under "Surgical Cricothyroidotomy." However, needle cricothyroidotomy is usually deemed the only type of emergency surgical airway that is indicated in children under the age of 12 years. Although generally there are no contraindications to needle cricothyroidotomy, adult patients can be ventilated for only approximately 15 to 20 min and should have an alternative airway secured immediately (by surgical cricothyroidotomy, endotracheal intubation, or tracheostomy).

COMPLICATIONS   Complications after needle cricothyroidotomy are less frequent than after surgical cricothyroidotomy. Bleeding at the puncture site and infection may occur. Inadvertent perforation of the esophagus or back wall of the trachea or larynx is infrequent. Massive subcutaneous emphysema will develop during ventilation. The catheter may also be misplaced in the soft tissues of the neck.

EQUIPMENT NEEDED

1. Personal protective equipment
2. A 14- or 12-gauge sheathed needle catheter
3. A 3-mL syringe
4. Adapter from the end of a 7-mm endotracheal tube
5. Wall oxygen source at 15 L/min (40 to 50 lb/in^2) connected by tubing with a Y connector or fashioned with a side hole (a bag-valve-mask device can be substituted but is not optimal)

PATIENT PREPARATION AND POSITIONING   See the discussion under "Surgical Cricothyroidotomy."

STEPS OF PROCEDURE

1. The operator should be positioned above the head of the patient.
2. Locate the cricoid ring. Place the index finger at the sternal notch and palpate cephalad until the first rigid structure is felt (cricoid ring). Roll the finger one finger breadth above to locate the "hollow" between the cricoid and thyroid cartilages. This is the cricothyroid membrane (Fig. 16-7).

FIG. 16-7. Needle cricothyroidotomy: palpating the cricothyroid membrane.

3. Attach a 3-mL syringe to the catheter (12- or 14-gauge).
4. Introduce the catheter into the subcutaneous tissue at a 90° angle to the skin. Aspirate gently while advancing the catheter over the needle. When air suddenly returns (indicating entry into the airway), change the angle to 45°, and advance the catheter over the needle into the larynx. Withdraw the needle and syringe (Figs. 16-8).

FIG. 16-8. Needle cricothyroidotomy: puncturing the skin with the needle and catheter.

5. Disconnect the 3-mL syringe from the bare needle.
6. Withdraw the plunger from the syringe and attach the plungerless 3-mL syringe barrel to the catheter in the neck.
7. Attach the adapter (from the end of a 7-mm endotracheal tube) to the end of the inserted catheter or the open end of the 3-mL syringe (Fig. 16-9 and Fig. 16-10), or place a 7-mm endotracheal tube into the empty syringe barrel and inflate the balloon (Fig. 16-11).

FIG. 16-9. Needle cricothyroidotomy: holding the catheter in place.

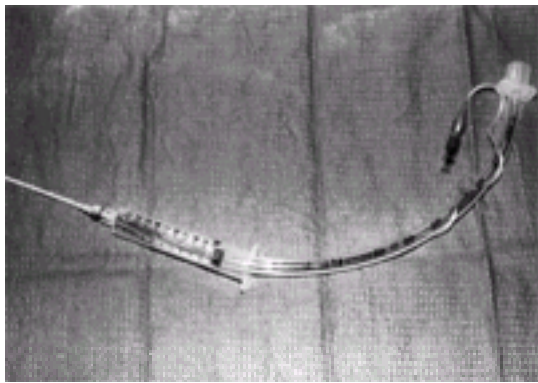
FIG. 16-10. Needle cricothyroidotomy: adapter-syringe-catheter setup.


FIG. 16-11. Needle cricothyroidotomy: endotracheal tube-syringe-catheter setup.

8. Attach the oxygen source to the adapter and start ventilation using 100% oxygen. Intermittent jet insuflation (50 lb/in^2) can be achieved by occluding the Y connector or side hole in the connecting tubing. Insuflate 1 s; then release the occlusion for 4 s. To achieve the required high pressures, it is best to use a jet injector regulated by a flowmeter attached to a wall unit on a tank. An unregulated wall unit or tank is a less optimal choice.
9. The operator must hold the catheter in place at all times until a definitive airway is obtained. The catheter is easily displaced with minimal movement. (The inspiration-to-expiration ratio may be as high as 1:10 or 1:15 due to the high resistance to flow. Ventilation will be inadequate, and a definitive airway must be obtained. This is only a temporary airway.)

DRESSING AND STABILIZATION   Stabilization is achieved by the operator until another choice of airway is established, either tracheostomy or oro- or nasotracheal intubation (if possible). Dressings are not necessary.

DEVICE REMOVAL   A needle cricothyroidotomy catheter should be removed as expediently as possible. The catheter almost always becomes inadvertently dislodged from the airway, and the ability to ventilate is poor.

17 VASCULAR ACCESS

Bharat B. Sutariya
William A. Berk

Obtaining access to the venous and arterial circulation enables the administration of drug, crystalloid, and blood products and measurement of central venous and arterial pressures. About one-third—or more than 32 million emergency department (ED) patients each year—require vascular access. This chapter discusses indications, techniques, and potential complications of vascular access.

During resuscitation, venous access should be obtained at the site of the largest vein that is accessible without disrupting resuscitation. When peripheral sites are not available, central veins should be accessed for monitoring of central venous pressure or the administration of drugs directly into the central circulation.

VASCULAR ACCESS BY ENDOTRACHEAL TUBE

A number of medications may be administered by endotracheal tube in the critical minutes of resuscitation before intravenous (IV) access is obtained. These include atropine, diazepam, epinephrine, isoproterenol, lidocaine, and naloxone but *not* sodium bicarbonate, calcium chloride, or bretylium. The American Heart Association Advanced Cardiac Life Support (ACLS) and Pediatric Advanced Life Support (PALS) guidelines recommend increasing IV dosages of resuscitation medications by a factor of 2 to 3 with dilution of 3 to 5 mL before administration via endotracheal tube. Epinephrine as a preparation of 1 mg/mL (1:1000) should be given in a dosage of 0.1 mg/kg (standard dosage). Drug administration is followed by several positive-pressure ventilations using a bag-to-tube device. [1]

ISSUES OF FLOW DYNAMICS

Infusion rate is crucial in resuscitation for severe hypovolemia or hemorrhage. Fluid in a medical catheter behaves for practical purposes according to the Poiseuille law:

$$\text{Rate of flow} = \frac{\pi \times (\text{catheter radius})^4 \times \text{pressure gradient}}{8 \times \text{dynamic fluid viscosity}}$$

The fact that flow is a function of the fourth power of the radius of the tube lumen means that the internal catheter diameter is a major limiting factor. [2] A fluid delivery system is only as effective as its slowest component, whether this is intravenous tubing, in-line filters, or the catheter itself. Flow rates may also be affected by pressure and viscosity, the latter being an especially important consideration in relation to red blood cell transfusion. Rate of infusion is also directly proportional to catheter length, which is why a long central catheter will have a slower infusion rate than a shorter catheter of the same caliber in a peripheral vein. [3]

Placement of two large-bore 16-gauge or greater catheters is indicated in stable adult trauma patients whose injuries could cause potentially life-threatening hemorrhage or for initial therapy of medical patients with hypovolemic shock. In the management of exsanguination, an 8.5-Fr catheter with a manually operated pressure bag or a wall-mounted external pneumatic device delivers crystalloid at the rate of almost 1 L/min. A second catheter may be needed for drug infusion. Rapid infusion of larger volumes of fluid should be accompanied by careful monitoring for volume overload, especially in older patients and those with cardiovascular disease.

Volume repletion and measurement of central venous pressure can be accomplished by a Y-arm catheter sheath passed percutaneously into the femoral vein. An 8.5-Fr catheter can then be used for volume repletion, while a smaller catheter can simultaneously be inserted through the other arm of the Y and directed into the right atrium for the measurement of central venous pressure. Femoral catheters should generally be left in place no longer than 48 h, since iliofemoral thrombophlebitis can result. However, with sterile technique and the use of Silastic catheters, the deep femoral system may safely be employed for a longer duration.

Pressure infusion increases flow two to three times above that achieved by gravity alone and is superior to the use of on-line hand-pumped bulbs. Pressure devices are available for the administration of packed red blood cells. Use of a standard urologic Y irrigation set augments flow rates by reducing resistance in the tubing leading to the catheter site. For maximum infusion rates of either blood or crystalloid, use of blood administration tubing eliminates on-line micropore filters, stopcocks, and one-way valves, which increase resistance. Addition of saline to packed red blood cell infusions decreases viscosity, increasing the speed of transfusion. [2]

Volume repletion is effective through IV catheters placed distal to an inflated military antishock trouser (MAST) suit. In patients with abdominal hemorrhage, lines in the legs as well as those in the arms augment volume.

Warming of crystalloid and blood before infusion is essential when volume resuscitation is massive. Crystalloid may be stored in a heating bath or oven, safely microwaved, or warmed with a heating coil or heat packs. Blood warming coils that allow transfusion rates of up to 500 mL/min are now available. Alternatively, cold-packed red blood cells may be warmed by diluting them with an equal amount of warmed saline (up to 60°C); this will also decrease viscosity and thus enhance flow.[2] An in-line microwave blood warmer may be used to heat blood safely to 49°C without any significant increase in hemolysis. [2,4]

VENOUS ACCESS SITES

Peripheral venous catheterization is a routine everyday component of emergency medical practice. The normal human anatomy offers many potential sites for catheterization (Fig. 17-1 and Fig. 17-2). The arm veins are associated with an increased risk of phlebitis and are often technically more difficult to access than leg veins. The cephalic vein, in both the forearm and the upper arm, is large, constant, and straight; easily catheterized, it is the time-honored choice for peripheral access in both adults and children. The superficial radial vein at the wrist is well developed in adults, though it is difficult to locate in a small child. Veins of the hand are usually accessible even in obese persons but are short, tortuous, and difficult to stabilize. Veins in the antecubital fossa are excellent in emergency situations, but an armboard is necessary to prevent catheter kinking or dislodgement with movement. This is a relatively uncomfortable position for patients if access is required

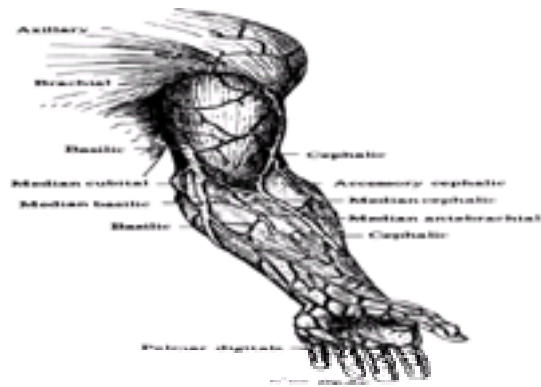
beyond a few hours. The large basilic vein in the upper arm is usually not visible, but with practice it can be catheterized by palpating the brachial artery and searching "blindly" for the medially placed vein. Puncture of the brachial artery is common but rarely of clinical significance if care is taken to prevent hemorrhage or hematoma formation; transitory paresthesias may also occur.


FIG. 17-1. Veins of the upper extremity.
FIG. 17-2. Veins of the torso and lower extremities.

Veins in the legs often require cutdown for catheter placement. The superficial saphenous vein at the ankle is large, constant, and easy to isolate and cannulate. The proximal great saphenous vein in the thigh may be found reliably 5 cm below the inguinal ligament at the junction of the medial and middle third of the thigh in the supine patient. The deep femoral vein is accessible percutaneously, just medial to the femoral artery (Fig. 17-2). In the pulseless patient, the landmark is the junction of the medial and middle third of the inguinal ligament. From the great saphenous and deep femoral veins, advancement of catheters into the right atrium for the measurement of central venous pressure is possible.

Peripheral venous catheterization should not be attempted distally in an extremity involved by cellulitis, burns, or serious injury or when drainage occurs to an area that has sustained an acute serious injury (e.g., the right arm in the presence of a gunshot wound to the right chest). In such situations, the proximal veins may not be patent. Catheterization of arms in the presence of an indwelling fistula or serious neck trauma should also be avoided. Hyperosmolar fluids and agents known to cause chemical phlebitis or sclerosis of peripheral veins should not be infused through such veins.

Internal jugular, subclavian, or femoral vein catheterization is performed when peripheral access is impossible or when the measurement of central venous pressure is desired. The external jugular vein can provide reliable access in both adults and children. Although this vein is readily distended by the Valsalva or Trendelenburg maneuvers, scant subcutaneous support can make it difficult to catheterize. Access to central veins without the risk that attends direct internal jugular and subclavian puncture is a major advantage. In young children, intraosseous infusion provides rapid and reliable access in emergencies. A bone marrow or intraosseous infusion needle placed in the proximal, distal tibial, or distal femoral bone marrow can provide emergency access.

TECHNIQUE FOR PERIPHERAL VENOUS ACCESS

Care must be taken to minimize the risk of local infectious complications, which occur in up to one-third of patients undergoing venous catheterization and may rarely result in septicemia. Insertion of peripheral venous catheters should be preceded by a surgical prep and followed routinely by placement of a sterile dressing. Consideration of the indications for venous access and what constitutes appropriate and adequate access in individual patients will minimize risk and facilitate management of emergencies when they occur. If peripheral veins are small, size and visibility can be enhanced by application of hot, moist compresses for 5 min, by tapping gently on the vein before attempting puncture, or by application of nitroglycerin ointment (0.4% for children less than 1 year old; 2% for others) over an area 1 in. in diameter for 2 min and then wiping off. Once access has been obtained, gentle circumferential occlusive taping may be necessary if stability of the site is tenuous, with the IV line looped and secondarily secured to prevent traction at the point at which the line penetrates the skin. The size of the catheter can usually be determined by the color of the hub; otherwise, it should be written on the tape dressing. When venous access is required primarily for drug administration, consideration should be given to placing a saline or heparin lock. By comparison with adults, obtaining IV access in children is often a challenge. Children tend to be more anxious and thus uncooperative. Generous subcutaneous fat may prevent vessel palpation and direct visualization. Finally, a child's vessels are smaller, and children readily lose body heat, which promotes vasoconstriction.

Complications

Complications from placement of peripheral IV lines include hematoma formation, phlebitis, and cellulitis. Phlebitis may occur in up to 75% of hospitalized patients. There is general agreement that catheters should not be left in place for longer than 3 days before replacement. Nerve and tendon damage, deep venous thrombosis, suppurative thrombophlebitis, and septicemia are rare. The unusual event of extravasation of irritative, vasoconstricting, or tissue-toxic substances such as 50% dextrose, epinephrine, phenytoin, and some drugs used for chemotherapy of malignancies may cause problems ranging from minor pain and inflammation to full-thickness sloughing of skin, necessitating skin grafting. In rare situations, reactive arterial vasospasm has led to ischemia and ultimately tissue necrosis in extremities with very distally placed IV lines that may have infiltrated. Catheter-over-needle assemblies are now in common use and provide more stable, reliable access than the steel needles they replaced. Microparticulate matter in IV solutions is removed by in-line micropore filters.

CENTRAL VENOUS PRESSURE CATHETERIZATION AND MONITORING

Central venous catheterization should be performed (1) when rapid delivery of cardiac medications to the coronary circulation is required during cardiopulmonary resuscitation (CPR);[1,5] (2) for access when peripheral veins are inadequate; and (3) when measurement of central venous pressure is desired. Hypovolemic shock by itself is not, however, an indication for central venous catheterization. Many patients who require large-volume infusions or transfusion with multiple units of blood can be managed with large-bore peripheral IVs. Determination of central venous pressure is indicated when (1) massive volume repletion is administered to elderly patients or those with heart disease, (2) fluid administration is being monitored in patients with visceral trauma and severe head injuries, and (3) pericardial tamponade is suspected.

A variety of sites and techniques are available to access the central circulation. Most commonly, a catheter is placed in the upper vena cava via the internal jugular or subclavian vein; less commonly, via the external jugular vein. The femoral vein may also be used, but it requires subsequent immobilization of the leg and the procedure is accompanied by a higher rate of infection and thrombosis. Emergency physicians should become skilled in at least two approaches for central venous

catheterization, using one as primary while reserving the other as a backup.

Use of peripheral veins to access the central circulation and measure central venous pressure has the indisputable advantage of avoiding the risk associated with direct puncture of the subclavian and internal jugular veins. However, low flow is inevitable due to the long course of the catheter from the extremity to the superior vena cava. Peripheral sites also fail frequently due to catheter malposition and kinking. In the arm the brachial-basilic system must be used, since catheters in the cephalic system often become kinked in the plexus of veins at the shoulder. Smooth passage and correct tip positioning are more likely if the patient is sitting with his or her head angulated sharply toward the catheterized arm, the arm is held abducted, and the catheter is wire-guided. In emergency situations, however, this time-consuming approach to the central circulation is often impractical. The femoral and axillary veins are safe and reliable alternatives. However, in the presence of cardiac arrest, internal jugular or subclavian lines are highly desirable for drug administration.

Anatomy

A brief review of anatomy is warranted (Fig. 17-1 and Fig. 17-3). The major veins of the upper thorax are deeply and centrally placed and well protected by the clavicles, sternum, and strap muscles. The internal jugular veins join the subclavian veins to form the brachiocephalics (innominates), which, in turn, join to become the superior vena cava. The sternocleidomastoid muscle attaches separately by two heads to the sternum and clavicle; the triangle formed by these two heads and the clavicle is just above the internal jugular vein. The right internal jugular has a straight path into the superior vena cava, whereas all the other major tributaries curve. Both external jugular veins enter the subclavian veins at close to right angles. The subclavian veins lie immediately posterior to the junction of the medial and middle thirds of the clavicle and are anterior and inferior to the artery; the pleura are immediately posterior and inferior to the subclavian vessels (Fig. 17-4). The internal jugular vein usually lies anterolateral to the carotid. The basilic and brachial veins join to form the axillary vein. The cephalic vein joins the axillary vein more superiorly, just before it becomes the subclavian vein. The axillary vein continues the distal subclavian vein and runs medial to the axillary artery from the distal arm. The femoral vein is medial to the femoral artery. The relative locations of components of the neurovascular-lymphatic bundle in the groin from lateral to medial can be recalled by the mnemonic NAVEL (nerve, artery, vein, empty space, lymphatic).

FIG. 17-4. Coronal section through the midclavicle.

Equipment and General Technique for Central Venous Catheterization

All equipment should be at the bedside, including a central venous (CV) pressure manometer if CV pressure monitoring is desired. Catheter-through-needle devices, whose large 14-gauge insertion needles are prone to complications and whose 16-gauge catheters allow maximum gravity-assisted flow of 100 to 150 mL/min, have been largely supplanted by wire-guided (Seldinger) catheters. [6] Their use allows use of a small needle to place any size catheter into a vessel.

The patient should be placed in a neutral to maximum of 30° head rotation and 15° Trendelenburg's position, and the entire route of the neck should be prepped so that all three approaches are possible in case the primary approach fails. The right side is preferred over the left, since (1) the lung apex is slightly lower, (2) there is a straight relationship between the right internal jugular vein and the superior vena cava, and (3) the left-sided thoracic duct cannot be injured. With unilateral chest trauma in the absence of suspected vessel injury, the attempt should be on the injured side in order to protect the uninjured hemithorax in the event of complications from the procedure.

When the procedure is performed electively, preceding the approach for catheter placement with a 22-gauge needle attached to a 5- or 10-mL syringe filled with lidocaine facilitates local anesthesia and allows the operator to "locate" the vein. After landmarks are identified, an 18-gauge needle is then inserted into the vein (Fig. 17-5A). Gentle, continuous negative pressure on the syringe should be maintained until free flow of blood is obtained. The syringe is removed and a fingertip is used to occlude the hub before wire insertion (Fig. 17-5B). This often forgotten or ignored maneuver is important to prevent aspiration of air, particularly in internal jugular or subclavian vein catheterizations. The needle is then removed (Fig. 17-5C), leaving just the wire in the vein. A small skin incision (1 to 2 mm) is often made over the wire (Fig. 17-5D) to facilitate smooth entry of the catheter, which is threaded over the wire and into the vein with a twisting motion (Fig. 17-5E). The wire is then removed, leaving only the catheter in place (Fig. 17-5F). If a large-bore catheter is necessary, the apparatus is used with a venodilator. In this situation, the venodilator is removed with the wire, leaving the large-bore 8.5-Fr catheter sheath in place.
FIG. 17-5. Seldinger technique of catheter insertion (wire-guided). (From Conahan TJ III, Schwartz AJ, Geer RT: Percutaneous catheter introduction: The Seldinger

The principal advantages of wire-guided catheters are (1) use of a small (and thus safer) needle for insertion; (2) the step-up capability with a venodilator, allowing for the higher flow rates often required in trauma resuscitation; (3) the flexibility of exchanging standard intravenous catheters, central venous catheters, and Swan-Ganz catheters without repeated stabs; and (4) the use of J wires to access the central circulation from the external jugular vein.

Ultrasound visualization of the central vein while puncture is attempted reduces the number of punctures necessary for cannulation and the time required to establish central access while also reducing the incidence of complications. The technique is particularly helpful when the traditional landmark-based techniques fail or are impractical due to vascular anomalies or body habitus, or when patients with a coagulopathy require central venous access. [7,8]

Complications

The three most common serious complications of direct puncture of a central vein are pneumothorax, arterial puncture, and local infection. With subclavian puncture, the incidence of pneumothorax is 2 to 4 percent, significantly greater than with either internal jugular approach. The incidence of arterial puncture, 3 to 7 percent, is similar for all approaches. In children, success rates for subclavian venous catheterization are higher than for internal jugular venous catheterization and the complication rate is lower. Other, less common complications include hydrothorax, chylothorax (left side), hydromediastinum, air or catheter embolism, thrombosis, dysrhythmia, nerve injuries, osteomyelitis of the clavicle, catheter tip perforation of the superior vena cava (causing hydromediastinum or hydrothorax) or right atrium (causing hydropericardium), knotting with other catheters, and puncture of endotracheal tube cuffs. [9] Care in executing the procedure and in the selection of patients who will benefit from central venous catheterization will minimize the occurrence of complications.

Technique of Commonly Used Approaches

EXTERNAL JUGULAR VEIN   The external jugular vein is a superficial, readily accessible vessel that lies in the subcutaneous tissue over the sternocleidomastoid muscle. The vein courses inferior and joins the subclavian vein under the clavicle (Fig. 17-3). Central venous access via this route has an increased success rate (57 to 95%) if a J wire-guided catheter assembly is used. Success is enhanced by introducing the wire through a 16-gauge catheter rather than through a needle, using a J tip with no more than a 3-mm radius, exaggerating head tilt with marked traction on the skin of the neck, and—when initial attempts with wire through needle techniques are met with resistance at the level of the clavicle—twisting the tip of the J wire 180° before making a second attempt. It is also recommended that a small syringe (insulin or TB syringe) be attached to the introducing needle-catheter assembly for both stabilization and to maintain negative pressure. The external jugular vein is very pliable and collapses easily during initial skin puncture. Gently withdrawing the needle back while maintaining suction improves chances of catheterization.

The main disadvantage of the external jugular catheterization is difficulty in securing the catheter in the neck. The venous valves within its course may impede catheter placement as well. The constant movement of the patient makes most external jugular lines short-lived. Also, turning of the neck impedes flow of the infusion, making the line unreliable for fluid or medications unless it is constantly watched.

INTERNAL JUGULAR VEIN   There are three traditional approaches to catheterization of the internal jugular vein. The central approach may be the most popular. After the patient is placed in Trendelenburg position, the needle should puncture the skin 1 cm below the apex of a triangle at the midpoint formed by the tendinous and muscular heads of the sternocleidomastoid muscle. The palpation and definition of the margin of the carotid artery is not as important as in the anterior approach but is helpful in locating the vein and to avoid puncture of the artery. Held at a 60° angle with the plane of the skin, the needle is directed slightly lateral to the axis of the body (lateral to the pulsation of carotid artery). Common helpful landmarks for needle direction include the ipsilateral nipple and a plane parallel to the medial border of the lateral head of the sternocleidomastoid muscle. Blood return should be obtained within 3 cm, since the vein is very superficial here. If the attempt fails, the needle should be withdrawn completely before the next attempt.

In the lateral or posterior approach, the head is turned slightly away from the selected side; after the patient is placed in Trendelenburg postion, the needle is inserted at the posterior margin and deep to the sternocleidomastoid muscle two to three fingerbreadths above the clavicle and directed toward the suprasternal notch (Fig. 17-6). Frequently, the external jugular vein crosses the lateral wall of the sternocleiomastoid muscle at this point. If it does, the needle should be inserted at the junction of the crossing at a 90° angle to the external jugular vein. Blood should be aspirated within 4 to 5 cm. The carotid artery is just behind this path, albeit slightly posterior, and may be at increased risk for puncture.
FIG. 17-6. A. Posterior approach for internal jugular venipuncture. **B.** Central approach. **C.** Anterior approach. (From *Textbook of Advanced Life Support,* 2d ed. Dallas, American Heart Association, 1990, pp 149–150. With permission.)

The anterior approach and its variants may well be the most technically difficult. After the carotid is identified, the needle is entered at the midpart of the medial border of the sternocleidomastoid. With the fingers over the carotid, the needle is directed 30 to 45° from the midline plane toward the ipsilateral nipple. This approach has the greatest likelihood of carotid puncture and appears to be the least favored of the IV cannulation approaches.

SUBCLAVIAN VEIN   The subclavian vein is still the most commonly used site for central venous access. The right side is preferred because the pleural dome is lower on that side. The fact that the point of insertion is in a broad, flat area of the chest makes it ideal for use when central venous access will be required for a prolonged period. The patient is placed in the Trendelenburg position. If the patient is a child, a towel is placed under the thoracic spine. This may also be helpful in some adults.

The *infraclavicular* subclavian approach is the most commonly taught technique. There is no universal agreement on exactly where the needle should enter (Fig. 17-7). The bisection of the middle and medial thirds of the clavicle is an appropriate landmark. Another is a point just lateral and inferior to the junction of the clavicle and first rib. For this latter approach the needle is aimed at the bisection of the junction. Using the former landmark, the skin is penetrated about 1 cm inferior to the clavicle and directed inferomedially. With the index or middle finger of the other hand in the suprasternal notch, the needle is aimed at the superior and most posterior portion of the ipsilateral clavicular head (Fig. 17-7). Inferomedial orientation of the needle bevel facilitates entry of the wire or catheter into the brachiocephalic vein. Vessel entry occurs at a depth of 3 to 4 cm.
FIG. 17-7. Infraclavicular subclavian venipuncture.

For the *supraclavicular* subclavian approach, the patient's head is turned slightly away from the involved side. The needle enters just above the clavicle, 1 cm lateral to the insertion of the clavicular head of the sternocleidomastoid muscle and 1 cm posterior to the clavicle. It is then directed to bisect the angle formed between the sternocleidomastoid and the clavicle, at an angle of 10° above the horizontal, with the tip pointing just caudad to the contralateral nipple. Keeping the bevel up prevents trapping of the wire or catheter against the inferior wall of the vessel. Vessel puncture occurs at a depth of 2 to 3 cm.

FEMORAL VEIN   Femoral vein catheterization is used when the vessels of the upper body are not suitable, and when access is required above and below an injury. Although femoral vein catheterization is somewhat easier than subclavian or internal jugular catheterization, the insertion site is difficult to sterilize and keep clean, and patient movement may make it difficult to keep the line secured.

The patient should be supine with the ipsilateral hip in a neutral to slightly externally rotated position. The approximate position of the femoral vein can be determined by dividing the distance between the anterior superior iliac spine and the pubic tubercle into three equal segments (Fig. 17-2). The femoral artery usually lies at the junction of middle and distal thirds. If the femoral pulse is palpable, the needle puncture site should be 1.5 cm medial and 1.5 cm inferior to the inguinal ligament. Once venous blood is obtained, the guide wire is inserted though the needle, the needle is removed, and the catheter is inserted over the wire.

This access can be used for the measurement of central venous pressure, for intravenous pacing, for Swan-Ganz pulmonary artery catheterization, and to administer large volumes of fluids rapidly; the increased risk of infection and thrombosis make it less than ideal as a route for hyperalimentation. It is not an ideal central access site for administration of ACLS medications.

AXILLARY VEIN   The axillary vein (Fig. 17-2) is used for central venous access when the femoral, subclavian, and jugular veins are unavailable. This useful technique is unfortunately rarely used by emergency physicians. With practice, the success rate for central access via the axillary vein is similar to that for puncture of the internal jugular or subclavian vein. There is no risk of pneumothorax and the method has the advantage that, when arterial puncture occurs, direct pressure can be applied.

Patients are placed supine with head-down tilt and the arm abducted to 45°. In this position the axillary vein follows a straight course from the arm to the subclavian vein. An insertion point is chosen approximately 2.5 cm inferior to the axillary pulse and lateral to the midclavicular line. The introducer needle is then inserted along a line formed by the insertion point and suprasternal notch, at an angle of 30° to the skin, and directed parallel to the course of the artery toward the chest wall. In children and thin adults, the artery is easily palpable.

VENOUS CUTDOWN

The basilic vein in the antecubital fossa and the saphenous vein in the leg are the most commonly utilized vessels for cutdowns. The basilic vein is located two fingerbreadths above and two fingerbreadths medial to the olecranon. The saphenous vein is just anterior to the malleolus at the ankle and is also accessible in the proximal thigh three fingerbreadths below the midpoint of the inguinal ligament (Fig. 17-8). Although experienced operators may be able to complete the procedure in less than a minute, for most operators 5 or 6 min will be required. In many situations, this implies that cutdown should be resorted to only when percutaneous access has failed or is deemed likely to be unsuccessful.
FIG. 17-8. Venous cutdown. **A.** A skin incision is made perpendicular to the course of the vein. **B.** Skin retracted and vein exposed. **C.** Proximal and distal ties are passed under the vein. If the vein is to be sacrificed, the distal suture is tied to prevent bleeding, and the ends are left long to help stabilize the vein during cannulation. The proximal tie is not tied at this point, but traction on it will control back bleeding. **D.** The vein is stretched flat and incised at a 45° angle. Approximately one-third of the lumen must be exposed. Traction on the proximal tie will control back bleeding. (From Roberts JR, Hedges JR: *Clinical Procedures in Emergency Medicine,* 2d ed. Philadelphia, Saunders, 1991, p 321. With permission. Parts B and C first appeared in Vander Salm TJ et al: Atlas of Bedside Procedures. Boston, Little, Brown, 1979.)

The operator begins by prepping and anesthetizing the skin. A transverse skin incision is made, and by blunt dissection the subcutaneous tissue is separated until the vein is exposed. Any accompanying artery is identified by slipping a forceps or hemostat under the vessels and applying pressure; pulsatile flow will be evident in the artery. (However, with patients who are in shock, this maneuver may be unsuccessful.) After freeing the vein from the surrounding tissues, two separate sutures are passed beneath the vein, one proximally and one distally. The proximal sutures are left untied, while the distal suture is tied to occlude the vein. The ends of the sutures are kept long so that they can be used for applying traction to the vein. A small incision is made in the vein between the proximal and the distal sutures. (It should not be cut through and through). While applying traction on the vein, the operator inserts the catheter into the vein. Some cutdown kits contain a vein "holder," which may help to prepare the vein to accept a catheter. The proximal suture is tied to secure the catheter in the vein and the skin is closed. Care must be exercised throughout the procedure, since poor technique can result in injury to a tendon or nerve or extensive hemorrhage from soft tissue.

An alternate method of cannulating the vessel is to perform a "mini-cutdown" (Fig. 17-9). In this technique, the vein is fully exposed and an over-the-needle catheter is inserted into the vein under direct visualization. Great care must be taken to avoid through-and-through puncture. The advantage of this technique is that it is easier to perform, especially in young children; and the vessel does not have to be sacrificed. Extensive tissue dissection and complete isolation of the vein are avoided, there is no need to place proximal and distal suture ties, and the catheter can be discontinued with simple pressure at the site.
FIG. 17-9. The vessel is elevated with a hemostat and occluded with gentle traction from a distal tie. The needle is inserted and the sheath is advanced into the vessel. The vessel should not be tied off with this techinque.

The potential complications of venous cutdown include infection, phlebitis, and laceration of a nerve or artery.

INTRAOSSEOUS VASCULAR ACCESS

When vascular access cannot be obtained through other sites, intraosseous infusion may be life- or limb-saving. This method of vascular access, usually considered for children, may be used in adults as well. After 5 years of age, however, red marrow is steadily replaced by yellow marrow in the limbs, making infusion more difficult, and decreasing the infusion rate.

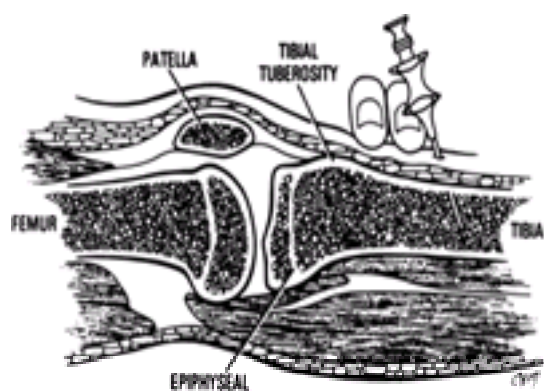
For pediatric patients up to 5 years of age, the tibia is the preferred site (Fig. 17-10). In adults, the most commonly used site is the medial malleolus. Although the sternum offers higher infusion rates for adults, this approach is attended by the potentially disastrous complication of puncture into the thoracic cavity. The tibia is technically more difficult in adults than in children because the adult bone is thicker and the needle tends to slip off the bone. Other potential insertion sites include the distal femur, clavicle, humerus, and ileum.


FIG. 17-10. The needle is inserted 2-cm distal to the tibial tuberosity on the medial aspect of the tibia. It is inserted in a caudal direction, away from the joint space.

A word about skeletal vascular anatomy is in order. Arterial supply to bones is by a nutrient artery that pierces the cortex and bifurcates into ascending and descending branches; these further divide into arterioles that pierce the endosteal surface to become capillaries. The capillaries drain into medullary venous sinusoids within the medullary space; these then drain into a central venous channel. Catheter placement in the sinusoids provides ready access to the venous circulation.

Technique

Either standard bone marrow aspiration needles or specialized intraosseous infusion needles must be used because standard intravenous stylets and spinal needles are likely to bend during the procedure. For the proximal tibia, the puncture site is 1 to 2 cm distal to the midpoint between the tibial tuberosity and the medial aspect of the tibia; for the distal tibia, it is the medial surface of the ankle just proximal to the medial malleolus; and for the distal femur, it is the dorsal surface at the point where the condyles join the shaft of the bone. After prepping and anesthetizing skin and periosteum, the operator inserts the needle with the point directed away from the joint space (distally if the site is the proximal tibia, proximally at the other two sites). The needle is grasped in the palm of the hand and directed into the bone using a twisting motion to break through the cortex. Once this has occurred, resistance decreases and crepitus is encountered as the needle enters the marrow cavity. The stylet is then removed and aspiration with a syringe is performed to obtain blood and marrow for confirmation of positioning. If shock is present, aspiration may be unsuccessful; if this is the case, cautious infusion of several milliliters of saline should be attempted with careful observation for extravasation. If there is none, then the needle may be assumed to be positioned in the marrow cavity. A postprocedure x-ray should be performed to rule out the complication of iatrogenic fracture.

Complications

The incidence of infection, including both cellulitis and osteomyelitis, is less than 1 percent, similar to that for other techniques. The potential for infection can be minimized by limiting the duration of intraosseous infusion and avoiding hypertonic solutions. Fractures of the tibia have been reported. Fat embolism is rare and has been reported only in adult patients. Injury to the growth plate has also been mentioned as a potential complication, but there are no reports of serious morbidity arising from an injury to developing bone.

VASCULAR ACCESS IN CHILDREN

Scalp Vein Access

Scalp veins are easily accessible in children less than 1 year of age and provide a good route for maintenance fluid and drug administration (Fig. 17-11). The superficial temporal, posterior auricular, and supratrochlear veins are the most easily catheterized scalp veins. In all cases, the vein must be differentiated from its respective artery. Arteries are generally more tortuous; they pulsate, and they fill from below, whereas veins fill from above.

FIG. 17-11. A tourniquet is placed around the infant's head and the needle inserted 0.5 cm from the intended puncture site in the direction of blood flow.

The operator begins by shaving and prepping an area large enough to secure butterfly needle wings. A rubber-band tourniquet is placed around the head proximal to the venipuncture site and a butterfly needle—usually 23 to 27 gauge—is advanced into the vein. The needle is then taped at the skin entry point and at the butterfly with cotton support under the wings. A cover (medicine cup) may be used to protect the area. Complications from this procedure include infection, bleeding, extravasation of fluid or medications, and inadvertent arterial puncture.

Umbilical Vein Access

In the first 1 to 2 weeks after birth, the umbilical vessels offer easy central venous access. Even a severely dehydrated umbilical stump may yield good vessels with adequate preparation. In a normal infant, there are two small umbilical arteries and a single larger vein. The arteries arise from the internal iliac artery while the vein is continuous with the portal vein.

The operator begins by cleansing the cord. A transverse cut is made 1 cm above the junction of skin and cord, at which point a purse-string suture is placed. The single large vein and two smaller arteries are identified. A 3.5- to 5.0-Fr catheter is inserted into the vein and advanced to 4 to 5 cm in a term infant; further advancement may cause liver damage. The catheter should be filled with saline solution and flushed properly prior to placement to ensure an air-free system.

The most common complications relate to vascular insufficiency induced by the catheter. Evidence of ischemia—such necrotic enterocolitis, liver necrosis, poor peripheral circulation, or abdominal distention—is an indication for immediate removal of the catheter. The potential for infectious complications is equivalent to that for other indwelling catheters.

ARTERIAL ACCESS

Arterial cannulation should be performed when emergency physicians are managing patients with conditions requiring arterial pressure monitoring or repeated arterial blood sampling—for example, hypertensive crisis, cardiogenic shock, and respiratory failure. Although the radial artery is the most frequently employed site, extensive experience using the brachial, femoral, and dorsalis pedis arteries has shown them to be equally satisfactory. In infants and neonates, the temporal or umbilical and dorsalis pedis arteries are most often accessed, although radial artery cannulation is also acceptable. While many operators are most familiar with the radial artery site, use of the femoral artery leaves the arm clear for other procedures and, in the presence of shock, the femoral artery is less difficult to cannulate percutaneously.

Assessment and Complications

Although catheterization of the radial artery is associated with up to a 20 percent incidence of temporary flow obstruction by Doppler study, permanent ischemic complications requiring surgical reanastomosis or amputation are quite rare. Confirmation of collateral flow through a patent ulnar artery can be obtained by performing the Allen test: while the patient clenches the wrist for 1 min the examiner compresses the radial and ulnar vessels with thumb and forefinger.[10] On release of ulnar compression, the patient partially extends the fingers, which are observed for rubor accentuated in comparison to the untested side. Patent ulnar circulation is indicated by return of rubor within 7 s; an equivocal result is 7 to 14 s. Greater than 14 s is considered definitely abnormal. If ulnar cannulation is contemplated, patency of the radial artery can be tested by the same test, with release of that vessel following compression. Percutaneous cannulation of the brachial or femoral arteries may be possible when the radial pulse is absent in a hypotensive patient. The technique is similar to radial artery cannulation, although a careful groin prep, preceded by removal of hair at that site to minimize the risk of infection, is necessary. With profound hypotension, cutdown to the radial artery may be required to cannulate the artery. This is performed through a transverse incision, with the artery punctured by utilizing a technique identical to the percutaneous approach, only under direct vision. The wound should be sutured and the catheter affixed with a silk suture. Serious complications—infection and occlusion—are most closely related to duration of cannulation and are much more common among critically ill patients than among those undergoing monitoring as an adjunct to a surgical procedure. During a typical stay in an intensive care unit, the incidence of local infection can be expected to approach 20 percent, while that of generalized sepsis from primary catheter infection is 4 percent, with little site-dependent variation. Other complications include hematoma formation and hemorrhage requiring transfusion.

Technique

The patient's nondominant extremity should be selected for radial artery cannulation. The wrist is placed in mild extension by placing a roll of gauze behind it and taping it to a splint. A sterile prep is applied and the operative area draped. Local infiltration should be performed with a small amount of lidocaine so that the pulse is not obscured. While a 20- or 22-gauge 1.25-in. Teflon catheter over a needle is held in one hand, the radial pulse is palpated with the other. The skin over the radial aspect of the wrist is punctured with the needle pointing proximally and at a 45° angle with the plane of the skin. The needle is advanced into the artery until pulsations appear. The catheter is then slid off the needle into the artery. If pulsatile flow ceases, the catheter may be withdrawn until arterial flow again appears, and a second attempt may be made to advance the catheter. If this is unsuccessful, the procedure must be repeated. After each attempt, care should be taken to apply pressure to the site long enough to prevent hematoma formation. Once in the artery, the catheter is connected to the monitoring system and flushed through a three-way stopcock with a sterile cap. The catheter should then be secured to the skin at its hub using silk or nylon suture. Kits are available for wire-guided arterial catheterization.

If cutdown is necessary to achieve arterial puncture, exposure of the artery is performed in a manner similar to that outlined for venous cutdown above. When 1 cm of artery is visible, the vessel is isolated by passing two lengths of silk suture beneath it, using a hemostat. A catheter through needle device is passed through the skin distal to the area of exposure and advanced into the site. The artery may then be punctured and the catheter advanced. The suture, which is used only to control the artery, may then be removed and the skin incision closed.

SPECIAL PROBLEMS RELATED TO VENOUS ACCESS

Complications of Total Parenteral Nutrition

Central venous catheter placement for total parenteral nutrition (TPN) may be done short-term as a part of hospital care or long-term at home or in extended-care facilities. TPN is usually administered through a catheter placed into either the subclavian or jugular vein. The incidence of mechanical and septic complications depends upon the skill, experience, and commitment of both the patient and the nutrition support team.[11] Suspicion of line sepsis demands immediate consultation. Most patients should be admitted, although the catheter may not need to be removed in selected cases.

Catheter occlusions occur in approximately 5 percent of patients receiving long-term TPN. If the first-line remedy of flushing the catheter with normal saline or heparin solution fails, thrombolytic agents, such as urokinase, may be used to lyse clots that obstruct the lumen of catheter without obstructing the vessel. The recommended dose of urokinase ranges from 5000 to 15,000 IU, depending on the type of intravascular device and its filling volume. A syringe with 1 to 2 mL of urokinase solution is instilled into the catheter, which is then clamped for 30 min. If no blood return is achieved, the maneuver may be repeated, with urokinase left in the catheter for 60 min. If there is still no return, then a third attempt may be made, this time leaving the urokinase solution in place for 12 h. Failure to clear the catheter after 12 h suggests either organized thrombus or anatomic abnormality; further diagnostic study such as angiography and ultrasound-Doppler duplex scanning may be indicated. Some authors have reported high success rates infusing ethanol (up to 3 mL of 70% solution) for presumed lipid occlusions or hydrochloric acid (HCl, 0.1N, up to 3 mL) to clear presumed mineral oil or other precipitates.

Catheter-related sepsis in patients receiving TPN is usually a result of catheter contamination by organisms colonizing the skin. Gram-negative bacteremia, sepsis syndrome, and fungemia are treated by removal of catheter in association with appropriate antimicrobial therapy. Gram-positive infections can often be managed with the catheter left in place while antibiotic therapy is administered. The delivery of TPN through peripherally inserted central catheters (PICCs) is associated with slightly lower infection rates but a higher rate of mechanical failure. Because there is a considerably increased risk of both infection and thrombosis when femoral lines are used for TPN, this mode of access is less than optimal for patients requiring parenteral nutrition. Other reported complications include pulmonary embolism,

line fracture, embolized catheter fragment, mediastinitis, superior vena cava syndrome, pneumothorax, air embolism, and lymphatic duct injury.

Accessing Indwelling Catheters

It is increasingly common for patients to present to EDs with specialized devices, such as Hickman catheters, which have been placed to provide long-term IV access. Such devices facilitate outpatient treatment in an era of increasing cost-consciousness. Emergency physicians can access these devices to obtain specimens for laboratory study as well as to administer IV fluids and medications.

When indwelling catheters are accessed, meticulous care should be taken to maintain sterility at the site. Depending on the type of device (implanted versus externalized), specialized equipment may be required to obtain access. Five milliliters of either normal saline or heparin flush (100 U/mL) is injected and then withdrawn gently to ensure catheter patency. Blood for laboratory study is collected only after a dead-space volume (5 to 10 mL) has been collected and discarded. Since these devices are heparinized, coagulation studies performed on such samples are unreliable; blood for these studies should be obtained from other sites. After access has been terminated, implanted devices should be flushed with heparin solution of 1000 U/mL strength. Other externalized devices should be flushed using a solution of 100 U/mL strength.

Arteriovenous fistulas and shunts should be used only for access in the most extreme of emergency situations, since complications, including loss of the access site, are common. The smallest needle appropriate to the task at hand should be inserted. Afterward, local pressure should be applied for 5 min or more, and these arterialized sites should be carefully monitored for hemorrhage for 12 h.

18 INVASIVE MONITORING, PACING TECHNIQUES, AND AUTOMATIC AND IMPLANTABLE DEFIBRILLATORS

Edward S. Bessman

During critical resuscitations the emergency physician may be called upon to institute invasive pressure monitoring or to use emergency pacing techniques. Emergency physicians must also be familiar with the relevant aspects of automatic external defibrillators and implantable cardioverter defibrillators. This chapter reviews these technologies as applied to emergency cardiac care.

INVASIVE MONITORING TECHNIQUES

General Considerations

Invasive pressure monitoring should never be the initial step in resuscitation. When clinically indicated, arterial line or pulmonary artery catheter (PAC) placement may be considered after initial stabilization is completed. If possible, these procedures should be deferred until the patient reaches the more controlled environment of the intensive care unit, unless there will be a significant delay.

The two essential components of any pressure monitoring system are a properly placed and secured catheter and a functioning pressure transducer-monitor. Ideally, the transducer and line for pressure monitoring should be set up and ready for use prior to the patient's arrival in the emergency department. Examples of transducer systems are illustrated in Fig. 18-1.
FIG. 18-1. Arterial pressure monitoring systems. **A.** Systems for continuous flush with heparinized saline solution connected to a mechanical pressure transducer. **B.** System for manual flush. Either system can be used with an electronic pressure transducer, shown in **B.** The pressure done should be maintained at the level of the patient's heart. [From Beal JM (ed): *Critical Care for Surgical Patients.* New York, Macmillan, 1982. Used by permission.]

Arterial Cannulation

Arterial lines offer several advantages over monitoring blood pressure with an arm cuff. The arterial line provides continuous measurement of blood pressure and can be used for easy sequential sampling of blood gases. In the setting of marked vasoconstriction or hypotension, the arterial line usually gives more accurate pressure readings than a blood pressure cuff. The American College of Cardiology/American Heart Association practice guidelines for patients with acute myocardial infarction recommend intraarterial pressure monitoring for patients with severe hypotension or cardiogenic shock or who are receiving potent vasoactive infusions. [1] Other appropriate scenarios include hypertensive crisis, hypothermic cardiac arrest, and prolonged emergency department resuscitation.

The radial and femoral arteries are readily accessible for rapid cannulation. Percutaneous puncture is preferred. In hypotensive patients it may be easier to cannulate the femoral artery (because it is a larger vessel with constant landmarks) than the radial artery. Cutdown on the radial artery is an alternative in such patients. It is prudent to document the result of Allen's test for ulnar artery patency prior to radial arterial line placement, although its accuracy is questionable. [2] If the test result is positive, another site should be considered, but if that is not practical, then the clinician may have to proceed with radial artery cannulation. [3]

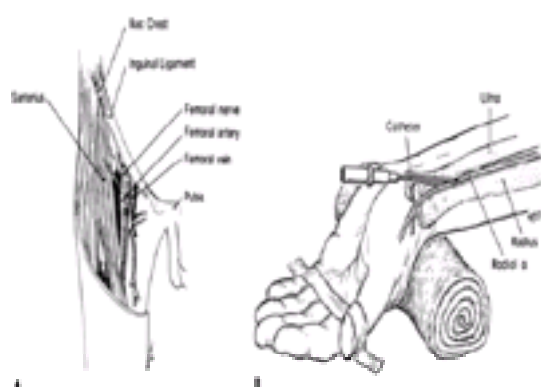
Landmarks for radial and femoral artery cannulation are shown in Fig. 18-2. The catheter (usually 20 gauge, 2 in long for radial cannulation and 18 gauge, 4 in long for femoral cannulation) can be introduced by direct puncture threaded over the needle or by Seldinger technique threaded over a guidewire. Freely flowing, pulsatile, bright-red blood indicates proper placement. With marked hypotension or hypoxia, arterial blood flow may be mistaken for venous (nonpulsatile, dark blood returned). In all cases, connection to the transducer should reveal an arterial waveform if the catheter is in the proper position. Failure to visualize a waveform can be due to venous placement, air in the line, a closed stopcock, or a malfunction in the transducer or monitor.


FIG. 18-2. Anatomic landmarks for arterial line placement. **A.** Femoral triangle. Note that the femoral artery lies lateral to the vein and midway between the pubis and the iliac crest. **B.** Radial aspect of the wrist. Note that mild extension of the wrist aids in successful placement. [From Beal JM (ed): *Critical Care for Surgical Patients.* New York, Macmillan, 1982. Used by permission.]

The complication rate for either radial or femoral artery cannulation is about 7 percent.[4] These include local hematoma and hemorrhage; both can usually be controlled with a pressure dressing. Arterial occlusion, thrombosis, or embolization with distal ischemia may occur; they are associated with placement in smaller vessels or in atherosclerotic vessels, with prolonged catheterization, and with use of end arteries that supply areas with poor collateral circulation. Sepsis may result from local infection at the insertion site. Using the femoral or radial site can minimize these complications, along with proper attention to sterile technique and removal of the line as soon as feasible after the patient is stabilized.[1]

Pulmonary Artery Cannulation

A PAC is helpful in the measurement of critically ill patients with hemodynamic instability, particularly in the setting of acute myocardial infarction. Most important, the PAC can help to differentiate between shock due to intravascular volume depletion and that due to extensive left ventricular (LV) dysfunction. When the balloon tip of a PAC is properly wedged in a branch of the pulmonary artery, the pressure sensed by the catheter corresponds approximately to that in the left atrium. Left atrial pressure (which equals LV filling pressure) is an excellent indication of the adequacy of fluid resuscitation. If this pressure is low (<12 mmHg), additional fluid resuscitation is indicated. If this pressure is high (>20 mmHg), additional fluids are unlikely to improve cardiac performance; instead diuresis, afterload reduction, inotropic support, or vasopressors should be considered. Although the PAC can yield useful diagnostic information (Table 18-1 and Table 18-2), the distinction between the need for more fluids and the need for more LV support is its most useful application during resuscitation.[1] Volume assessment via central venous pressure monitoring is less reliable than PAC, especially in the presence of valvular or pulmonary disease.

Type of Shock	CO	PCWP	SVR
Cardiogenic	↓	↑	↑
Hypovolemic	↓	↓	↑
Septic	↓ or ↑	↓	↓
Neurogenic	↑	↓	↓
Anaphylactic	↓	↓	↓

Abbreviations: CO, cardiac output; PCWP, pulmonary capillary wedge pressure; SVR, systemic vascular resistance; ↑, increased; ↓, decreased.

TABLE 18-1 Hemodynamic Diagnosis of Shock States

Cardiac index, (L/min)/m²	>2	I	II
	<2	III	IV
		<18 PCWP >18	

Note: Initial therapy and prognosis can be determined by class. Mortality rates by class are 1%, 11%, 18%, and 60% for classes I–IV, respectively. Patients in class I require supportive care only. Patients in class II require treatment for pulmonary edema due to lower pulmonary capillary wedge pressure. Patients in class III may improve with fluid administration. Patients in class IV require maximal circulatory support for cardiogenic shock.
Abbreviation: PCWP, pulmonary capillary wedge pressure.

TABLE 18-2 Hemodynamic Subsets in Acute Myocardial Infarction

A standard PAC is shown in Fig 18-3. The catheter has two fluid paths, one that terminates at the tip (the distal port) and a second that opens 10 to 15 cm from the tip (the proximal port). A third lumen connects to a 1.5-mL balloon located at the tip of the catheter. When inflated during insertion, the balloon surrounds the tip of the PAC to prevent it from causing injury to the heart or great vessels as well as to help float the catheter through the heart as it is advanced. A temperature sensor is located about 5 cm proximal to the catheter tip and can be used to measure cardiac output via the thermodilution technique.
FIG. 18-3. Pulmonary artery thermodilution catheter. [From Beal JM (ed): *Critical Care for Surgical Patients.* New York, Macmillan, 1982. Used by permission.]

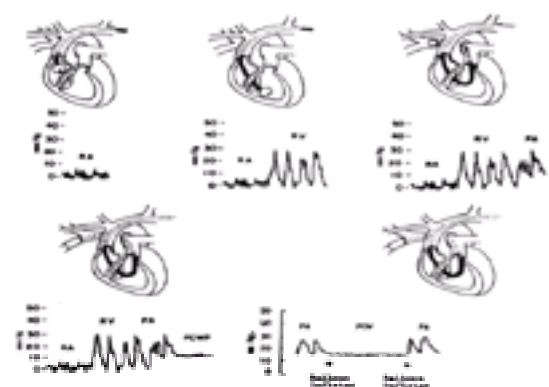
The procedure for insertion is described in detail elsewhere[5] but briefly is as follows. After central venous access is secured (see Chap. 17, "Vascular Access") the PAC, which has already been attached to a monitor and a pressure transducer, is slowly advanced through the introducer sheath. Once the tip of the catheter enters the vein, the balloon is inflated. By observing the pressure waveform transmitted via the distal port, the operator can follow the progress of the catheter through the heart and, ultimately, into a branch of the pulmonary artery (Fig. 18-4). Fluoroscopy is helpful to ensure quick and proper placement but rarely is available in the emergency department.


FIG. 18-4. Hemodynamic aspects of balloon catheter insertion into the pulmonary artery. [From Gottlieb AJ (ed): *The Whole Internist Catalog.* Philadelphia, Saunders, 1980. Used by permission.]

With the PAC in position, the clinician can occlude the branch pulmonary artery by inflating the balloon and wedging it in the artery. This gives the pulmonary artery occlusion pressure, or, as it is more commonly known, the pulmonary capillary wedge pressure, which best reflects the pressure in the pulmonary capillary bed and the left atrium. The clinician can also rapidly measure pulmonary artery pressure, cardiac output, and central venous pressure. These measurements, when combined with arterial pressure measurement, enable the clinician to calculate systemic vascular resistance. These parameters are useful in the diagnosis and treatment of various shock states and in guiding therapy in acute myocardial infarction (Table 18-1 and Table 18-2).

As with arterial cannulation, therapeutic procedures or definitive care should not be delayed solely to allow PAC placement. Complications include all the complications of central venous line placement (Chap. 17). In addition, cardiac dysrhythmias and right bundle branch block may occur as the catheter traverses the heart. Other potential complications include pulmonary embolism or infarction, knotting of the catheter, infection, and rupture of a small branch of the pulmonary artery.

The safety of PACs in the critical care environment has been questioned recently because of an association between its use and increased mortality rates. [6] Current consensus favors the continued use of PACs[1] but underscores the need for definitive investigation. [7] Thus, the appropriateness of PAC insertion in the emergency department setting for a given patient must be weighed carefully. The advent of newer techniques, such as transesophageal echocardiography, [8,9] transthoracic impedance cardiography,[10] and magnetic resonance velocimetry[11] may further reduce the role of PACs in the emergency department.

EMERGENCY PACING TECHNIQUES

General Considerations

Emergency cardiac pacing may be instituted either prophylactically or therapeutically. Prophylactic indications include those situations where there is high risk of atrioventricular block. Therapeutic indications include symptomatic bradyarrhythmias, asystole, and overdrive pacing. Since it can be instituted quickly and noninvasively, transcutaneous pacing is the technique of choice in the emergency department. Transvenous pacing should be used in patients who require prolonged pacing or who have a very high (>30 percent) risk of heart block. Detailed guidelines are available in Chap. 24 and Chap. 48.

Transcutaneous Pacing

Transcutaneous pacing has become the emergency technique of choice because of its easy application. It uses externally applied electrodes to deliver an electric impulse directly across the intact chest wall to stimulate the myocardium. Transcutaneous pacers differ from standard pulse generators in several important ways. The pulse duration of the stimulating impulse is longer and the current output higher than for standard internal leads. Muscle contraction (usually the chest wall or diaphragm) is notable during pacing, especially at higher outputs. This results in a twitching or bucking activity that can make assessment of cardiac output by palpation of the radial, carotid, or femoral pulse unreliable during transcutaneous pacing. The higher current outputs used make cardiac monitoring with standard electrocardiogram (ECG) monitors problematic due to interference from the large-amplitude pacing spike. Most transcutaneous pacing units come equipped with a monitor that automatically filters the pacing spike so that simultaneous monitoring is possible.

The external pacing electrodes are quickly and easily applied to the chest and back. If separate defibrillator pads or paddles are used, they should be placed at least 2 to 3 cm away from the pacing pads. There is little risk of electrical injury to health care providers during transcutaneous pacing. The electrodes are insulated, and chest compressions [cardiopulmonary resuscitation (CPR)] can be administered directly over them while pacing, although it is recommended that pacing be discontinued during CPR to minimize inappropriate stimulation of the patient due to electrical artifacts. Inadvertent contact with the active pacing surface results only in a mild shock. In the setting of bradyasystolic arrest, it is reasonable to turn the stimulating current to maximum output and then decrease the output if capture is achieved. In a patient with a hemodynamically compromising bradycardia (but not in cardiac arrest), the operator should slowly increase the output from the minimum setting until capture is achieved. Capture is assessed by following the ECG on the filtered monitor of the pacing unit and palpation of peripheral pulses. The hemodynamic response to pacing must also be assessed, either by blood pressure cuff or arterial catheter. Ideally, pacing should be continued at 1.25 times the threshold of initial electrical capture.

As with other pacing systems, transcutaneous pacing may be fixed rate (asynchronous) or demand (synchronous). Asynchronous pacing delivers an electrical impulse at a regular interval without regard to intrinsic cardiac pacemaker activity. This creates the risk of precipitating dysrhythmias if a pacing stimulus is given during the vulnerable period of ventricular repolarization. Synchronous pacing is therefore safer, since the pacing impulse is delivered only if an intrinsic electrical complex is not sensed within a preset interval. An increasing number of defibrillators include a built-in transcutaneous pacemaker. These units are equipped with multifunctional electrodes that allow defibrillation, pacing, and ECG monitoring through one set of pads. This development ensures that pacing will be available as soon as the defibrillator reaches the patient in cardiac arrest.

Failure to capture with transcutaneous pacing may be related to electrode placement or the patient's size. Patients who are conscious or who regain consciousness during transcutaneous pacing may experience discomfort due to muscle contraction. Analgesia with incremental doses of morphine or sedation with a benzodiazepine makes this discomfort tolerable. There is no evidence of clinically significant myocardial damage from properly performed transcutaneous pacing. [12] Nonetheless, transcutaneous pacing should be used for temporary stabilization only and should always be followed as soon as feasible by an internal pacing technique if there is a prolonged need for pacing.

Transvenous Pacing

Transvenous pacing consists of endocardial stimulation of the right ventricle by an electrode introduced into a central vein. The most commonly encountered difficulties with transvenous pacing are securing venous access and obtaining proper placement of the stimulating electrode, both of which can be time consuming. Venous access routes most commonly used include the subclavian, internal or external jugular, femoral, and brachial. Transvenous pacing catheters can be inserted through a variety of venous introducers. A soft, flexible, semifloating bipolar catheter is preferred. This type of pacer is safest to use and takes advantage of any forward blood flow that may be present.

Placement of the catheter tip into the apex of the right ventricle is the key to successful transvenous pacing. Several techniques can aid successful placement. Fluoroscopic guidance is the surest method of right ventricular placement but is rarely available in the emergency department. Electrocardiographic guidance is useful in patients with narrow complexes and/or P waves when fluoroscopy is unavailable. Balloon-tipped floating catheters may aid placement when used in conjunction with ECG and fluoroscopic guidance or when used alone. The balloon is inflated after catheter insertion into a central vein. Forward blood flow then directs the catheter tip toward the ventricle as the operator slowly advances the catheter. As with all balloon-tipped catheters, the balloon should always be deflated prior to withdrawal; the catheter should never be pulled back with the balloon inflated.

When patients have decreased or no forward blood flow (including many circumstances in which transvenous pacing would be used in the emergency department), positioning of the pacer tip within the right ventricle is difficult. Balloon-tipped catheters are not much of an aid in placement during low- or no-flow states. In a true emergency, the pacemaker electrodes are connected to the power source and the catheter advanced blindly in hopes that the tip will encounter the endocardium of the right ventricle and that capture will result. In this setting a right internal jugular venous access route should be used. From this approach, the catheter traverses a straight line into the right ventricle and rarely curls in the atrium or deflects into the inferior vena cava.

Pacer settings vary with the clinical situation. An initial rate of 80 to 100 impulses/min is appropriate for most patients. Asynchronous mode (sensitivity off) is used initially in patients requiring emergency pacing for hemodynamically unstable bradycardias. The ECG should be followed to determine the presence or absence of capture (Fig. 18-5). Output should initially be set at maximum (usually 20 mA) and then decreased after capture is achieved. With optimal tip position, capture should occur at less than 2 mA. Pacing should be continued at 1.5 to 2 times the threshold output required for capture. Subsequent rate and sensitivity settings should be

adjusted as clinically indicated by the patient's hemodynamic status and underlying rhythm disturbance.
FIG. 18-5. Pacing with intermittent capture. "P" indicates paced beats and "A," pacer artifact without capture.

Chest radiographs should be obtained after the patient is stabilized to ensure proper tip placement and to evaluate the possibility of pneumothorax from the preceding central venous line placement. Finally, care should be taken to firmly affix the pacing catheter to the insertion site prior to transferring the patient. Transvenous pacing is best used in urgent rather than emergent situations, particularly when there is adequate time to utilize fluoroscopy. In the setting of cardiac arrest, transcutaneous pacing is preferred.

Transthoracic pacing is mentioned here largely for historic reasons, since external pacing techniques have largely replaced its use. However, whenever transvenous pacing is tried but unsuccessful, transthoracic pacing may still be attempted. When the latter technique is performed blindly, the likelihood of successful placement is low, with risk of liver, pulmonary artery, diaphragm, lung, or coronary artery puncture. [13] Although it has not been studied, use of ultrasound-guided placement may improve placement.

AUTOMATIC AND IMPLANTABLE DEFIBRILLATORS

In 1933, William Kouwenhoven observed in dogs that closed-chest electrical shocks delivered within 30 s of inducing ventricular fibrillation (VF) were 98 percent effective in terminating the dysrhythmia. After 2 min of VF, the rate of resuscitation fell to 27 percent. He reported similar results in human subjects. [14] Modern research indicates that the likelihood for successful resuscitation decreases roughly 10 percent/min after the onset of VF. Thus, the goal of emergency cardiac care is to deliver defibrillation as quickly as possible.

Two recent technological developments have led to the more rapid application of defibrillation. Automatic external defibrillators allow first responders to rapidly institute defibrillation. Even laypersons, such as family members or bystanders, can learn to use these devices. In addition, implanted defibrillators allow patients with frequent malignant ventricular dysrhythmias to carry their own defibrillators with them at all times. Emergency physicians need to be familiar with these devices and the special considerations associated with their use.

Automatic External Defibrillators

Automatic external defibrillators (AEDs) have relatively simple controls and can be used by minimally trained providers to initiate defibrillation. At the patient's right sternal border and cardiac apex, the operator places electrode pads, which are used both for monitoring and defibrillating. Once attached, the AED analyzes the cardiac rhythm and initiates its treatment algorithm. A fully automatic device will deliver a countershock once ventricular tachycardia or VF has been sensed. The AED gives an audible announcement that defibrillation will commence, and the only way the operator can prevent discharge is to turn off the device. A semiautomatic AED analyzes the rhythm and then advises whether a shock is indicated. The operator must press the control button in order to initiate defibrillation; the operator may also override the AED and administer a countershock even if the device has not sensed a shockable rhythm.

AEDs shock patients in VF several times sequentially until an organized cardiac rhythm results or until the maximum number of shocks allowed by the programmed algorithm is reached. Many devices also provide a record of rhythms and events during their use, which allows the emergency physician to subsequently reconstruct the sequence of events during resuscitation.

An AED may be placed on an unstable patient in anticipation of subsequent deterioration, but the device should not be activated until or unless the patient is pulseless. Since motion artifacts may confuse the rhythm-analysis circuitry, the AED should not be in the sensing mode during CPR, during transport, or if the patient has a seizure. Unlike transcutaneous pacemakers, AEDs can deliver a debilitating shock to the operator or other personnel, and the same precautions regarding contact with the patient during defibrillation should be followed with AEDs as with standard defibrillators. The failure of an AED to restore a perfusing rhythm is a poor prognostic sign often associated with long arrest times or arrest rhythms other than VF. When an AED fails to resuscitate a patient in arrest, the cardiac rhythm should be identified and treated. If the rhythm is refractory VF, drug therapy should be instituted while continuing further defibrillation attempts.

AEDs are most effective in tiered emergency medical services systems where AED-equipped first responders reach the patient rapidly and are backed up by the later arrival of paramedics with full advanced life-support capabilities. [15] There is ongoing interest in making AEDs available for widespread use by nonmedical personnel and the lay public. [16,17]

Implantable Cardioverter-Defibrillators

The first human placement of an implantable cardioverter-defibrillator (ICD) took place in 1980 at the Johns Hopkins Hospital. [18] Since that time it has become the treatment of choice for sudden cardiac death, reducing mortality from about 30 to 45 percent/year to less than 2 percent/year. [19] This remarkable efficacy, coupled with the failure (and potentially proarrhythmic effects) of pharmacologic therapy and the increasing sophistication and miniaturization of the devices, has led to an explosion in ICD use. Through 1994 there had been over 50,000 ICDs implanted worldwide; in 1995 there were more than 20,000 implantations in the United States alone.

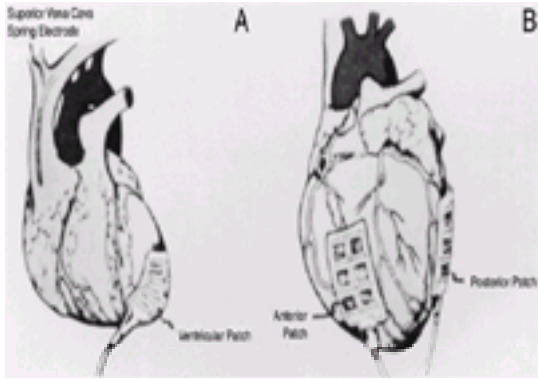
An ICD consists of a pulse generator, a lead system with both sensing and shocking electrodes, circuitry to analyze the cardiac rhythm and trigger defibrillation, and a power supply. There are currently three generations of ICDs. In each successive generation, the devices have become smaller, more sophisticated, more reliable, and easier to implant. Second-generation ICDs are still quite common. These devices generally were placed by thoracotomy or sternotomy, and defibrillation occurred through electrodes positioned inside or outside the pericardium. Rate-sensing electrodes were placed epicardially or transvenously (Fig. 18-6). The sensing algorithms for second-generation ICDs were relatively unsophisticated; they reliably detected ventricular tachycardia and VF but would cause the devices to inappropriately shock supraventricular rhythms as well. Roughly one-third of patients with second-generation ICDs receive at least one shock triggered by a supraventricular tachycardia during the working life of the device.


FIG. 18-6. Typical second generation ICD electrode arrangements. **A.** Spring-patch pathway. **B.** Patch-patch pathway. (From Chapman PD, Veseth-Rogers JL, Duquette SE: The implantable defibrillator and the emergency physician. *Ann Emerg Med* 18:579, 1989. Used by permission.)

Third-generation ICDs have a volume of about 60 mL, or roughly one-quarter that of second-generation devices. The sensing-pacing-defibrillation electrodes are placed transvenously, and the device itself is generally implanted subcutaneously in the subpectoral region or in an abdominal pocket. A subcutaneous patch electrode may be used to help lower the defibrillation threshold. On a chest radiograph, at first glance these devices can easily be mistaken for conventional pacemakers. Careful examination of the electrodes will reveal their true nature (Fig. 18-7). Newer ICDs are better at discriminating supraventricular tachycardia and are capable of a variety of responses to ventricular tachycardia and VF. Most are programmed to follow a tiered approach to ventricular dysrhythmias: antitachycardia pacing, low-energy cardioversion, and finally defibrillation. Depending on the frequency of discharge and whether the pacemaker function is used, the latest ICDs have a projected life span of about 8 years.
FIG. 18-7. Chest radiograph of a patient with a nonthoracotomy implanted third generation defibrillator. The ICD is in the left subpectoral area. The electrodes (arrows) have been placed transvenously. The proximal spring electrode is positioned at the junction of the superior vena cava and the right atrium. The distal electrode is in the right ventricle; only a portion of its lead is visible.

EMERGENCY DEPARTMENT EVALUATION AND THERAPY   ICDs are remarkably effective in preventing sudden cardiac death. The most common cause of death in patients with ICDs is congestive heart failure, which should be managed in standard fashion in the emergency department. However, the most common reason an ICD patient comes to the emergency department is to be evaluated for the appropriateness of a previously delivered shock. Causes of inappropriate shock delivery are summarized in Table 18-3. In evaluating a patient complaining of one or more ICD shocks, it is important to determine the number of shocks delivered, the activity of the patient at the time, and any prodromal symptoms or postshock trauma. Recent changes in antiarrhythmic drug dosage should be noted. The physical examination should focus on the vital signs, the cardiovascular status, the generator pocket, and evidence of incidental trauma. The patient should be monitored during the evaluation. An ECG should be obtained and interpreted with the knowledge that ST-segment elevations or depressions due exclusively to the shock will resolve within 15 min. A chest radiograph may reveal electrode migration, displacement, or fracture. Drug levels of antiarrhythmics should be determined and electrolyte disturbances explored.

False sensing
  Supraventricular tachycardia with rapid ventricular response
  Muscular activity (shivering, diaphragmatic contraction)
  Extraneous source (tapping of chest wall, vibrations, pacer spikes)
  Sensing T waves as QRS complex (double counting)
  Sensing lead fracture or migration

Unsustained tachyarrhythmia

ICD-pacemaker interactions

Component failure

TABLE 18-3   Potential Causes of Inappropriate ICD Shock Delivery

Since admission criteria are often institution- and cardiologist-specific, consultation with the patient's cardiologist is essential. General admission guidelines include all unstable patients, patients with two or more shocks in a 1-week period, the presence of correctable causes of dysrhythmia (e.g., electrolyte imbalances, drug toxicity, or ischemia), any sign of infection, mechanical disruption of the ICD or leads, and patients who need additional cardiologic investigation for possible malfunction of the device.

For an ICD patient in cardiac arrest, normal basic and advanced resuscitation measures are indicated. If defibrillation is necessary, the operator should avoid placing either paddle directly over the ICD. The presence of epicardial patch electrodes may shield the myocardium from the countershock and may therefore necessitate repositioning of the paddles. CPR may be performed in the usual fashion. If the ICD should discharge during CPR, the provider may perceive a small electrical shock, but it is neither uncomfortable nor dangerous.

Occasionally it may become necessary to temporarily deactivate the ICD, as in the case of inappropriate shock for a stable rhythm. Second-generation devices may be deactivated by placing a donut-shaped magnet over the right upper quadrant (Fig. 18-8) of the pulse generator for 30 s until the intermittent beeping ceases and a solid tone is heard. The magnet is then removed. If this does not succeed, then deactivation is attempted by placing the magnet over the opposite corner of the pulse generator (some are surgically positioned upside down). The response of third-generation devices to a magnet can be complex, but generally defibrillation is deactivated only when the magnet is present. This requires taping the magnet to the skin overlying the ICD. Defibrillation can be reenabled by removing the magnet. Some third-generation devices are programmed so that they cannot be deactivated by a magnetic field. All ICDs should be evaluated by a cardiologist after exposure to a magnet.

FIG. 18-8. Correct magnet placement to deactivate second generation ICD. (From Chapman PD, Veseth-Rogers JL, Duquette SE: The implantable defibrillator and the emergency physician. *Ann Emerg Med* 18:579, 1989. Used by permission.)

19 CEREBRAL RESUSCITATION

Gary S. Krause
Blaine C. White

Cerebral resuscitation continues to affect a substantial portion of the population of the United States. Data from the ARIC (Atherosclerotic Risk in Communities), CHS (Cardiovascular Health Study), and the NHLBI (National Heart, Lung, and Blood Institute) show that about 600,000 people suffer a new or recurrent stroke each year. Furthermore, stroke is the leading cause of serious, long-term disability in the United States. Three million Americans are currently permanently disabled because of stroke, and 31 percent of stroke survivors need help caring for themselves, 20 percent need help walking, 71 percent have an impaired vocational capacity when examined an average of 7 years later, and 16 percent have to be institutionalized. The direct and indirect cost of stroke in 1998 was estimated at over $40 billion. In addition, cardiopulmonary resuscitation for victims of cardiac arrest, both within and outside of the hospital, succeeds in restoring spontaneous circulation in about 70,000 patients a year in the United States. At least 60 percent of these patients subsequently die in the hospital as a result of extensive brain damage; only 3 to 10 percent of resuscitated patients are finally able to resume their former lifestyles. Clearly, the development of effective interventions to prevent these sequela of brain ischemia and reperfusion would enormously enhance the value of the investment already made and would return thousands of now lost patients to renewed vigorous and productive time with their families and in our society.

There are two important issues involved in the ongoing effort to reduce this neurologic morbidity. One is discovery of the mechanisms involved in tissue injury and repair, and the other is the identification of clinically effective therapy. Clinical trials conducted more than a decade ago utilizing postresuscitation treatment with barbiturates[1] or calcium antagonists[2] were disappointing. More recently, clinical treatment of stroke with the radical scavenger tirilazad was found ineffective, [3] and laboratory investigations of treatment with glutamate receptor antagonists after resuscitation from cardiac arrest produced disappointing results. [4] The wide variety of therapeutic agents now in single-drug clinical trials (e.g., involving thrombolysis, glutamate release inhibition, N-methyl-D-aspartate receptor antagonism, opioid antagonism, calcium channel blockade, free radical scavenging, membrane stabilization, intercellular adhesion molecule-1 antagonism, ganglioside administration, and growth factor administration) suggests that understanding of the mechanisms involved in damage and repair in neurons remains incomplete.

Four major observations have provided the foundation for investigation of brain injury by ischemia and reperfusion: [5] (1) rapid loss of high-energy phosphate compounds during ischemia followed by their recovery within the first 15 min of reperfusion, (2) morphologic evidence that most structural damage occurs during reperfusion, especially in selectively vulnerable zones, (3) progressive brain hypoperfusion during postischemic reperfusion, and (4) prolonged suppression of protein synthesis in selectively vulnerable neurons.

Cardiac arrest resulting in ischemic-anoxic brain injury is characterized by three phases: ischemia, early reperfusion, and late reperfusion. We have published extensive reviews of our theoretical model of the causal interactions of neuronal injury and repair mechanisms during ischemia and reperfusion. [5,6] Briefly, primary injury mechanisms include, at a minimum, activation of phospholipases and proteolytic enzymes (calpain) during ischemia and generation of radicals accompanied by lipid peroxidation during reperfusion. This chapter outlines the crucial role of calcium and iron in these injury mechanisms and suggests possible therapies to ameliorate brain injury following an ischemic insult.

ISCHEMIC PHASE

Morphologic studies have shown that the extent of tissue injury observed following ischemia largely reflects damage incurred during reperfusion and have identified specific populations of brain neurons that are exceptionally susceptible to damage and death. These selectively vulnerable neurons include the pyramidal neurons in layers 3 and 5 of the cortex and those found in the CA1 and hilus of the hippocampus. Minimal ultrastructural injury is seen in the brain during complete ischemia. Some margination and clumping of nuclear chromatin is seen by 10 to 15 min of complete ischemia. Mitochondria may be slightly swollen, but their structure does not show major degenerative alterations for up to 30 min of complete ischemia. Similarly, some swelling of the endoplasmic reticulum (ER) may be seen during ischemia, but the polyribosomes remain appropriately associated with the ER, and disaggregation of polyribosomes does not occur during complete ischemia. Nuclear and plasma membranes show a normal, well-defined bilaminar structure without evidence of holes or general structural disintegration.

In contrast to the paucity of morphologic findings, there are severe biochemical alterations. With the onset of cardiac arrest there is precipitous decline in brain oxygen content, which approaches zero within 6 to 12 s. The brain has very limited reserves of glucose, glycogen, or phosphocreatine; therefore, oxygen depletion leads to a sharp decline in tissue adenosine triphosphate (ATP) levels, which approach zero within 4 min. Anaerobic glycolysis and ATP depletion lead to lactic acidosis and hypoxanthine accumulation, respectively, during the ischemic phase. Since about 80 percent of the brain's ATP is used to maintain transmembrane ionic gradients for potassium, sodium, and calcium, these ionic gradients also decay rapidly. During complete ischemic anoxia, these ions equilibrate between the extra- and intracellular fluid within 5 to 10 min of the insult.

The high cytosolic calcium level, thought to be a major initiating event leading to cell death, [7] causes four key events: the activation of membrane phospholipase A_2, proteolytic cleavage of xanthine dehydrogenase, activation of the proteolytic enzyme calpain, and release of excitatory neurotransmitters such as glutamate. Phospholipase A_2 cleaves a fatty acid, primarily arachidonate, from the cell membrane lipids, yielding a free fatty acid and in the process damaging the membrane's structure. The proteolysis of xanthine dehydrogenase in brain endothelial cells produces xanthine oxidase, which will react with hypoxanthine to produce the superoxide radical (O_2^-) upon reperfusion. Proteins that are degraded by calpain during either ischemia or reperfusion include microtubule-associated 2, tubulin, neurofilament protein, spectrin, protein kinase C, calcium/calmodulin kinase II, and the translation initiation factors eIF4E and eIF4G.

EARLY REPERFUSION

During early reperfusion, ATP levels and total adenylate charge recover rapidly. If the ischemic insult has been less than 20 min, the membrane ionic gradients also recover quickly. After much longer insults of 1 to 3 h, total tissue calcium loads actually increase during reperfusion. It is felt that this reflects extensive and irreversible cell membrane injury during these very prolonged periods of ischemia.

Arachidonate is rapidly oxidized by both cyclooxygenase and lipoxygenase, and returns to preischemic levels within 30 min of reperfusion. Several vasoactive substances are produced by the metabolism of arachidonate. The prostaglandins are the products of cyclooxygenase, and the leukotrienes are the products of lipoxygenase. The production of the vasodilatory prostaglandin prostacyclin is severely inhibited during early reperfusion. Thus, vasospastic compounds predominate in the leukotriene and prostaglandin products. While the free arachidonic acid levels rapidly return to baseline during reperfusion, leukotrienes remain markedly elevated for at least 24 h. The time course of leukotriene elevation may explain the alterations in blood flow seen in the postischemic brain (the "no-reflow" phenomenon). Restoration of normal or mildly hypertensive systemic arterial pressure produces an initial brain hyperperfusion. However, within 1 h, global brain perfusion has dropped to levels of 20 to 40 percent of normal, where it remains for up to 1 to 2 days. This phenomenon occurs without a change in intracranial pressure and was originally thought to lead to failure of high-energy metabolism and neuronal death during reperfusion. However, therapy that inhibited postischemic brain hypoperfusion had little effect on neurologic outcome.

Membrane lipids are extensively peroxidized by iron-dependent radical reactions during reperfusion. Within the first 30 s of reperfusion, there is a brief burst of oxygen-based free radical production, although the precise identity of the radical species remains unknown. Xanthine oxidase and cyclooxygenase, whose substrates are hypoxanthine and arachidonate respectively, produce O_2^- as a side product. Availability of a transition metal, such as iron, is required for reaction of oxygen radicals with tissue macromolecules, including lipids (lipid peroxidation). The brain glia have abundant stores of oxidized (ferric) iron, mostly in ferritin and transferrin, forms in which the iron is unable to act as a catalyst for oxygen radical reactions. However, O_2^-, which is present in excessive amounts during early reperfusion, promotes reduction of ferric iron and release of ferrous iron from ferritin, and lipid peroxidation in the reperfused brain has been demonstrated by many laboratories and maps to selectively vulnerable neurons. These reactions also appear to be involved in the genesis of the postischemic hypoperfusion phenomenon, which is

inhibited by superoxide dismutase and deferoxamine or U74006F, a lipid peroxidation chain terminator.

Excitatory amino acid neurotransmitters appear to play a role in the injury produced by focal brain ischemia such as stroke; it is unclear whether the same holds true in global brain ischemia. However, excitatory neurotransmitter uptake is inhibited by arachidonate and products of lipid peroxidation, and thus continued stimulation of receptors may contribute to neuronal damage by as yet unidentified mechanisms.

Protein synthesis is suppressed during ischemia by lack of ATP.[8] However, even with the rapid restoration of ATP levels that accompanies reperfusion, there is a severe suppression of protein synthesis that varies with duration of ischemia, brain region, and individual proteins. Whereas most regions of the brain recover their ability to synthesize protein following a short ischemic period, protein synthesis in the selectively vulnerable regions is depressed by about 90 percent early in reperfusion and does not recover significantly. Failure of protein synthesis is due to a disruption in the formation of new ribosomal translation complexes. Initiation, the rate-limiting step in translation, requires the coordinated assembly of the ribosomal subunits, the mRNA to be translated, and the amino-acyl tRNA for the first amino acid (always methionine in eukaryotes). This process is orchestrated by a family of proteins named eukaryotic initiation factors (eIFs). The eIF4 and eIF2 complexes are the major regulatory points for translation initiation. Cellular mRNAs vary greatly in their binding efficiency to eIF4E, and under normal physiologic situations message selection for translation initiation is modulated by altering the phosphorylation of Ser ^{209} on eIF4E. However, under conditions of cellular stress (e.g., heat shock, viral infection, or starvation), rates of global protein synthesis are downregulated by phosphorylating Ser ^{51} on the a subunit of eIF2 [eIF2a(P)].

Studies have now identified three important changes in eIFs that occur during brain ischemia and reperfusion: (1) a modest degree of proteolytic degradation of eIF4E occurs during ischemia, but without change in its phosphorylation state during either ischemia or reperfusion;[9,10] (2) there is substantial proteolytic degradation of eIF4G mediated by calpain during both ischemia and reperfusion;[11,12] and (3) probably most important, there is an approximately twentyfold increase in eIF2a(P) during early reperfusion. In nonischemic tissue, phosphorylated eIF2a is found exclusively in astrocytes. [13] After only 10 min postischemic reperfusion, there is prominent eIF2a(P) immunostaining in the cytoplasm of neurons in both the hippocampus and cortex. After 1 h of reperfusion, eIF2a(P) is prominent in both the nuclei and cytoplasm of selectively vulnerable neurons in both the hippocampus and cortex; nuclear eIF2a(P) is never seen in ischemia-resistant neurons. By 4 h reperfusion, the pattern of nuclear eIF2a(P) immunostaining in vulnerable neurons suggests nuclear condensation consistent with the early stages of apoptosis. These results provide a mechanism for the inhibition of protein synthesis in vulnerable neurons during reperfusion and, together with other evidence suggesting a role for eIF2a(P) in causing apoptosis, may represent a fundamental phenomenon in the causal pathway leading to the death of vulnerable neurons. It is interesting to note that animals treated with 20 U/kg insulin at resuscitation are able to dephosphorylate eIF2a(P) and recover protein synthesis in vulnerable hippocampal neurons by 90 min reperfusion. Thus, growth factors, including fibroblast growth factor, nerve growth factor, insulin-like growth factor 1, and insulin, all of which have been shown to improve neuronal survival in the laboratory, may have a role in limiting and repairing neuronal damage. [6]

LATE EVENTS DURING REPERFUSION

Brain tissue ionic concentrations are indistinguishable from normal after 4 h of reperfusion following a 15-min cardiac arrest. The tissue iron has been recovered into high-molecular-weight species by 8 h of reperfusion. However, after 8 h large shifts of the concentrations of calcium, potassium, and sodium are observed. These shifts most likely reflect equilibration between the cytosol and the interstitial fluid for these ions. Electron microscopic examination of brains fixed in situ after 8 h reperfusion reveals in the vulnerable neurons an obvious general degradation of membrane structure with large holes in the plasmalemma. Nuclear chromatin is densely clumped, with grossly abnormal nuclear architecture. Mitochondrial architecture is well preserved. The ER is dilated and ragged, and normally arranged polyribosomes are virtually nonexistent. Histochemical evidence of lipid peroxidation can be seen by as early as 90 min following a 10-min arrest and involves approximately 30 percent of the neurons in the cortex and most neurons in CA1 and the hilus. [14] Membrane injury by lipid peroxidation produces degradation of membrane structure to the point that the membrane becomes freely permeable to ions and the cell is irreversibly injured.

THERAPY

Clearly, the first priority in the treatment of cerebral ischemia is the reestablishment of blood flow. Trials of thrombolytics have shown tissue plasminogen activator to be of some benefit in select subgroups of stroke patients, but it must be administered within a 3-h window. [15] Methods of restoring spontaneous circulation in cardiac arrest are described in Chap. 8, Chap. 10, and Chap. 20.

Because the ultimate extent of injury observed following ischemia largely reflects damage incurred during reperfusion (reperfusion injury), effective therapy must not only limit ongoing mechanisms of damage but also facilitate repair of the damage that has already occurred. Optimum therapy to obviate continuing injury and salvage viable brain tissue is unknown.[16] Most therapeutic studies use animal models, use pretreatment, or contain small numbers of patients. However, a few general principles can be stated. Perfusion should be maintained at normal levels. It does not appear that intracranial pressure is increased in the postresuscitation period, and therefore therapies directed at increased intracranial pressure (hyperventilation and osmotic agents) are unnecessary. Hypotension should be avoided for obvious reasons. Oxygenation should be maintained at or near normal levels. Hyperoxia should be avoided, since it is toxic to the lungs and may increase brain damage. Prearrest hyperglycemia is associated with poor neurologic outcome, and although glucose administered postinsult has not been adequately studied, hyperglycemia should probably be avoided.[17] As mentioned above, several other therapies have been advocated, but human studies have failed to show efficacy. These therapies include pentobarbital coma, calcium antagonists, and glucocorticoids.[18,19]

Ischemic injury of the brain is complex, and this complexity indicates that single-drug therapeutic approaches will continue to fail. The pattern of ATP and ionic recovery and DNA transcription during reperfusion shows that several cellular systems are intact following prolonged ischemia and reperfusion. Future investigation of therapeutic approaches may combine calpain antagonists, iron chelators, lipid peroxidation chain reaction terminators, and growth factors to forestall further lipid peroxidation and to stimulate repair mechanisms. Effective therapeutic protocols will be identified only by continued studies.

20 NEWER RESUSCITATIVE TECHNIQUES

James E. Manning
Christopher W. Barton
Laurence M. Katz

Despite advances in the science of cardiopulmonary-cerebral resuscitation, the prospects for long-term survival with good neurologic recovery remain exceedingly poor. A major limitation of present therapy is the marginal blood flow generated by closed-chest cardiopulmonary resuscitation (CPR). Cardiac output has been reported to be 25 to 33 percent of normal at best and decreases with time delays to initiation of CPR. With increasing duration of arrest and progressive loss of peripheral arterial resistance, even optimally performed closed-chest CPR is unlikely to result in return of spontaneous circulation (ROSC).

Successful resuscitation of the patient in cardiac arrest requires at least some minimal amount of blood flow to the heart. Myocardial perfusion during closed-chest CPR has been shown to be directly related to the pressure gradient across the coronary vasculature. This gradient is equal to the aortic pressure minus the right atrial pressure and is termed the *coronary perfusion pressure* (CPP). Aortic pressure largely determines the CPP gradient and is dependent upon the level of residual peripheral arterial vasomotor tone. Research has shown that the CPP gradient is greatest during the relaxation phase of CPR chest compressions (CPR diastole). Both laboratory and clinical data indicate that a CPP of at least 15 mmHg is almost always required to achieve ROSC. Yet human studies indicate that CPP gradients attained with standard CPR are usually in the ineffective range of 1 to 8 mmHg.

Much of the research into cardiopulmonary resuscitation has focused on methods to improve artificial perfusion during cardiac arrest. In addition to the originally described "conventional" CPR technique, several alternative methods of performing closed-chest CPR have been investigated (Table 20-1). Vasoconstrictor agents have long been used as the pharmacologic adjunct to improve vital organ perfusion by increasing aortic pressure and coronary perfusion pressure. Adrenergic-mediated vasoconstriction remains the major pharmacologic intervention in all forms of cardiac arrest. Although epinephrine has been the principal drug used, other adrenergic agents have been studied and, more recently, nonadrenergic vasoconstrictors as well.

Mechanical piston CPR

Simultaneous compression and ventilation (SCV CPR)

Interposed abdominal compression (IAC CPR)

CPR with abdominal binding

CPR with medical antishock trousers (MAST)

High-impulse CPR

Circumferential thoracic vest CPR

Active compression-decompression (ACD CPR)

Phased chest and abdominal compression-decompression (Lifestick)

TABLE 20-1   Alternative Methods of Closed-Chest CPR

Noninvasive and invasive monitoring techniques have been examined in an effort to identify clinically useful and reliable parameters to guide resuscitative efforts (Table 20-2).

Noninvasive
  Ventricular fibrillation amplitude
  End-tidal carbon dioxide (ETco₂)
  Median frequency of ventricular fibrillation

Invasive
  Arterial pressure
  Coronary perfusion pressure (CPP)
  Central venous oxygen saturation

TABLE 20-2   Monitoring Techniques for Assessing CPR Effectiveness

Invasive perfusion techniques capable of providing near-normal artificial vital organ perfusion have also been described (Table 20-3). Direct mechanical ventricular assistance (or actuation) and cardiopulmonary bypass have been reported in laboratory models and a few clinical reports. Methods of artificial perfusion using aortic balloon catheters have recently been described in laboratory investigations. These newer invasive techniques have attempted to address the issue of clinical

feasibility during sudden cardiac death.

Open-chest manual cardiac compression

Minimally invasive direct cardiac massage (MID CM)

Direct mechanical ventricular assistance (DMVA)

Cardiopulmonary bypass (CPB)

Hemopump

Aortic catheter perfusion techniques

   —Selective aortic arch perfusion (SAAP)/selective aortic perfusion and
     oxygenation (SAPO)
   —Intermittent ascending aortic occlusion

TABLE 20-3   Invasive Perfusion Techniques

Reperfusion-induced injury is a major focus of research in many fields of medicine and for numerous ischemic diseases states, including cardiac arrest, and is discussed in detail elsewhere (see Chap. 19). Cerebral resuscitation with favorable neurologic outcome after prolonged global ischemia will be the ultimate obstacle to overcome in cardiac arrest therapy. Brain-oriented therapies, such as hypothermia, may substantially improve postresuscitation neuronal survival and functional neurologic recovery. Pharmacologic agents capable of limiting ischemia-induced cellular damage and reperfusion-induced injury from reactive oxygen species will likely be an important form of therapy for cardiac arrest patients in the resuscitation and postresuscitation phases.

This chapter briefly discusses some of the alternative methods of closed-chest CPR, pharmacologic agents, monitoring methods, and invasive perfusion techniques that are presently undergoing investigation and hold promise for the future clinical management of cardiac arrest.

ALTERNATIVE METHODS OF CLOSED-CHEST CPR

The rationale for most of the alternative methods of closed-chest CPR that have been decribed are based on one of two proposed mechanisms of blood flow during CPR chest compression. The *cardiac pump theory* proposes that compression of the heart between the sternum and the spine squeezes blood out of the ventricles in a forward flow direction in a manner generally similar to normal myocardial contraction. The *thoracic pump theory* proposes that pressurization of the entire thorax, not just the heart, is responsible for blood flow and that the heart serves only as a passive or partially compressed conduit for blood flow. Net forward blood flow occurs due to competent closure of venous valves during diastole at the thoracic inlet during chest compression. The evidence for and against each theory is beyond the scope of this chapter, but it is accurate to state that the precise mechanism of blood flow during closed-chest CPR remains controversial and may vary based on individual anatomic features. Alternative methods of performing closed-chest CPR have largely been based on efforts to exploit one or both of the two proposed mechanisms.

High-Impulse CPR

In 1984, Maier et al reported a laboratory study comparing compression rates of 100 per minute and 150 per minute with the conventional rate of 60 per minute advocated prior to 1986.[1] They observed increases in cardiac output that were roughly linear to the increase in compression rate, while stroke volume remained relatively constant. The compression force and velocity of impact used with these rapid CPR compression rates led to the term "high-impulse" CPR. This work was partially responsible for the increase in the recommended CPR compression rate from 60 min^{-1} to 80 to 100 per minute.

Interposed Abdominal Compression CPR (IAC CPR)

Compression of the abdomen during cardiac arrest generates aortic pressures similar to chest compressions. The hypothesis that CPR diastolic aortic pressure and venous return from the abdomen might be augmented by abdominal compressions led to the idea of IAC CPR. One person performs the chest compressions of standard CPR while another person applies a similar compression over the central abdomen during the relaxation phase of chest compression. The hemodynamic effects of IAC CPR in laboratory investigations have not been consistent, but most have shown increases in CPR diastolic aortic pressure, coronary perfusion pressure, and cardiac output. Results of clinical studies of IAC CPR have been highly variable. Some studies have shown no evidence of improved resuscitation outcome, whereas others have demonstrated significant improvements in ROSC and survival to hospital discharge.[2] Differences in study populations and the technical performance of IAC CPR may be the reasons for the variable results obtained. At present, the data supporting the use of IAC CPR are not sufficient to recommend its routine application. It could also be argued that IAC CPR is physiologically very similar to high-impulse CPR with the compressions performed by two persons rather than one. However, if perfusion with standard CPR is judged to be inadequate, attempting IAC CPR is a reasonable alternative intervention.

Active Compression-Decompression CPR (ACD CPR)

Standard CPR involves a forceful or "active" chest compression phase with elastic recoil of the chest wall during the relaxation phase ("passive" decompression). The ACD CPR device consists of a circular suction cup connected to a handle with a force gauge (Fig. 20-1). With the suction cup securely attached at the midsternal chest, CPR is performed with force applied both downward (active compression) and upward (active decompression) during CPR. [3] One advantage of the ACD CPR device is that it tends to decrease the venous system pressure to a greater extent than the arterial pressures during the active decompression phase. This may increase venous return and increase the coronary perfusion pressure gradient during CPR diastole. Although initial clinical reports have indicated some improvement in ROSC and survival, a large randomized clinical trial in in-hospital cardiac arrest (773 patients) and out-of-hospital cardiac arrest (1011 patients) showed no improvement in survival for the ACD CPR device as compared with standard CPR.[3] There is presently insufficient evidence to support the routine use of ACD CPR. However, as noted for other alternative CPR techniques, if standard CPR is judged to be ineffective, ACD CPR is another option. Unlike some of the other alternative techniques, ACD CPR requires a special device, and this limits its applicability.

FIG. 20-1. The Ambu CardioPump (Ambu International Inc., Copenhagen, Denmark) is used for active compression-decompression cardiopulmonary resuscitation (ACD-CPR). The silicone rubber suction cup is positioned mid-chest at the level of the nipples. Using the circular plastic handle, the device is pushed downward during the compression phase followed by active withdrawal during the decompression phase. Force of compression and decompression is measured by the gauge located within the handle and is easily viewed by the operator during CPR. (From Lurie KG, Shultz JJ, Callaham ML, et al: Evaluation of active compression-decompression CPR in victims of out-of-hospital cardiac arrest. *JAMA* 271:1405, 1994, with permission.)

Phased Chest and Abdominal Compression-Decompression

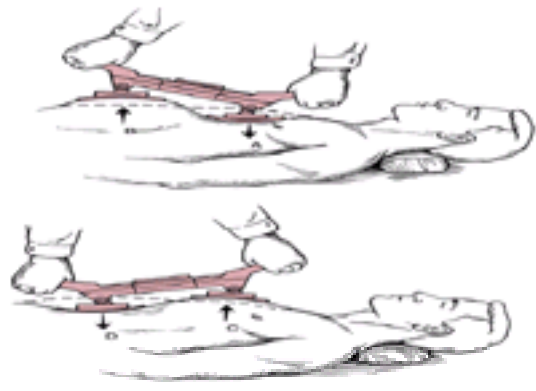
Tang et al have described the use of a device that combines the concepts of IAC CPR and active compression-decompression. [4] This technique involves the use of a device called the Lifestick resuscitator. This device has chest and abdominal pads connected to an adjustable rigid frame with a handle at each end (Fig. 20-2). The pads are attached to the sternum and the upper abdomen by an adhesive. Using a seesaw motion, the chest and abdomen are compressed in an alternating pattern. The preliminary report of this technique by Tang et al in a survival model of swine cardiac arrest showed improved CPP, ROSC, and 48-h survival. At present, there have been no reports of the use of this device in human cardiac arrests.


FIG. 20-2. Sequencing compression-decompression with the Lifestick resuscitator. The subject's head is on the right. Chest compression (**A**) is coincident with abdominal decompression (**B**). This is followed by chest decompression (**C**) and abdominal compression (**D**). (From Tang et al,[4] with permission.)

Circumferential Thoracic Vest CPR

As noted above, the thoracic pump theory proposes that cyclic fluctuations in intrathoracic pressure created by CPR chest compressions are responsible for blood flow. Thus, efforts to maximize the intrathoracic pressure generated while limiting trauma to the chest would be advantageous. This led to the conception of the circumferential thoracic vest CPR device. This involves the placement of a vest around the thorax and pressurizing the thorax from all directions as opposed to localized pressure over the lower sternum (Fig. 20-3). Halperin et al have reported their preliminary experience in humans with a refined circumferential vest CPR device and found significant improvements in coronary perfusion pressure and initial ROSC. [5] In patients failing prolonged resuscitative efforts, peak CPR–systolic aortic pressure increased from an average of 78 mmHg with manual CPR to an average of 138 mmHg with vest CPR. In 34 patients randomized to receive manual CPR versus vest CPR after an average of 11 min of unsuccessful manual CPR, 8 of 17 vest CPR patients had ROSC compared with only 3 of 17 manual CPR patients. Although this appears to be a promising alternative method of CPR, a substantial amount of clinical investigation is still needed to clarify its potential benefit. Such clinical investigations have been hampered by issues of informed consent.
FIG. 20-3. A comparison of the thoracic vest system for cardiopulmonary resuscitation (vest CPR) with the standard manual CPR. The vest contains a bladder that is inflated and deflated by the pneumatic system. Defibrillation can be accomplished during chest compression through the flat defibrillator electrodes (*dashed circles*) under the vest. The ECG can be recorded through the same electrodes. The lower panels show schematic representations of transverse sections of the midthorax during vest CPR and manual CPR. The thoracic size during chest relaxation is shown by the solid lines. The arrows indicate force applied to the thorax during chest compression. With vest inflation, there is a relatively uniform decrease in the dimensions of the thorax. With manual CPR, the sternum is displaced during compression (*arrow*) and the lateral thorax can bulge, thereby increasing thoracic volume and reducing the intrathoracic pressure generated during compression. (From Halperin et al,[5] with permission.)

PHARMACOLOGIC INTERVENTIONS

Adrenergic Therapy

Adrenergic drugs have been the primary agents studied and utilized in all types of cardiac arrest. Epinephrine is the predominant adrenergic drug and remains the recommended agent. The mechanism of action of adrenergic therapy in cardiac resuscitation has been convincingly shown to be primarily alpha adrenergic receptor–mediated vasoconstriction in the peripheral arterial system resulting in increased aortic pressure and thus increased coronary perfusion pressure. In addition to epinephrine, several other pure alpha-adrenergic or mixed alpha- and beta-adrenergic agents have been studied. However, none of these agents has been shown to increase ROSC or long-term survival as compared with epinephrine.

The appropriate dosage of adrenergic drugs during cardiac arrest is the subject of ongoing controversy. Although based on early animal studies and on very limited anecdotal clinical evidence, an epinephrine dose of 1 mg was the standard recommendation for many years. Laboratory investigations and clinical reports in the 1980s suggest that substantially higher doses were required for optimal beneficial effect. These studies led to large, randomized, controlled clinical trials in the early 1990s that showed variable effects on the rate of ROSC but failed to show improvement in survival to hospital discharge or neurologic outcome. [6] Although no benefit was demonstrated, no adverse results were identified with the use of higher doses of epinephrine. Still, there have been anecdotal complaints from intensivists that the temporary ROSC achieved unnecessarily diverts intensive care resources for futile situations. The American Heart Association has left the option of using higher doses of epinephrine open to the clinician's discretion in the clinical arena. [6]

Nonadrenergic Vasoconstriction

Although adrenergic therapy has been the pharmacologic cornerstone of vasoconstrictor therapy, there are nonadrenergic agents capable of producing significant arterial vasoconstriction; these could prove beneficial in the treatment of cardiac arrest. The most promising nonadrenergic agent is vasopressin. Laboratory studies and early clincial reports have shown favorable effects as compared with epinephrine. Linder et al reported a small randomized clinical study comparing intravenous vasopressin (40 U) with intravenous epinephrine (1 mg) and showed a significant increase in initial ROSC, hospital admission, and 24-h survival. [7] There was also a trend toward improved survival to hospital discharge. Another nonadrenergic agent that has undergone only limited laboratory investigation is angiotensin II. The use of nonadrenergic vasoconstrictor agents either alone or in conjunction with adrenergic vasoconstrictor agents may prove to be more effective than adrenergic therapy alone.

Adenosine Antagonism

Release and accumulation of adenosine in ischemic tissues and adenosine's role as a depressant of cardiac pacemaker automaticity has been more clearly defined in recent years. There is limited clinical evidence to suggest that aminophylline can reverse these effects (by acting as an adenosine antagonist) and may be useful in the treatment of bradydysrhythmias associated with myocardial ischemia. Clinical studies have shown favorable initial response to aminophylline bolus, but long-term survival does not appear to be affected. [8,9] Laboratory studies have shown no apparent benefit of aminophylline in cardiac arrest. Thus, adenosine antagonism remains an unproven therapy. However, given the dismal prospects for survival associated with bradyasystolic arrest, a clinician could not be faulted for administering aminophylline in such a setting, especially if there was no response to standard therapy. However the caveat noted earlier for high-dose epinephrine would apply here also.

Amiodarone

Amiodarone is an antiarrhythmic agent with a complex electropharmacologic profile that has been used for long-term control of a variety of atrial and ventricular dysrhythmias. Despite its reportedly limited effect on ventricular effective refractory period after acute intravenous administration, it has been shown to be effective in the treatment of acute unstable ventricular dysrhythmias refractory to lidocaine and procainamide. In a randomized, double-blind, multicenter clinical trial, two amiodarone regimens (low-dose and high-dose) were compared to a standard bretylium regimen in 302 patients with refractory, hemodynamically unstable ventricular tachycardia and ventricular fibrillation. [10] The high-dose amiodarone regimen (an initial rapid infusion of 150 mg over 10 min, followed by 1 mg/min for 6 h and 0.52 mg/h thereafter to 48 h) was equivalent to bretylium in terms of suppression of subsequent unstable ventricular dysrhythmias and showed a better side-effect profile. Amiodarone is, therefore, an emerging antiarrhythmic agent in the treatment of acute ventricular dysrhythmia, especially those cases that are refractory to more traditional antiarrhythmic therapy.

Magnesium

Clinical studies have shown improved survival with magnesium supplementation in the setting of acute myocardial infarction. The cardioprotective effects of magnesium are thought to be related to suppression of automaticity, coronary vasodilation, platelet inhibition, and inhibition of calcium influx. Although an association between hypomagnesemia and cardiac dysrhythmias has been recognized, the value of magnesium in the treatment of acute, life-threatening ventricular dysrhythmias has not been established. Thel et al reported a randomized, double-blind, placebo-controlled clinical trial of magnesium administration in 156 in-hosptial cardiac arrest patients.[11] Administration of magnesium (initial 2 g bolus during cardiac arrest followed by an infusion of 8 g over 24 h) showed no difference in ROSC, survival to 24 h, survival to hospital discharge, or Glasgow Coma Scale score on discharge as compared with placebo. However, among survivors to hospital discharge (21 percent in each group), quality of life assessed by Karnofsky performance status was better in the magnesium group, and no adverse effects of magnesium administration were noted. Thus, the use of magnesium in cardiac arrest remains incompletely defined. Magnesium administration during cardiac arrest seems acceptable based on clinical judgment, especially in cases of suspected hypomagnesemia or refractory cardiac arrest.

Routes for Medication Delivery

Recommended routes for the administration of resuscitation drugs include intravenous, endotracheal, and intraosseous routes. Intravenous administration is considered optimal, with central venous delivery preferred over peripheral venous delivery provided that there is no delay in gaining central venous access. Intracardiac drug injection has largely been discouraged. Central arterial administration of medications has received little attention but may be a useful alternative, especially for delivery of vasoconstrictor agents, which have their effector sites in the peripheral arterial system.

Catheterization to measure arterial pressure during cardiac arrest is becoming a more accepted intervention to help guide resuscitative efforts. Thoracic aortic catheterization via a femoral artery approach allows for both pressure monitoring and homogeneous arterial drug administration. When aortic arch and central venous routes of epinephrine administration were compared in a laboratory model, aortic arch delivery resulted in a more rapid increase in CPR diastolic aortic pressure, a greater magnitude of aortic pressure increase, and a maximal response consistently seen within 30 to 50 s of injection. [12] The rapidity of initial and maximal aortic pressure response suggests that adrenergic therapy could be rapidly adjusted based on a parameter reflecting vital organ perfusion. Thus, thoracic aortic catheterization allows for both rapid delivery of vasoconstrictor agents to effector sites and rapid assessment of therapeutic effect, such that therapy can be rapidly titrated on an individual basis. The major limitation of this route is the need to establish central arterial access.

TECHNIQUES FOR ASSESSMENT OF RESUSCITATIVE EFFORTS

The lack of an accurate and readily measurable parameter to guide resuscitative efforts has long frustrated clinicians and clinical investigators. Pulse quality, pupillary reactivity, serial blood gases, and the coarseness of ventricular fibrillation were the only parameters available until relatively recently. None of these was sufficiently accurate to allow for therapeutic adjustments on an individual case basis. Fortunately, recent technological advances have led to monitoring techniques which allow for much more accurate assessment and guidance of therapy.

Capnometry or End-Tidal Carbon Dioxide

Capnometry (the measurement of exhaled end-tidal carbon dioxide levels) has become a valuable and standard monitoring tool in the emergency department. Although used primarily to assess endotracheal tube placement and monitor ventilation, end-tidal carbon dioxide (ET CO_2) can also be used to assess blood flow. ETCO_2 is proportional to pulmonary perfusion, which, in turn, reflects systemic perfusion. It is this principle that makes ET CO_2 monitoring of value in the assessment of perfusion during CPR.

The use of quantitative or semiquantitative ETCO_2 as an indicator of the effectiveness of artificial perfusion has received considerable attention over the past decade or so. Laboratory models or cardiac arrest demonstrated a statistically significant correlation between ETCO_2 and coronary perfusion pressure, suggesting that ETCO_2 could serve as a useful noninvasive method to monitor the effectiveness of resuscitative efforts and to guide therapy. In one clinical study, the initial ET CO_2 served to predict which patients would regain a pulse during the resuscitation. Those patients with an ET CO_2 of at least 15 mmHg on arrival in the emergency department (ED) had a greater than 90 percent probability of regaining a pulse, while those patients with an ET CO_2 of less than 15 mmHg almost never regained a pulse.[15] In many of these patients, a sudden, dramatic increase in the ETCO_2 was noticed well before a pulse could be detected. Unfortunately, ETCO_2 does not always correlate precisely with coronary perfusion pressure, and the relationship between the two can be affected by therapeutic interventions such as adrenergic therapy. While these studies cannot be used as an endorsement for deciding when to quit or continue CPR, they do lend support to the validity of ET CO_2 as a reflection of cardiac output. ETCO_2 is the most accurate noninvasive method of monitoring CPR effectiveness currently available, and its use is encouraged. The most appropriate way to use ET CO_2 is to maintain minute ventilation relatively constant while adjusting the mechanics of CPR chest compression and titrating adrenergic therapy in an effort to maximize the ETCO_2.

Ventricular Fibrillation Waveform Analysis

It has long been recognized that the coarseness of the ventricular fibrillation (VF) waveform has a rough correlation with the duration of cardiac arrest and the prospects for successful defibrillation with ROSC. With the onset of VF, there is a gradually progressive decrease in the peak-to-trough amplitude of the VF waveform in the absence of resuscitative interventions. The recorded amplitude of the VF waveform, however, is subject to such factors as body habitus, electrode location, and contact, and instrumentation. Using mathematical formulas (the fast Fourier transform) and high-speed computers, a digital characterization of the VF waveform can be derived. This method provides a discreet digital number with which to describe the distribution of frequencies present in the waveform. One measure, the median or centroid frequency, has been found to correlate with defibrillation success and to predict the duration of VF. As VF continues without resuscitation, the median frequency gradually deteriorates over time. When effective resuscitation measures are instituted, the median frequency promptly increases. [14] Such interventions as invasive perfusion support or pharmacologic therapy with epinephrine or vasopressin have successfully raised the median frequency of VF and have been associated with enhanced resuscitation success in animal models. The median frequency (or other measures derived from the fast Fourier transform) may eventually find their way to the bedside in the form of a monitor used by the clinician to guide therapy during resuscitation attempts.

Invasive Hemodynamic Pressure Monitoring

Laboratory and clinical studies have demonstrated that both aortic pressure and CPP correlate strongly with coronary blood flow and ROSC. Although placement of arterial pressure catheters is a common occurrence in critical care medicine, arterial catheterization is not routinely performed in cardiac arrest patients. This is partially because of the technical difficulties associated with performing this during CPR. However, arterial pressure monitoring provides a very useful parameter to guide resuscitative efforts. The CPR-diastolic arterial pressure is the major predictor of the actual CPP. Thus, adjusting therapeutic interventions to maximize CPR-diastolic arterial pressure will result in greater CPP and improved chances of survival.

Central venous catheterization in addition to arterial and aortic catheterization allows for the accurate measurement of the aortic-to-right atrial pressure gradient or CPP. Although clearly one of the most useful measurable parameters in human resuscitation, it has been studied by only a few investigators and only as an in-hospital procedure. Thus, out-of-hospital cardiac arrest patients undergoing CPP monitoring have generally been in arrest for an extended period of time. Paradis et al reported that ROSC in the ED correlated with achieving a CPP greater than 15 mmHg among patients with prolonged cardiac arrest. [15] None of the patients with ROSC survived, suggesting that CPP monitoring after prolonged cardiac arrest is likely to be of limited benefit. Thus, efforts to perform invasive monitoring more rapidly upon hospital arrival or even in the prehospital setting should be pursued. The feasibility of performing prehospital invasive hemodynamic monitoring has been demonstrated with the use of a commercially available, lightweight, and portable monitoring system that can be easily transported to the scene of out-of-hospital cardiac arrest.

Central Venous Oxygen Saturation Monitoring

Rivers et al have reported the use of central venous oximetry in evaluation of cardiac arrest patients. [16] Central venous oxygen saturation yields important information about tissue oxygen delivery/consumption balance and was predictive of ROSC. A central venous oxygen saturation of less than 30% resulted in a zero percent ROSC rate, whereas a value greater than 72% resulted in a 100 percent ROSC rate. Impending ROSC was foreshadowed by an abrupt or gradual increase in central venous oxygen saturation. Interestingly, a supranormal central venous oxygen saturation, termed *venous hyperoxia,* was frequently seen during the early phase of ROSC, followed by a return to normal levels.

INVASIVE PERFUSION TECHNIQUES

Direct Mechanical Ventricular Assistance

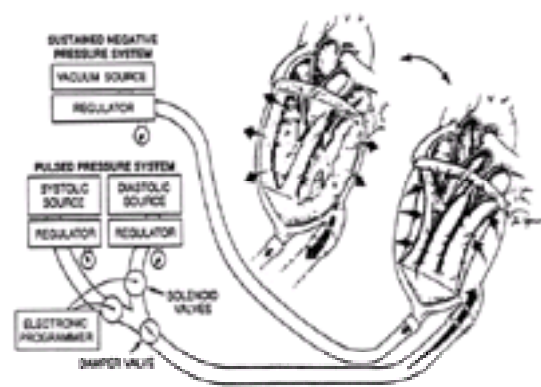
Direct mechanical ventricular assistance (DMVA) was first described by Anstadt et al in 1965 and several laboratory studies have investigated this technique in cardiac arrest models. DMVA utilizes a cup-shaped device that fits around the ventricles and is held in place by a vacuum at the apex of the heart (Fig. 20-4). Cyclic positive and negative pressures are transmitted to a flexible diaphragm on the inner surface of the cup, resulting in compression and reexpansion of the ventricles, respectively. The major difference between DMVA and open-chest manual compression of the heart is the active ventricular dilatation, which enhances ventricular filling for the next compression phase. DMVA has been shown to generate higher arterial pressures and greater cardiac output than open-chest manual compression. The clinical utility of this technique in the treatment of cardiac arrest has not been established. The major advantage of DMVA is that it can be sustained for an extended period of time. The major limitation of DMVA is the requirement of a thoracotomy, which largely precludes its use within an effective time frame for most victims of out-of-hospital cardiac arrest.


FIG. 20-4. Direct mechanical ventricular assistance (DMVA). Schematic diagram of DMVA drive system and cup. Note the device actuates the ventricular myocardium into systolic (*right*) and diastolic (*left*) configurations. (From Anstadt MP, Anstad GL, Lowe JE: Direct mechanical ventricular actuation: A review. *Resuscitation* 21:7, 1991, with permission.)

Cardiopulmonary Bypass

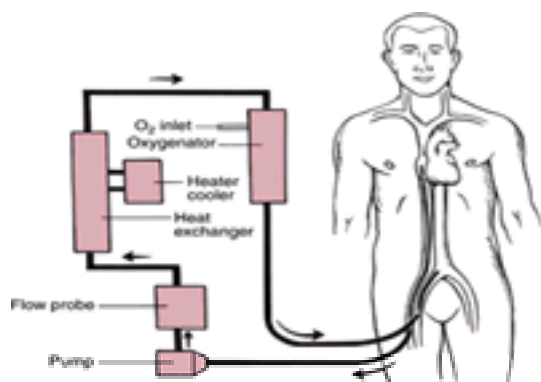
Cardiopulmonary bypass (CPB) (Fig. 20-5) is an effective means of providing sustained global perfusion and has been advocated in the treatment of cardiac arrest. Several laboratory studies have demonstrated improved ROSC and neurologic recovery with CPB compared with standard advanced cardiac life support (ACLS) interventions. There are also several case series describing the successful use of femorofemoral CPB in the treatment of cardiac arrest. The major advantages of CPB are that it can be performed with only a femoral vessel cutdown, artificial perfusion can be sustained for an extended period of time, and perfusion support can be gradually withdrawn. The major disadvantage is the equipment, skill, and time required to perform CPB. A recent report of 10 cardiac arrest victims in whom CPB was initiated in the ED showed that ROSC was achieved in all 10, but there were no long-term survivors. [17] The average-time from onset of arrest to onset of CPB support was 32 min. In order to achieve long-term survival, the time interval to CPB support must be much shorter. Unless the technique can be extended to the prehospital setting, it will be of very limited value in the treatment of victims of out-of-hospital cardiac arrest. However, technological advances offer the prospect of developing CPB devices that can be used in the prehospital setting.


FIG. 20-5. Schematic diagram of CPB system used.

Hemopump

The Hemopump is a catheter-based temporary ventricular assist device consisting of an axial flow pump component at the distal end of the catheter powered by an

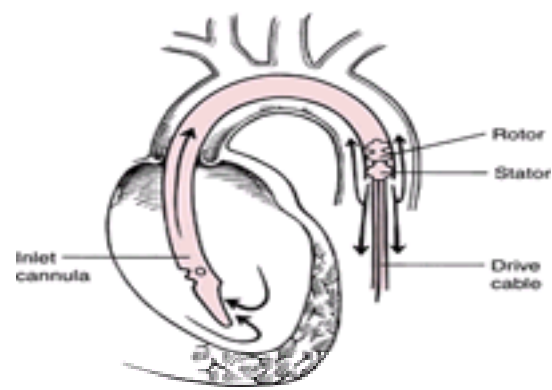
external motor via a flexible drive cable that runs the length of the catheter. The distal tip of the axial flow pump component is advanced from a femoral artery into the left ventricle (Fig. 20-6). When it is in operation, forward blood flow is generated by blood entering the axial flow pump component in the left ventricle and exiting in the aortic arch. Laboratory investigation in a cardiac arrest model has demonstrated sustained mean arterial pressures of approximately 60 mmHg and cardiac output averaging 2.3 L/min.[18] The major drawback with the use of this device in the setting of cardiac arrest is that one must be able to insert the catheter from a femoral artery to the left ventricle.


FIG. 20-6. Schematic diagram of the Hemopump positioned in the left ventricle.

Aortic Catheter Perfusion Techniques

During the past decade, there has been an interest in the use of aortic balloon occlusion catheters to enhance vital organ perfusion during cardiac arrest. The use of standard intraaortic balloon pumping has been shown to increase CPP during closed-chest CPR, but the effect is not dramatic. However, the use of aortic balloon catheters for the infusion of resuscitation solutions during cardiac arrest holds greater promise for improving resuscitation outcome.

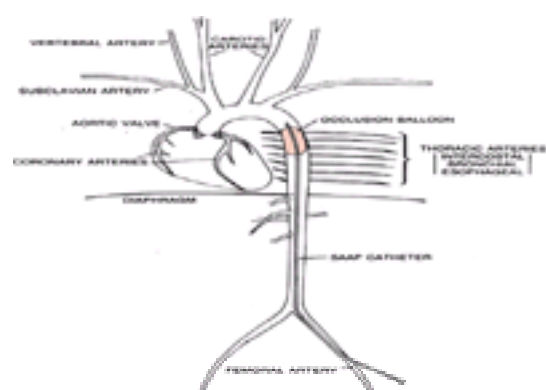
Selective aortic arch perfusion (SAAP) as described by Manning et al [19] or selective aortic perfusion and oxygenation (SAPO) as described by Paradis et al [20] uses a large-lumen balloon occlusion catheter positioned in the descending aortic arch to provide selective perfusion of the heart and brain during cardiac arrest (Fig. 20-7). The catheter is inserted into a femoral artery (percutaneously or via a cutdown) and blindly advanced into the thoracic aorta. With the balloon inflated and pressure cuffs applied to the upper arms, the coronary and cerebral circulations are relatively isolated for brief perfusion. The resuscitation solution infused consists of an oxygenated blood substitute, such as a perfluorocarbon emulsion or polymerized hemoglobin solution, that might contain various agents to enhance restoration of spontaneous cardiac contraction, maintain neuronal viability, and limit both myocardial and neuronal reperfusion injury. One of the major advantages of SAAP is the ability to administer agents to combat reperfusion injury at the moment of reperfusion or just prior to it. SAAP was designed for use in the prehospital as well as the in-hospital setting. Although laboratory results have been very favorable, the efficacy of this invasive perfusion technique in human cardiac arrest has not been studied.


FIG. 20-7. Selective aortic arch perfusion (SAAP). Positioning of the SAAP balloon occlusion catheter at the end of the descending aortic arch through a femoral artery. Placement of the balloon at this level restricts flow to aortic arch vessels including coronary arteries. (From Manning et al, [19] with permission).

Tang et al have described the use of a balloon occlusion catheter positioned in the ascending aortic arch. [21] Laboratory investigations of this technique have shown marked increases in coronary perfusion with intermittent balloon occlusion. Infusion of fluid via the catheter results in isolated coronary artery perfusion. The technical feasibility of rapidly and reliably positioning the tip of this catheter in the ascending aortic arch may prove to be a significant challenge in the clinical setting.

Minimally Invasive Direct Cardiac Massage

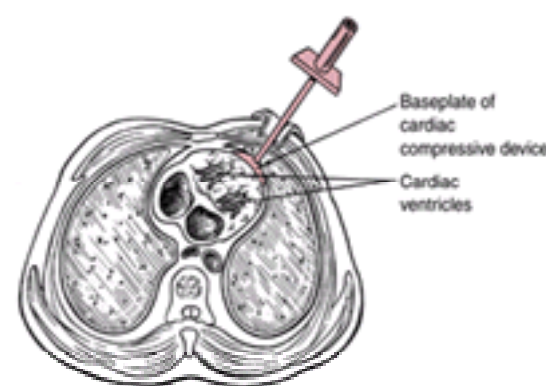
In 1995, Buckman et al reported the use of a relatively simple device for the rapid initiation of internal cardiac compression through a small thoracic incision. [22] The technique, called minimally invasive direct cardiac massage, uses a rectangular, curved, padded plate connected to a handle to compress the heart through an intercostal incision at the anterolateral left chest at the level of the lower sternum (Fig. 20-8). In a swine cardiac arrest model, the device generated CPP and cardiac output similar to that produced by manual open-chest cardiac massage. It has been suggested that a modified device could potentially be inserted via a smaller (2 to 3-cm) intercostal incision.


FIG. 20-8. The heart-contacting baseplate and a portion of the stem of the cardiac compressive device are inserted into the thorax through a small, parasternal incision. The manually-operated handle remains outside the chest. The base plate is positioned directly on the cardiac ventricles, lying within an intact pericardium. Manual depression of the device compresses the heart and produces an artificial systole.

21 ACID-BASE DISORDERS

David D. Nicolaou
Gabor D. Kelen

The homeostasis of the human organism is critically dependent upon the function of its proteins. Protein function is optimal at specific levels of acidity. Thus, plasma acidity is closely regulated.

Many diseases including those presenting an imminent life threat produce acid-base disturbances that provide important clues concerning the nature of the underlying illness and suggest immediate therapeutic interventions. The following is a practical approach to the clinical evaluation of acid-base disorders.

MEASUREMENT OF PLASMA ACIDITY

Plasma hydrogen ion concentration ($[H^+]$) is normally 40 meq (40 mmol) per liter and corresponds to a pH of 7.4. It is inconvenient to work with such small concentrations, and the negative base 10 logarithm of the hydrogen ion concentration (pH) is therefore often used to express plasma acidity. Because pH is a logarithmic transformation of $[H^+]$, the relationship of $[H^+]$ to pH is not linear for all pH values (Table 21-1). However, for pH values from 7.20 to 7.50, the relationship between hydrogen ion concentration and pH is nearly linear; pH changes of 0.01 unit correspond to approximately 1 mmol/L change in $[H^+]$.

pH	[H⁺]
6.8	158
6.9	126
7.0	100
7.1	79
7.2	63
7.3	50
7.4	40
7.5	32
7.6	25
7.7	20

TABLE 21-1   pH and Hydrogen Ion Concentrations

Plasma Acid Homeostasis

Plasma hydrogen ion concentration is influenced by rate of endogenous production, rate of excretion, and buffering capacity of the body. Buffers mitigate the impact on plasma pH of large changes in available hydrogen ion. A buffer pair consists of a weak acid and its conjugate base, which are in equilibrium, as seen in Eq. (1), below:

$$[HA] \Leftrightarrow [H^+] + [A^-] \tag{1}$$

Addition or removal of hydrogen ion causes a shift in the equilibrium, resulting in a reduction or increase in $[H^+]$, respectively. The effectiveness of a buffer system is optimal when the concentrations of its base and conjugate acid are equal; that is, the system is equally able to buffer excess protons or to release them. This point is the dissociation constant, or K_A.

Equation (1) can now be written quantitatively to describe the hydrogen ion concentration, as shown in Eq. 2.

$$[H^+] = K_A \frac{[HA]}{[A^-]} \tag{2}$$

Equation (2) demonstrates that a buffer system's efficiency is determined by how close its pK_A is to physiologic pH. Buffer systems that are effective at physiologic pH include hemoglobin, phosphate, proteins, and bicarbonate (Fig. 21-1).[1] One can consider the hydrogen ion concentration to be the result of all physiologic buffers acting on the common pool of hydrogen ions.
FIG. 21-1. Schematic representation of hydrogen ion homeostasis.

If the base 10 logarithm of each term in Eq. (2) is taken and the resulting equation is applied to the bicarbonate/carbonic acid buffer system, the familiar Henderson-Hasselbalch equation— Eq. (3)—results.

$$pH = pK + \log \frac{[HCO_3^-]}{[H_2CO_3]}$$

(3)

This equation demonstrates the interrelationship between carbonic acid, bicarbonate, and pH; any two of these determine the third.

The clinical utility of the Henderson-Hasselbalch equation, however, is limited. The values of each term in Eq. (3) except pH are not convenient to measure. The bicarbonate concentration is approximated by the total CO_2,* but carbonic acid must be calculated from the P_{CO_2} and the solubility constant of CO_2 in blood. This requires substitution of the pK_A with a modified value. Finally, the logarithm of all terms must be calculated.

However, if all constants are inserted into the Henderson-Hasselbalch equation and the antilog of all its terms is taken, the resulting simplified equation— Eq. (4)—is of great clinical utility. [2]

$$[H^+] = 24 \times \frac{P_{CO_2}}{[HCO_3^-]}$$

(4)

The Kassirer-Bleich equation may be used to calculate the concentration of any component of the bicarbonate buffer system provided that the concentrations of the other two components are known. It therefore allows clinicians to determine, for example, what the pH *must be* when the P_{CO_2} and the bicarbonate concentration are known. Performing such a calculation using values reported by the laboratory permits the clinician to check the internal consistency of the reported data. (In fact, hospital laboratories do not measure $[HCO_3^-]$ but calculate the number based on pH and P_{CO_2} measurements.)

PHYSIOLOGY OF ACID PRODUCTION AND EXCRETION

The bicarbonate/carbonic acid buffer system is an open system; that is, the quantity of buffer present in the system is not fixed but varies according to physiologic need. This flexibility is largely provided by pulmonary excretion of P_{CO_2} which can vary significantly and rapidly according to the exigencies of the acid-base milieu. The kidney regulates both bicarbonate excretion and the formation of new bicarbonate and is able to change the rate of these processes when demanded by the acid-base milieu, while pulmonary response to immediate renal compensation requires hours to days to complete.

Hepatic Influence on Acid-Base Balance

Although the lungs and kidney are traditionally considered the cornerstone organs of acid-base balance, increasing attention is being given to the role of the liver in acid-base homeostasis. Approximately 1 mol each of bicarbonate and ammonium is generated every day by protein catabolism. The irreversible synthesis of urea by the liver results in consumption of virtually all of this bicarbonate. The rate of this reaction is closely tied to both extracellular pH and bicarbonate concentration. This control, mediated by glutaminase and carbonic anhydrase, can result in significant retention and neutralization of bicarbonate during acidosis. The fixation of ammonium ions into urea slows, but the kidney increases ammonia synthesis and excretion. This process not only prevents ammonia accumulation but also allows hydrogen ion trapping in the distal tubule. Furthermore, hepatic cells without the cellular machinery to fix ammonia into urea avidly use excess ammonia to synthesize glutamine.[3] Thus, the liver is the "third organ" of acid-base balance.

Renal Influence on Acid-Base Balance

The maintenance of bicarbonate homeostasis by the kidney requires reclamation of the daily filtered load of bicarbonate, 85 percent of which occurs in the proximal convoluted tubule. The Na^+,K^+-ATPase system extrudes sodium into plasma and draws potassium into the tubule cell. The filtrate in the tubule lumen, however, has a sodium concentration equal to that of plasma. An antiporter of sodium and hydrogen ion is driven by this gradient, transporting sodium from the tubule lumen into the tubule cell in exchange for hydrogen ion. The hydrogen ion combines with filtered bicarbonate in the tubule lumen, producing carbonic acid. Carbonic anhydrase, resident in the luminal cell membrane, catalyzes the conversion of carbonic acid to water and CO_2. CO_2, which is soluble, diffuses down a concentration gradient into the tubule cell, where cytoplasmic carbonic anhydrase regenerates carbonic acid (and thereby creates the CO_2 concentration gradient). The carbonic acid dissociates, providing hydrogen ion for extrusion and bicarbonate, which enters the plasma. If the rate of proton extrusion is reduced by tubular disease, bicarbonate will be lost until the serum concentration has fallen to a level that can be reclaimed by the limited hydrogen ion extrusion available. This is the pathophysiology underlying proximal renal tubular acidosis (RTA).

The kidney reclaims the balance (approximately 15 percent) of filtered bicarbonate in the distal tubule. Carbonic anhydrase in the cytoplasm of distal tubule cells generates carbonic acid, which dissociates. An electrogenic H^+-ATPase on the luminal cell membrane secretes the resulting hydrogen ion into the tubule lumen, where it is titrated by inorganic phosphate or binds to ammonia and is "trapped" in the tubule lumen. The bicarbonate resulting from dissociation of intracellular carbonic acid diffuses into plasma. The loss of H^+ and HCO_3^- from the cell maintains electroneutrality, so the process of bicarbonate reclamation in the distal tubule is *sodium-independent.* Thus, the process of proton secretion in the distal tubule functions not only to reclaim filtered bicarbonate but also to excrete protons generated by metabolism. The failure of proton secretion is the mechanism underlying distal renal tubular acidosis.

The kidney also generates new bicarbonate in the distal tubule in a *sodium-dependent* process. A Na^+,K^+-ATPase on the antiluminal cell membrane creates a low intracellular sodium concentration. At the same time, intracellular glutamine is metabolized to bicarbonate and ammonium. Sodium then moves from the tubule lumen into the tubule cell down its concentration gradient, and ammonium moves from the tubule cell into the tubule lumen. (Impairment of ammonium excretion results in its incorporation into urea in the liver, a process that *consumes* bicarbonate.) Bicarbonate formation by this process may increase 6 to 10 times over 4 to 5 days when acidosis so demands. However, drugs that alter uptake or delivery of sodium to the distal tubule significantly affect this process.

The effect of the kidney on acid-base balance is to prevent bicarbonaturia and to excrete the daily metabolic load of acid. The process of acid excretion allows the kidney to regenerate bicarbonate in proportion to the quantity consumed by buffering of the daily acid load. The result is that urine, especially under conditions of acidosis, can be made almost entirely free of bicarbonate.

FUNDAMENTAL ACID-BASE DISORDERS

Any condition that disturbs acid-base balance by increasing $[H^+]$—whether through endogenous production, decreased buffering capacity, decreased excretion, or exogenous addition—is termed *acidosis.* Similarly, any condition that decreases $[H^+]$ is termed *alkalosis.* The terms *acidemia* and *alkalemia* refer to the net imbalance of $[H^+]$ in the blood. The difference between acidosis and acidemia is not merely semantic but of great clinical importance. For example, a patient with an acidosis and an alkalosis of equal magnitude will have a normal pH. A patient with these disturbances, then, has neither acidemia nor alkalemia but has both an acidosis and an alkalosis. It is therefore important to appreciate that while acidemia is diagnostic of acidosis and alkalemia of alkalosis, a normal or high pH does not exclude acidosis and a normal or low pH does not exclude the presence of an alkalosis.

Acid-base disturbances are further classified as either respiratory or metabolic. Respiratory acid-base disorders first affect P_{CO_2}, while metabolic disorders first alter bicarbonate concentration. If there were no compensatory mechanism, the Kassirer-Bleich equation states that the magnitude of change in either P_{CO_2} or $[HCO_2^-]$ would directly determine the magnitude of change in the pH. However, physiologic mechanisms tend to mitigate pH changes by effecting offsetting changes in bicarbonate and CO_2 levels. For example, the P_{CO_2} (and thus $[H^+]$) is elevated in respiratory acidosis, but the corresponding fall in pH is attenuated over time by renal retention of bicarbonate.

Compensatory mechanisms are, by definition, not "disorders." Such mechanisms constitute normal physiologic responses to acid-base derangements, and such terms as a *compensatory respiratory alkalosis* are therefore not only confusing but also misleading. The clinician is concerned with the adequacy of compensation, however, because failure of adequate compensation implies the presence of another primary acid-base disturbance. For example, a patient with metabolic acidosis who does not exhibit adequate respiratory compensation has a superimposed respiratory acidosis. Normal compensatory responses to each primary acid-base disturbance have been established through careful study and are presented later in this chapter.

It is important to note that compensatory mechanisms return the pH toward but not to normal.† The fact that compensatory mechanisms cannot become complete is evident when one considers that complete compensation would necessarily remove the (physiologic) stimulus driving the compensation. [1]

The "normal" values of pH, P_{CO_2} and $[HCO_3^-]$ for a given laboratory are ranges, intended to include 95 percent of patients without an acid-base disorder. The normal pH range is 7.35 to 7.45, the normal P_{CO_2} range is 35 to 45 mmHg, and the normal $[HCO_3^-]$ is usually 21 to 28 meq/L. However, a patient may have no value outside the "normal range" and still have significant acid-base disturbances. As detailed further below, a patient with a wide anion gap acidosis and a concomitant metabolic alkalosis of near-equal magnitude will have a normal pH, P_{CO_2} and $[HCO_3^-]$. On the other hand, abnormal-appearing values may, in fact, be appropriate for a given simple acid-base disturbance. For example, in the presence of a metabolic acidosis ($[HCO_3^-]$ = 15; pH = 7.3), an appropriate respiratory compensation should result in a P_{CO_2} of about 30 mmHg. The P_{CO_2} is below the "normal" range but at the expected level for the degree of (metabolic) acidosis. In this example, the finding of 40 mmHg for P_{CO_2}, a "normal"-appearing value, actually implies the presence of a respiratory acidosis, since the expected physiologic respiratory response is inadequate.

The Anion Gap

The principle of electroneutrality requires that plasma have no net charge. The charge of the predominant plasma cation, sodium, must therefore be "balanced" by the charge of plasma anions. Although bicarbonate and chloride constitute a significant fraction of plasma anions, the sum of their concentrations does not equal that of sodium. There must therefore be other anions present in the serum that preserve electroneutrality. These anions are mostly serum proteins, phosphate, sulfate, and organic anions such as lactate and the conjugate bases of ketoacids. Because these substances are not commonly measured, they are termed *unmeasured anions* (UA). Unmeasured cations (UC) also exist largely in the form of Ca^{2+} and Mg^{2+}. Since all cations, both measured and unmeasured, must equal all anions (both measured and unmeasured),

$$MC + UC = MA + UA$$

it follows that

$$MC - MA = UA - UC = \text{anion gap (AG)}$$

Thus substituting measured ions

$$[Na^+] - ([HCO_3^-] + [Cl^-]) = AG$$

The difference between the serum sodium (the contribution of potassium, largely an intracellular ion, is usually neglected) and the sum of serum chloride and bicarbonate, then, equals the concentration of the unmeasured anions. Correction of serum sodium for hyperglycemia is unnecessary because this condition similarly reduces chloride concentrations. [4]

The unmeasured anion concentration is commonly called the *anion gap* (AG), and in the past its normal value had been considered to be 12 ± 4 meq/L. Recent reports have suggested that a normal anion gap value of 7 ± 4 meq/L may be more appropriate to electrolyte measurements made with ion-specific electrodes. [5] However, the value used by the clinician should reflect institutional practice. [6] As with other acid-base concepts, the accepted "normal" range for the AG is less important than whether it has changed in relation to the patient's steady-state (baseline) value. Thus, a relative change in AG is more important than the actual value. However, virtually all values above 15 meq/L can be considered abnormal even when there is no previous comparison value available.

The anion gap may change even in the absence of acid-base disturbances. It may rise when (unmeasured) cations are decreased, as in severe states of hypomagnesemia, hypokalemia, and hypocalcemia. A reduced or even negative anion gap may result from an increase in unmeasured *cations,* such as lithium and unmeasured positively charged proteins resulting from myeloma and polyclonal gammopathies, or a decrease in unmeasured anions such as albumin and gamma globulin. A narrow or negative anion gap may also be the result of confounders of chloride measurement. Bromide is measured as chloride on an equimolar basis by chloride-specific electrodes. Other techniques of chloride measurement may produce even more inaccurate results in the presence of bromide. [7] Triglyceride levels greater than 600 mg/dL produce overestimation of chloride levels measured by colorimetric techniques and may also result in underestimation of serum sodium, resulting in an apparently negative anion gap. [4]

While increases in the AG are traditionally considered in the context of metabolic acidosis, elevation of the anion gap may be seen with any acid-base disturbance. Metabolic and respiratory alkalosis, for example, may elevate the AG by 2 to 3 meq/L because of elevations in lactate produced by enhancement of glycolysis. Penicillin and carbenicillin, as anions, produce elevations in the AG. Their charges must be balanced by sodium, which is retained by renal tubules at the cost of enhancing secretion of potassium and hydrogen ion. This effect is enhanced by the presence of the poorly reabsorbed penicillin and carbenicillin ions in the tubule lumen, the negative charges of which serve as an electrical gradient for hydrogen and potassium ion secretion. The result is an elevated AG with a hypokalemic alkalosis, illustrating the principle that anions principally cleared by the kidney may elevate the AG, particularly when aldosterone activity is high.

However, elevation of the AG is most commonly associated with metabolic acidosis. The unmeasured anions associated with an elevated AG and metabolic acidosis are listed in Table 21-2. Traditional mnemonics for the differential diagnosis of an elevated AG acidosis unfortunately suggest that iron, theophylline, cyanide, biguanides, and other compounds *are* unmeasured anions. These substances actually elevate the anion gap by producing lactic acidosis, discussed later in this chapter. The result of using traditional mnemonics in evaluating elevated AG acidosis may be a satisfaction-of-search error, where the discovery of lactic acidosis provides a ready explanation for the elevated AG and thereby inhibits pursuit of the causes of lactic acidosis. We suggest that the differential diagnosis of metabolic acidosis with an elevated AG should emphasize distinctions between endogenous and exogenous unmeasured anion sources and avoid mixing the differential diagnosis of lactic acidosis with that of increased unmeasured anions.

TABLE 21-2   Unmeasured Anions Associated with an Elevated Anion Gap and Metabolic Acidosis

Clinical use of the AG requires an appreciation of its limitations. While an AG greater than 30 meq/L is usually caused by lactic acidosis or ketoacidosis, these conditions may exist even when the AG is normal. An AG value less than 25 meq/L has been found to be an insensitive indicator of elevated lactate levels in critically ill patients,[8] and in trauma patients the postresuscitation AG does not predict lactate levels.[9] Thus, the "normal" AG does not exclude the presence of increased concentrations of unmeasured anions. As noted previously, an AG increased from baseline but still within the "normal" range may be a clue. Direct measurements of lactate, formate, ketoacids, methanol (parent of formic acid), ethylene glycol (parent of oxalic acid and numerous other organic acids), and salicylate should be ordered when the AG is "normal" but the presence of any these substances is suspected.

A common clinical problem is the diagnosis of mixed acid-base disturbances in the presence of an elevated AG. Simple acid-base disturbances that produce elevated AGs are referred to as *wide*-AG *metabolic acidoses*. If a wide-AG metabolic acidosis is the only disturbance, then the change (elevation from baseline) in value of the AG (sometimes referred to as the *delta gap*)[1c] should exactly equal the change (decrease) in the $[HCO_3^-]$. This is a one-to-one relationship. This concept is represented mathematically in Eq. (5).

$$\Delta \uparrow AG = \Delta \downarrow [HCO_3^-] \tag{5}$$

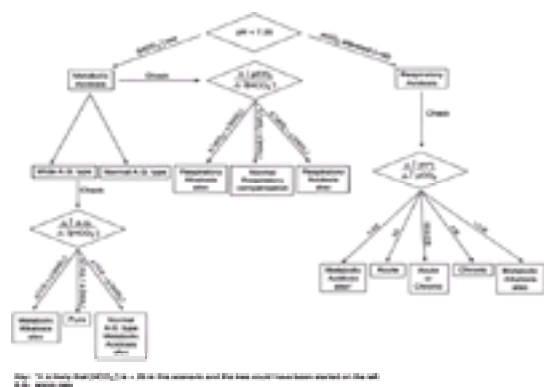
This simple relationship can be used to great advantage in determining the presence of other metabolic acid-base disturbances. If the $[HCO_3^-]$ is even lower than predicted by the delta AG, then there must be a concomitant hyperchloremic (i.e., non-AG type) metabolic acidosis (Fig. 21-2*A*). Similarly, if the decrease in $[HCO_3^-]$ is less than expected based on the delta AG, there must be a concomitant metabolic alkalosis present. Note that acute respiratory conditions (respiratory acidosis or alkalosis) do not affect these determinations. Potential acid-base disturbances related to respiratory status must be further determined, as discussed below (Fig. 21-2*A*, Fig. 21-2*B* and Fig. 21-2*C*).


FIG. 21-2A. Algorithm for determination of type of acidosis and mixed acid-base disturbances when pH indicates acidemia.
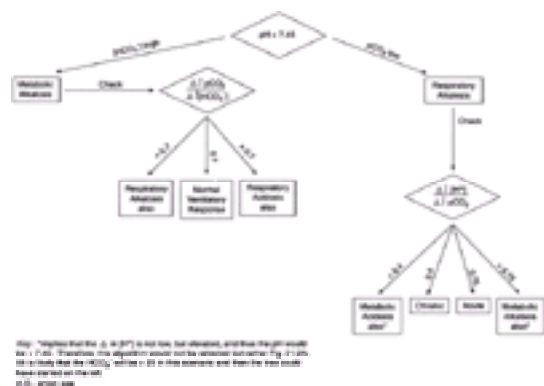

FIG. 21-2B. Algorithm for determination of type of alkalosis and mixed acid-base disturbances when pH indicates alkalemia.

FIG. 21-2C. Algorithm to check for acid-base disturbances when pH is in "normal" range.

Parameters Required for Clinical Acid-Base Evaluation

Clinical evaluation of acid-base disorders is an art requiring the synthesis of information gleaned from the clinical encounter and the laboratory. The history should emphasize events that may result in the gain or loss of acid or base, such as vomiting, diarrhea, or ingestion of acids or bases. There may also be evidence of diseases of the organs of acid-base homeostasis: the liver, kidneys, and lungs.

Laboratory evaluation requires blood samples for determination of electrolyte concentrations (potassium, sodium, chloride, and bicarbonate) and blood gases (pH, P_{CO_2} and bicarbonate concentration). Most clinical laboratories measure two of the parameters reported in blood gas results, most commonly the pH and P_{CO_2}, and use the Henderson-Hasselbalch equation to calculate the third.

Blood samples for acid-base evaluation are traditionally obtained by arterial puncture, but there is some evidence that venous blood may be used instead. Arterial and capillary values of pH and CO_2 content in normal patients and those with diabetic ketoacidosis correlate well (correlation coefficient 0.9 and 0.98, respectively). Recent work has demonstrated high correlations between arterial and venous pH ($r = 0.9689$) and arterial and venous bicarbonate concentrations ($r = 0.9543$) in emergency department (ED) patients with diabetic ketoacidosis.[11] The correlation between venous and arterial blood gas values in patients with severe shock remains uncertain, but in other circumstances, the use of venous values seems reasonable. Inexperienced clinicians frequently resort to arterial blood gas (ABG) determination as a means to "know" the pH. However, the pH per se is often the least important value for diagnosis and management. When respiratory status is not compromised, the pH can be calculated from knowing the venous $[HCO_3^-]$ alone, as described below.

METABOLIC ACIDOSIS

Metabolic acidosis may result from bicarbonate loss per se, administration of acid, or endogenous production and accumulation of acid. Loss of bicarbonate occurs in externalization of intestinal contents (e.g., vomiting, enterocutaneous fistulae) and renal wasting of bicarbonate (e.g., renal tubular acidosis, carbonic anhydrase inhibitor therapy). Administration of acid occurs primarily in total parenteral nutrition, where patients receive hydrochloric salts of basic amino acids. Finally, endogenous acids accumulate in renal tubular acidosis, ketoacidosis, and lactic acidosis.

Metabolic acidosis results in a decreased serum bicarbonate concentration, and its development causes respiratory compensation through increases in alveolar ventilation, resulting in a reduction in P_{CO_2}. The steady-state relationship between the P_{CO_2} and the bicarbonate concentration, determined from a study of 60 patients who had only metabolic acidosis of more than 24-h duration is shown in Eq. (6)[12]‡

$$P_{CO_2} = (1.5 * [HCO_3^-] + 8) \pm 2 \qquad (6)$$

When the bicarbonate concentration is greater than about 8 meq/dL, the relationship between P_{CO_2} and bicarbonate is simpler: *P_{CO_2} falls by 1 mmHg for every 1 meq/dL fall in bicarbonate.* Use of these relationships allows the clinician to calculate the expected P_{CO_2} from the measured bicarbonate concentration. If the expected P_{CO_2} value differs from the measured value in uncomplicated steady-state metabolic acidosis, a respiratory disorder also exists. For example, if the [HCO_3^-] is 15, the expected P_{CO_2} is about 30 mmHg. If it is higher than this value (say 35 mmHg), then by definition there is also concomitant primary respiratory acidosis (see Fig. 21-2A). If the value is lower than expected (say 25 mmHg), then there is a concomitant respiratory alkalosis. This latter case is not an "overcompensation" but rather a second primary disturbance occurring simultaneously. These are important concepts. The body cannot tolerate both a metabolic and respiratory mechanism for acidosis simultaneously, as one cannot buffer or compensate for the other.

The ED patient's illness can, unfortunately, rarely be assumed to be in steady state. Pierce and colleagues, in physiologic studies of otherwise healthy persons with acute metabolic acidosis caused by diarrhea, discovered that the completeness of the respiratory response to metabolic acidosis depends upon the duration of the acidosis, the time course of its development, and its severity.[13] If acidosis develops quickly, the P_{CO_2} is often higher than that observed in steady state; the more rapid and severe the acidosis, the larger the difference between the observed P_{CO_2} and the predicted steady-state P_{CO_2}. When bicarbonate concentration is then held constant, steady-state P_{CO_2} is reached in 11 to 24 h. When acidosis develops or is corrected more slowly, there is no lag in respiratory compensation.

There are limits to the adequacy of respiratory compensation during metabolic acidosis. A study early in the twentieth century of diabetic ketoacidosis by Kety and colleagues found that respiratory minute volume actually declined when pH fell below 7.10.[14] This finding led both Albert et al.[12] and Pierce et al.[13] to initiate bicarbonate therapy if their subjects' pH fell below 7.10. The nature of respiratory compensation in untreated severe metabolic acidosis is therefore unknown. Furthermore, these studies appear to have ensconced 7.10 as the definition of "severe" metabolic acidosis. It is particularly important to appreciate any contribution to the acidosis from inadequate respiratory response. Simply initiating bicarbonate therapy when a pH of less than 7.1 is encountered may miss the respiratory insufficiency, which, if addressed, may obviate the need to use solutions containing HCO_3^-. Further, administration of HCO_3^- in the face of inadequate ventilatory response actually exacerbates the respiratory acidosis, as the HCO_3^- is converted to CO_2 and H_2O. The development of metabolic acidosis in which the pH is below 7.10 is probably associated with a very high risk of ventilatory insufficiency. There is another limit to respiratory compensation. The lowest level that P_{CO_2} can attain is about 12 mmHg. The restriction of air movement and the CO_2 generated by the exertion required for rapid ventilation limits the attainable nadir for P_{CO_2}. The superimposition of respiratory acidosis upon a patient in such straits will result in a rapid decline of pH to levels at which organ function and pharmacotherapy will fail. Mechanical ventilation should usually be instituted in such situations.

The serum potassium level is affected by metabolic acidosis. The movement of hydrogen ion into cells is associated with extrusion of potassium. Changes in potassium concentration are more substantial in inorganic acidosis, though elevated serum potassium values are typically seen in diabetic ketoacidosis. Generally, for each 0.10 change in the pH, serum [K^+] will increase by approximately 0.5 meq/L. Whatever the mechanism of the acidosis, it is important to remember that low-normal or low serum potassium values probably reflect severe intracellular potassium depletion. The reversal of the acidosis in such circumstances may result in severe hypokalemia, with attendant cardiovascular effects.

Causes of Metabolic Acidosis

Metabolic acidosis results in a depression of serum bicarbonate, whose negative charge must be replaced. The negatively charged species are either unmeasured anions (elevated-AG acidosis) or chloride (normal-AG acidosis, also referred to as hyperchloremic metabolic acidosis).

The causes of elevated-AG metabolic acidosis are listed in Table 21-2. We reemphasize that the anion gap may be within the normal range even when a metabolic acidosis associated with increased concentrations of unmeasured anions is present. A comparison with the patient's steady-state AG is warranted or measurement of specific anions in such cases is indicated. However, caution is necessary when serum ketone testing is performed, as the chemical reaction used to measure serum ketones has an important limitation: the nitroprusside reaction for ketones is positive only for species whose carbonyl moiety has an a-methyl group. The major ketone present in the serum of patients with diabetic ketoacidosis may be b-hydroxybutyrate, which has no a-methyl group and is not detected by the nitroprusside reaction. The result may be a paradox: initial serum ketone assays in a patient with clinically severe diabetic ketoacidosis are only weakly positive yet rise in spite of clear clinical improvement. This occurs because appropriate resuscitation alters the hepatic $NAD/NADH_2$ ratio and the restoration of NAD concentrations allows oxidation of b-hydroxybutyrate to acetoacetate. The addition of several drops of hydrogen peroxide to serum will also oxidize b-hydroxybutyrate to acetoacetate in cases where this distinction is clinically important. See Chap. 203 for a detailed discussion.

Lactic acidosis occurs whenever lactate production exceeds lactate utilization or metabolism and is classically of two types. The first, in which tissue hypoxia is present and lactate production is elevated, is referred to as type A. Normal tissue oxygenation and impairment of lactate utilization define the second, called type B. Type B lactic acidosis is further subdivided. B_1 lactic acidosis is associated with systemic disorders such as diabetes, renal insufficiency, sepsis, and leukemia; type B_2 is associated with various substances, especially biguanides (phenformin, metformin), salicylates, methanol, iron and isoniazid; and type B_3 is associated with hereditary metabolic diseases.

The pyruvate produced by glycolysis may be transported across mitochondrial membranes and metabolized in the Krebs cycle under aerobic conditions. However, under anaerobic conditions, it is oxidized to lactate by lactate dehydrogenase. This reaction is reversible, but the conversion of lactate to pyruvate in the liver requires NAD. Thus, it is not surprising that many patients with type B lactic acidosis have underlying liver disease. For example, an alcoholic may develop lactic acidosis after giving up heavy drinking because impaired gluconeogenesis prevents pyruvate fixation into glucose, while the metabolism of ethanol has left little NAD available to convert lactate to pyruvate. The distinction between type A and type B lactic acidosis is useful in conceptualizing the therapeutic approach. However, there is some impairment of lactate utilization in both types, usually because of impaired hepatic oxygenation or perfusion in the case of type A and because of underlying liver disease in type B.

Differential Diagnoses of Wide-AG Acidosis

Note that an ABG is completely immaterial in determining whether a wide-AG metabolic acidosis exists. The determination is made with simple venous electrolytes. The differential diagnosis falls into four broad categories: renal failure (uremia), lactic acidosis, ketoacidosis (DKA, AKA, SKA), and ingestions (methanol, ethylene glycol, salicylates).

Renal failure should be evident from the serum chemistries. Positive serum ketones point to one of the ketoacidoses. In known insulin-dependent diabetes mellitus (IDDM), DKA is likely, although there is usually a small component of lactic acidosis also. In alcoholics who have recently stopped binge drinking, AKA should be considered. Starvation ketosis will be found in patients with inadequate recent oral intake (fasting, dieting, or protracted vomiting).

Determination of the osmolal gap will help differentiate two of the ingestants from other etiologies. Elevated gaps are seen in methanol and ethylene glycol poisoning. Although methanol is measured in most hospital laboratories, determination of ethylene glycol levels is still performed off-site in many institutions. A widened osmolal gap without evidence of methanol ingestion may determine the diagnosis long before confirmatory laboratory evidence is available. Calculation adjustments to the osmolal gap may need to be made if ethanol is a coingestant (see Chap. 23 for detailed discussion).

When the diagnosis remains in doubt or poor tissue perfusion is a diagnostic possibility, lactate levels should be specifically sent. It should be noted that several

poisonings may result in lactic acidosis, including isoniazid (INH), iron, carbon monoxide (CO), methemoglobin, and cyanide. This is but one reason why the authors shun the overtaught mnemonic of *MUDPILES.* For example, this mnemonic does not clearly reflect the fact that INH and iron exert their effects on the AG through lactic acidosis. Also, ethanol is frequently taught as a cause of wide-AG acidosis. *Ethanol should never be considered the etiologic source of any significant metabolic acidosis.* While ethanol alcohol metabolism may lead to very mild lactic acidosis, usually in association with AKA, its effect is very mild and all but clinically immaterial.

Severe acidosis that is resistant to treatment is seen in various B1 lactic acidoses and ingestions. AKA and SKA tend to be mild. Acidosis seen in initial stages of renal failure may be severe but is stable ([HCO_3^-] about 15 meq/L) in chronic renal failure. Concomitant acid-base disturbance may further assist in determining the etiology. The triple acid-base disturbance of wide-AG metabolic acidosis, metabolic alkalosis, and respiratory alkalosis is seen with sepsis (lactic acidosis), and salicylate poisoning. The latter may be associated with a mild temperature elevation also.

Finally, the relationship of [HCO_3^-] to the anion gap and expected P_{CO_2} compensation must be examined in every patient with wide anion gap acidosis to determine if other (respiratory) acid-base disturbances exist (see Fig. 21-2*A*).

Differential Diagnosis of Unchanged (Normal) AG Acidosis

The non-AG type of acidosis is often referred to as "normal" anion gap acidosis. As discussed above, issues related to the AG are relative, so the term *unchanged* or *non-AG type* is preferred. Some texts refer to this as hyperchloremic metabolic acidosis.

Non-AG acidosis results from loss of bicarbonate, failure to excrete hydrogen ion, or administration of hydrogen ion. Bicarbonate may be lost from either the urine or gastrointestinal tract and is usually accompanied by potassium. However, potassium-sparing diuretics, hypoaldosteronism, urinary tract obstruction, and type IV renal tubular acidosis all result in loss of bicarbonate with retention of potassium (Table 21-3).

With a tendency to hyperkalemia	With a tendency to hypokalemia
Subsiding DKA	Renal tubular acidosis—type I
Early uremic acidosis	(classical distal acidosis)
Early obstructive uropathy	Renal tubular acidosis—type II
Renal tubular acidosis—type IV	(proximal acidosis)
Hypoaldosteronism (Addison's disease)	Acetazolamide
	Acute diarrhea with losses of HCO_3^- and K^+
Infusion or ingestion of HCl, NH_4Cl, lysine-HCl, or arginine-HCl	Ureterosigmoidostomy with increased resorption of H^+ and Cl^- and losses of HCO_3^- and K^+
Potassium-sparing diuretics	Obstruction of artificial ileal bladder
	Dilution acidosis

TABLE 21-3   Causes of Normal Anion Gap Metabolic Acidosis

One should be wary of the traditional classification based on K^+, as serum [K^+] itself is dependent on the actual pH. Thus, in severe acidosis, a normal range [K^+] may be deceiving unless the clinician corrects for the degree of acidosis.

Since all diuretics have a tendency to result in mild contraction alkalosis, the metabolic acidosis that occurs simultaneously with potassium-sparing diuretics may not be evident, as the two distinct physiologic processes may simply cancel each other out (see Fig. 21-2*C*). Since the AG is unchanged, there is no clue that two opposed processes may be occurring.

Acetazolamide exerts its effect through carbonic anhydrase inhibition, inducing a functional RTA.

Treatment of Acidosis

Acidemia has numerous negative physiologic consequences, impairing the function of many different organs through mechanisms not yet well understood. Cardiac contractile function is reduced, probably due to impaired oxidative phosphorylation as well as intracellular acidosis. The threshold for ventricular fibrillation falls while the defibrillation threshold rises. Hepatic and renal perfusion decline, along with systemic blood pressure, while pulmonary vascular resistance increases. The physiologic effects of catecholamines are attenuated, and when acidosis is sufficiently severe, vascular collapse may result. A catabolic state develops, including a generalized increase in metabolism, resistance to insulin, and inhibition of anaerobic glycolysis. Finally, the effect of hypoxia on all organs is aggravated. [15]

The treatment of acidosis reflects that of the underlying disorder but particularly emphasizes restoration of normal tissue perfusion and oxygenation. As noted above, the most important step is to determine whether there is a respiratory component to the acidosis (i.e., a primary respiratory acidosis), because the treatment approach differs. If there is inadequate respiratory compensation, the most appropriate treatment will be to first correct the respiratory problem.

The adverse effects of acidemia make the concept of buffer therapy teleologically appealing, but the role of buffer therapy in both cardiac arrest and severe metabolic acidosis is uncertain. The traditional therapeutic buffer, sodium bicarbonate, may have negative effects in the treatment of acidosis. Bicarbonate therapy results in the generation of significant quantities of CO_2, which diffuses readily into cells—particularly those of the central nervous system—and may therefore cause paradoxical worsening of intracellular acidosis. An abrupt CO_2 load may also exceed the ventilatory capacity of a maximally ventilating patient, producing respiratory failure. After successful treatment with bicarbonate, "overshoot" alkalosis may result; this problem occurs most commonly in organic acidosis, when reversal of the acidosis results in reformation of bicarbonate. Finally, bicarbonate therapy imposes an osmotic and sodium load (1000 meq/L of typical 1N solution). These concerns suggest that bicarbonate therapy should not be used in the ED treatment of mild to moderate metabolic acidosis. Bicarbonate therapy is reasonable, however, in situations where the effects of acidosis are so severe that they preclude or jeopardize therapy for the underlying disease (Table 21-4).

Indication	Rationale
Severe hypobicarbonatemia (<4 meq/L)	Insufficient buffer concentrations may lead to extreme increases in acidemia with small increases in acidosis
Severe acidemia (pH <7.20) with signs of shock or myocardial irritability that is not rapidly responsive to supportive measures	Therapy for the underlying cause of acidosis depends upon adequate organ perfusion
Severe hyperchloremic acidemia*	Lost bicarbonate must be regenerated by kidneys and liver, which may require days

*No specific definition by pH exists. The presence of serious hemodynamic insufficiency despite supportive care should guide the use of bicarbonate therapy for this indication.

TABLE 21-4   Indications for Bicarbonate Therapy in Metabolic Acidosis

When bicarbonate is used, Adrogue and Madias [15] recommend administering 0.5 meq/kg bicarbonate for each meq/dL desired rise in [HCO_2^-]. The goal is to restore adequate buffer capacity ([HCO_3^-] > 8 meq/dL) or achieve clinical improvement in shock or dysrhythmias. Bicarbonate should be given as slowly as the clinical situation permits; 1.5 ampules of sodium bicarbonate in 500 mL D_5W produces a nearly isotonic solution for infusion. Adequate time should be allowed for the desired

effect to be achieved, and close monitoring of acid-base balance, especially in patients with organic acidosis, is critical.

Newer buffers appear to show promise in the treatment of metabolic acidosis. Carbicarb, an equimolar solution of sodium bicarbonate and sodium carbonate (CO_3^{2-}), produces significantly less CO_2 than an equimolar dose of bicarbonate. The carbonate ion, a strong base, combines avidly with protons to form bicarbonate, resulting in increased pH, an increased bicarbonate concentration, and limited CO_2 production. Clinical studies of Carbicarb use in lactic acidosis models have shown improvements in pH with little or no change in P_{CO_2}.[16,17] However, large-scale studies in ED patients do not yet exist, and Carbicarb, while promising, remains experimental.

METABOLIC ALKALOSIS

Metabolic alkalosis is typically classified as chloride-sensitive and chloride-insensitive, indicating the treatment approach itself. Metabolic alkalosis results from either gain of bicarbonate or loss of acid. The relationship of metabolic alkalosis to chloride balance defines both pathophysiologic features of the disease and its therapy. Bicarbonate and chloride represent the major serum anions whose concentration may be readily altered, and their homeostasis is therefore closely intertwined.

Conditions that produce chloride loss, such as vomiting (which also produces acid loss), diarrhea, diuretic therapy, and chloride-wasting diseases (e.g., cystic fibrosis and chloride-wasting enteropathy) all tend to reduce both serum chloride concentration and extracellular volume. The reduction in extracellular volume produces increased mineralocorticoid activity, which enhances sodium reabsorption and potassium and hydrogen ion secretion in the distal tubule, which, in turn, enhance bicarbonate generation. The resulting increase in serum bicarbonate concentration eventually exceeds the tubule's maximum ability to reabsorb filtered bicarbonate. The resulting alkaline urine, because its anionic content is mostly bicarbonate, is largely free of chloride (<10 meq/L), though when diuretics have been administered, the urine chloride may be normal. The result is hypokalemic, hypochloremic alkalosis that responds to normal (chloride-responsive alkalosis).

Other diseases that cause metabolic alkalosis are usually associated with normovolemia or hypervolemia and often hypertension. These diseases usually cause excess mineralocorticoid activity, resulting in the same pathophysiologic cascade described above. However, the excess mineralocorticoid activity is not associated with hypovolemia, so the urine chloride is generally normal or elevated (>10 meq/L) and the alkalosis cannot be reversed with normal saline. Diseases producing "chloride-unresponsive alkalosis" and hypertension include renal artery stenosis, renin-secreting tumors, adrenal hyperplasia, hyperaldosteronism, Cushing syndrome, Liddle syndrome, and exogenous mineralocorticoids (e.g., licorice, Florinef). Chloride-unresponsive alkalosis caused by Bartter syndrome and Gitelman syndrome is usually associated with normotension.

The compensation for metabolic alkalosis involves reduction in alveolar ventilation, but the exact relationship between P_{CO_2} and hydrogen ion concentration is not well established. Most studies to date have been conducted either in dialysis patients or patients with conditions that predispose to alveolar hyperventilation (e.g., sepsis, pneumonia). As a guideline, P_{CO_2} in patients with significant metabolic alkalosis should rise 0.7 mmHg for each milliequivalent increase in [HCO_3^-]. The P_{CO_2} also rarely rises above 55 mmHg in compensation for metabolic alkalosis.

The physiologic effects of alkalemia are substantial. Neurologic abnormalities—especially tetany, neuromuscular instability, and seizures—are common. Reduction in hydrogen ion concentration results in reductions in ionized calcium, potassium, magnesium, and phosphate levels. Constriction of arterioles occurs, resulting in reduced coronary and cerebral blood flow. Finally, refractory dysrhythmias may develop.[15] Alkalemia may be of particular concern in patients with chronic obstructive pulmonary disease (COPD) because of the shift of the oxygen-hemoglobin to the left, making O_2 less available to the tissues. Many such patients are taking diuretics, which lead to a contraction alkalosis. Also, the alkalotic environment tends to depress ventilatory drive further.

Therapy of alkalemia, as with all acid-base disorders, emphasizes treatment of the underlying cause and careful supportive care. Acetazolamide produces significant bicarbonaturia and is effective in the treatment of metabolic alkalosis, but its use requires very careful monitoring of potassium, magnesium, and phosphate concentrations. If alkalemia is severe ([HCO_3^-] > 45 mmol/L) and associated with serious signs or symptoms not responsive to supportive care, the use of intravenous hydrochloric acid should be considered. A 0.1 normal solution (100 mmol/L), infused at no more than 0.2 mmol/kg/h through a central venous catheter is used; higher concentrations may produce degradation of catheter material.[18] The dose is calculated as shown in Eq. (7), with the result in millimoles of bicarbonate.

$$\text{Dose} = (\Delta[HCO_3^-])(\text{weight})(0.5) \tag{7}$$

RESPIRATORY ACIDOSIS

Respiratory acidosis is defined by alveolar hypoventilation and is diagnosed when the P_{CO_2} is greater then the expected value. Acute respiratory acidosis may have origins such as increased CO_2 production (high-glucose diet) and abnormal gas exchange (e.g., pneumonia). Final common path is inadequate ventilation.

Inadequate minute ventilation is most frequently due to head trauma, chest trauma, or disease or excess sedation. The chronic hypoventilation seen in extremely obese patients is often referred to as the *pickwickian syndrome,* after an obese character in Charles Dickens' *Pickwick Papers.* Patients with severe COPD have increased dead space and frequently also have a decreased minute ventilation.

In general, a rise in the P_{CO_2} stimulates the respiratory center to increase respiratory rate and minute ventilation. However, if the arterial P_{CO_2} chronically exceeds 60 to 70 mmHg, as may occur in 5 to 10 percent of patients with severe emphysema, the respiratory acidosis may depress the respiratory center. Under such circumstances, the stimulus for ventilation is provided primarily by hypoxemia acting on chemoreceptors in the carotid and aortic bodies. Giving oxygen could take away the main stimulus to breathe, causing the P_{CO_2} to rise abruptly to extremely dangerous levels. Consequently, one should not administer oxygen to patients with COPD without carefully watching for the development of apnea or hypoventilation.

Evaluation of ventilation requires attention to several important clinical issues. First, the ventilation that would be expected based on assessment of the respiratory rate and depth should be compared to the actual ventilation of the patient (i.e., P_{CO_2}). A "normal" P_{CO_2} of 40 mmHg in a tachypneic, dyspneic patient probably reflects significant ventilatory insufficiency. Second, the impact of respiratory acidosis on PA_{O_2} in such a patient may be considerable. The alveolar gas equation suggests that if inspired oxygen concentration and respiratory quotient do not vary, increases in P_{CO_2} will result in reductions in PA_{O_2}.

The relationship of P_{CO_2} to hydrogen ion concentration in acute respiratory acidosis is suggested by the Kassirer-Bleich equation:

$$\Delta[H^+] = 0.8(\Delta P_{CO_2}) \tag{8}$$

Each 1-mmHg increase in P_{CO_2} results in a 1-mmol increase in [H^+]. Across the linear portion of the pH–hydrogen ion concentration relationship, then, each 1-mmHg increase in P_{CO_2} should theoretically produce a 0.01-unit decrease in pH. The actual relationship between changes in P_{CO_2} (up to values of 90 mmHg) and changes in [H^+] determined in normal humans is about 8:10, as shown in Eq. (7). Thus, a 10-mmHg increment in P_{CO_2} produces an 8-mmol increase in hydrogen ion concentration, with little change in bicarbonate concentration (usually 1 meq/dL) or urinary acid excretion.[19] If the [H^+] is higher or lower than that suggested by the change in the P_{CO_2}, a mixed disorder is present.

The adaptation to chronic respiratory acidosis is complex. Over time, chronic elevation of P_{CO_2} results in a reduction in the sensitivity of carotid sinus sensitivity to hypercapnia; ventilatory drive is then controlled by Pa_{CO_2}. The acidosis results in significant increases in renal bicarbonate generation and avid reclamation of filtered bicarbonate. The relationship between [H^+] and [HCO_3^-] in chronic respiratory acidosis at steady state, derived from studies in humans, is shown in Eq. (9).

$$\Delta[H^+] = 0.3(\Delta P_{CO_2}) \tag{9}$$

It is rarely certain during a given clinical encounter whether a patient has an acute respiratory acidosis, a chronic respiratory acidosis, or an acute exacerbation of chronic COPD. Evaluation of the acid-base status in such circumstances does not require "baseline" arterial blood gas values. Instead, the change in hydrogen ion concentration is compared with the change in P_{CO_2}. If this ratio is 0.3, the patient has a chronic respiratory acidosis; if it is 0.8, the patient has an acute respiratory

acidosis. States resulting in other ratios suggest a mixed acid-base disturbance, as shown in Table 21-5.

Ratio = Δ[H⁺]/ΔPco₂				
Ratio < 0.3	Ratio = 0.3	0.3 < Ratio < 0.8	Ratio = 0.8	Ratio > 0.8
Change in hydrogen ion concentration is less than accounted for by chronic change in Pco₂. Metabolic alkalosis is also present.	Change in hydrogen ion concentration matches chronic change in Pco₂. Chronic respiratory acidosis is present.	Change in hydrogen ion concentration is larger than accounted for by chronic change in Pco₂. Chronic respiratory acidosis plus either acute respiratory alkalosis or metabolic acidosis is present, examine pH.	Change in hydrogen ion concentration matches acute change in Pco₂. Acute respiratory acidosis is present.	Change in hydrogen ion concentration is larger than accounted for by acute or chronic change in Pco₂. Metabolic acidosis is also present.

TABLE 21-5   Evaluation of Acid-Base Status in Respiratory Acidosis

Treatment of respiratory acidosis is primarily designed to improve alveolar ventilation. In general, if the minute ventilation is doubled, the P_{CO_2} will be reduced by 50 percent. In patients with COPD, bronchodilators such as aminophylline or various sympathomimetic agents such as isoproterenol or adrenalin, together with careful administration of small amounts of oxygen, may substantially improve ventilation. However, ventilating assistance may be required in some patients who do not respond adequately to lesser measures, particularly if the pH falls below 7.25 to 7.30. Unfortunately, it may be extremely difficult to extubate such patients later.

In patients with a chronic respiratory acidosis, reduction of the P_{CO_2} should generally proceed slowly. The minute ventilation for a 70-kg person is normally about 6 L/min, and in COPD patients it may be less than 4 L/min. In a patient with COPD and severe hypercarbia, it may be wise to start treatment with a minute ventilation of about 5 L/min and then gradually increase it according to the clinical response and changes in P_{CO_2}.

Rapid correction of a chronic respiratory acidosis can cause sudden development of a severe combined metabolic and respiratory alkalosis with resulting dysrhythmias. A rapid rise in pH can cause an abrupt fall in ionized calcium. The resulting ionic hypocalcemia can then cause dangerous dysrhythmias or seizures. In patients with a chronic respiratory acidosis, the arterial P_{CO_2} should not be reduced by more than 5.0 meq/h.

RESPIRATORY ALKALOSIS

Respiratory alkalosis is defined by alveolar hyperventilation and exists when P_{CO_2} is less then expected. It is caused by conditions that stimulate respiratory centers, including central nervous system tumors or stroke, infections, pregnancy, hypoxia, and toxins (e.g., salicylates). Anxiety, pain, and overventilation of patients on mechanical ventilators also cause respiratory alkalosis.

Whatever the etiology, the clinical symptoms of acute respiratory alkalosis are predictable from its physiologic effects. Acute reduction in P_{CO_2} produces a reduction in hydrogen ion concentration, resulting in an increase in negative charge on anionic buffers. The now relatively negatively charged proteins instead bind calcium, and this reduction in ionized calcium produces carpopedal spasm and paresthesias. [15] Hypocapnia also produces substantial reductions in cerebral blood flow, and results in reduced tissue oxygen delivery because of increased hemoglobin oxygen binding.

The theoretical relationship of hydrogen ion concentration and P_{CO_2} predicted by the Kassirer-Bleich equation is that a 1-mmol decrease in [H⁺] results from each 1-mmHg reduction in P_{CO_2}. The actual observed relationship is very close to that predicted by the Kassirer-Bleich equation. [20] Each mmHg reduction in P_{CO_2} results in a 0.75-mmol reduction in [H⁺] (Eq. 10). [20]

$$\Delta[H^+] = 0.75(\Delta P_{CO_2}) \tag{10}$$

Chronic respiratory alkalosis is unique among the acid-base disorders in that its compensation may be complete. Compensatory events include bicarbonaturia and a reduction in acid excretion, requiring 6 to 72 h to develop fully and at least 1 week to normalize pH. The steady-state relationship between hydrogen ion concentration and P_{CO_2} in chronic respiratory alkalosis observed in normal human subjects at high altitude is shown in Eq. (10). [21]

$$\Delta[H^+] = 0.4(\Delta P_{CO_2}) \tag{11}$$

Therapy for acute respiratory alkalosis emphasizes identification and treatment of the underlying cause. The use of paper-bag rebreathing in the treatment of respiratory alkalosis should be avoided. Callaham evaluated paper-bag rebreathing in voluntarily hyperventilating volunteers and found that while the inspired P_{CO_2} increased by 20 mmHg in 30 s, it never increased above 40 mmHg. However, inspired oxygen concentration fell by an average of 27 mmHg in 180 s, and in 5 percent of subjects the fall was greater than or equal to 42 mmHg. [22] If the cause of hyperventilation is actually cellular hypoxia, such a fall could be catastrophic. [23] Furthermore, there is evidence that expectation of efficacy and suggestion, rather than elevations of inspired CO_2 tension, are responsible for relief of symptoms in hyperventilation. [24] An oxygen mask might provide benefits similar to those of paper-bag rebreathing with less risk of hypoxia.

Chronic respiratory alkalosis is seen at high altitudes, particularly among mountaineers climbing over 12,000 ft (where the partial pressure of O_2 is significantly diminished). Acetazolamide is frequently prescribed to counter the physiologic respiratory effects of such ascents.

CLINICAL APPROACH TO ACID-BASE PROBLEMS AND MIXED ACID-BASE DISTURBANCES

The evaluation of an acid-base problem begins with a history and physical examination, with particular attention to sources of acid or alkali gain or loss and to diseases that affect renal, hepatic, or pulmonary function. Blood should be obtained for gas analysis and electrolyte determination, and the anion gap should be calculated. Finally, blood gas results should be checked for internal consistency using the Henderson-Hasselbalch or Kassirer-Bleich equation— Eq. (3) or Eq. (4).

Note that in metabolic acidosis, where the respiratory response appears clinically appropriate, both the P_{CO_2} and pH can be predicted. Thus, a single ABG to prove there is no abnormal respiratory component may be all that is necessary and further evaluation can be determined from serum (venous) [HCO_3^-] alone. For example when, the [HCO_3^-] is 15, the expected physiologic respiratory compensatory response is expected to be a decline in P_{CO_2} equal to the decline in [HCO_3^-]—i.e., in this scenario, 30 mmHg. The values for both known [HCO_3^-] and predicted P_{CO_2} can then be inserted in the Kassirer-Bleich equation– Eq. (4)—to determine the [H⁺], which in this case is calculated to be about 48. The [H⁺] can then be related to the corresponding pH, which, as noted earlier, is close to linear for values from 22 to 55 nmol/L, in this case about 7.32.

Methodical interpretation of laboratory results followed by correlation with the clinical scenario is necessary to prevent erroneous acid-base evaluation. While we suggest one method that has worked well for us, the particular method used matters less than the consistency of its application. However, we do frown on reliance on "acid-base disturbance maps." First, they may be misleading, particularly where there is more than one primary disturbance. Second, they offer no understanding of the processes. Without an understanding of the complex but not difficult to master concepts of interrelationships in acid-base balance, the clinician misses diagnoses and has little understanding of the appropriate approach to therapy. As long as the method selected reflects the acid-base relationships presented in this chapter, the result should be the same. One suggested method follows:

1. Look at the pH. If it is decreased, the primary or predominant disturbance is acidosis. If the pH is increased, the predominant disturbance is alkalosis.
2. If the pH indicates acidosis, the primary (or predominant) mechanism can be ascertained by examining the [HCO_3^-] and P_{CO_2} (see Fig. 21-2A).

a. If the $[HCO_3^-]$ is low (implying a primary metabolic acidosis) then the AG should be examined and, if possible, compared with a known steady-state value.

   i. If the AG is increased compared to the known previous value, or is greater than 15, then by definition a wide-AG metabolic acidosis is present and the absolute change in the AG should be compared with the absolute change in the $[HCO_3^-]$ from normal.

   ii. If the AG is unchanged, then the disturbance is a nonwidened (sometimes termed *unchanged AG* or *hyperchloremic*) metabolic acidosis.

   iii. If the change in the AG is equal to the change in the $[HCO_3^-]$, then the wide AG-acidosis is termed *pure*. If the AG has risen more than the $[HCO_3^-]$ has decreased, then there is also likely to be a concomitant metabolic alkalosis. If the change in the AG is less than the change in the $[HCO_3^-]$, then a non-AG acidosis is also present. (This is a difficult concept, but two separate physiologic mechanisms both resulting in increased $[H^+]$ can occur simultaneously.)

   iv. Next examine whether the ventilatory response is appropriate.

     1. If the decrease in the P_{CO_2} equals the decrease in the $[HCO_3^-]$, there is appropriate respiratory compensation. Note that the pH will not return to normal.

     2. If the decrease in the P_{CO_2} is greater than the decrease in the $[HCO_3^-]$, there is a concomitant respiratory alkalosis. (Although there are other formulas for this comparison, this is the simplest, as explained earlier in the text.)

     3. If the decrease in the P_{CO_2} is less than the decrease in $[HCO_3^-]$, there is also a concomitant respiratory acidosis.

b. If the P_{CO_2} is elevated (rather than the $[HCO_3^-]$ decreased), the primary disturbance is respiratory acidosis (see Fig. 21-2*A*). The next step is to figure out which type it is by examining the ratio of (the change in) $[H^+]$ to (the upward change in) the P_{CO_2}.

   i. If the ratio is 0.8, it is considered acute.

   ii. If the ratio is 0.33, it is considered chronic.

   iii. If the ratio is between 0.8 and 0.33, it is probably an acute exacerbation of the chronic condition.

   iv. If the ratio is greater than 0.8, there must be a metabolic explanation for the excess $[H^+]$.

   v. If the ratio is less than 0.33, a metabolic alkalosis must also be present.

3. If the pH is greater than 7.45, the primary or predominant disturbance is a metabolic alkalosis (see Fig. 21-2*B*).

a. It is best to look at the $[HCO_3^-]$ first. If it is elevated, there is a primary metabolic alkalosis. There is an expected ventilatory response, although it is quite varied. The ratio of the change upward in P_{CO_2} to the change upward in $[HCO_3^-]$ can be examined.

   i. If the ratio is much less than 0.7, there is also a respiratory alkalosis (in addition to the metabolic alkalosis). If the ratio is more or less 0.7, this is likely to be a compensatory ventilatory response. If the ratio is well above 0.7, respiratory acidosis is concomitantly present.

b. If the P_{CO_2} is low, there is a primary respiratory alkalosis and the ratio of the change in $[H^+]$ to the change in P_{CO_2} should be examined. Acute respiratory alkalosis has a ratio of about 0.75. If the ratio is well above 0.75, there is probably also a concomitant metabolic alkalosis to explain the greater than expected decline in $[H^+]$. If the ratio is smaller, the condition is either chronic or there may also be a metabolic acidosis component.

4. Every ABG that shows no or minimal pH derangement should still call for examination of the P_{CO_2} and $[HCO_3^-]$, as there may well be a mixed acid-base disturbance (see Fig. 2C). As noted earlier, it is quite possible for the pH, $[HCO_3^-]$, and P_{CO_2} all to be normal and yet for there to be significant acid-base disturbances. The only clue will be the anion gap. Take the example of a $[Na^+]$ of 145, $[Cl^-]$ 97, $[K^+]$ 4.5, and $[HCO_3^-]$ of 25 and a normal ABG. All the numbers look reasonably normal. However, the AG is 23, so by definition there must be a wide-AG metabolic acidosis. The only explanation for the normal numbers is that there must be a concomitant metabolic alkalosis.

---

*The "bicarbonate concentration" measured by the clinical laboratory is actually the total CO_2, a figure that is the sum of bicarbonate and dissolved CO_2 plus H_2CO_3. The latter term is the P_{CO_2} multiplied by the solubility coefficient of CO_2 in blood (a), 0.03. Thus, total $CO_2 = [HCO_3^-] + (0.03) (P_{CO_2})$. Most clinicians simply neglect the second term when the P_{CO_2} is normal; when hypercapnia is present, however, the second term contributes significantly to total CO_2.[1]

†The sole exception is in chronic respiratory alkalosis, where bicarbonate levels may decline to a level that nearly normalizes the pH such that differentiating the actual pH from normal falls within the range of lab error.

‡The constants in this equation (orginally $P_{CO_2} = 1.54*[HCO_3^-] + 8.36 \pm 2$) have been rounded for ease of use.

22 BLOOD GASES: PATHOPHYSIOLOGY AND INTERPRETATION

Mark P. Hamlin
Peter J. Pronovost

Human lungs serve two distinct functions: ventilation and oxygenation. Ventilation, which determines the clearance of carbon dioxide from the body, is a function of the rate and depth of breathing. Oxygenation is the diffusion of oxygen from the lungs to the bloodstream for subsequent delivery to the tissues. The separation between oxygenation and ventilation is dramatically demonstrated by the apnea test for determining brain death. During this test, 100% oxygen is insufflated via a thin catheter placed near the carina in an apneic, unventilated patient. The peripheral oxygen saturation is 90 to 100% despite no clearance of carbon dioxide with severe acidosis. This dramatic example clearly distinguishes the two functions.

VENTILATION

Minute Ventilation

Minute ventilation (V_M), the total amount of new air moved in and out of the airways and lungs each minute, is equal to the tidal volume (V_T) multiplied by the respiratory rate (f). The normal V_T is about 7 mL/kg, or 500 mL in an adult, and the normal f is 12 breaths per minute. Therefore, the normal minute ventilatory volume required to maintain a partial pressure of carbon dioxide (P_{CO_2}) of 40 mmHg averages about 6 L/min. However, the V_M required to maintain a normal P_{CO_2} depends on the amount of CO_2 being produced and the amount of dead space in the lung. People who are exercising or patients who are febrile or hypermetabolic have increased CO_2 production and thus a V_M greater than 10 to 20 L/min, while patients who are severely hypothermic may have decreased CO_2 production and thus V_M equals 2 L/min. A V_M less than 2 L/min, even in a hypothermic patient, leads to respiratory acidosis. The f occasionally rises to as high as 40 to 50 breaths per minute, and the V_T can become almost as great as the forced vital capacity, which is about 4500 to 5000 mL, or 65 to 70 mL/kg in a young adult male. However, at rapid rates a person usually cannot sustain a V_T greater than 40 percent of the vital capacity for more than a few hours.

Dead Space

Approximately 30% of the air that a person breathes does not participate in the alveolar gas exchange process and is thus called dead space ventilation (V_{DS}). Dead space ventilation is made up of anatomic dead space and alveolar dead space. Anatomic dead space is the volume of air that fills the conducting airways (trachea, bronchi, and bronchioles), while alveolar dead space is the volume of air in alveoli that are not perfused. The combination of alveolar and anatomic dead space is called the physiologic dead space, which in a young male adult with a V_T of 500 mL is about 150 mL (about 2 mL/kg of body weight), or about 30% of the V_T.

Dead space can be increased by certain disease states, such as adult respiratory distress syndrome (ARDS), where the physiologic dead space can exceed 60% of the V_T. The increased dead space requires a tremendous increase in the V_M (usually by an increase in the respiratory rate) to prevent the development of respiratory acidosis.

Alveolar Ventilation

The main function of the pulmonary ventilatory system is to continually renew the air in the alveoli, where it is brought in close proximity to the pulmonary capillary blood. The rate at which new air reaches these areas is called alveolar ventilation (V_A), or $V_M - V_{DS}$. Consider a patient with myasthenia gravis who is developing progressive respiratory failure. The patient's baseline V_A is [$V_M(500 \times 12 = 6$ L/min$) - V_{DS}(150 \times 12 = 1.8$ L/min$) = V_A(4.2$ L/min$)$]. If the patient's V_T is decreased to 250 due to weakness, the patient cannot simply double f but must increase it almost 4 times, to 42 breaths per minute [$(250 \times 42 = 10.5$ L/min$) - (150 \times 42 = 6.3$ L/min$) = 4.2$ L/min], to maintain the same alveolar ventilation. An increased f increases the patient's work of breathing and may lead to respiratory failure.

GAS PRESSURES

Pressure is caused by the constant impact of moving molecules against a surface. Therefore, the pressure of a gas acting on the surfaces of the respiratory passages and alveoli is proportional to the sum of the impaction forces of all the molecules striking the surface at any given instant. The important gases to consider in the lung are oxygen, nitrogen, and carbon dioxide. The rate of diffusion of each gas is directly proportional to its partial pressure.

The concentration of a gas in solution (e.g., blood) is determined not only by its partial pressure but also by the solubility coefficient of the gas. The solubility coefficients for the important respiratory gases at body temperature are oxygen, 0.024; carbon dioxide, 0.57; carbon monoxide, 0.018; and nitrogen, 0.012. Thus, carbon dioxide is more than 20 times as soluble as oxygen, and oxygen is twice as soluble as nitrogen. The solubilities help determine the quantity of gas dissolved in the fluids of the body, which is a major factor in determining the rate at which the gas can diffuse through tissues.

Diffusion of Gases

Major factors that affect the rate of gas diffusion in a fluid include (1) the partial pressure of the gas, (2) the solubility of the gas in the fluid, (3) the surface area

available for diffusion, (4) the distance through which the gas must diffuse, (5) the molecular weight of the gas, and (6) the temperature of the fluid.

The greater the solubility of the gas and the greater the surface area for diffusion, the greater the number of molecules available to diffuse for any given pressure difference. On the other hand, the greater the distance the molecules must diffuse, the longer it takes for the diffusion to occur. Finally, the greater the velocity of the molecules, which at any given temperature is inversely proportional to the square root of the molecular weight, the greater the rate of diffusion of the gas. All these factors can be expressed in a single formula:

$$D = \frac{PAS}{d\sqrt{MW}}$$

where D = diffusion rate
P = pressure difference between the two ends of the diffusion pathway
A = cross-section area of the pathway
S = solubility of the gas
d = distance of diffusion
MW = molecular weight of the gas

The characteristics of a gas determine its solubility and molecular weight, which determine the diffusion coefficient of the gas. The diffusion coefficient, which equals $S\sqrt{MW}$, determines the relative rates at which different gases at the same pressure will diffuse. If the diffusion coefficient of oxygen is 1.0, the relative diffusion coefficients of other gases of respiratory importance are carbon dioxide, 20.3; carbon monoxide, 0.81; nitrogen, 0.53; and helium, 0.95.

Oxygen, carbon dioxide, and nitrogen are all highly soluble in lipids and consequently are also highly soluble in cell membranes. The major limitation to the movement of these gases in tissues is the rate at which the gases can diffuse through the tissue water, an important consideration in pulmonary edema.

The respiratory unit is composed of a respiratory bronchiole, alveolar ducts, atria, and alveoli. The alveolar walls are extremely thin and closely applied to an almost continuous network of interconnecting capillaries. The membrane through which gaseous exchange between the alveolar air and the pulmonary blood occurs is known as the respiratory (pulmonary) membrane. For oxygen to get from the alveolus into the pulmonary capillary bed, it must pass through four separate layers, referred to collectively as the alveolar-capillary, or respiratory, membrane. These layers include (1) a layer of fluid, called alveolar fluid, lining the alveolus and containing surfactant that reduces its surface tension; (2) the alveolar epithelium, composed of very thin epithelial cells and a basement membrane; (3) a very thin interstitial space between the alveolar epithelium and the capillary membrane; and (4) the capillary endothelial membrane and its basement membrane, which fuses with the alveolar basement membrane in many places.

The average diameter of the pulmonary capillaries is less than 8 mm, which means that red blood cells must actually squeeze through them. Therefore, at least part of the red blood cell membrane touches the capillary wall. Where this occurs, oxygen does not have to pass through significant amounts of plasma as it diffuses from the alveolus to the red blood cell. This reduces the diffusion distance and thus increases the rapidity of diffusion of gases between the alveolus and the hemoglobin molecules.

Gas Diffusion Through the Respiratory Membrane

The total diffusing surface area of the lung is enormous (160 m^2) and very thin (averaging 0.63 mm). These characteristics, combined with the solubility of CO_2 and O_2, make the lungs very efficient for maximizing gas exchange. The factors that determine how rapidly a gas passes through the respiratory membrane are (1) the thickness of the membrane, (2) the surface area of the membrane, (3) the diffusion coefficient of the gas in the water of the membrane, and (4) the pressure difference between the two sides of the membrane.

Thickness of the membrane is rarely a significant impediment to the transfer of CO_2, but O_2, being 20 times less soluble than CO_2, can be effected by processes that increase the diffusion distance. Two common clinical entities that increase the diffusion distance are pulmonary edema and pulmonary fibrosis, which explains the common finding of hypoxemia in patients with congestive heart failure. Another example of how the factors that determine gas diffusion can be applied clinically is the treatment of carbon monoxide poisoning with 100% oxygen, or hyperbaric oxygen, to increase the pressure difference between the two sides of the alveolar capillary membrane and thus facilitate oxygen loading.

The surface area of the respiratory membrane may be greatly decreased by a variety of conditions, such as atelectasis, resection of lung tissue, or emphysema. In emphysema, many of the alveoli coalesce, with dissolution of alveolar walls. The new alveolar chambers are much larger than the original alveoli, but the total surface area of the respiratory membrane available for gas diffusion is considerably decreased. When the total surface area of the lung is decreased to approximately one-third to one-fourth normal, exchange of gases through the membrane is impeded significantly, even under resting conditions. During strenuous exercise, even the slightest increase in dead space in patients with severe emphysema can seriously interfere with the exchange of gases.

The pressure difference across the respiratory membrane is the difference between the partial pressure of the gas in the alveoli and the partial pressure of the gas in the blood. In room air, the normal difference between the partial pressure of alveolar oxygen (PA$_{O_2}$) and the partial pressure of arterial oxygen (Pa$_{O_2}$), (PA$_{O_2}$ − Pa$_{O_2}$), or [P(A − a)$_{O_2}$], is 2 to 10 mmHg. The normal difference between the partial pressure of alveolar carbon dioxide (PA$_{CO_2}$) and the partial pressure of arterial carbon dioxide (Pa$_{CO_2}$), (PA$_{CO_2}$ − Pa$_{CO_2}$), or [P(A − a)$_{CO_2}$], is zero. An increase in the P(A − a)$_{CO_2}$ is due to an increase in dead space. The dead-space air does not participate in gas exchange and thus dilutes the alveolar CO_2.

ALVEOLAR GASES

Inspired Gases

Air at sea level has an average barometric pressure of 760 mmHg and contains approximately 21% oxygen and 0.04% carbon dioxide, with nitrogen making up most of the remainder. Thus, the partial pressures of oxygen and carbon dioxide in the air at sea level are 159 and 0.3 mmHg, respectively (Table 22-1).

Value	Air	Inspired Air in Trachea	Average Alveolar Gas	Average Expired Gas
P$_{O_2}$	159.0	149.3	104.0	120.0
P$_{CO_2}$	0.3	0.3	40.0	28.0
P$_{N_2}$	597.0	563.4	569.0	565.0
P$_{H_2O}$	3.7	47.0	47.0	47.0
Total	760.0	760.0	760.0	760.0

TABLE 22-1   Partial Pressure of Gases while Breathing Room Air, mmHg

Alveolar air does not have the same concentration of gases as atmospheric air. The reasons for the difference include the following: (1) dry atmospheric air that enters the respiratory passages is humidified before it reaches the alveoli, (2) alveolar air is only partially replaced by atmospheric air with each breath, (3) oxygen is

constantly being absorbed from the alveolar air, and (4) carbon dioxide is constantly diffusing from the pulmonary blood into the alveoli.

Humidification of Inspired Air

When air enters the respiratory passageways, water immediately evaporates from the surfaces of these passages and humidifies the inhaled air. At 37°C (98.6°F), water has a vapor pressure of 47 mmHg. Therefore, once the gas mixture is fully humidified, the partial pressure of the water vapor in the gas mixture is 47 mmHg (regardless of barometric pressure). This partial pressure is designated P_{H_2O} and must be subtracted from atmospheric pressure (760 mmHg) prior to calculation of the partial pressures of the dry gases in the alveolus (760 − 47 = 713). The remaining gases are predominantly nitrogen (79%, or 563 mmHg), oxygen (21%, or 149 mmHg), and CO_2 (0.04%, or 0.3 mmHg) ([Table 22-1](#)). If the patient is breathing 60% oxygen (fraction of inspired oxygen [Fi_{O_2}] = 0.6, the inspired oxygen pressure (Pi_{O_2}) in the trachea or bronchi is determined as follows:

$$Pi_{O_2} = (PB - P_{H_2O})Fi_{O_2}$$
$$= (760 - 47)(0.6)$$
$$= 427.8 \text{ mmHg}$$

where PB is barometric pressure (assumed to be 760 mmHg at sea level).

Rate at Which Alveolar Air Is Renewed by Atmospheric Air

The functional residual capacity of the lungs, which is the amount of air remaining in the lungs at the end of normal expiration, is approximately 2500 to 3000 mL (35 to 45 mL/kg). Only 350 mL of new air is brought into the alveoli with each new V_T and the same amount of old alveolar air is expired.

The slow replacement of alveolar air helps prevent sudden changes in gas concentrations in the blood. This helps to prevent excessive changes in tissue oxygenation, tissue carbon dioxide concentration, and tissue pH when ventilation is temporarily interrupted. This is also the basis of preoxygenation of patients prior to elective intubation, which could be more accurately described as denitrogenation, or replacing the alveolar nitrogen with oxygen.

Oxygen Concentration and Partial Pressure in the Alveoli

Oxygen is continually being absorbed into the blood in the alveolar capillaries, and new oxygen is continually entering the alveoli from the atmosphere. The more rapidly oxygen is absorbed, the lower its concentration in the alveoli. The more rapidly new oxygen is brought into the alveoli from the atmosphere, the higher its concentration becomes. Therefore, oxygen concentration in the alveoli is controlled by the rate of absorption of oxygen into the blood and the rate of entry of new oxygen into the lung.

Carbon Dioxide Concentration in the Alveoli

Carbon dioxide is continually formed and discharged into the alveoli and continually removed from the alveoli by ventilation. Therefore, the two factors that determine the PA_{CO_2} are (1) the rate of excretion of carbon dioxide from the blood into the alveoli and (2) the rate at which carbon dioxide is removed from the alveoli by V_A.

At a normal rate of V_A of 4.2 L/min, the PA_{CO_2} is usually 40 mmHg. If V_A is doubled, the PA_{CO_2} is reduced to 20 mmHg. If V_A is decreased to 2.1 L/min, the PA_{CO_2} rises to 80 mmHg. These estimations change with metabolic activity, nutritional state, temperature, and so on.

Alveolar Gas Equation

Inspired gas in the trachea has a partial pressure of oxygen (P_{O_2}) of about 149 mmHg and a P_{CO_2} of about 0.3 mmHg. As the warm, water-saturated air enters the alveoli, oxygen diffuses through the alveolar capillary membranes into the plasma and carbon dioxide diffuses from the blood into the alveoli. The mixed venous blood brought to the pulmonary capillaries normally has a P_{O_2} of about 40 mmHg and a P_{CO_2} of 46 mmHg. On the average, for each milliliter of oxygen that leaves the alveolus, 0.8 to 1.0 mL of carbon dioxide enters it. This relationship is defined as the respiratory quotient (RQ), which can be expressed as

$$RQ = \frac{\text{rate of } CO_2 \text{ production}}{\text{rate of } O_2 \text{ consumption}}$$

In order to determine how well the lungs are functioning at oxygenation, the difference between PA_{O_2} and Pa_{O_2} is often estimated. To estimate PA_{O_2} from the Pi_{O_2} and Pa_{CO_2}, one needs a correction factor to determine how much oxygen is consumed for each 1.0 mmHg of Pa_{CO_2} resulting from carbon dioxide that enters the alveoli. Thus, for the usual circumstances, in which the RQ is 0.8, the alveolar gas equation is

$$PA_{O_2} = (PB - P_{H_2O})(Fi_{O_2}) - (Pa_{CO_2})/RQ$$

In room air (Fi_{O_2} = 0.21) at sea level with a Pa_{CO_2} of 40 mmHg, the PA_{O_2} is expected to be

$$PA_{O_2} = (760 - 47)(0.21) - (40)/0.8 = 150 - 50 = 100$$

The normal difference between PA_{O_2} and Pa_{O_2} is 2 to 10 mmHg.

End-Tidal Gases

Expired air is a combination of dead space air and alveolar air, and its overall composition is determined by the proportion of each in expired air. Dead space air is expired first. Then progressively more alveolar air becomes mixed with the dead space air until all the dead space air has finally been washed out. At the end of normal exhalation nothing but alveolar air is expired. Therefore, to collect alveolar air for study, one simply collects end-tidal gas. Determination of end-tidal carbon dioxide (ET_{CO_2}) levels is a useful measure of the adequacy of ventilation. In patients with normal lungs, ET_{CO_2} is approximately 3 mmHg lower than PA_{CO_2}, but in patients with obstructive airways disease, typically asthma, there can be a large difference between ET_{CO_2} and PA_{CO_2}, since dead space air is never fully exhaled and thus neither is pure alveolar air. The use of ET_{CO_2} monitors is responsible for the reduction in undetected esophageal intubations.

ARTERIAL BLOOD GASES

Partial Pressure of Arterial Carbon Dioxide

ALVEOLAR VENTILATION   Carbon dioxide diffuses so rapidly that the Pa_{CO_2} usually provides an excellent index of the adequacy of ventilation. If the Pa_{CO_2} is greater than normal in a patient with a normal or low arterial pH, one can assume that V_A is inadequate. The patient may have a low respiratory rate or tidal volume or may also have increased dead space due to emphysema, pulmonary emboli, or increased carbon dioxide production as in thyroid storm or sepsis. An elevated Pa_{CO_2} in the presence of metabolic alkalosis usually reflects compensatory effort to restore arterial pH to normal while an increased Pa_{CO_2} in a patient with metabolic acidosis generally indicates impending respiratory failure.

DEAD SPACE   When the ventilation of an alveolar-capillary unit is normal but perfusion of the alveolar capillary is absent, the ventilation of these alveoli and their associated airways is referred to as dead space, or high ventilation-perfusion (V/Q) mismatching. V_{DS} and the tidal volume (V_T) are often expressed as a ratio (V_{DS}/V_T). This is determined in a pulmonary function laboratory (or a bedside metabolic cart) by measuring the Pa_{CO_2}, measuring the *average* expired gas (PE_{CO_2}) (not

to be confused with ET_{CO_2}), and using the Bohr equation:

$$\frac{V_{DS}}{V_T} = \frac{Pa_{CO_2} - PE_{CO_2}}{Pa_{CO_2}}$$

The normal values are

$$\frac{V_{DS}}{V_T} = \frac{40 - 28}{40} = \frac{12}{40} = 0.3$$

When the physiologic dead space is increased, some of the work of ventilation is wasted because a greater fraction of ventilated air never reaches the functioning alveolar-capillary units. A patient with a dead space greater than 0.6 generally requires mechanical ventilation to maintain normal Pa_{CO_2}.

TRANSPORT OF CARBON DIOXIDE IN THE BLOOD   Under resting conditions, each 100 mL of blood transports an average of 4 mL of carbon dioxide from the tissues to the lungs. Transport of carbon dioxide is not as great a problem as is transport of oxygen because, even under the most abnormal conditions, carbon dioxide can usually be transported in far greater quantities than can oxygen. However, carbon dioxide in the blood does affect acid-base balance.

The carbon dioxide formed in cells diffuses out in the form of carbon dioxide rather than bicarbonate because the cell membrane is almost impermeable to bicarbonate ions. As the carbon dioxide enters the capillary, it initiates a number of almost instantaneous reactions essential for carbon dioxide transport.

First, a small portion of the carbon dioxide is transported to the lungs dissolved in plasma. The dissolved portion is approximately 0.36 mL of carbon dioxide in each 100 mL of blood. This is about 9% of all carbon dioxide transported.

Much of the dissolved carbon dioxide in the blood reacts with water to form carbonic acid; a reaction facilitated by carbonic anhydrase inside the red blood cells speeds up the reaction about 500-fold. The reaction occurs so rapidly that it reaches almost complete equilibrium within a fraction of a second. This allows tremendous amounts of carbon dioxide to react with red blood cell water even before the blood leaves the tissue capillaries.

In another fraction of a second, the carbonic acid formed in the red blood cells dissociates into hydrogen and bicarbonate ions. Most of the hydrogen ions then combine with the hemoglobin in the red blood cells because hemoglobin is a powerful acid-base buffer. At the same time, many of the bicarbonate ions diffuse into the plasma; to offset this ionic shift, chloride ions diffuse into the red blood cells. This diffusion is made possible by the presence of a special bicarbonate-chloride carrier protein in the red blood cell membrane that rapidly shuttles these two ions in opposite directions. Thus, the chloride content of venous red blood cells is greater than that of arterial red blood cells. This phenomenon is called the chloride shift.

The reversible combination of carbon dioxide with water in the red blood cells, under the influence of carbonic anhydrase, accounts for at least 60 to 70% of all the carbon dioxide transported from the tissues. Indeed, when a carbonic anhydrase inhibitor (acetazolamide) is administered to block the action of carbonic anhydrase in the red blood cells, carbon dioxide transport from the tissues becomes very poor and the tissue P_{CO_2} rises abruptly.

CARBAMINOHEMOGLOBIN AND CARBAMINOPROTEINS   Carbon dioxide also reacts directly with hemoglobin to form carbaminohemoglobin ($Hb–CO_2$). Since this reversible reaction occurs with a very loose bond, the carbon dioxide is easily released into the alveoli, where the P_{CO_2} is lower than that in the tissue capillaries. A small amount of carbon dioxide (usually equivalent to about 0.5 to 1.0 meq/L of bicarbonate) also reacts in this way with the plasma proteins, forming carbaminoproteins. This reaction is much less significant because the quantity of these proteins is only about one-fourth to one-half the quantity of hemoglobin.

The theoretical quantity of carbon dioxide that can be carried to the lungs in combination with hemoglobin and plasma proteins is approximately 20 to 30% of the total quantity transported—that is, about 1.5 mL of carbon dioxide in each 100 mL of blood. However, this reaction is much slower than the reaction of carbon dioxide with water, and it is doubtful that more than 15 to 25% of the total quantity of carbon dioxide is transported this way.

CARBON DIOXIDE DISSOCIATION CURVE   Carbon dioxide can exist in the blood as free carbon dioxide and in chemical combinations with water, hemoglobin, and plasma proteins. The total quantity of carbon dioxide combined with the blood in all forms depends on the Pa_{CO_2}.

The normal blood Pa_{CO_2} averages about 40 mmHg in arterial blood and 46 mmHg in mixed venous blood. Although the normal total concentration of carbon dioxide in the blood is about 50 mL/dL (vol%), only 4 mL/dL of this is actually exchanged during normal transport of carbon dioxide. Thus, the concentration of carbon dioxide rises to about 52 mL/dL after the blood passes through the tissues and falls to about 48 mL/dL after the blood passes through the lungs.

EFFECT OF THE OXYGEN-HEMOGLOBIN REACTION ON CARBON DIOXIDE TRANSPORT: THE HALDANE EFFECT   An increase in the carbon dioxide level in the blood causes oxygen to be displaced from the hemoglobin, and this promotes oxygen release to tissues at the capillary level. The reverse is also true; binding of oxygen with hemoglobin tends to displace carbon dioxide as blood moves through the pulmonary capillaries. Indeed, this so-called Haldane effect is quantitatively far more important in promoting carbon dioxide transport than the Bohr effect (see the section on "Oxyhemoglobin Saturation") is in promoting oxygen transport.

CHANGE IN BLOOD ACIDITY DURING CARBON DIOXIDE TRANSPORT   The carbonic acid formed when carbon dioxide enters the blood in the tissue capillaries decreases the pH. However, the buffers of the blood prevent the hydrogen ion concentration from rising greatly. Ordinarily, arterial blood has a pH of approximately 7.40, and as the blood acquires carbon dioxide in the tissue capillaries, the pH falls to approximately 7.35. The reverse occurs when carbon dioxide is released from the blood in the lungs. Under conditions of high metabolic activity or when blood flow through the tissues is extremely sluggish, the decrease in pH in the blood as it leaves the tissues can be 0.50 or more.

CHANGES IN RESPIRATORY QUOTIENT   As stated above, the RQ is the ratio of CO_2 produced to O_2 consumed. The RQ for the standard patient metabolizing a mixed diet of carbohydrates, fats, and protein is approximately 0.8. The RQs of the individual components are listed below:

Nutritional source	RQ
Carbohydrates	1.00
Protein	0.83
Fats	0.7

Thus, the RQ can change in patients who eat (or are fed) diets containing predominantly fat or carbohydrates. Relying heavily on carbohydrates for a patient with little respiratory reserve can lead to respiratory acidosis due to an increase in required V_M. However, the effect of diet on RQ is usually only an issue in the intensive care unit in a minority of patients with severe lung disease who are attempting to wean from mechanical ventilation.

MONITORING OXYGENATION AND VENTILATION   A patient who is awake, alert, comfortable, and cooperative and has normal vital signs is generally oxygenating and ventilating adequately. However, if a patient is tachypneic and/or tachycardic and appears to be anxious and/or confused, hypercarbia or hypoxemia should be suspected. In comatose patients, it is sometimes very difficult to judge how well the patient is oxygenating or ventilating without serial blood gas determinations.

Cyanosis as a sign of inadequate oxygenation is almost worthless when the hemoglobin is less than 10 g/dL. Under such circumstances, the arterial oxygen saturation (Sa_{O_2}) must be less than 65%, corresponding to a Pa_{O_2} of about 30 to 35 mmHg, before the patient looks cyanotic. It must be remembered that oxygenation and ventilation are two separate systems. A frequent clinical misconception is that a patient with an adequate Sa_{O_2} must be ventilating adequately. This assumption is incorrect and dangerous, particularly with patients who are receiving supplemental oxygen. This is discussed below under "Noninvasive Monitoring, Pulse Oximetry."

Partial Pressure of Arterial Oxygen

The Pa_{O_2} in normal, healthy young adults breathing room air at sea level is considered to be 90 to 100 mmHg. The Pa_{O_2} is extremely important because it not only

reflects the functional capabilities of the lungs but also determines the rate at which oxygen enters the tissue cells.

Factors that affect the Pa_{O_2} include the $\dot{V}_A$, the Fi_{O_2}, the functional capabilities of the lungs, the mean airway pressure in mechanically ventilated patients, and the oxyhemoglobin dissociation curve.

ALVEOLAR VENTILATION   If the patient hyperventilates, the Pa_{CO_2} tends to fall and the Pa_{O_2} tends to rise. If the Pa_{CO_2} falls by 1 mmHg, the Pa_{O_2} rises by about 1.0 to 1.2 mmHg; in accordance with the law of additive partial pressures. The lungs can make up for some pulmonary dysfunction by hyperventilating. This is seen in pregnant patients who have normal arterial blood gas values at term showing normal pH, a Pa_{CO_2} of 30 to 32, a Pa_{O_2} of 110 to 115, and a serum bicarbonate level of 20 to 22 meq/L. This is due to an increase in $\dot{V}_M$ (predominantly due to increased V_T), with resultant respiratory alkalosis with increased urinary excretion of bicarbonate to compensate.

FRACTION OF INSPIRED OXYGEN   Unfortunately, the Fi_{O_2} is often not considered adequately in evaluating the Pa_{O_2}. If a patient is receiving oxygen by nasal cannula, the actual delivered Fi_{O_2} is usually only 25 to 30 percent. With a properly fitting face mask, the inhaled Fi_{O_2} is usually less than half that delivered to the mask. The approximate Pa_{O_2} values that might be expected in normal persons who are inhaling various concentrations of oxygen are listed in Table 22-2.

Fi_{O_2}	0.21 (room air)	0.4	0.6	0.8	1.0
Expected Pa_{O_2}*	100	227	370	512	655

*Assuming a $PA_{O_2} - Pa_{O_2}$ of 10 mmHg and a Pv_{O_2} of 40 mmHg.

TABLE 22-2   Expected Pa_{O_2} in Patients Inhaling Various Concentrations of Oxygen, mmHg

The expected PA_{O_2} when the patient is given oxygen can be estimated by multiplying the actual delivered percentage of oxygen by 6. Thus, a patient getting 60% oxygen would be expected to have a PA_{O_2} of about 60 × 6, or 360 mmHg.

ALTITUDE   The Pa_{O_2} expected when a patient is breathing room air varies with height above sea level. The greater the altitude, the lower the P_{O_2} in the air and the greater the tendency for the patient to hyperventilate (Table 22-3).

Altitude Above Sea level, ft	Atmospheric Pressure, mmHg	P_{O_2} in Air, mmHg	PA_{O_2}, mmHg	Pa_{O_2}, mmHg*
0	760	159	105	100
2,000	707	148	97	92
4,000	656	137	90	85
6,000	609	127	84	79
8,000	564	118	79	74
10,000	523	109	74	69
20,000	349	73	40	35
30,000	226	47	21	19

*Assuming ideal circumstances with a $PA_{O_2} - Pa_{O_2}$ of 5 mmHg or less.

TABLE 22-3   Changes in P_{O_2} at Various Altitudes

The Pa_{O_2} drops about 3 to 4 mmHg for each 1000-foot rise above sea level. Up to an altitude of approximately 10,000 ft, the Sa_{O_2} remains about 90 percent. However, above 10,000 ft, the Sa_{O_2} progressively falls about 1 percent for each 1 mmHg drop in P_{O_2} until at 20,000 ft altitude the Pa_{O_2} is about 35 mmHg and the Sa_{O_2} is only about 65 percent.

When a person breathes air at 30,000 ft, where the barometric pressure is about 226 mmHg, the Pa_{O_2} is only 21 mmHg. At this height above sea level, almost three-fourths of the alveolar air is nitrogen. However, if the person breathes pure oxygen instead of air, most of the space in the alveoli formerly occupied by nitrogen becomes occupied by oxygen. Nevertheless, even if the person is breathing 100% oxygen at 30,000 ft, the Pa_{O_2} is only 139 mmHg (Table 22-4).

Altitude, ft	Barometric Pressure, mmHg	WHILE BREATHING AIR		WHILE BREATHING 100% O_2	
		PA_{O_2}, mmHg	PA_{CO_2}, mmHg	PA_{O_2}, mmHg	Oxygen Saturation, %
0	760	159	40	673	100
10,000	523	110	40	436	100
20,000	349	73	40	262	100
30,000	226	47	40	139	99
40,000	141	29	36	58	87
50,000	87	18	24	16	22

TABLE 22-4   Effects of Acute Exposure to Low Atmospheric Pressure on Alveolar Gas Concentrations and on Sa_{O_2}

AGE   Even in healthy individuals, pulmonary changes that cause a fall in the Pa_{O_2} occur with advancing age. On the average, the Pa_{O_2} falls about 3 to 4 mmHg per decade after the patient reaches 20 to 30 years of age. Thus, an otherwise normal 20-year-old patient with a Pa_{O_2} of about 90 to 100 mmHg (breathing room air at sea level) might be expected to have a Pa_{O_2} of only about 75 to 80 mmHg at 80 years of age.

Alveolar-Arterial Oxygen Differences

One method of determining the degree to which lung function is impaired is to determine the alveolar-arterial oxygen gradient [$P(A - a)_{O_2}$]. The Pa_{O_2} can be determined from arterial blood samples and the PA_{O_2} and be determined from the alveolar air equation previously discussed. One can also estimate the PA_{O_2} in patients with a normal cardiac output breathing room air by subtracting the Pa_{CO_2} from 145. This is possible because PA_{O_2} and PA_{CO_2} add up to about 145 mmHg

when a patient breathes room air at sea level. Since the PA_{CO_2} is usually the same as the Pa_{CO_2}, the PA_{O_2} can be estimated from the arterial gas pressure by the following formula:

$$PA_{O_2} = 145 - Pa_{CO_2}$$

If the patient has a Pa_{CO_2} of 40 mmHg,

$$PA_{O_2} = 145 - 40 = 105 \text{ mmHg}$$

This equation can be used to determine the $P(A - a)_{O_2}$. The PA_{O_2} is estimated from the above formula, and the Pa_{O_2} is determined from arterial blood gas analysis. If the Pa_{O_2} were 90 mmHg, the $P(A - a)_{O_2}$ would be 15 mmHg, which is relatively normal. A $P(A - a)_{O_2}$ of 20 to 30 mmHg on room air usually indicates mild pulmonary dysfunction, and a $P(A - a)_{O_2}$ greater than 50 mmHg on room air usually indicates severe pulmonary dysfunction. The causes of an increased A-a gradient include intrapulmonary shunt (relatively less ventilation than perfusion, or a low V/Q ratio), intracardiac shunt, and diffusion abnormalities.

Oxyhemoglobin Saturation

NORMAL RELATIONSHIPS   When arterial blood gas study results are obtained, clinicians are often concerned by PaO_2 levels in the 60 to 90-mmHg range. A Pa_{O_2} of 60 mmHg correlates to an Sa_{O_2} of 90%. Furthermore, if the hemoglobin level is 15.0 g/dL and the tissue removes 5.0 mL of oxygen from each 100 mL of blood, the P_{O_2} of the venous blood falls to about 36 mmHg, which is only 4 mmHg below the normal value. Thus, the tissue P_{O_2} often changes minimally despite a marked fall in Pa_{O_2}.

On the other hand, if the Pa_{O_2} rises far above the upper limit of normal (90 to 100 mmHg), the oxygen saturation of hemoglobin cannot rise above 100%. Therefore, even if the Pa_{O_2} rose to 600 mmHg or more, the saturation of hemoglobin would increase only 1 to 2% because, at Pa_{O_2} of 100 mmHg, the Sa_{O_2} is only 98 to 99%. This, combined with some evidence (predominantly in animals) that an Fi_{O_2} greater than 50 can be associated with pulmonary toxicity, should guide the clinician to supply only the amount of oxygen required to produce a Pa_{O_2} between 70 and 100 mmHg.

Under circumstances of normal body temperature [37°C (98.6°F)] and blood pH 7.40, certain standard relationships exist between the oxyhemoglobin saturation and the plasma P_{O_2} (Table 22-5). Thus, the relationship between Sa_{O_2} and plasma P_{O_2} is almost linear when the Sa_{O_2} is 60 to 90%. However, as the Sa_{O_2} rises above 90%, the P_{O_2} begins to rise much faster than the saturation. A simplification to remember for clinical practice is that a Pa_{O_2} of 30, 40, 50, and 60 correspond approximately to an Sa_{O_2} of 60, 70, 80, and 90 percent, respectively.

Oxygen saturation, %	100.0	98.4	95	90	80	73	60	50	40	35	30
P_{O_2}, mmHg	677	100	80	59	48	40	30	26	23	21	18

TABLE 22-5   Relation Between Oxyhemoglobin Saturation and Plasma P_{O_2}

FACTORS AFFECTING OXYHEMOGLOBIN DISSOCIATION   The best known of the factors affecting the oxyhemoglobin dissociation curve are pH, temperature, and the amount of 2,3-diphosphoglycerate (2,3-DPG) in the red blood cells. Other related factors include P_{CO_2} and exercise.

pH   The more acidic the blood, the more readily hemoglobin gives up its oxygen and the higher the Pa_{O_2} (the partial pressure of oxygen dissolved in blood) is for a particular oxyhemoglobin saturation. In contrast, alkalosis makes hemoglobin hold on to its oxygen more tightly, lowering the Pa_{O_2} present at a particular oxyhemoglobin saturation. In general, a rise or fall in pH of 0.10 causes a fall or rise (i.e., an opposite change) in the Pa_{O_2} of about 10% (Table 22-6).

pH	7.60	7.50	7.40	7.30	7.20	7.10	7.00
PaO_2, MMHG*	80	90	100	111	122	134	148

*Assuming a temperature of 37°C (98.6°F) and a hemoglobin saturation of 98.4%.

TABLE 22-6   Changes in Pa_{O_2} Related to pH

Partial Pressure of Carbon Dioxide   A shift of the oxyhemoglobin dissociation curve, as a result of changes in the blood levels of carbon dioxide (Haldane effect) and hydrogen ions (Bohr effect), enhances oxygenation of the blood in the lungs and promotes release of oxygen from the blood in the tissues. As the blood passes through the lungs, carbon dioxide diffuses from the blood into the alveoli. This reduces the blood P_{CO_2} and decreases the hydrogen ion concentration because of the resulting decrease in the blood carbonic acid level. Both changes shift the oxyhemoglobin dissociation curve to the left. With a shift to the left, the quantity of oxygen binding to hemoglobin at any given Pa_{O_2} is increased, allowing greater oxygen transport to the tissues. Then, when the blood reaches the tissue capillaries, the opposite effect occurs. Carbon dioxide entering the blood from the tissues shifts the curve to the right. This displaces oxygen from the hemoglobin and delivers oxygen to the tissues at a higher P_{O_2} than would otherwise occur.

Temperature   As blood temperature increases, hemoglobin gives up oxygen more readily, raising the P_{O_2} in the plasma. The opposite occurs during cooling. For each 1°C rise in temperature, the Pa_{O_2} rises about 5% (Table 22-7). With hypothermia, the P_{CO_2} falls by about the same amount.

Temperature, °F	104.0	102.2	100.4	98.6	95.0	86.6
Temperature, °C	40	39	38	37	35	32
Pao₂, mmHg*	117	111	105	100	90	76

*Assuming a pH of 7.40 and a hemoglobin saturation of 98.4%.

TABLE 22-7   Po_2 Levels at Various Temperatures

Exercise   During strenuous exercise, several factors can shift the oxyhemoglobin dissociation curve to the right. Exercising muscles release large quantities of carbon dioxide and other acids, increasing the hydrogen ion concentration in muscle capillary blood. In addition, the temperature of the muscle often rises as much as 3 to 4°C, and phosphate compounds are also released. All these factors acting together shift the oxyhemoglobin dissociation curve of the blood in the muscle capillaries considerably to the right. This allows oxygen to be released to the muscle at a Po_2 as high as 40 mmHg even though as much as 75% of the oxygen has been removed from the hemoglobin. In the lungs, the shift occurs in the opposite direction, allowing pickup of extra amounts of oxygen from the alveoli.

2,3-Diphosphoglycerate   Except for hemoglobin, the compound present in greatest quantity in red blood cells is 2,3-DPG. A normal concentration of 2,3-DPG in a red blood cell keeps the oxyhemoglobin dissociation curve shifted slightly to the right all the time. In addition, under hypoxic conditions lasting longer than a few hours, the quantity of 2,3-DPG increases considerably, shifting the oxyhemoglobin dissociation curve even farther to the right. This can cause the Po_2 in the plasma to be as much as 10 mmHg higher than it would have been otherwise. However, the presence of increased 2,3-DPG makes it more difficult for the hemoglobin to combine with oxygen in the lungs.

If the concentration of 2,3-DPG falls, as it does in stored blood or during sepsis, the hemoglobin holds on to its oxygen more tightly and the Pao_2 tends to fall. This is an important consideration during large-volume resuscitations with banked blood.

Other Methods of Evaluating Oxygenation

Pao₂/Fio₂ RATIO   A quick way to estimate the impairment of oxygenation is to calculate the Pao_2/Fio_2 ratio. Normally, the ratio is about 500 to 600, which usually correlates to a pulmonary shunt (QS/QT) of about 3 to 5%. However, if a patient has a Pao_2 of 80 mmHg on 40% oxygen, the Pao_2/Fio_2 ratio is 80/0.4, or 200. A Pao_2/Fio_2 ratio of less than 200 corresponds with a QS/QT of about 20%. The usual relationship between Pao_2/Fio_2 ratios and the QS/QT in patients with a normal cardiac output is shown in Table 22-8. Pao_2/Fio_2 ratios are also used as criteria for the diagnosis of ARDS/acute lung injury (ALI). In a patient with alveolar infiltrates in at least 3 of 4 quadrants on chest x-ray, a normal pulmonary capillary wedge pressure, and a mechanism known to cause ARDS/ALI, a Pao_2/Fio_2 of less than 300 indicates ALI, while a ratio less than 200 indicates ARDS. However, some researchers no longer distinguish between ARDS and ALI and classify all patients with a Pao_2/Fio_2 ratio less than 300 as having ARDS.

Pao₂, mmHg	Fio₂, mmHg	Ratio	QS/QT, %	Abnormality
240	0.4	600	5	None
120	0.4	300	10	Minimal
100	0.4	250	15	Mild
80	0.4	200	20	Moderate
60	0.4	150	30	Severe*
40	0.4	100	40	Very severe*

*In trauma or septic patients, ventilatory assistance and PEEP to reduce the QS/QT to 15 percent should be considered. The higher the QS/QT, the greater the need for ventilatory assistance and PEEP.

TABLE 22-8   Interpretation of Pao_2/Fio_2 Ratio

Physiologic Shunting in the Lung (Venous-Arterial Admixture)

Although abnormal gas diffusion or distribution in the lungs can cause abnormal blood gas values, the most important cause is usually V/Q mismatching. When considering ventilation and perfusion, there can be four types of alveolar capillary units: (1) if ventilation and perfusion are normal, the unit is normal; (2) if there is ventilation without perfusion, the unit is considered to be dead space (or high V/Q); (3) if there is perfusion without ventilation, the unit is considered to be a (right-to-left) shunt (or low V/Q); and (4) if there is neither ventilation nor perfusion, the unit is silent.

The amount of physiologic shunting in the lung, or venous-arterial admixture (QS/QT), is probably the most sensitive guide to the onset and progression of acute respiratory failure. The shunt is that fraction of blood passing through the lungs without being oxygenated. Normally, the amount for venous-arterial admixture is about 3 to 5 percent of the cardiac output. This small amount of shunting is largely due to the drainage of deoxygenated blood in bronchial veins into oxygenated blood in pulmonary veins.

Physiologic shunting is harder to determine than alveolar-arterial oxygen differences because it requires drawing both arterial and mixed venous (pulmonary artery) blood samples and determining their oxygen contents. Mixed venous samples from the pulmonary artery are preferable to those obtained from central venous pressure catheters. However, central venous blood does give a reasonable estimate of the amount of shunting present if cardiac output is relatively normal.

Although an Fio₂ of 1.0 was generally used in the past to determine the amount of physiologic shunting in the lung, the high Fio_2 in itself may cause increased shunting. Now the shunt with an Fio₂ of 0.4 is considered to be a better indicator of lung function.

The QS/QT can be calculated from a modification of Berggren's formula:

$$\frac{QS}{QT} = \frac{Cc_{O_2} - Ca_{O_2}}{Cc_{O_2} - Cv_{O_2}}$$

where Cco_2 is the pulmonary capillary oxygen content, Cao_2 is the arterial content, and Svo_2 is the mixed venous oxygen content. Thus, if Cco_2 is 20 mL/dL, Cao_2 is 19 mL/dL, and Svo_2 is 14 mL/dL, the shunt is

$$\frac{QS}{QT} = \frac{20 - 19}{20 - 14} = \frac{1}{6} = 17\%$$

The amount of shunting in the lung can also be estimated from arterial blood alone, using an assumption that the arteriovenous oxygen difference is approximately 5

mL/dL.

In general, if cardiac output doubles, the amount of shunt associated with a particular P(A – a) O_2 increases by about 50 percent (Table 22-9). This is partly related to the fact that, if only a small amount of blood is going through the lung, the blood flow tends to go to well-ventilated alveoli. If cardiac output increases, there is increasing likelihood that some of the blood will go through less well-ventilated tissue.

Pa_{O_2}	$P(A-a)O_2$ on 100% O_2	Q_S/Q_T, % CO = 2.5 L/min	CO = 5 L/min	CO = 10 L/min
600	70	2	4	8
500	170	5	10	17
400	270	8	16	25
300	370	11	19	32
200	470	13	24	38
150	520	14	26	42
100	570	16	31	47
90	580	20	34	50
80	590	22	36	53
70	600	24	39	56
60	610	26	44	61
50	620	33	50	67

Abbreviation: CO, cardiac output.

TABLE 22-9   Relation Between the Physiologic Shunt in the Lung (Q_S/Q_T) and P(A – a)O_2 while Breathing 100% O_2

Thus, if cardiac output is high, relatively mild hypoxemia can result from a high shunt. For example, at a Pa O_2 of 300 mmHg, if the cardiac output is 2.5 L/min, the shunt might be 11 percent, but at a cardiac output of 10.0 L/min, the shunt would be 32 percent. To factor in the changes due to an increased or decreased cardiac output, one uses the shunt index (SI). The SI is the percent shunt divided by the cardiac index. For example, at a normal cardiac index of 3.5 (L/min)/m^2 and a shunt of 5.0 percent, the SI is 5.0/3.5 = 1.4. If a patient has a shunt of 20 percent with a cardiac index of 2.5 (L/min)/m^2, the SI is 8.0. Patients with an SI above 5.0 usually require oxygenation support.

If the cardiac index is not known, the critical QS/QT is about 20 to 25 percent. Above these values, the patient usually has enough of a V/Q abnormality to warrant oxygenation support and positive end-expiratory pressure (PEEP).

Oxygen Availability

Oxygen availability is determined by the amount of oxygen brought to the capillaries, or oxygen delivery (D O_2), and the dissociation of oxygen from hemoglobin at the tissues. To a certain extent, a good heart, which can increase cardiac output appropriately, can make up for bad lungs and a low hemoglobin level. The reverse is also true. However, a combination of poor oxygenation, low hemoglobin level, and low cardiac output may be rapidly fatal.

OXYGEN CONTENT   The oxygen content of blood is determined primarily by the hemoglobin level and the oxyhemoglobin saturation. When fully saturated, each gram of hemoglobin measured clinically can carry 1.34 mL of oxygen. Thus, a patient with a hemoglobin concentration of 15.0 g/dL can carry about 20.1 mL of oxygen per 100 mL in the red blood cells when the hemoglobin is fully saturated. Although the Pa O_2 determines the rate at which oxygen enters the tissues, it contributes very little to the total oxygen content of blood. Each millimeter of mercury of Pa O_2 represents only 0.0031 mL of oxygen in 100 mL of blood. Thus, a patient with a normal PaO_2 of 100 mmHg has only 0.31 mL of oxygen dissolved in the plasma.

The oxygen content of arterial blood (Ca O_2) can be calculated from the following formula:

$$Ca_{O_2} = [Hb](1.34)(Sa_{O_2}/100) + (Pa_{O_2})(0.003)$$

Thus, in a patient with a hemoglobin concentration of 15.0 g/dL, an Sa O_2 of 98%, and a PaO_2 of 100 mmHg,

$$Ca_{O_2} = (15)(1.34)(98/100) + (100)(0.003)$$
$$= 20.0 \text{ mL } O_2 \text{ per deciliter of blood}$$

If the hemoglobin concentration falls to 10.0 g/dL, even if Sa O_2 and PaO_2 remain the same, CaO_2 falls by about a third. For example,

$$Ca_{O_2} = (10)(1.34)(98/100) + (100)(0.003)$$
$$= 13.132 + 0.30$$
$$= 13.4 \text{ mL } O_2 \text{ per deciliter of blood}$$

Even with only 10 g of hemoglobin, the red blood cells are carrying over 40 times as much oxygen as is the plasma.

CARDIAC OUTPUT   Oxygen content (in milliliters per liter of blood) multiplied by cardiac output (in liters per minute) is equal to D O_2. Thus, the DO_2 in a patient with 15.0 g of 98% saturated hemoglobin, a PaO_2 of 100 mmHg, and a cardiac output of 5 L/min is

$$D_{O_2} = (Ca_{O_2} \text{ per dL})(10)(\text{cardiac output})$$
$$= \{[\text{hemoglobin}](1.34)(Sa_{O_2}/100)$$
$$+ (Pa_{O_2})(0.003)\}(10)(\text{cardiac output})$$
$$= [(15)(1.34)(98/100) + (100)(0.003)](10)(5)$$
$$= [(19.698 + 0.3)](50)$$
$$= (19.998)(50) = (20)(50)$$
$$= 1000 \text{ mL/min}$$

The factor 10 is used to convert oxygen content from milliliters per 100 mL of blood to milliliters per liter of blood.

Since the normal oxygen consumption of an average resting adult male is about 250 to 300 mL/min [approximately 3 (mL/kg)/min], the tissue on average takes up about 25% of the oxygen brought to it, although the percent oxygen extraction varies by organ. Thus, the Sa O_2 falls from about 98% in arterial blood to about 73% in mixed venous blood. If there is no change in oxygen consumption but cardiac output doubles to 10 L/min, the amount of oxygen removed from each liter of blood is halved, and the venous oxyhemoglobin saturation will be about 85%. On the other hand, if cardiac output falls to 2.5 L/min, venous oxyhemoglobin saturation will fall to about 48 percent.

OXYGEN DISSOCIATION IN THE TISSUES   The ability of blood to give up more oxygen (increasing the arteriovenous oxygen difference) as cardiac output falls and thus maintain oxygen delivery is an important defense mechanism sometimes referred to as oxygen reserve. Unfortunately, there is a limit to this so-called oxygen reserve because the PO_2 in most tissues seldom falls below 26 mmHg, which is the P_{50} for hemoglobin (PO_2 at which hemoglobin is 50% saturated).

The lowest value to which the PO_2 in capillaries can fall is about 18 to 20 mmHg because this is the usual capillary-mitochondrial gradient for oxygen. The saturation at a PO_2 of 20 mmHg is referred to as the S_{20}, and this is normally about 33%. The only places where the P O_2 in venous blood is normally as low as 20 mmHg are the coronary sinus, renal medulla, and perhaps the jugular venous bulb at the base of the brain. A relatively mild degree of alkalosis can raise the S $_{20}$ by 4 to 5%, thereby

greatly reducing oxygen availability to the myocardium. Thus, alkalosis (e.g., when metabolic acidosis is treated with bicarbonate) in low-flow states can be deleterious.

COMBINATION OF HEMOGLOBIN WITH CARBON MONOXIDE   Carbon monoxide combines with hemoglobin at the same point on the hemoglobin molecule that oxygen does. Furthermore, it binds about 230 times more strongly than oxygen does. Therefore, an alveolar carbon monoxide level of 0.4 mmHg, which is $\frac{1}{230}$ that of the Pa_{O_2}, allows the carbon monoxide to compete equally with oxygen for combination with hemoglobin, causing half the hemoglobin in the blood to bind with carbon monoxide instead of oxygen. An alveolar carbon monoxide level of 0.7 mmHg (about 0.1% in air) can be lethal. Oxygen at high alveolar pressures displaces carbon monoxide from hemoglobin much more rapidly than atmospheric oxygen does. Patients with carbon monoxide poisoning can also benefit from simultaneous administration of 4 to 5% carbon dioxide, which strongly stimulates the respiratory center, increasing V_A, reducing the alveolar carbon monoxide concentration and allowing increased carbon monoxide to be released from the blood. A 96% oxygen and 4% carbon dioxide therapy removes carbon monoxide from the blood 10 to 20 times more rapidly than would be removed by breathing room air. The half-life of Hb—CO in a patient breathing room air is 2 to 3 h; if the patient is breathing 100% O_2, the half-life is about 20 to 30 min. The most effective way to clear Hb—CO is by increasing the Pa_{O_2} above that attainable by breathing 100% oxygen—that is, in a hyperbaric oxygen chamber.

OTHER METHODS OF EVALUATING BLOOD GASES

Pulmonary Artery Catheters

A number of pulmonary artery catheters have been developed to continuously monitor mixed venous oxygen saturation (Sv_{O_2}). The normal Sv_{O_2} is about 70 to 75%. A change in Sv_{O_2} could serve as an early warning of inadequacy of perfusion and oxygenation. A rise in Sv_{O_2} can signal an increase in cardiac output and D_{O_2} beyond that required for metabolism, shunting of blood from tissues (sepsis), or an inability of the peripheral tissues to extract and utilize O_2 (cyanide poisoning). It can also be simply a reflection of the location of the catheter tip in a persistently wedged position so that pulmonary capillary (oxygenated) blood is being analyzed. A fall in Sv_{O_2} below 50 to 60% is usually due to a significant decrease in cardiac output or lung function and requires urgent investigation. It is important to remember that, while a change in Sv_{O_2} may indicate important physiologic change, there can be major changes in the patient's condition without corresponding changes in the Sv_{O_2}. A major criticism of the usage of Sv_{O_2} to guide therapy is that it is a measure of all of the blood returning to the lungs and can give no information about the adequacy of perfusion of individual organ systems, such as the kidneys, brain, heart, or liver.

Noninvasive Monitoring

PULSE OXIMETRY   The use of pulse oximetry for monitoring Sa_{O_2} and pulse amplitude in the fingers, nose, or toes can provide early warning of pulmonary or cardiovascular deterioration before it is clinically apparent. This technique employs a microprocessor that continuously measures pulse rate and oxyhemoglobin saturation. The photosensor is not heated and does not require calibration. Oxyhemoglobin is red and reduced hemoglobin is blue, and each has a different absorption of light at their given wavelengths. Because the ratio of transmittance at each of the two wavelengths (660 nm, red, and 940 nm, infrared) varies according to the percentage of oxyhemoglobin, pulse oximeters can be programmed to calculate and display the percentage of oxyhemoglobin saturation at each pulse.

There is a predictable correlation between noninvasive Sa_{O_2} monitoring and measured arterial oxygen saturation from arterial blood gas over a wide range of values. Pulse oximetry has only a minimal error, of 1 to 2 percent, above 60% saturation. However, a number of factors can limit the effectiveness and accuracy of pulse oximetry, including impaired local perfusion (e.g., in patients who are hypothermic or on vasopressors); ambient light, particularly flourescent (easily eliminated by placing a towel over the pulse oximeter); nail polish (particularly blue, which absorbs near 660 nm); abnormal hemoglobin; and very high P_{O_2}. Carboxyhemoglobin falsely raises oxyhemoglobin saturation readings because bedside pulse oximeters read carboxyhemoglobin as oxyhemoglobin, while methemoglobin lowers them (at high levels of methemoglobin the pulseoximeter will read 85% regardless of the actual blood oxygenation, as may be seen after the treatment of cyanide poisoning). Fetal hemoglobin has nearly the same absorption spectrum as hemoglobin A and thus has little effect on the readings.

It is important to remember that a pulse oximeter does not provide a good measure of the adequacy of ventilation of patients on supplemental oxygen. A quick calculation using the alveolar gas equation shows that a person on 50% oxygen would be able to increase the Pa_{CO_2} to greater than 230 mm Hg before that saturation would drop below 90 [Pa_{O_2} = 0.5(713) − 230/0.8 = 356 − 287 = 69].

CAPNOGRAPHY   By providing a real-time estimate of Pa_{CO_2}, capnography is a useful and accurate means of assessing ventilation, respiratory gas exchange, and carbon dioxide production, and it can give some indication of cardiovascular status (primarily cardiac output). Although the measurement of end-tidal carbon dioxide partial pressure (PET_{CO_2}) usually underestimates Pa_{CO_2} by about 3 mmHg, it may be greater if the patient has a high dead space. However, the difference between PET_{CO_2} and Pa_{CO_2} is constant for a given patient, provided that the V_{DS}/V_T ratio and airway resistance are not changing.

Mainstream and side-stream infrared capnometers are commercially available. A mainstream capnometer connects directly to the endotracheal tube, thus providing real-time breath-by-breath analysis. The major disadvantages of this system are its size and bulk and the fact that it cannot be used in nonintubated patients. Side-stream capnometers aspirate gas at the sample site. The principal advantages of this system are that it reduces mechanical dead space and can be used in nonintubated patients; however, many mechanical factors related to gas sampling require much expert attention and time, and can affect the results.

Because carbon dioxide production is directly dependent on metabolic rate, there are a large number of conditions that can lower PET_{CO_2}. However, sudden decreases in PET_{CO_2} suggest mechanical problems in the airway, hypoventilation, or increased dead space. A gradual decrease in the PET_{CO_2} is usually due to changes in the lung itself. Increases in the PET_{CO_2} are generally due to hypermetabolic states or unrecognized inadequate ventilation. If a simultaneous Pa_{CO_2} value is available, one can estimate the $P(A − a)_{CO_2}$ (using PET_{CO_2} as a proxy for PA_{CO_2}). Normally, this is less than 3 mmHg, and if it suddenly increases, one should suspect a pulmonary embolus or drastic reduction in cardiac output.

The most frequent use of PET_{CO_2} is to evaluate the adequacy of ventilation. Inadvertent esophageal intubation, tracheal extubation, and endotracheal tube obstruction can be readily detected. These monitors can reduce the number of arterial blood gas determinations obtained and can be very useful in weaning patients from mechanical ventilatory support. They can also be useful in determining the adequacy of circulation during cardiopulmonary resuscitation.

Pulse oximetry and, to some extent, capnography have become standard monitors in most locations that provide for the acute care of unstable patients. While understanding that they have limitations, the clinician can use them for second-to-second indications of the adequacy of ventilation and oxygenation.

CLINICAL APPROACH TO THE VENTILATOR AND RESPIRATORY FAILURE

As mentioned earlier, it is best to think of blood gases as participating in two separate systems: oxygenation and ventilation. When interpreting blood gas values, the clinician can evaluate the oxygenation system with the Pa_{O_2} and the ventilation system with the Pa_{CO_2} and pH. The therapies can also be separated into oxygenation and ventilation.

Oxygenation

There are generally five causes of hypoxemia (low Pa_{O_2} in the blood). They include hypoventilation, low Fi_{O_2}, V/Q mismatch, shunt, and diffusion.

HYPOVENTILATION   As seen from the alveolar air equation, hypoventilation causes hypoxemia by having a high carbon dioxide. This is usually corrected with increased V_A, which reduces the P_{CO_2}. If a patient is on supplemental oxygen, hypoventilation is rarely a cause of hypoxemia, since the Fi_{O_2} would be significantly elevated.

LOW INSPIRED OXYGEN   This causes hypoxemia in two clinical situations. The first is at altitudes where the atmospheric pressure is reduced and thus Pi_{O_2} is reduced. The second, more common cause is inadvertent administration of hypoxic gases to a patient. This most commonly occurs when an E cylinder (green oxygen canister) becomes empty. A full E cylinder contains 2200 lb/in^2 of pressure and 660 L of oxygen. Since oxygen is stored as a gas, the amount of oxygen in an E cylinder is directly proportional to the pressure. Thus, a canister with 1100 lb/in^2 contains approximately 330 L of oxygen. If one knows how much oxygen, in liters, is

contained in an E cylinder and the flow rate of oxygen, one can determine when the E cylinder will become empty. This calculation should be performed for all patients receiving supplemental oxygen from an E cylinder.

VENTILATION-PERFUSION MISMATCH   V/Q mismatch is the most common cause of hypoxemia. Atelectasis, pneumonia, congestive heart failure, pulmonary embolus, and ARDS all cause V/Q mismatch. V/Q mismatch causes hypoxemia because areas of low V/Q ratios (low ventilation and high perfusion) act like a shunt. However, these disorders respond to supplemental oxygen.

SHUNT   Shunt occurs when areas of the lung are perfused but not ventilated. Hypoxemia due to shunt does not respond to supplemental oxygen. Severe ARDS and cardiac anomalies, such as tetralogy of Fallot, are examples of shunt.

DIFFUSION   As discussed previously, oxygen diffuses rapidly across the alveolus. This factor does not generally cause hypoxemia at rest. Rather, it usually causes hypoxemia during exercise.

Treatment

Treatment for hypoxemia is supplemental oxygen. There are three levels of therapy for hypoxemia: (1) supplemental oxygen via nasal canula or face mask; (2) noninvasive ventilation, such as a continuous positive airway pressure (CPAP) or bilevel positive pressure ventilation (BiPAP) mask, in which a patient is given positive-pressure ventilation via a face mask; and (3) mechanical ventilation via an endotrachial tube. Due to entrainment of air around a face mask, the maximum amount of supplemental oxygen that can be administered is 60% but varies with the tightness of the seal. If a patient is still hypoxemic, the clinician needs to administer one of the positive-pressure modes of ventilation. For invasive and noninvasive mechanical ventilation, it is helpful to think of oxygenation separately from ventilation. Specifically, Fi_{O_2} and PEEP or CPAP should be used to control oxygenation. Both Fi_{O_2} and PEEP or CPAP should be titrated upward until hypoxemia is resolved.

Ventilation

Ventilatory failure is often diagnosed by a P_{CO_2} that is greater than expected for a given bicarbonate level. However, the diagnosis can also be made clinically with a high sensitivity by evaluating the respiratory rate, (f), the use of accessory muscles, and the degree of distress. Ventilatory failure can be broken into two broad categories: (1) neuromuscular disorders, including stroke, Guillain-Barré syndrome, and drugs, such as narcotics, that alter the drive to breath; and (2) increased work of breathing, which can be due to asthma, chronic obstructive pulmonary disease, ARDS, and sepsis, which increase C_{O_2} production.

Ventilatory failure is usually treated with mechanical ventilation either invasively or noninvasively. Like oxygenation, ventilation can be thought of as a separate system and is controlled by f and V_T, the components of V_M (Table 22-10). When the P_{CO_2} is elevated, f and V_T can be changed to increase the V_M and reduce the P_{CO_2}.

	P_{O_2}	P_{CO_2}
Ventilator variables	Fi_{O_2}	V_T
	PEEP	f

*f, respiratory rate.

TABLE 22-10   An Approach to the Ventilator Management of Hypoxic and Hypercarbic Patients*

AutoPEEP   When placing patients who may have obstructive airway disease on mechanical ventilation, it is important to evaluate for autoPEEP. AutoPEEP, or dynamic hyperinflation, occurs when a patient receives a breath from the ventilator prior to fully exhaling the previous breath. Dynamic hyperinflation is usually caused by a limitation to airflow, such as asthma. Such limitation results in a buildup of intrathoracic pressure and has the same physiologic consequences as does PEEP: decreased right heart preload, increased right heart afterload, and decreased left heart afterload). Indeed, autoPEEP is an unfortunate cause of pulseless electrical activity in ventilated patients, and the physiologic characteristics are similar to those of a tension pneumothorax and result in decreased preload. While one may suspect a diagnosis of autoPEEP in a wheezing patient with increased airway pressures, autoPEEP can be directly measured from the ventilator by blocking the exhalation port (usually found under the ventilator) just prior to inhalation (end exhalation). The pressure that the manometer reads is the measure of autoPEEP. Like regular PEEP, autoPEEP of 5 mmHg or greater can decrease preload.

If autoPEEP is detected, the treatment is to change the ventilator settings to allow a longer time for exhalation or to have a smaller breath to exhale. This is best accomplished by decreasing f, decreasing V_T, and increasing the inspiratory-to-expiratory ratio. In patients with obstructive airway disease and elevated P_{CO_2}, one must be cautious about attempting to normalize the P_{CO_2}, since this may result in significant autoPEEP. Rather, an elevated P_{CO_2} may have to be accepted until the obstructive airway disease is reversed.

23 FLUID AND ELECTROLYTE PROBLEMS

Michael Lodner
Christine M. Carr
Gabor D. Kelen

Fluid and electrolyte disturbances encompass a broad spectrum of acute and chronic disease. The body deals with abnormalities under a specific stratification. Its first concern is oxygenation and ventilation, the second is circulation, and then equilibrium of acid-base status. Although derangements in any of these are often interrelated, abnormalities in any of these often lead to fluid and electrolyte derangement that may correct once the underlying abnormality itself is addressed. There are some general principles to follow in the initial evaluation of patients with fluid and electrolyte disturbances:

1. Treat the patient, not the laboratory value, particularly if the abnormality was unexpected. An aberrant laboratory value may simply be spurious. Errors occur obtaining, labeling, performing, and reporting laboratory tests. The patient's history and physical examination should be reviewed to determine whether the abnormality is congruous with the patient's presentation. When results remain seemingly inexplicable, the test should be repeated.

2. Often the rate of change defines the severity of an ailment, not the absolute value. In the same light, the rate of correction should generally mirror the rate of derangement. The rapid correction of disorders that developed slowly may lead to worse iatrogenic outcome or possible overcorrection. The body often can help itself once the underlying disorder is corrected. Full deficit correction of electrolytes is rarely appropriate during the initial period. As a rule of thumb, approximately half the deficit is replaced during the initial period (8 to 12 h), and the situation is then further addressed.

3. When fluids and electrolytes are altered, they should be corrected in the following orderly fashion:

   1. Volume
   2. pH
   3. Potassium, calcium, and magnesium
   4. Sodium and chloride

Equilibrium of fluid, electrolytes, and pH depends on adequate tissue perfusion and often corrects spontaneously with resolution of the underperfused state.

4. Lastly, fluids, electrolytes, and pH status are all intertwined. Correction of any one facet must be undertaken with deference to the overall effect. For example, correction of the pH will have a significant effect on the serum potassium, ionized calcium, and ionized magnesium. Rapid replacement of volume may result in a dilutional non-anion-gap acidosis that, in turn, will decrease serum potassium.

FLUIDS

Compartments

A prerequisite to the anatomy of body fluids and the physiologic principles that maintain normal fluid and electrolyte balance is a firm understanding of the extent and composition of the various body fluid compartments. Homeostasis is the maintenance of the composition of the internal environment that is essential for health. This includes consideration of the distribution of water in the body, along with appropriate maintenance of pH and electrolyte balance.

Water is the major constituent of the body and accounts for between 50 and 70 percent of total body weight (Fig. 23-1). The proportion of total body water (TBW) varies with age, gender, and lean body mass. For example, fat contains very *little* water; therefore, the more lean body mass there is, the larger is the proportionate TBW. In the healthy average male, TBW approximates up to 60 percent of weight. [1] Since females have relatively more subcutaneous adipose tissue and less muscle, they have less water or about 50 percent TBW. Similarly, muscle mass decreases with age and sometimes is replaced by fat, leading to a lower percentage of TBW.

As a function of	TBW	ICF	ECF	IF	IVF
Total Weight	60%	40%	20%	15%	5%
TBW		67%	33%		
ECF compartment				75%	25%
FIG. 23-1. Relationship of fluid compartment to body weight and each other. *Abbreviations:* IVF, intravascular fluid; IF, interstitial fluid, ECF, extracellular fluid; ICF, intracellular fluid; TBW, total body water.

The water of the body is divided into two basic functional compartments. The intracellular fluid (ICF) compartment accounts for approximately two-thirds of TBW, and the extracellular fluid (ECF) compartment accounts for approximately one-third of TBW. Most cell membranes are freely permeable to water, and thus, at steady state, the osmolality (discussed below) of these two compartments is equal. A change in osmolality of one compartment results in the passive movement of water from the area of lower osmolality to the area of higher osmolality.

The electrolyte concentration of ICF varies greatly from tissue to tissue. Skeletal muscle accounts for a large proportion of the intracellular component, and thus it is customary to use its electrolyte concentration as representative of the total body intracellular electrolyte concentration. Electrolytes are further classified according to electronic charge, cations (positively charged ions) and anions (negatively charged ions). The principal cations in the intracellular compartment are K^+ and Mg^{2+}, whereas the principal anions are PO_4^- and proteins (Table 23-1).

Solution	Plasma Fluid	Interstitial Fluid	Intracellular Fluid
Cations			
Sodium	142	144	10
Potassium	4	4.5	150
Magnesium	2	1.0	40
Calcium	5	2.5	
Total	153	152	200
Anions			
Chloride	104	113	
Phosphates	2	2	120
Sulfates	1	1	30
Bicarbonate	27	30	10
Protein	13	1	40
Organic acids	6	5	
Total	153	152	200

Note: The major components of each compartment are in bold.

TABLE 23-1   The Electrolyte Concentration of Body Fluids (meq/L)

The ECF is partitioned by vascular epithelium into an intravascular compartment and the interstitial (sometimes referred to as extravascular) compartment. The intravascular compartment contains circulating plasma and accounts for approximately 20 to 25 percent of extracellular water. The interstitial compartment bathes all cells and accounts for approximately 75 to 80 percent of extracellular water. The interstitial compartment is much more complicated in that it has a rapidly equilibrating functional component and several slowly equilibrating nonfunctioning components. The nonfunctioning components account only for a small percentage of extracellular water, which includes the connective tissue water and the "transcellular" water, made up of the cerebrospinal and joint fluids. A dynamic equilibrium exists between the intravascular and interstitial compartments. There is a constant movement of fluid back and forth across the capillary bed between the intravascular and interstitial spaces. This movement is determined by the permeability of the membrane, the net difference between the hydrostatic pressure gradient (which drives fluid out of the intravascular space), the oncotic pressure gradient (which holds fluid within the intravascular space), and tissue turgor pressure countering the hydrostatic pressure. At the arteriolar end, there is a net efflux. At the venule end, there is a net influx. This simple system known as the Starling hypothesis[2] is insufficient to account for the large volume of fluid exchange that actually occurs and for the transport of nutrients and materials to and from tissues. It has been calculated that capillaries exchange water with interstitial fluid up to 300 times/min in the forearm capillary beds. NaCl, urea, and glucose exchange 40 to 120 times/min.[3] Vasomotion of the capillaries (rhythmic contraction and relaxation) determines rate of flow. During the dilator phase, hydrostatic pressure is high, and fluid filters out readily. During the constrictor phase, flow is diminished, and fluid readily enters the capillaries throughout their length. Vasomotion depends on vasomotor nerve outflow, hormones, and local concentrations of tissue metabolites.

One can readily appreciate how a malfunction or imbalance in this system can be buffered to some extent but will ultimately lead to edema (high hydrostatic pressures, loss of vasomotion, decreased oncotic pressure, and decreased tissue turgor).

The proportionate relationship of the fluid compartment to body weight and TBW can be quite confusing, depending on whether the compartment is spoken in terms of body weight or TBW (see Fig. 23-1). For example, the ECF is 20 percent of total body weight but 33 percent of TBW.

Solutes

The other difficulty in understanding fluid and electrolytes is in the understanding of the various terms that are used and commonly misused to describe them. In considering the effects of various physiologically important substances and the interactions between them, the number of molecules, electrical charges, or particles of a substance per unit volume of a particular body fluid are more meaningful than simply the weight of a substance per unit volume. Therefore, concentrations are often expressed in moles, equivalents, or osmoles per liter. The use of grams per 100 mL expresses the weight of electrolytes per unit volume but does not enable a physiologic comparison of the solutes in solution.

The term *mole* describes the chemical basis for quantifying substances. It represents the molecular weight of a substance in grams (g) and is the standard unit of expressing the amount of a substance in the Systeme International d'Unites (SI) unit system. However, this quantification gives no direct information as to the number of osmotically active ions in a solution or to the electrical charges they carry. For example,

$$1 \text{ mol (mole) of NaCl} = 23 \text{ g (Na)} + 35.5 \text{ g (Cl)} = 58.5 \text{ g}$$
$$\text{thus}$$
$$1 \text{ mmol (millimole)} = 58.5 \text{ mg}$$

Equivalents represent the chemical combining activity of electrolytes. An equivalent (eq) of an ionized (charged) substance is 1 mol divided by its valence, whereas a milliequivalent (meq) is that figure expressed in milligrams (mg). In any given solution, the number of milliequivalents of cations is balanced precisely to the same number of milliequivalents of anions. This is referred to as electroneutrality. For example,

$$1 \text{ mol of NaCl dissociates to 1 eq of Na}^+ \text{ and 1 eq of Cl}^-$$
$$1 \text{ eq of Na}^+ = 23 \text{ g/L} = 23 \text{ g, but 1 eq of Ca}^{2+} = 40 \text{ g/2} = 20 \text{ g}$$

When considering the osmotic pressure of a solution, it is more descriptive to discuss this in terms of osmoles and milliosmoles. The osmolal concentration of a substance in a fluid is measured by the degree to which it depresses the freezing point, 1 mol/L of ideal solute depressing the freezing point 1.86°C. Osmoles refer to the actual number of osmotically active particles present in a solution. One osmole (osm) equals the molecular weight of the substance (in grams) divided by the number of freely moving particles each molecule liberates in solution. This is not dependent on the equivalents (electrochemical combining activity) each substance possesses.

Osmolarity is the number of osmoles per liter of solution, whereas osmolality is the number of osmoles per kilogram of solvent. Thus, the volume of the various solutes in the solution and the temperature affect osmolarity but not osmolality. The density of water is 1, so 1 L = 1 kg. Therefore, in water-based systems (such as the human body) where osmotically active substances are dissolved in plasma that is 91 to 93 percent H_2O, osmolal concentrations can be expressed as osmoles per liter (osm/L). This more closely approximates osmotic pressure, since osmolarity will be 7 to 9 percent lower than osmolality.

The serum osmolality can be measured directly by determining the freezing point of the serum, or it can be estimated by adding the measured [Na $^+$], [Cl$^-$], and bicarbonate to the glucose and blood urea nitrogen (BUN) divided by their respective molecular weights divided by 10 (to yield mg/dL):

$$\text{mosm/L} = 2 \times [\text{Na}^+] + \frac{\text{glu}}{18} + \frac{\text{BUN}}{2.8}$$

Since the sum of the measured [Cl$^-$] and bicarbonate approximate the measured [Na$^+$], twice the measured [Na$^+$] is generally used in this calculation.

The normal serum osmolality ranges from 275 to 295 mosm/L. The urine and serum osmolality are much more accurate to use to diagnose the state of hydration than hematocrit, serum proteins, or BUN, since these are dependent on factors other than hydration. The presence of other osmotically active agents must be taken into account, since they influence serum osmolality. The presence of these osmotically active agents should be suspected when the measured osmolality differs from the calculated osmolality by greater than 10. This is termed an osmotic gap. If an *osmotic gap* is encountered, the following should be considered:

1. Laboratory analytic error
2. Decreased serum water content
   Hyperlipidemia
   Hyperproteinemia
3. Additional low-molecular-weight substances in the serum
   Ethanol, methanol, isopropyl alcohol, ethylene glycol, acetone, ethyl ether, paraldehyde, lactate, or mannitol

The osmolal gap can be used to estimate the blood alcohol level (BAL), since osmolality increases 22 mg/dL for every 100 mg/dL of ethanol. Other substances can be similarly estimated (Table 23-2).

$$\text{BAL (estimated)} = \text{osmolal} \times (100/22)$$

Substance	Factor
Ethanol	4.6
Methanol	3.2
Ethylene glycol	6.3
Isopropyl alcohol	5.9
Mannitol	18
Glycerol	9

Note: The osmolal gap is multiplied by the factor to arrive at an estimated level of mg/dL.

TABLE 23-2   Contribution to Osmolal Gap of Osmotic Substances

The differences in ionic concentrations between the ICF and ECF are maintained by a semipermeable cell membrane. A semipermeable membrane is one that allows the free passage of solvent (H_2O) but not solute (crystalloid such as cations and anions, or colloids such as plasma proteins). At equilibrium, the concentration of molecules in the fluid of one compartment is equal to that in all the others. If free water is lost from one compartment, its concentration of molecules increases. This attracts water into that compartment until the concentration equalizes. The solutes (particles) that can not freely pass from one compartment to the next through the semipermeable membrane create the osmotic gradient (i.e., exert a force on water) and are termed *effective* osmoles. These include the electrolytes and, in most tissues, glucose. Glucose readily enters red blood cells, hepatocytes, and osmoreceptors in the brain and thus exerts no force on water in relation to these cellular compartments. The solutes (particles) that distribute across the semipermeable membrane freely and therefore don't contribute to the osmotic gradient are termed "ineffective" osmoles.

Tonicity is used to describe the osmolality of a solution relative to plasma. Solutions with the same osmolality are said to be *isotonic,* those with comparatively higher osmolality are *hypertonic,* and those with lower osmolality are *hypotonic.* Tonicity is created by *effective* osmoles. Effective osmoles exert a force on water. The *ineffective* osmoles (urea, ethanol, methanol, or ethylene glycol) contribute to serum osmolality but not to tonicity. They do not exert a force on water across a semipermeable membrane as they freely diffuse.

Homeostasis

Fluid balance is exceedingly important to maintain homeostasis. To maintain balance, an average normal adult requires approximately 2000 to 3000 mL intake of water per day. This accounts for the volume of water lost in a day due to insensible and urinary losses. The insensible losses include the respiratory tract (500 to 700 mL/day), the skin (250 to 350 mL/day), and the feces (100 mL/day). This insensible loss can accelerate dramatically in the setting of fever (500 mL per 1°C fever), sweating (up to 1500 mL), and gastrointestinal losses.

The disorders of fluid balance may be classified into three categories: volume, concentration, and composition. Although all of these are interrelated, they are each separate entities.

1. Disturbances of volume occur when an isotonic solution is added or lost from a fluid compartment. Solute will not transfer from an adjacent compartment; only the volume of that compartment will change as long as the osmolality remains the same in the different compartments.
2. Disturbances of concentration occur when water alone is added or lost from a fluid compartment. The concentration of osmotically active particles will change, exerting an osmotic force into the compartment with the higher osmolality. This will continue until osmolality balances between the two compartments.
3. Disturbances of composition occur when the concentration of ions changes within a compartment without significantly altering the total number of osmotically active particles.

It is important to note that the volume lost is relative to the overall volume. A child who loses fluid is much more susceptible to its effects since this absolute quantity is a greater percentage of its overall volume. Signs of volume loss are related to not only volume but also to rate of loss. The faster the loss, the less time the body has to counterregulate and the greater the deleterious effects will be. They include weight loss, thirst, tachycardia, oliguria, and dry mucous membranes.

Flexibility in the body's ability to control water volume is provided by two mechanisms: antidiuretic hormone (ADH) and aldosterone. In the setting of volume depletion with increased serum osmolality and/or decreased plasma volume, the posterior pituitary is stimulated to release ADH and renin (from the kidney), stimulating the adrenal gland to release aldosterone. The ADH leads to retention of free water in the collecting ducts of the kidneys while aldosterone stimulates retention of Na$^+$ in the renal tubules, leading to further retention of water. In the setting of extra body water, there is a decrease in serum osmolality and/or an increase in plasma volume. This leads to a suppression of ADH secretion from the posterior pituitary and suppression of aldosterone release from the adrenal gland. The suppression of ADH leads to free water diuresis.

Overall, volume status is a much more potent stimulator of ADH than is osmolality. Therefore, change in volume alone will have a greater influence on ADH. For example, hypovolemia is a stronger stimulus for ADH secretion than hypo-osmolality is an inhibitor. Nausea and pain are considered to be of even greater potency for ADH stimulation.

CLINICAL ASSESSMENT OF VOLUME STATUS

Volume Loss

Volume loss can often be suspected from the history. Poor oral intake or history of vomiting, diarrhea, poorly controlled diabetes, renal disease, or adrenal disease are suggestive. With moderate volume loss, there may be postural hypotension and possibly a resting tachycardia. There may be narrowing of the pulse pressure. Jugular venous pressure will be difficult to appreciate clinically (assuming no right heart disease). Patients with moderate to severe volume loss may be weak and

often have altered sensorium. They may be hypotensive even when recumbent. Mucous membranes will be dry, tissue turgor decreased, and eyes sunken (usually a finding in the pediatric population, along with sunken fontanelles). Oliguria is frequently in accompaniment. Volume loss may be sufficient to induce shock.

Laboratory findings include hemoconcentration (interpretable only if baseline values are known) and, usually, increased creatinine and urea nitrogen levels. In an acute setting, the ratio of urea nitrogen to creatinine will be 20:1 or even greater. Serum [Na$^+$], as explained, in and of itself, reveals nothing about volume status. If the volume loss is extrarenal, then urine [Na$^+$] will be less than 10 meq/L.

Treatment depends on the underlying disorder, but the cornerstone is volume repletion. Treatment is detailed elsewhere in this chapter and, for shock states, in the relevant chapters in this volume.

Volume Overload

Volume overload is most often encountered in disease states where excretion of free water is impaired. Most of these conditions are related to renal disease, diseases that impair blood flow to the kidneys (resulting in Na$^+$ retention), diseases that diminish intravascular osmolality (liver failure and low-protein states), or diseases that cause undesirable Na$^+$ retention by various mechanisms. Decreased intravascular osmolality results in a functional intravascular contraction, with expanded interstitial and cellular volume. These are discussed elsewhere in this chapter.

Volume overload clinically manifests as edema, whether peripheral or central (e.g., pulmonary). Early findings are weight gain, resting tachycardia, and peripheral edema. Jugular venous pressure is elevated. If severe, volume overload eventually results in severe right heart failure with resultant anasarca and ascites, and ultimately severe left heart failure, with pulmonary edema and pump failure manifesting as hypotension. Unfortunately, the contracted intervascular volume from hypotension causes the kidney to conserve Na$^+$, exacerbating the problem.

Specific treatments are discussed in this chapter and elsewhere in this volume.

ELECTROLYTES

Electrolyte abnormalities are often challenging to diagnose and treat. Overall, each disorder can be assessed with the same general approach. Increased concentration (hyper-) is a result of (1) excess total body amount, (2) shift among compartments, and (3) a relative fluid loss. Decreased concentrations (hypo-) are a result of (1) depleted total body amount, (2) shift among compartments, and (3) relative fluid gain.

SODIUM (Na$^+$)

The total body Na$^+$ content is between 40 and 50 meq/kg, which is approximately 2800 meq in a normal 70-kg man. It is found predominantly in the ECF space (98 percent) with a concentration of approximately 140 meq/L. One-third of this is fixed in bone while two-thirds is readily exchangeable. The intracellular concentration is usually less than 10 to 12 meq/L. Na$^+$, which is primarily responsible for the osmolality of the ECF space, moves passively into cells along its concentration gradient and then is actively "pumped" back out against its concentration gradient. When physiologic alterations cause intracellular-extracellular osmotic disequilibrium, movement of solute across the cell membrane is not the predominant corrective action but, rather, movement of water. The water travels to the fluid space with the higher osmolal concentration in an attempt to restore osmotic equilibrium.

Disorders of Na$^+$ often accompany disorders of water regulation where either *too little* or *too much* water is present in the body relative to solute. Therefore, hyponatremia and hypernatremia can occur with normal, low, or high total body Na$^+$ content, and with hypovolemic, euvolemic, and increased TBW states. This point cannot be overemphasized. The serum [NA$^+$] reveals nothing by itself of the patient's volume status. Determination of the serum [Na$^+$] is generally indicative of body fluid tonicity. The regulation of Na$^+$ and regulation of water are closely coupled. Together they are regulated by two controls: by ADH (vasopressin) and by the renin-angiotensin-aldosterone system. ADH release is stimulated by increases in serum osmolality, but a much more potent response is to volume depletion. ADH stimulation increases renal water absorption and decreases urine output by increasing tubular water permeability and by increasing water reabsorption in the collecting ducts of the kidney. Renin is synthesized by the kidney in response to decreased intravascular volume or pressure and stimulates the production of aldosterone in the adrenal gland. Aldosterone acts on the distal tubules to increase Na$^+$ reabsorption, and water passively follows.

Aberrant levels of Na$^+$ should be diagnosed on clinical grounds through history and physical examination findings and confirmed with laboratory evaluation. Clinical signs of increase or decrease tend to occur early and are greater in severity if the rate of Na$^+$ change in the extracellular space is rapid. Diagnosis should be suspected and confirmed early in patient management and corrected within the appropriate time frame to prevent the dangerous sequelae associated with these abnormalities.

Hyponatremia

Hyponatremia is strictly defined as a measured serum [Na$^+$] less than 135 meq/L. This can result from primary water gain and/or greater Na$^+$ loss (than water), alteration in the distribution of body water, or aberrant laboratory measurement. The development of symptoms is more related to the rate of change of the serum [Na$^+$] than the absolute value. Values less than 120 meq/L are more likely to lead to symptoms, even when slowly developing. Common presenting symptoms include, but are not limited to, confusion, lethargy, nausea, vomiting, anorexia, muscle cramps, and hypothermia, and culminate ultimately in seizures and coma. Seizures are quite likely at [Na$^+$] of 113 meq/L or less.

PATHOPHYSIOLOGY   The pathophysiologic changes of hyponatremia are most obvious when serum [Na$^+$] levels fall below 120 meq/L in less than 12 to 24 h. The central nervous system (CNS) effects are usually the most obvious, but cardiovascular and musculoskeletal dysfunction may also occur.

Central Nervous System   As serum [Na$^+$] fall, the osmotic gradient that develops across the blood-brain barrier causes water to move into the brain, causing apathy, agitation, headache, altered consciousness, seizures, and even coma. The severity of symptoms is dependent not only on the rapidity but also the magnitude of the fall in the serum [Na$^+$]. Acute hyponatremia occurring in 24 h or less and resulting in a serum [Na$^+$] of less than 120 meq/L, or a rate of fall of 0.5 meq/L or more per hour, can cause muscular twitching, seizures, and coma. The mortality rate with acute severe hyponatremia with CNS changes has been reported to be as high as 50 percent in adults. In animals in which serum [Na$^+$] is reduced to 110 mmol/L in 2 h, the mortality rate is 88 percent, and there is gross evidence of brain edema. When plasma Na$^+$ is lowered slowly during several days or weeks by a combination of Na$^+$ depletion and water ingestion, patients are usually less symptomatic, but even patients with chronic hyponatremia may experience focal weakness, hemiparesis, ataxia, and a positive Babinski sign.

As hyponatremia develops, the osmotic equilibrium between brain and plasma allows movement of increased amounts of water into the brain. However, brain swelling is less than would be predicted on the basis of the osmotic shifts alone. The brain's adaptation to hyponatremia is accomplished by two mechanisms: (1) movement of interstitial fluid into the cerebrospinal fluid and (2) loss of cellular potassium and organic osmolytes. With acute hyponatremia, water moves into the brain from the plasma, causing an increase in the hydrostatic pressure of the cerebral interstitial fluid. The increased interstitial pressure accelerates the clearance of interstitial fluid into the cerebrospinal fluid, which is returned to the systemic circulation via the arachnoid villi. The movement of Na$^+$-rich interstitial fluid out of the brain reduces brain Na$^+$, which in turn reduces the osmotic gradient for water moving into the brain.

The loss of sodium, potassium, and chloride from the brain provides most of the protection against cerebral edema in the first hours of hyponatremia; however, when hyponatremia is sustained, the brain slowly loses other intracellular osmolytes, mainly amino acids. Losses of organic osmolytes during prolonged or severe hyponatremia are especially important in defending the brain against swelling.

The adaptive changes that protect the brain from excessive swelling also render it susceptible to dehydration during correction of the fluid and electrolyte problem. Indeed, there is often more risk of brain damage during treatment than from the hyponatremia itself. The rate of rise of brain intracellular potassium and organic osmolytes during correction of the hyponatremia is much slower than the rate of loss of these substances during the development of the problem. If correction of hyponatremia occurs more rapidly than the brain can recover solute, the higher plasma osmolality may dehydrate and injure the brain, producing what is now called

the *osmotic demyelination syndrome,* or *central pontine myelinolysis* (CPM). (See section on "Complications of Therapy.")

Cardiovascular System   The cardiovascular response to hyponatremia depends primarily on the effective arterial blood volume, which may be increased, decreased, or normal depending on the underlying disorder. Intravascular volume is determined in part by the distribution of water between the ICF and ECF compartments. Thus, in volume-depleted patients, hyponatremia can cause a further decrease in the intravascular volume by allowing movement of water out of the ECF compartment into the ICF space. Accordingly, shock occurs at lesser degrees of TBW depletion in hyponatremia than similar fluid deficits when the plasma is hypertonic or isotonic.

ADH is one of the main factors opposing the hypovolemic effect of fluid shifts induced by hyponatremia. The ADH is released primarily as a response to the decreased effective arterial blood volume that often accompanies hyponatremic edematous disorders. Nonosmotic stimulation of ADH release overrides the hypo-osmotic suppressive effect of hyponatremia, and increased ADH is present in almost all hyponatremic conditions. The function of ADH in this setting initially may seem paradoxical, because it potentiates the hyponatremic state by increasing water reabsorption by the renal tubules. ADH is also a potent vasoconstrictor, however, and even at the low ADH concentrations that are characteristic of clinical hyponatremia, it increases peripheral vascular resistance, thereby increasing blood flow to the liver and kidneys at the expense of the skin and muscle.

Musculoskeletal System   Most patients with hyponatremia have normal muscle tone and function. However, muscle cramps and weakness can occur during strenuous exercise, especially if excess sweating is replaced with water. These symptoms usually resolve rapidly when the serum [Na$^+$] is corrected back toward normal.

Renal System   The usual renal response to hyponatremia is production of dilute urine; however, this process is abrogated to some extent by the presence of increased concentrations of ADH. The amount of ADH present depends on the primary disease process and the effective arterial blood volume.

A urine [Na$^+$] less than 10 meq/L usually indicates that the renal handling of Na$^+$ is intact and that the effective arterial blood volume is contracted. In contrast, a urine [Na$^+$] greater than 20 meq/L often indicates intrinsic renal tubular damage or a natriuretic response to hypervolemia. The urine [Na$^+$] will also vary somewhat according to the ongoing gains and losses of salt and water. Urine [Na$^+$] will tend to increase if the underlying disease significantly impairs renal function.

DIAGNOSIS   The diagnosis and ultimate etiology of hyponatremia are determined via a staged algorithm (Fig. 23-2). Since Na$^+$ and its attendant anions are the primary determinants of ECF osmolality, hyponatremia is usually accompanied by hypo-osmolality. However, hyponatremia may be associated with a normal or even elevated plasma osmolality. Therefore, the first step in the evaluation of a patient with a low measured [Na$^+$] should include a clinical evaluation of ECF volume status and both measured and calculated plasma osmolality. This provides a means for the first tier in categorizing hyponatremic disorders. In *true* hyponatremia, the plasma osmolality is reduced, whereas in *factitious* hyponatremic states, the plasma osmolality is either normal or increased.
FIG. 23-2. Algorithm for diagnosis of hyponatremia.

HYPERTONIC HYPONATREMIA (P$_{osm}$ > 295)   Hyponatremia with an increase in osmotically active solutes occurs when there is an accumulation of large quantities of solutes restricted primarily to the ECF space. In this setting, there is a net movement of water from the ICF to the ECF, thereby effectively diluting the ECF [Na$^+$]. The most common cause of this is hyperglycemia. Each 100-mg/dL increase in plasma glucose decreases the serum [Na$^+$] by 1.6 to 1.8 meq/L. The differential diagnosis of hypertonic hyponatremia is shown in Table 23-3. Treatment of hyponatremia in this class includes reduction of the ECF hypertonicity by correction of the underlying disorder with close observation. Unless detected during the very acute phase, or in the face of renal failure, an osmotic diuresis is likely, resulting in total body Na$^+$ deficit. Volume depletion is often associated, and, thus, volume repletion with Na$^+$-containing fluids is required.

TABLE 23-3   Etiology of Hyponatremia

ISOTONIC HYPONATREMIA (P$_{osm}$ 275–295)   Hyponatremia associated with normal plasma osmolality is often termed *pseudohyponatremia.* High levels of plasma proteins and lipids increase the nonaqueous, non-Na$^+$-containing fraction of plasma. This represents an artifact in serum [Na$^+$] measurement. Na$^+$ usually is distributed within 910 and 930 mL in each liter of plasma. Since traditional methods of Na$^+$ measurement employ a "mass per volume" of serum method (such as flame emission spectrophotometry, or FES), the laboratory analysis reports a factitious lower value of [Na$^+$] than the serum truly contains. The true [Na$^+$] and osmolality of plasma water are normal. The differential diagnosis of isotonic hyponatremia is shown in Table 23-3. Treatment of hyponatremia itself in this class is not required.

HYPOTONIC HYPONATREMIA (P$_{osm}$ < 275)   This category of hyponatremia results in intracellular volume expansion with consequent derangement of cellular functions. This category can be further subdivided into classifications based on functional ECF volume (Fig. 23-2) and urinary [Na$^+$] (accounting for possible recent use of diuretics). The assessment of ECF should focus on predisposing factors, once volume status is ascertained. In addition to the electrolytes and plasma osmolality already obtained, urine electrolytes and osmolality should be added. This will help facilitate classification into hypovolemic, hypervolemic, and euvolemic categories.

Hypovolemic hyponatremia is associated with a loss of both Na$^+$ and water, often with disproportionate water replacement through oral intake or the administration of hypotonic fluids. Losses of Na$^+$ may be either renal or extrarenal.

Patients with extrarenal losses of Na$^+$ and water will demonstrate a urinary [Na$^+$] of less than 20 meq/L. The unequal balance of electrolyte and water loss produces a

contracted ECF and hyponatremia. This is maintained by the physiologic effect of volume depletion on the kidneys inhibiting the excretion of free water. The impairment of water excretion to defend ECF volume at the expense of tonicity is accomplished by four mechanisms:

1. Decreased glomerular filtration
2. Increased proximal tubular reabsorption of solute and water
3. Decreased delivery of fluid to the diluting segment of the nephron
4. ADH released by nonosmotic stimuli

The differential diagnosis of hypovolemic hyponatremia from extrarenal losses is shown in Table 23-3.

The decreased ECF volume may also be due to renal losses (see Table 23-3). In this setting, the urinary [Na$^+$] will be greater than 20 meq/L. The clinical manifestations are usually due to the volume deficit rather than the hyponatremia itself. Treatment of hypovolemic hyponatremia includes reexpansion of the ECF volume with isotonic saline and appropriate correction of any underlying disorder.

Euvolemic hyponatremia is described as having a combination of normal volume status and hyponatremia. Although these patients may have a slightly increased ECF volume, they are not clinically edematous and have near-normal total body Na$^+$ content despite the presence of hyponatremia. When symptoms are present, they usually relate to CNS hypotonicity. Urinary [Na$^+$] is usually greater than 20 meq/L and may be much higher in instances of ADH excess. The most notable cause of euvolemic hyponatremia is the syndrome of inappropriate ADH (SIADH) secretion. This is characterized by six criteria:

1. Hypotonic hyponatremia
2. Inappropriately elevated urinary osmolality (usually greater than 200 mosm/kg)
3. Elevated urinary [Na$^+$] (typically greater than 20 meq/L)
4. Clinical euvolemia
5. Normal adrenal, renal, cardiac, hepatic, and thyroid function
6. Correctable with water restriction

The diagnosis of SIADH is primarily made by exclusion (Table 23-4). The other causes of euvolemic hyponatremia are listed in Table 23-3. Some of these may stimulate ADH secretion. Treatment for patients with euvolemic hyponatremia requires fluid restriction and appropriate workup and management of the underlying disorder. Admission is usually warranted.

Central Nervous System Disease	Pulmonary Disease	Carcinoma
Tumor	Tumor	Lung
Trauma	Pneumonia	Pancreas
Infection	Chronic obstructive	Thymoma
Cerebral vascular accident,	pulmonary disease	Ovarian
subarachnoid hemorrhage	Lung abscess	Lymphoma
Guillain-Barré syndrome	Tuberculosis	
Delerium tremens	Cystic fibrosis	
Multiple sclerosis		

TABLE 23-4   Etiology of Syndrome of Inappropriate Antidiuretic Hormone (SIADH)

Hypervolemic hyponatremia is described as TBW in great excess. These patients present with manifestations of volume overload, such as peripheral and/or pulmonary edema. They usually have impaired ability to excrete a water load. This allows for water retention in excess of Na$^+$ retention. These patients can be further categorized into two groups (Table 23-3): The first of these is generalized edematous states without advanced renal insufficiency. These patients have urinary [Na$^+$] of less than 20 meq/L. They include patients with cirrhosis and/or ascites, congestive heart failure, and nephrotic syndrome. The second category is advanced acute or chronic renal insufficiency. These patients have urinary [Na$^+$] in excess of 20 meq/L.

Management of patients with hypervolemic hyponatremia includes optimizing treatment for the underlying disorder coupled with judicious salt and water restriction. Often diuretics are required to aid in management. Dialysis may be necessary.

EMERGENCY TREATMENT OF SEVERE HYPONATREMIA   While specific or general treatment of hyponatremia for the condition discussed may be initiated in the ED, there is little urgency to address the hyponatremia itself immediately when [Na$^+$] is above 120 meq/L. In cases where hyponatremia is severe (less than 120 meq/L), develops rapidly (a greater than 0.5-meq/L decrease in serum [Na$^+$] per hour), or is associated with a patient in extremis (i.e., coma or seizures), administration of 3% saline solution (513 meq/L) is usually indicated. This can be administered at 25 to 100 mL/h, with careful observation for fluid overload and the rise in serum [Na$^+$] levels. The rise in [Na$^+$] should be no greater than 0.5 to 1.0 meq/L per hour. In the face of seizures, this can be increased to 1 to 2 meq/L per hour. It is sometimes necessary to administer concomitant furosemide to reduce the amount of water present in the body, allowing more rapid correction of plasma [Na$^+$].[4]

CALCULATION OF SODIUM DEFICIT   In hypovolemic patients, the Na$^+$ deficit should be calculated and replaced with normal saline solution. The formula is

$$\frac{(\text{desired plasma } [Na^+] - \text{actual plasma } [Na^+]) * (TBW)}{} = \text{total body Na}^+ \text{ deficit (in meq/L)}$$

COMPLICATIONS OF THERAPY   Complications with the treatment of acute hyponatremia, especially when there is no underlying CNS, hepatic, or renal disorder, are uncommon and occur in fewer than 2 percent of patients. In chronic hyponatremia, brain edema is usually not severe, and little evidence exists that chronic hyponatremia itself causes brain damage. Nevertheless, these patients appear to be at greater risk for brain injury (CPM) during the correction process. The injury reportedly occurs after the hyponatremia has been corrected and progresses in a predictable manner. These neurologic changes are believed to be due to correction of the serum [Na$^+$] at a rate faster than the brain can adapt to the higher osmolality. In patients with chronic hyponatremia, other factors contributing to the CPM may include alcoholism, malnutrition, toxins, and metabolic imbalance.

Brain histology in fatal cases shows myelinolysis and demyelination of central pontine and extrapontine myelin-bearing neurons. In typical cases, the neurologic findings include fluctuating levels of consciousness, behavioral disturbances, dysarthria, dysphagia, or convulsions progressing to pseudobulbar palsy and quadriparesis. Improvement may occur after several weeks of severe debilitation, but some patients are permanently impaired.

In patients with chronic severe hyponatremia, the threshold for the production of CPM is a rate of correction of Na$^+$ levels faster than 0.5 meq/L per hour (12 meq/L per day). In patients with acute severe hyponatremia, correction at rates exceeding 0.5 to 1.0 meq/L per hour, with or without diuretics, does not usually cause any problems. Severe neurologic complications have occurred almost exclusively in clinically hypernatremic patients treated with hypertonic or isotonic saline without the addition of furosemide or an osmotic diuretic. Similar patients treated with the same fluids but with furosemide almost uniformly have done well. Patients with chronic hyponatremia corrected at a rate less than 0.5 meq/L per hour have also done well.

Hypernatremia

Hypernatremia is strictly defined as serum [Na$^+$] greater than 150 meq/L. The most frequent cause of hypernatremia is a decrease in TBW secondary to either reduced intake or excessive loss. The main defense against hypernatremia is likely thirst. A 2 percent increase in plasma osmolality should stimulate thirst and

thereby increase free water intake. The problem arises when patients, such as those in a coma or those who are bedridden, are unable to obtain adequate fluid. All hypernatremic states are hyperosmolar (Table 23-5).

TABLE 23-5   Etiologic Classification of Hypernatremia

Clinical manifestations are much more severe with acute rapidly developing hypernatremia than with chronic hypernatremia. In the elderly and in infants (two groups at great risk), the morbidity and mortality rates are high when [Na$^+$] is greater than 160 meq/L. Symptoms usually occur when plasma osmolality exceeds 350 mosm/kg of water. Neurologic dysfunction predominates (Table 23-6).

Manifestations	Osmolality, mosm/kg
Restlessness, irritability	350–375
Tremulousness, ataxia	375–400
Hyperreflexia, twitching, spasticity	400–430
Seizures and death	>430

TABLE 23-6   Clinical Manifestations of Hypernatremic States Related to Serum Osmolality

Virtually all hypernatremia encountered in the ED is related to volume loss, usually severe. There are two potential mechanisms seemingly opposed but having the same result. The first is the ADH response to low volume and hypertonicity. The renal response to ADH, conservation of free water, results in low urine output (less than 20 mL/h) that has a high osmolality (usually greater than 1000 mosm/kg H$_2$O). The second mechanism is failure of ADH response, either central or peripheral (vide infra). In essence, the patient cannot excrete Na$^+$ properly. Urine osmolality is low (200 to 300 mosm/kg with urinary [Na$^+$] of 60 to 100 meq/kg).

Finally, one mechanism of hypernatremia may result in hypervolemia. This is excessive intake of Na$^+$. Usually, the kidney is able to regulate Na$^+$ at a very constant level. However, if the kidneys are impaired, then serum [Na$^+$] will increase and a dangerous ECF volume expansion will occur. Note that even large volumes of normal saline administration by itself cannot result in hypernatremia, because the [Na$^+$] is only 154 meq. However, administration of concentrated Na$^+$ solutions (e.g., hypertonic saline, addition of NaHCO$_3$ to normal solution) can result in euvolemic or hypervolemic hypernatremia.

DIABETES INSIPIDUS   A particularly interesting cause of hypernatremia is diabetes insipidus (DI), which results in excessive loss of hypotonic urine. Diabetes insipidus may be central in origin (due to a failure of secretion of ADH) or nephrogenic (due to renal unresponsiveness to ADH). About 30 percent of central DI is idiopathic and about 70 percent is secondary to neoplasms (25 percent), pituitary surgery (20 percent), or trauma (15 percent). Most of the remaining 10 percent is due to various granulomas (tuberculosis, sarcoidosis, or eosinophilic granuloma) or local vascular problems (aneurysms, thrombosis, or Sheehan syndrome). Nephrogenic DI may be primary (familial) or secondary to a wide variety of causes, including hypercalcemia, hypokalemia, renal disorders, various drugs (including lithium, demeclocycline, amphotericin B, aminoglycosides, and cisplatin), hematologic disorders (sickle cell disease and myeloma), malnutrition, or amyloidosis.

Traumatic DI is typically triphasic. After an initial polyuria from insufficient ADH secretion by hypothalamic cells, there is a transient second phase lasting 1 to 7 days characterized by release of previously formed hormone from the posterior pituitary and resolution of the polyuria. In the third phase, central DI returns after the released hormone has been utilized. Regeneration of cells that secrete ADH may occur weeks to months after injury. The ADH-secreting cells have their cell bodies in the hypothalamus, and these are not usually completely destroyed by trauma.

Differentiation between central and nephrogenic DI is best achieved by noting (1) the response of serum and urine osmolarity to water deprivation (trying to reach a serum osmolarity greater than 295 mosm/L) and (2) the response to 5 units of subcutaneous aqueous vasopressin. Patients with central DI show little or no response to dehydration but respond well to vasopressin (urine osmolarity of 800 mosm/L or greater). Nephrogenic DI shows little or no response to dehydration or vasopressin.

PATHOPHYSIOLOGY   Because Na$^+$ does not freely penetrate tissue cell membranes, ECF and plasma volume tend to be maintained in hypernatremic dehydration until the water loss is greater than 10 percent of body weight. Although there may be rather profound dehydration in some patients with severe hypernatremia, shock is an infrequent occurrence. When the dehydration results in loss of 10 percent of body weight, skin turgor becomes reduced and the skin of the abdomen has a characteristic "doughy" feel when it is pinched between the fingers.

Acute symptomatology is seen in many patients once serum [Na$^+$] exceeds 158 meq/L. Patients tend to become irritable, and infants may also have a high-pitched cry or wail alternating with periods of severe lethargy. As dehydration and hypernatremia become more severe, one may see increased muscle tone or even coma with eventual seizures. Fever can be both a contributing cause and a result of hypernatremic dehydration.

Restlessness and irritability occur when serum osmolality increases to between 350 and 375 mosm/kg, while ataxia and tremulousness tend to occur when osmolality is between 375 and 400 mosm/kg. When serum osmolality rises above 400 mosm/kg, asynchronous jerks and tonic spasms are apt to occur. Death usually occurs at an osmolality above 430 mosm/kg.

Permanent sequelae are not uncommon in children when serum [Na$^+$] exceeds 160 to 165 meq/L. Up to 16 percent of children with hypernatremia develop chronic neurologic deficits as a consequence. The overall mortality rate of hypernatremia is above 10 percent. If the plasma osmolality exceeds 350 mosm/kg, the incidence of severe morbidity or mortality may exceed 25 to 50 percent.

Hypocalcemia, which is frequently seen in patients with hypernatremia, may contribute to the CNS symptomatology. However, the mechanism of the hypocalcemia is unclear.

Massive brain hemorrhage or multiple small hemorrhages and thromboses may occur when hypernatremia causes enough cellular dehydration and resultant brain shrinkage to cause tearing of cerebral blood vessels. This has been observed most frequently in neonates following acute administration of a large Na$^+$ load. As a

consequence, the amount of sodium bicarbonate administered to acidotic infants must be limited.

If the hypernatremia persists for more than a few days, the brain dehydration may resolve, and brain water content may return to normal or near-normal levels due to accumulation in the brain cells of amino acids known as *idiogenic osmoles,* particularly taurine. The formation of these idiogenic osmoles increases intracellular osmolality, attracts water back into the brain cells, and restores their cellular volume. If the hypertonicity develops gradually, this protective mechanism tends to prevent severe brain cell shrinkage.

TREATMENT   The cornerstone of treatment is volume replacement. There are many opinions regarding appropriate initial fluid and subsequent therapy. Where volume is the issue, we believe volume should be replaced first with either normal saline or Ringer's lactate. Either of these will have, by definition, a lower [Na$^+$] than the patient's serum. Plasma-expanding fluids should continue until tissue perfusion is restored. Once perfusion has been established, the solution should be converted to 0.45% saline or other isotonic solution. This should continue until the urine output is at least 0.5 mL/kg per hour. The reduction in [Na$^+$] should not exceed 10 to 15 meq/L per day. A calculation to estimate free water deficit is

$$\text{water deficit (in liters)} = TBW * (1 - \text{actual } [Na^+]/\text{desired } [Na^+])$$

As a general rule, each liter of water deficit results in a rise of serum [Na$^+$] of 3 to 5 meq/L.

Rapid correction of hypernatremia, especially if it is chronic, can cause seizures and severe neurologic sequelae. Unless the hypernatremia is of short duration, idiogenic osmoles are presumably present in brain cells. Consequently, too rapid rehydration and lowering of serum [Na$^+$] can cause brain cells to swell, resulting in cerebral edema and an increased likelihood of seizures, permanent neurologic sequelae, or even death. Serum electrolyte levels should be monitored frequently to ensure that the appropriate rate of decline of serum [Na$^+$] occurs.

In the case of acute hypernatremia, serum [Na$^+$] levels can be corrected rather rapidly with little fear of cerebral edema because idiogenic osmoles will not yet be present in brain cells. However, rapid fluid administration in patients with hypernatremia due to excessive Na$^+$ administration may result in hypervolemia and pulmonary edema.

In children with acute severe Na$^+$ excess and a serum [Na$^+$] of more than 180 to 200 meq/L, peritoneal dialysis using a high-glucose (7.5%), low-Na$^+$ dialysate may be lifesaving, but must be done with frequent monitoring of serum electrolyte levels.

In the case of central DI, administration of either vasopressin or 1-deamino-8- D-arginine vasopressin (dDAVP) must be undertaken carefully, and fluid intake should be regulated so that the serum [Na$^+$] does not drop too rapidly.

POTASSIUM (K$^+$)

Elemental K$^+$ is the major intracellular cation of the body. The normal intracellular concentration is 100 to 150 meq/L, while the normal extracellular concentration is 3.5 to 5.0 meq/L. The total body K$^+$ store ranges from 35 to 55 meq/kg or 3500 meq in a healthy 70-kg man. Approximately 70 to 75 percent of total body K$^+$ is found in muscle tissue; therefore, in patients with severe muscle wasting, total body stores may be as low as 20 to 30 meq/kg. Daily intake of K$^+$ ranges from 50 to 150 meq. Foods high in K$^+$ include oranges, grapefruit, tomatoes, bananas, avocados, and raisins. K$^+$ is excreted predominantly by the kidneys (90 percent) and with some loss in the stool and by sweating. K$^+$ is filtered freely through the glomerulus and then reabsorbed in the proximal and ascending tubules. It is secreted in the distal tubule in exchange for Na$^+$. In healthy individuals, the kidneys are able to excrete up to 6 meq/kg per day. Even in severe K$^+$ deficit, 5 to 15 meq/L may be excreted.

In the absence of an acid-base disturbance, measuring extracellular [K$^+$] is a reasonably accurate way to assess total body K$^+$ in relatively healthy patients. A decrease in measured serum [K$^+$] from 4 to 3 meq/L represents a total body deficit of approximately 200 to 400 meq. An increase in measured serum [K$^+$] from 4 to 5 meq/L represents a total body K$^+$ increase of approximately 100 to 200 meq/L. Extracellular K$^+$ represents about 2 percent of total body K$^+$, or 70 meq, and is influenced by two important variables: total body K$^+$ stores, and distribution between the ICF and ECF spaces. Significant and rapid intracellular to extracellular shifting occurs in response to severe injury (i.e., surgical stress, trauma, or burns), acid-base imbalance, catabolic states, increased extracellular osmolality, or insulin deficiency. These shifts are important when viewed in light of the role of K$^+$ in maintaining the resting membrane potential. The normally balanced intracellular-extracellular gradient facilitates propagation of electrical impulses. This is particularly important in the functioning of the heart.

Hypokalemia

Hypokalemia is defined as a serum [K$^+$] of less than 3.5 meq/L. The most frequent causes of hypokalemia are intracellular shifts and increased losses (Table 23-7). K$^+$ tends to shift into cells as the pH of the ECF rises in exchange for hydrogen ions. A rise in the pH of 0.10 generally causes a 0.5 ± 0.2-meq/L decrease in serum [K$^+$] levels. This relationship applies to metabolic acid-base derangements. Although the reasons are unclear, respirator alkalosis and acidosis have minimum effect on K$^+$ shift. K$^+$ losses usually involve either the gastrointestinal tract or the kidneys. It is important to note that the hypokalemia associated with vomiting has very little to do with the actual K$^+$ lost in the vomitus and much more to do with the metabolic alkalosis that follows. The hypovolemia from volume loss leads to increases in aldosterone secretion, which acts on the kidney to preserve Na$^+$ and bicarbonate in exchange for K$^+$. The resultant alkalosis also causes K$^+$ to shift into cells in exchange for H$^+$.

TABLE 23-7   Etiology of Hypokalemia

The clinical manifestations of hypokalemia usually start when serum concentrations reach 2.5 meq/L, although they may appear sooner with rapid decreases in concentration. The symptoms result from abnormalities in membrane polarization and affect almost every system. Manifestation by system includes

Neuromuscular: Generalized malaise, weakness, fatigue, hyporeflexia, cramps, and paresthesias all begin as early signs. Paralysis (even of the respiratory muscles) and rhabdomyolysis are seen at levels below 1.5 meq/L.

Gastrointestinal: The gastrointestinal tract demonstrates an increased tendency to intestinal ileus.

Renal: Hypokalemia increases renal tubular production of ammonia, which may aggravate hepatic encephalopathy. Its direct effect on the kidney results in urinary-concentrating defects and decreased glomerular filtration and tends to cause a metabolic alkalemia with increased acid excretion in the urine (paradoxical aciduria). Severe hypokalemia can lead to nephrogenic DI with volume loss.

Endocrine: Hypokalemia leads to glucose intolerance.

Cardiovascular: Perhaps the most important effects are those on the cardiovascular system. These include worsening hypertension, orthostatic hypotension, potentiation of digitalis, and dysrhythmias. The classic electrocardiographic (ECG) abnormalities associated with hypokalemia include T-wave flattening, prominent U waves, and ST-segment depression. Tachyarrhythmias predominate.

TREATMENT   The treatment of hypokalemia is quite simple: replacement of K$^+$. This can be done orally in stable patients who are able to tolerate oral intake. Either foods rich in K$^+$, salt substitutes, or K$^+$ supplements will work. Intravenous replacement is appropriate for patients with severe hypokalemia. It can also be given as 10 to 20 meq/L in 100 mL of 0.9% saline. The ECG should be continually monitored for any patient receiving intravenous K$^+$. As a rule, no more than 40 meq of K$^+$ should be in a single liter of intravenous fluid and no more than 40 meq should be given in 1 h. Concentrations greater than 20 meq/L should be infused through a central line. A 20-meq infusion will raise serum [K$^+$] by approximately 0.25 meq/L.[5]

Hyperkalemia

Hyperkalemia is defined as measured serum [K$^+$] of greater than 5.5 meq/L. If hyperkalemia is noted, oliguric renal failure, severe hemolysis, or excessive tissue breakdown should be suspected. However, the most common cause of hyperkalemia is pseudohyperkalemia. This may be due to hemolysis during blood draw or from breakdown of cells if blood is not analyzed within 30 min of phlebotomy. Other causes of hyperkalemia are listed in Table 23-8.

TABLE 23-8   Etiology of Hyperkalemia

Clinical manifestations of hyperkalemia usually result from derangement in membrane polarization. Cardiac manifestations are the most serious. They include ECG changes ranging from

6.5 to 7.5 meq/L	:tall peaked T waves, short QT interval, and prolonged PR interval
7.5 to 8.0 meq/L	:QRS widening, and flattening of the P wave
10 to 12 meq/L	:the QRS complex may degrade into a "sine wave" pattern

Ventricular fibrillation, complete heart block, and asystole may occur. Death from hyperkalemia is usually the result of diastolic arrest or ventricular fibrillation. Neuromuscular manifestations include weakness, paresthesias, areflexia, and ascending paralysis. The gastrointestinal symptoms include nausea, vomiting, intermittent intestinal colic, and diarrhea. Patients with slowly developing hyperkalemia often tolerate serum [K$^+$] of 7 to 8 meq/L, whereas, with acute elevations, significant problems, including cardiac arrest, can occur at most lower levels.

TREATMENT   If there are no cardiac derangements, the initial step in the treatment of hyperkalemia is to confirm the presence of "true" hyperkalemia. Immediate cessation of further K$^+$ administration as well as clinical determination of severity will drive management. Asymptomatic patients with relatively small elevation of K$^+$ (5.0 to 6.0 meq/L) require determination and treatment of the underlying cause. As patients become symptomatic, management must become more aggressive. It is divided into three phases:

1. Membrane stabilization (especially cardiac tissue)
2. Shift K$^+$ from ECF to ICF
3. Removal of K$^+$ from the body

Membrane stabilization can be achieved with calcium gluconate or calcium chloride. This is usually indicated in any patient with evidence of cardiac irritability or acutely elevated levels of greater than 7.5 meq/L. It acts to antagonize the effect of K$^+$ on the cardiac conduction system. It is administered in a dose of 10 to 20 mL of 10% calcium gluconate (4.6 meq/10 mL) or as 5 mL of 10% calcium chloride (13.6 meq/10 mL) intravenously over 2 to 5 min. The effect of calcium occurs within 1 to 3 min of administration and remains pharmacologically active for up to 1 h.

If calcium is to be given to a patient on digitalis, great caution must be exercised, as hypercalcemia potentiates the toxic cardiac effects of digitalis. If it is to be given in this setting, it is best added to 100 mL of D$_5$W and infused slowly over at least 20 to 30 min, allowing a more even distribution throughout the extracellular space.

Patients without evidence of cardiac irritability or instability may be approached more slowly. The shifting of K$^+$ to the ICF can be achieved in various ways. The administration of 50 g of glucose with 5 to 10 units of regular insulin intravenously will help to redistribute K$^+$. Onset of action is approximately 30 min, with duration of action from 4 to 6 h. Some authorities believe that in patients with normal pancreatic function, glucose administration alone suffices, as the patient's own physiologic mechanism will result in insulin secretion. After the initial glucose has been administered, 1 L of 20% glucose with 20 to 40 units of regular insulin may be infused over the next 2 to 4 h, if necessary. Sodium bicarbonate acts through both antagonism and redistribution. It should be administered as 50 to 100 meq (1 to 2 ampules) intravenously over 2 min. Its onset of action is 5 to 10 min, with duration of 1 to 2 h. Lastly, b agonists help to redistribute K$^+$ into cells. The most practical route of administration is nebulized albuterol.

The removal of K$^+$ from the body can be achieved in three ways: via the urine, via stool, or through dialysis. Diuretics block the reabsorption of K$^+$, leading to increased excretion. Furosemide is the drug of choice, administered at 40 mg intravenously. Other diuretic options include ethacrynic acid or other loop diuretics. For obvious reasons, avoid K$^+$-sparing diuretics. Cation-exchange resins such as sodium polystyrene (Kayexalate) can be taken either orally or rectally. Each gram of sodium resin exchanges and thus eliminates about 1 meq of K$^+$. Orally, 15 to 50 g of sodium polystyrene is given with 50 mL of a 20% sorbitol solution every 4 to 6 h. The sorbitol helps overcome the constipating effect of the resin and speeds bowel transit. Rectal administration is 20 g in 200 mL of a 20% sorbitol solution every 4 h, with the enema retained for at least 30 min. Care must be taken in patients with fluid overload or those sensitive to Na$^+$. Congestive heart failure may be precipitated. Dialysis is reserved for severely ill patients or those already on dialysis. Peritoneal dialysis or hemodialysis may be instituted depending on the situation.

If a dangerous tachyarrhythmia develops, all of the foregoing steps may have to be undertaken nearly simultaneously (Table 23-9). In patients with oliguric renal failure, hemodialysis (or peritoneal dialysis) stat consultation for dialysis should also be undertaken.

Therapy	Mechanism	Dose	Onset of Action	Duration of Hypokalemic Effect
Ca gluconate (10%)	Antagonism	10–20 mL IV	1–3 min	30–50 min
Na bicarbonate	Antagonism and redistribution	50–100 meq IV	5–10 min	1–2 h
Insulin plus glucose	Redistribution	20 U regular insulin with 50 g glucose IV over 1 h	30 min	4–6 h
Diuretics Furosemide Ethacrynic acid	Excretion	40 mg IV 50 mg IV	With diuresis	With diuresis
Cation-exchange resin (sodium polystyrene)	Excretion	15–50 g PO or rectally with sorbitol	1–2 h	4–6 h
Peritoneal dialysis or hemodialysis	Excretion		Within minutes	During dialysis

TABLE 23-9 Emergency Therapy of Hyperkalemia

CALCIUM (Ca^{2+})

Calcium is the most abundant mineral in the body. The total body calcium is between 1.0 and 1.5 kg or 10 and 20 g/kg of body weight in an average-sized adult. Calcium, also the most abundant cation in the body, is 99 percent bound in bone as phosphate and carbonate (mineral apatite), with the remainder in the ECF compartment. The normal daily intake of calcium is 800 to 3000 mg, one-third of which is absorbed primarily in the small bowel via both active (vitamin D–dependent) and passive (concentration-dependent) absorption. Most of the calcium we ingest is found in milk and milk products. Most of this calcium is excreted through the gastrointestinal tract via the stool, with 200 mg or less in the urine.

The gradient between the intravascular and extravascular compartments is highly regulated to maintain a ratio of 10,000:1. The measured serum concentration of calcium ranges from 8.5 to 10.5 mg/dL and is maintained by the function of parathyroid hormone, vitamin D metabolites (1a,25-dihydroxyvitamin D $_3$, or calcitriol), and calcitonin.

Parathormone (parathyroid hormone, or PTH) is secreted by the parathyroid gland in response to low ionized calcium or magnesium levels. It raises serum calcium primarily by stimulating osteoclasts to increase bone resorption. It secondarily increases serum calcium by both indirect action in the kidney (increases calcium resorption and phosphorus excretion) and in conjunction with calcitriol to increase intestinal absorption. Calcitonin is influenced by elevations in serum calcium, epinephrine, glucagon, and gastrin. Its primary effect is to inhibit the activity of osteoclasts, with a limited secondary effect to potentiate calcium loss through the kidney. Vitamin D can be produced nonenzymatically by ultraviolet irradiation of skin or can be absorbed directly from the gastrointestinal tract. It is hydroxylated first in the liver and again in the kidney to create its more potent form. Upregulation of this process occurs with hypocalcemia or hypophosphatemia.

The intravascular calcium exists as 50 percent bound to plasma proteins, i.e., albumin (4.0 to 4.5 mg/dL), 45 percent free active ions (4.2 to 4.8 mg/dL), and 5 percent nonionized (bound to other substances in plasma and interstitial fluids). A laboratory value reported in meq/L is equal to half the amount in mg/dL; therefore, a value of 4.2 mg/dL = 2.1 meq/L (= 1.05 mosm/L).

Changes in hydrogen concentration result in changes to the ionized calcium concentration. This occurs because calcium binds to the protein in place of hydrogen ions. For example, hyperventilation leads to respiratory alkalosis and an attendant decrease in [H$^+$]. The decreased [H$^+$] causes an increase in protein-bound calcium and a decrease in serum ionized calcium (relative hypocalcemia).

It is the ionized fraction that is physiologic activity. Signs and symptoms of hypocalcemia usually occur when the ionized fraction drops below 3.0 mg/dL, while those associated with hypercalcemia occur with total serum calcium greater than 11 mg/dL.

Various factors affect serum calcium:

1. Serum protein, of which albumin is the major component. On average, 0.8 mg of calcium binds to 1 g of protein. Therefore, total serum [Ca^{2+}] = ionized [Ca^{2+}] + (0.8 * total protein). A 1-g decrease in albumin results in a 0.8 mg/dL decrease in calcium with no change in ionized fraction.
2. Alkalosis: decrease in ionized fraction with no change in the total serum calcium. Each 0.1 rise in pH lowers ionized [Ca^{2+}] by about 3 to 8 percent.
3. Acidosis: increase in ionized fraction with no change in the total serum calcium.

Hypocalcemia

Hypocalcemia is defined by an ionized calcium level of below 2.0 meq/L. In the presence of hypoalbuminemia, total calcium may be very low, yet ionized calcium remains normal. Some more common causes of hypocalcemia include shock, sepsis, renal failure, and pancreatitis. It is quite uncommon in ambulatory patients, except those with hypoparathyroidism (secondary to surgery) or in chronic renal disease.

ETIOLOGY (Table 23-10) **Movement into "Sick" Cells** The concentration of ionized calcium in the ECF is about 1.0 mmol/L or 10^{-3} M. The concentration of ionized calcium in the cytoplasm of most cells is about 10^{-7} M. This gradient of 10^4, or 10,000, to 1 is maintained by active metabolic processes. Any process that interferes with cell metabolism, such as shock or sepsis, will tend to reduce ionized calcium levels by allowing increased net movement of calcium across the cell membrane into the cytoplasm of the poorly functioning cells. Following trauma, serum calcium levels may be low, especially with the fat embolism syndrome, not only because of cell dysfunction and binding of calcium to free fatty acids, but also because of fatty inhibition of cell membrane calcium pumps.

TABLE 23-10 Etiology of Hypocalcemia

Pancreatitis Acute pancreatitis is an important cause of hypocalcemia. Pancreatic lipase breaks down fat into fatty acids and glycerol. The fatty acids combine with calcium to form insoluble calcium soaps and reduce serum calcium levels. The combination of necrotic fat cells plus calcium soaps makes up much of what is recognized as the fat necrosis of pancreatitis. In addition, as protein moves into the inflammatory exudate, the resultant hypoproteinemia may cause total calcium levels to fall. Pancreatitis can also reduce PTH secretion and the response of tissues to it. If total calcium levels fall below 7.0 or 8.0 mg/dL, there is an increased chance of severe complications from pancreatitis.

Drugs A large number of drugs can cause hypocalcemia (Table 23-11). One of the most frequently used of these is cimetidine. This histamine receptor–blocking

agent apparently lowers serum calcium levels by decreasing the synthesis or secretion of parathyroid hormone.

Cimetidine
Phosphates (e.g., enemas, laxatives)
Dilantin, phenobarbital
Gentamicin, tobramycin, actinomycin
Cisplatin
Heparin
Theophylline
Protamine
Glucagon
Norepinephrine
Citrate (blood)
Loop diuretics
Glucocorticoids
Magnesium sulfate
Sodium nitroprusside

TABLE 23-11   Drugs that Can Cause Hypocalcemia

Postoperative Hypocalcemia   HYPOPARATHYROIDISM   Currently, more than 10 percent of postparathyroidectomy patients may have hypoparathyroidism as defined by a fasting calcium level of less than 8.5 mg/dL and a simultaneous inorganic phosphorus level of greater than 4.5 mg/dL. Postoperative hypocalcemia can be due to hypoparathyroidism from the permanent surgical removal of parathyroid tissue, from transient ischemia of the parathyroid glands in patients who have extensive bilateral neck surgery, or because of long-term hypercalcemic suppression of the nonadenomatous parathyroid glands.

HUNGRY-BONE SYNDROME   The term *hungry-bone syndrome* was coined by Albright and now indicates postparathyroidectomy hypocalcemia due to rapid remineralization of the skeleton. During this accelerated remineralization, a persistent hypocalcemia and hypophosphatemia may be severe enough to cause tetany. These patients may require vigorous calcium and vitamin D supplementation for prolonged periods of time.

The hungry-bone syndrome may be found in over 10 percent of patients after parathyroid surgery. Patients are at risk if they have a fasting calcium level of less than 8.5 mg/dL and a simultaneous inorganic serum phosphorus of less than 3.0 mg/dL on postoperative day 3 or later.

Renal Failure   Hypocalcemia is a frequent finding in renal failure. This may be partially due to the resulting hyperphosphatemia, but there is also decreased production of $1a,25\text{-}(OH)_2$-vitamin D in the kidney, which, in turn, causes decreased intestinal absorption of calcium. Secondary hyperparathyroidism with increased PTH levels often results from the chronic hypocalcemia. If PTH levels remain elevated and hypercalcemia develops in spite of cure of the renal failure by renal transplantation, the patient is said to have tertiary hyperparathyroidism.

Phosphate Overload   Phosphate overload from nonrenal causes may also lead to hypocalcemia. This is the presumed mechanism in the acute rhabdomyolysis of hyperpyrexia and major trauma. Excessive use of phosphate cathartics and sodium phosphate enemas can cause significant hyperphosphatemia in patients with renal disease, in children with Hirschsprung disease, and in small infants.

Hypomagnesemia   Hypomagnesemia in association with hypocalcemia may be seen in alcoholism, diuretic use, epilepsy, and renal failure. Neonatal hypomagnesemia leads to low PTH secretion, decreased responsiveness of bone cells to PTH, and decreased calcium mobilization from bone.

Idiopathic Hypoparathyroidism   Idiopathic hypoparathyroidism is probably an autoimmune disorder in which pernicious anemia, exostoses, moniliasis, Hashimoto disease, sterility, and Addison disease may be seen. This syndrome may also be associated with cataracts, mental retardation, intracranial calcifications, and papilledema due to increased intracranial pressure.

Nonsurgical Primary Hypoparathyroidism   Hypocalcemia with primary hypoparathyroidism has been reported from parathyroid infarction, metastases to the parathyroids, and hemochromatosis of the parathyroids.

Pseudohypoparathyroidism   Pseudohypoparathyroidism is a familial disorder characterized by decreased end-organ responsiveness to PTH resulting in hypocalcemia, hyperphosphatemia, parathyroid hyperplasia, and excessive serum PTH concentrations. These patients usually have a very low urinary cyclic AMP excretion that only slightly increases with infusion of parathormone. This condition may be inherited as an X-linked dominant trait with variable penetrance; the male to female ratio is 2 to 1. Patients are short and have round faces; brachycephaly; a short, thick neck; short, pudgy fingers and toes; and growth failure of the fourth and fifth metacarpals. Mental retardation, seizures, and subcutaneous soft tissue calcification may be seen. The skin can be dry and coarse, and the hair is often brittle.

Vitamin D Deficiency   Hypocalcemia due to vitamin D deficiency is rare in the United States. Infants born to vitamin D–deficient mothers who lack sunlight exposure and receive no vitamin D supplementation may have rickets. Breast milk has low vitamin D content, and breast milk feeding without sunshine exposure in unsupplemented infants may result in infantile rickets.

PHYSIOLOGIC EFFECTS   Although normal ionized calcium levels are 2.1 to 2.6 meq/L (1.05 to 1.3 mmol/L), serious physiologic changes do not usually occur until ionized levels in serum are less than 1.4 to 1.6 meq/L (0.7 to 0.8 mmol/L). Below those levels, hypocalcemia can cause a wide variety of signs and symptoms (Table 23-12).

General	Muscular
Weakness, fatigue	Spasms, cramps
Neurologic	Weakness
Tetany	Skeletal
Chvostek sign, Trousseau sign	Osteodystrophy
Circumoral and digital paresthesias	Rickets
Impaired memory, confusion	Osteomalacia
Hallucinations, dementia, seizures	Miscellaneous
Extrapyramidal disorders	Dental hypoplasia
Dermatologic	Cataracts
Hyperpigmentation	Decreased insulin secretion
Coarse, brittle hair	
Dry, scaly skin	
Cardiovascular	
Heart failure	
Vasoconstriction	

TABLE 23-12   Symptoms and Signs of Hypocalcemia

The severity of signs and symptoms depends greatly on the rapidity of the fall in calcium. The more acute the drop in the serum calcium, the more likely are significant pathophysiologic changes. As serum calcium levels fall, neuronal membranes become increasingly more permeable to sodium, enhancing excitation. Potassium and magnesium have an antagonizing effect on this excitation.

Decreased ionized calcium levels reduce the strength of myocardial contraction primarily by inhibiting relaxation. They also decrease the sensitivity of the heart to digitalis. Hypocalcemia should be considered in patients with refractory heart failure.

Low ionized calcium levels increase PTH secretion, which mobilizes calcium from bone and decreases renal tubular absorption of phosphate and bicarbonate. This, in turn, may cause an increased absorption of chloride, producing a tendency to hyperchloremic hypophosphatemic renal tubular acidosis. A ratio of chloride to

phosphate greater than 35 to 1 in meq/mg in the plasma is sometimes considered to be highly suggestive of hyperparathyroidism.

Increased cytoplasmic calcium activates phospholipase, which increases prostaglandin production and alters cell lipids. Increased cytoplasmic calcium also interferes with cell metabolism. Efforts by mitochondria to pump the excess calcium from the cytoplasm into the mitochondrial matrix greatly reduce adenosine triphosphate (ATP) formation. Consequently, giving calcium during shock or sepsis may transiently improve hemodynamics, but if cell metabolism does not also improve, some of the additional calcium moves into the cytoplasm within 30 to 40 min and further impairs cell metabolism.

Movement of calcium into ischemic cerebrovascular smooth muscle cells may cause persistent cerebral vasoconstriction with resultant failure of cerebral reperfusion after strokes or cardiac arrest. This may be a major cause of the poor results in management of these problems. Consequently, there has been some interest in the use of calcium blockers for cerebral resuscitation.

DIAGNOSIS   **Symptoms**   The most characteristic initial symptom of hypocalcemia following thyroid or parathyroid surgery is paresthesias around the mouth or in the fingertips. Hypocalcemia should be suspected in any patient who is irritable and has hyperactive deep tendon reflexes following neck surgery. It should also be suspected in patients who have seizures particularly if they have ever had thyroid surgery, even if many years previously.

Signs   A positive Chvostek or Trousseau sign is generally considered to be good clinical evidence of hypocalcemia. A positive Chvostek sign is a twitch at the corner of the mouth when the examiner taps over the facial nerve just in front of the ear. However, it is present in about 10 to 30 percent of normal individuals. Nevertheless, eyelid muscle contraction with the Chvostek maneuver is said to be almost diagnostic of hypocalcemia.

Trousseau sign, which is generally a more reliable indicator of hypocalcemia, is positive if carpal spasm is produced when the examiner applies a blood pressure cuff to the upper arm and maintains a pressure above systolic for 3 min. The fingers are spastically extended at the interphalangeal joints and flexed at the metacarpophalangeal joints. The wrist is flexed and the forearm is pronated.

Laboratory Findings   Signs of hypocalcemia may be found with normal total serum calcium levels if a patient is very alkalotic. Each 0.1 rise in pH lowers ionized calcium levels by about 3 to 8 percent. Consequently, a very alkalotic patient may have normal total serum calcium levels with ionic hypocalcemia. Similar signs and symptoms may be caused by hypomagnesemia, strychnine, or tetanus toxin.

Decreased plasma levels of ionized calcium are diagnostic, but one should also suspect ionic hypocalcemia if a patient has decreased levels of total calcium in the presence of normal plasma proteins. Primary hypoparathyroidism is characterized by a low serum PTH concentration, hyperphosphatemia, and hypocalcemia.

ECG   The most characteristic ECG finding in hypocalcemia is prolonged QT intervals. However, the T wave is of normal width, and it is the ST segment that is really prolonged. This finding is usually seen with total serum calcium levels less than 6.0 mg/dL.

X-rays   Radiologically, rickets is characterized by craniotabes, frontal skull bossing, rachitic rosary ribs, widened rib cage (Harrison groove), bowed legs, and, often, fractures. Other radiographic changes include cupping and splaying of the metaphyseal ends of long bones, widening between the metaphyses and epiphysis, bone demineralization, and thinning of cortical bone.

TREATMENT   Treatment of hypocalcemia is tailored to the individual and directed toward the underlying cause. If a patient is asymptomatic, oral calcium therapy with or without vitamin D may be all that is required. Calcium lactate, calcium glubionate, calcium ascorbate, calcium carbonate, and calcium gluconate are available in oral preparations. Milk, because of the large amount of phosphate present, is not really a very good source of calcium, except in normal growing children who also need the phosphate.

Symptomatic patients following thyroid or parathyroid surgery are often treated with parenteral calcium. With severe acute hypocalcemia, 10 mL of 10% $CaCl_2$ (or 10 to 30 mL of 10% calcium gluconate) may be given intravenously (IV) over 10 to 20 min followed by a continuous IV drip providing 1 g of $CaCl_2$ over a period of 6 to 12 h. If the patient is not asymptomatic or if the hypocalcemia is not severe and prolonged for more than 10 to 14 days, treatment with calcium may not be required. One should not administer calcium rapidly IV to asymptomatic patients with mild to moderate hypocalcemia because it can cause severe unnecessary cardiovascular, neuromuscular, and renal complications.

During massive transfusions, if the blood is being given faster than 1 unit every 5 min, 10 mL of 10% calcium chloride can be given after every 4 to 6 units of blood if a patient is in shock or heart failure in spite of adequate volume replacement therapy. Calcium is seldom required during transfusions for elective surgery.

Hypercalcemia

Hypercalcemia is a relatively common entity. It is defined as a total calcium level exceeding 10.5 mg/dL or an ionized calcium level exceeding 2.7 meq/L. Over 90 percent of occurrences are associated with hyperparathyroid or malignancy. Various mnemonics exist to help recall the long list of potential etiologies for hypercalcemia (Table 23-13).

Malignancy	Granulomatous disease
Lung (squamous cell cancer)	Sarcoidoses
Breast	Tuberculosis
Kidney	Histoplasmosis
Myeloma	Coccidioidomycosis
Leukemia	Immobilization
Endocrinopathies	Miscellaneous
Primary hyperparathyroidism	Paget's disease of bone
Hyperthyroidism	Postrenal transplantation
Pheochromocytoma	Recovery from acute renal failure
Adrenal insufficiency	Phosphate depletion syndrome
Acromegaly	
Drugs	
Hypervitaminosis D and A	
Thiazides	
Lithium	
Hormonal therapy for breast cancer	

TABLE 23-13   Causes of Hypercalcemia

PATHOPHYSIOLOGIC EFFECTS   The effects of hypercalcemia can be neuromuscular, cardiovascular, gastrointestinal, renal, and skeletal. Neuromuscular changes include decreased sensitivity, responsiveness, and strength of muscular contraction and nerve conduction. This causes increasing weakness and fatigue that may progress to ataxia and altered mental status.

In mild hypercalcemic states, the heart's conduction is slowed and automaticity is decreased with a shortening of the refractory period. There is also increased sensitivity to digitalis preparations.

Loss of renal concentrating ability, as might be expected with nephrogenic DI, is the most frequent renal effect of hypercalcemia. This is a reversible tubular defect, which results in polyuria and dehydration in spite of polydipsia. Potassium wasting results in hypokalemia in up to one-third of patients. Nephrocalcinosis and nephrolithiasis are caused by the hypercalcemia and aggravated by volume depletion. As the hypercalcemia persists, increasing microscopic calcium deposits in the kidney may result in progressive renal insufficiency.

Hypertension is seen with increased frequency in hypercalcemic patients, probably as a result of arteriolar vasoconstriction.

DIAGNOSIS   Hypercalcemic patients with plasma total calcium levels below 12.0 mg/dL are usually asymptomatic, but higher levels can cause a wide variety of

symptoms and signs (Table 23-14).

TABLE 23-14   Symptoms and Signs of Hypercalcemia

Patients with total calcium levels above 14 to 16 mg/dL are usually very weak, lethargic, and confused. Coma is uncommon, but calcium levels should probably be determined in any patient with coma of unknown etiology. Polyuria, in spite of polydipsia, tends to cause increasing volume depletion. Weariness and weakness are common with hypercalcemia. Polyuria and polydipsia are due to impaired renal tubular reabsorption of water. Total calcium levels above 15.0 mg/dL may cause somnolence, stupor, and even coma.

A mnemonic sometimes used for the signs and symptoms of hypercalcemia is *stones* (renal calculi), *bones* (osteolysis), *moans* (psychiatric disorders), and *groans* (peptic ulcer disease and pancreatitis). The most common gastrointestinal symptoms are anorexia and constipation, but these are very nonspecific.

Hypercalcemia should be suspected in patients with extensive metastatic bone disease, particularly if the primary site involves the breast, lungs, or kidneys, and in individuals with combinations of clinical problems such as renal calculi, pancreatitis, or ulcer disease. As with hypocalcemia, ionized calcium levels should be measured and/or total calcium levels should be correlated with serum proteins. If a patient is hypoproteinemic, total calcium levels may be normal or low in spite of increased ionized calcium levels.

On ECG, hypercalcemia may be associated with depressed ST segments, widened T waves, and shortened ST segments and QT intervals. Bradyarrhythmias may occur, and bundle branch patterns may progress to second-degree block and then complete heart block. Levels above 20 mg/dL may cause cardiac arrest.

TREATMENT   Up to one-third of patients with hypercalcemia have hypokalemia, and in those with malignant disease, more than half the patients may have hypokalemia. Some patients also have hypomagnesemia. The tendency toward hypokalemia and hypomagnesemia will be aggravated by diuresis and should be monitored carefully. A number of modalities are available to treat hypercalcemia (Table 23-15). Mithramycin, calcitonin, and hydrocortisone should be used in severe cases. Mithramycin is a cytotoxic drug that suppresses bone resorption and calcium release from bone. It is infused over 3 h. It is particularly useful in patients with metastatic bone disease. Calcitonin is also an osteoclast inhibitor but less toxic than mithramycin. When used in conjunction with corticosteroids, resistance to calcitonin may be delayed. Glucocorticoids are useful in patients with sarcoidosis, vitamin A or D intoxication, multiple myeloma, leukemia, or breast cancer. They work by inhibiting bone resorption and gastrointestinal absorption of calcium. It is also postulated that they cause Ca $^{2+}$ to shift inside cells where it may become bound to mitochondria. Gallium nitrate has been approved for use in the United States. [6] It acts by decreasing the solubility of base crystals. It is administered in a dose of 200 mg/m^2 added to 1 L of fluid in 24 h. It potentiates nephropathy and its use should be avoided in renal disease. Intravenous phosphates are no longer used.

TABLE 23-15   Treatment of Hypercalcemia

MAGNESIUM (Mg^{2+})

Mg^{2+} is a vital element in all biologic systems and is the key element in chlorophyll, the first link in the world's food chain. The total body content of Mg $^{2+}$ is 24 g, or 2000 meq. Of this, 50 to 70 percent is fixed in bone and is only slowly exchangeable. Most of the remaining Mg $^{2+}$ (approximately 40 percent) is found in the ICF space, with a concentration of approximately 40 meq/L. The distribution of Mg $^{2+}$ is similar to that of potassium, with the major portion intracellular. It is the second most abundant intracellular cation. Serum [Mg^{2+}] ranges between 1.5 and 2.5 meq/L. Mg^{2+} present in blood is 25 to 35 percent protein-bound, 10 to 15 percent complexed, and 50 to 60 percent ionized. The normal dietary intake of Mg $^{2+}$ is approximately 20 to 28 meq/day, or 240 to 336 mg/day, and is found in vegetables such as dry beans and leafy greens, meat, and cereals. The majority of Mg $^{2+}$ is excreted through the gastrointestinal tract in the stool (60 percent) with the remainder (40 percent) in the urine. The kidney is very capable of conserving Mg $^{2+}$. A person on an Mg^{2+}-free diet will excrete less than 1 meq/day through the urine. Mg $^{2+}$ promotes enzyme reactions within the cell during metabolism, helps in the production of ATP, participates in protein synthesis, and plays a role in coagulation, platelet aggregation, and neuromuscular activity.

Hypomagnesemia

The three major intracellular components—Mg^{2+}, K$^+$, and PO$_4^-$—usually travel together; therefore, the loss and deficiency of one constituent usually leads to the loss and deficiency of the others. As with most intracellular components, loss of total body Mg $^{2+}$ may occur when serum levels are normal.

ETIOLOGY   A wide variety of problems can cause hypomagnesemia (Table 23-16). In adults, magnesium deficiencies are most frequently seen in alcoholics, in malnourished patients, and in patients with cirrhosis, pancreatitis, or excessive gastrointestinal fluid losses. Diarrhea is usually more of a problem (Mg $^{2+}$ content of 10 to 14 meq/L) than upper gastrointestinal loss (1 to 2 meq/L).

TABLE 23-16   Causes of Hypomagnesemia

Intravenous hyperalimentation or treatment of diabetic ketoacidosis without providing adequate magnesium, especially in a previously malnourished patient, can cause an abrupt fall in plasma magnesium levels. This is largely due to magnesium being "pulled" into cells with glucose or as new lean body mass is synthesized. Hypophosphatemia, which can also develop with IV hyperalimentation, can contribute to the hypomagnesemia.

Renal wasting of magnesium can be seen with loop diuretics, hypophosphatemia, ketoacidosis, aminoglycosides, and nephrotoxic chemotherapeutic agents.

The normal renal threshold for magnesium (1.5 to 2.0 meq/L) is significantly decreased by cisplatin, diuretics, hypercalcemia, growth hormone, thyroid hormone, and calcitonin. Cisplatin causes dose-dependent, cumulative, reversible renal tubular injury. Even when the glomerular filtration rate is not diminished by cisplatin, renal magnesium wasting along with a secondary hypocalcemia and hypokalemia may develop. Potassium wasting is thought to occur as a result of impaired ATP production when magnesium is low. This in turn impairs the function of the membrane Na^+/K^+ transport system and causes loss of the normal Na^+/K^+ gradient. The accompanying hypocalcemia may be due to (1) impaired PTH release by the parathyroid gland, (2) decreased peripheral sensitivity to PTH, or (3) abnormal blood-bone calcium balance independent of PTH.

PHYSIOLOGIC EFFECTS   Magnesium is essential to a large number of vital enzymes, including membrane-bound ATPase. Consequently hypomagnesemia may result in a wide variety of neuromuscular, gastrointestinal, and cardiovascular changes (Table 23-17).

TABLE 23-17   Symptoms and Signs of Hypomagnesemia

Hypomagnesemia may cause increased muscular irritability similar to that seen with hypocalcemia. It can also cause many CNS signs and symptoms, including depression, vertigo, ataxia, and seizures. In severe chronic alcoholics, delirium tremens is often associated with moderate to severe magnesium deficiencies. Cardiac dysrhythmia, particularly in patients on digitalis, is often due to both potassium and magnesium deficiencies.

Some metabolic manifestations of magnesium deficiency include difficulties in treating hypokalemia, impaired PTH secretion, decreased response to thiamine, and vitamin D–resistant hypocalcemia. Other manifestations include hypothermia, hypotension, nephropathy, incomplete distal renal tubular acidosis, dysphagia, and anemia due to shortened red blood cell survival.

It has been noted that patients with severe acute pancreatitis and hypocalcemia usually have normal serum magnesium levels; however, there is an intracellular and total body magnesium deficiency. This may contribute to the severity of the pancreatitis and the pathogenesis of the hypocalcemia.

DIAGNOSIS   One cannot rely on plasma levels to diagnose magnesium deficiencies because it is not unusual to have severe total body magnesium depletion before plasma levels are lowered. The diagnosis of hypomagnesemia in the presence of normal serum calcium levels is suggested by increased neuromuscular irritability (hyperreflexia, positive Chvostek or Trousseau signs, tremor, tetany, or even convulsions). Hypomagnesemia should be suspected in alcoholics, cirrhotics, and patients on IV fluids for prolonged periods. Hypomagnesemia may also develop rapidly during IV hyperalimentation, especially when anabolism begins.

The ECG changes seen with magnesium deficiencies include prolonged PR and QT intervals, widened QRS complexes, depression of ST segments, and inversion of T waves, especially in the precordial leads. The changes may be somewhat similar to those caused by hypokalemia and/or hypocalcemia, and many of these changes may be related to Mg^{2+} deficiency altering cardiac intracellular potassium content.

TREATMENT   Hypokalemia, hypocalcemia, and hypophosphatemia are often present with hypomagnesemia and must be monitored carefully. Hypocalcemia does not develop until $[Mg^{2+}]$ falls below 1.2 mg/dL.

Patients with magnesium deficiency may require more than 50 meq of oral magnesium (6 g $MgSO_4$) per day. In chronic alcoholics with delirium tremens and in patients with severe proven hypomagnesemia, up to 8 to 12 g of $MgSO_4$ may be given intramuscularly or intravenously the first day. The first 10 to 15 meq (1.5 to 2.0 g) of IV $MgSO_4$ can be given over 1 to 2 h. This may be followed by up to 4 to 6 g/day thereafter.

If magnesium is being given rapidly, as in the treatment of eclampsia, the deep tendon reflexes (which disappear at about 3 to 4 meq/L) should be checked frequently, and blood levels should be measured once or twice daily. If deep tendon reflexes decrease or disappear, magnesium administration should stop, at least temporarily.

Hypermagnesemia

Hypermagnesemia is rarely encountered in emergency practice. A small elevation in serum concentration has little clinical significance. The most common etiology for hypermagnesemia can be found in patients with renal insufficiency or renal failure who ingest Mg^{2+}-containing drugs. Hypermagnesemia may be seen in the perinatal setting in both a mother and her neonate secondary to the treatment of preeclampsia/eclampsia. Other etiologies of hypermagnesemia include lithium ingestion, volume depletion, or familial hypocalciuric hypercalcemia (Table 23-18).

TABLE 23-18   Causes of Hypermagnesemia

PHYSIOLOGIC EFFECTS   Hypermagnesemia only rarely produces symptoms. Mg^{2+} significantly decreases the transmission of neuromuscular messages and thus acts as a CNS depressant and decreases neuromuscular activity. An initial finding in hypermagnesemic patients is nausea that appears with serum levels greater than 2.0 meq/L. Somnolence may develop as levels approach 3.0 meq/L. Deep tendon reflexes tend to disappear at serum concentrations of 4.0 to 8.0 meq/L, and respiratory compromise or apnea is seen at higher levels, approximately 8.0 to 12.0 meq/L. Hypotension, heart block, or cardiac arrest may be seen with levels approaching 15.0 meq/L. ECG abnormalities such as prolonged PR and QT intervals and increased QRS duration may be seen at any level above 5.0 meq/L.

DIAGNOSIS   Serum magnesium levels are usually diagnostic. The possibility of hypermagnesemia should be considered in patients with hyperkalemia or hypercalcemia. Hypermagnesemia should also be suspected in patients with renal failure, particularly in those who are taking magnesium-containing antacids, such as Maalox (see Table 23-18).

TREATMENT   The only treatment available is the immediate cessation of Mg^{2+} administration. If renal failure is not evident, dilution by IV fluids followed by furosemide (40 to 80 mg IV) may be helpful. In symptomatic patients, 1 ampule (10 mL of 10%) calcium gluconate or 5 mL of 10% IV $CaCl_2$ (given over 5 to 10 min is appropriate). Patients with renal failure may benefit from dialysis against a decreased Mg^{2+} bath that lowers serum Mg^{2+} levels.

CHLORIDE (Cl⁻)

Alteration in serum chloride is seldom a primary disturbance. Chloride is a major extracellular anion that has the reciprocal power of increasing or decreasing in concentration whenever changes occur in the concentration of other anions. For example in non-anion-gap metabolic acidosis, the decrease in serum [HCO_3^-] is replaced by Cl^-. Cl^- plays a major role in the maintenance of urinary output, ECF, acid-base, potassium balance, and normal anion gap. Cl^- concentration is approximately 70 percent that of Na^+ and is diffusable and active. [Cl^-] should be between 95 and 105 meq/L. Cl^- is easily absorbed in the intestine by active and passive transport coexistent with Na^+ and HCO_3^-. Hydrogen and chloride ions are secreted into the gastric fluid while HCO_3^- is transported into the bloodstream. Therefore, significant gastric loss of H^+ and Cl^- from vomiting results in metabolic alkalosis. A total of 90 percent of Cl^- is excreted through the kidney, with a small percentage (10 percent) secreted in sweat and stool.

Hypochloremia

Hypochloremia usually manifests when levels are less than 95 meq/L. It is usually caused by excessive diuresis, vomiting, or nasogastric tube drainage. Volume loss results in alkalosis. When Cl^- is lost via the urine or gastrointestinal fluids, there is an increase in both Na^+ and HCO_3^- resorption secondary to the volume contraction. Na^+ may be resorbed in the kidney with either Cl^- or HCO_3^- acid. When Cl^- levels become low, the Na^+ is exchanged for H^+, and HCO_3^- is accentuated in the renal tubules. This loss of H^+ in the urine further worsens the alkalosis. There is also an increased delivery of Na^+ to the distal nephron for H^+ and K^+ exchange. This exchange potentiates the loss of H^+ and K^+ in the urine, exaggerating the alkalosis further. Secondary skin losses from severe sweating or burns, along with states in which sweat has excessive Cl^- (cystic fibrosis), often lead to a metabolic alkalosis also.

APPROACH   There are no signs or symptoms specific for hypochloremia. However, the clinical approach may be based on the findings of the secondary effects. For example, if a metabolic alkalosis is diagnosed and is judged to be due to volume contraction, the approach is to address the metabolic alkalosis. In fact, [Cl^-] can largely be ignored. Vomiting, nasogastric tube drainage, diuretics, or volume depletion may lead to hypochloremia but virtually never without an associated metabolic alkalosis. The symptoms of metabolic alkalosis include muscle weakness, irritability, and hypoventilation. Patients usually present with symptoms of volume depletion from the aforementioned etiologies, and electrolyte levels demonstrate a low [Cl^-] and [Na^+].

It is important then to determine the urinary [Cl^-] because low urinary [Cl^-] (less than 10 meq/L) in the setting of metabolic alkalosis implies chloride-responsive alkalosis (see Chap. 21, "Acid-Base Disorders"). If the urinary Cl^- levels are higher (greater than 40 meq/L), the hypochloremia may be secondary to volume overload or dilution. Increased urinary Cl^- may also result from increased mineralocorticoid activity, which leads to the retention of HCO_3^- and Na^+ at the expense of H^+, K^+, and Cl^-. This results in further positive feedback derangement. The Na^+ retention leads to volume expansion that increases the Na^+ delivery to the distal tubule. This ultimately leads to a greater exchange with K^+ and H^+, resulting in more H^+ and K^+ urinary losses. This acts to further the metabolic alkalosis.

The treatment of Cl^--responsive metabolic alkalosis (urinary [Cl^-] 10 meq/L) is IV NaCl administration. Generally speaking, emergency practice concerns itself with addressing the acute issues associated with the underlying condition. Chloride deficit per se rarely needs separate or specific consideration in the ED setting. However, as emergency practice extends to the realm of acute extended care, it is worthwhile to note that total body deficit can be determined by:

$$\text{serum } Cl^- \text{ deficit} * 20\% \text{ of the body weight} = \text{total body } Cl^- \text{ deficit}$$

The total body Cl^- should be repleted by giving 25 percent of the calculated Cl^- deficit as KCl and 75 percent as NaCl. In the setting of renal insufficiency or failure, treatment options are more complicated in that NaCl administration may lead to volume problems and KCl may lead to hyperkalemia. The replacement method of choice, amino acid hydrochlorides or 0.1 N HCl, will lead to a non-anion-gap acidosis, worsening the underlying wide-anion-gap acidosis associated with renal failure.

Hyperchloremia

Excessive amounts of Cl^- are usually the result of administration of NaCl, volume depletion, or entities causing metabolic acidosis without a widened anion gap (see Chap. 21, "Acid-Base Disorders").

NaCl, KCl, or amino acid hydrochlorides readily dissociate and bind with bicarbonate, leading to metabolic acidosis. The effects of hyperchloremia are a result of volume depletion or acidosis. Since Na^+ and Cl^- travel together, high levels of serum Na^+ are associated with high levels of serum Cl^-. Bicarbonate is inversely proportional to Cl^-, so hyperchloremia is associated with non-widened-anion-gap metabolic acidosis. If Na^+ levels are normal in the face of elevated Cl^-, one must think of KCl or amino acid hydrochloride administration (again leading to non-anion-gap acidosis). Finally, bromism, rarely seen today, may present with hyperchloremia, as Br^- is factitiously measured as Cl^- in hospital laboratories. A narrow anion gap will be an important clue in this latter diagnosis.

APPROACH   Similar to hypochloremia, clinical conditions associated with hyperchloremia, are rarely considered from the perspective of the serum [Cl^-]. Rather, the [Cl^-] is used as a diagnostic adjunct. For example, in the setting of metabolic acidosis, an elevated [Cl^-] will merely help confirm the acidosis type when it is also noted that the anion gap is not widened. Thus, rather than seeking the cause of the hyperchloremia, clinicians can approach the differential diagnosis from the perspective of the nonwidened metabolic acidosis (see Chap. 21, "Acid-Base Disorders"). Similarly, when [Cl^-] is elevated in hypernatremic states, the differential diagnosis can

be considered from the perspective of elevated [Na$^+$] and the volume status of the patient (vide supra).

TREATMENT   If there is excess administration of chloride or excessive losses of bicarbonate, this should be corrected. Hyperchloremia due to dehydration is best treated by slowly administering increased isotonic fluids with little or no chloride. However, if too much isotonic fluid is given too rapidly, seizures due to cerebral edema may develop.

PHOSPHORUS

Phosphorus is an essential mineral that exists mainly as hydroxyapatite (85 percent) or as an intracellular constituent (10 to 15 percent). Only about 1 percent is in the ECF, and therefore serum measurements may not accurately reflect total body stores. Serum phosphate levels decrease with age from a high of 4.0 to 7.0 mg/dL in newborns to 3.0 to 5.0 mg/dL in adults. The total body phosphorus in a normal man is approximately 700 g (10 to 15 g/kg). This is predominantly in bone (80 percent), where phosphorus plays a major role in structural integrity. Serum Ca^{2+} and phosphate are inversely proportional, and the product of their two concentrations is approximately 30 to 40 mg/dL. When phosphorus is not in the form of hydroxyapatite, it may be extracellular where it is in the form of inorganic ions. Intracellular phosphorus is bound to protein or exists as organic esters. Levels of inorganic phosphates are normally between 2.3 and 4.5 mg/dL.

Phosphorus, unlike the other elements, is 85 percent free and only 15 percent bound to proteins. Phosphate may be present in different forms such as H$_2$PO$_4^-$ or HPO$_4^{2-}$, and levels change with pH. The 85 percent of phosphorus that is free can be bound to Na$^+$, Ca^{2+}, or Mg^{2+}. Plasma phosphorus levels, unlike Ca^{2+} or Mg^{2+}, demonstrate diurnal variation with a morning nadir and are affected by age, hormones (insulin and growth hormone), and the amount of carbohydrate ingestion. Therefore, fasting levels should be measured, since glucose infusion as well as carbohydrate and phosphorus ingestion lower serum levels.

Normal daily intake is between 10 and 12 mmol. Phosphorus absorption is proportional to dietary intake. Approximately 70 percent is absorbed via passive transport, with the remainder via active transport, which is dependent on 1,25-(OH)$_2$-vitamin D. phosphate deficiency is rarely caused by a decrease in phosphorus oral intake unless absorption is affected. Phosphate excretion is proportional to oral intake. Excretion is predominantly in the urine by the glomerulus, with the majority resorbed in the proximal tubules. This is regulated by PTH, which acts to lower serum phosphate by increasing renal excretion. Proximal tubule absorption increases when serum phosphate levels drop, as well as with hypoparathyroidism, volume depletion, hypocalcemia, or the presence of growth hormone. Excretion increases in the presence of volume expansion, hypercalcemia, acidosis, hypomagnesemia, hypokalemia, glucocorticoids, diuretics, calcitonin, or PTH. Phosphate is essential to a wide variety of biochemical reactions, especially energy metabolism in the form of high-energy phosphate and phosphocreatine.

Hypophosphatemia

Since phosphorus is abundant in many foods and readily absorbed, hypophosphatemia is relatively unusual. Mechanisms leading to hypophosphatemia are reduced oral intake, excessive loss, or shift from the ECF into cells. Significant hypophosphatemia is unlikely to be encountered in the ED, because it is most often associated with hyperalimentation. There may be a shift into cells seen with alkalosis (respiratory or metabolic). Alcoholics may be in a sufficiently poor nutritional state that hypophosphatemia becomes an issue. Other conditions that may on occasion present to the ED with complications related to phosphate depletion include hyperparathyroidism, malignancy with hypercalcemia (phosphaturia), renal tubular defects, and use of phosphate-binding antacids. As explained earlier, hypokalemia and hypomagnesemia are likely to be associated with hypophosphatemia. Conditions unlikely to be seen in ED practice but associated with hypophosphatemia include rapid healing, prolonged anabolic states, recovery from starvation or severe burns, and partial hepatectomy.

Redistribution phenomena also can occur with glucose infusion. Phosphorus is consumed during phosphorylation as glucose moves into cells. This is one of the theoretical reasons why potassium phosphate is advocated as part of K$^+$ replacement regimens in the treatment for diabetic ketoacidosis. However, it should not be the initial form of K$^+$ replacement in the ED, as significant hypophosphatemia is unlikely to occur for 12 to 24 h, and parenteral administration may cause precipitous falls in serum [Ca^{2+}]. (Also see Chap. 203, "Diabetic Ketoacidosis.")

DIAGNOSIS   Symptoms of hypophosphatemia are unlikely to appear until levels are quite low, usually less than 1 mg/dL. Patients with diabetic or alcoholic ketoacidosis or severe malnutrition may develop complications of hypophosphatemia. It should be particularly sought as a potential complication 12 to 24 h after initiating treatment for diabetic ketoacidosis and 24 to 96 h after treatment for alcoholic ketoacidosis. Detecting total body depletion cannot reliably be ascertained from blood phosphorus levels, as the ratio of intracellular to extracellular phosphorus is approximately 100:1.

PHYSIOLOGIC EFFECTS   The most frequent consequences of hypophosphatemia are hematologic and neuromuscular. Hypophosphatemia may be associated with depletion of ATP in platelets, red blood cells, and white blood cells, reducing their survival time and function. Platelet membrane changes may result in a bleeding tendency due to impaired aggregation. Phosphate deficiency also causes a tendency for red blood cells to become rigid spherocytes, thereby impairing capillary perfusion. In addition, decreased 2,3-diphosphoglycerate (2,3-DPG) increases the affinity of hemoglobin for oxygen, thereby reducing the arterial P$_{O_2}$ and oxygen availability to tissues. Phosphate depletion in macrophages may impair chemotaxis, phagocytosis, and intracellular killing, resulting in decreased resistance to infection.

Progressive weakness and tremors may be noted as blood phosphate levels fall below 0.5 to 1.0 mg/dL. Circumoral and fingertip paresthesias may be present along with absent deep tendon reflexes. Mental obtundation, anorexia, and hyperventilation may also occur. Myocardial function, as measured by left ventricular stroke work, may also be impaired.

TREATMENT   Fortunately, phosphate deficiency is easily reversible by correcting the underlying disorder and replacing phosphorus. Milk is an excellent source of phosphorus and contains 1000 mg/L. Tablets come in the form of sodium or potassium phosphate and must be given in divided doses.

For severe hypophosphatemia with blood levels less than 1.0 mg/dL (0.32 mmol/L) or symptoms, immediate IV replacement is required. Otherwise, oral preparations can be often used.

If the hypophosphatemia is recent and uncomplicated, the initial recommended daily dose is 2.5 mg/kg. Prolonged or multifactorial hypophosphatemia may require 5 mg/kg. Up to 25 to 50 percent more phosphorus is needed if a patient is symptomatic; however, less is required in the presence of hypercalcemia. Each dose is administered IV over 6 h, and serum phosphorus is checked after each dose. To minimize the risks of hyperphosphatemia, a total dose of no more than 7.5 mg/kg should be administered.

Risks of phosphate therapy include hypocalcemia, metastatic calcification, hypotension, and hyperkalemia from the potassium salts. One should switch to oral therapy as soon as possible.

Hyperphosphatemia

ETIOLOGY   Hyperphosphatemia may be due to reduced renal excretion, increased phosphate movement out of cells into the ECF, or increased phosphorus or vitamin D intake. Hyperphosphatemia is most apt to be seen with renal dysfunction. It may also be seen with hypoparathyroidism or any problem associated with hypocalcemia or hypomagnesemia.

PHYSIOLOGIC EFFECTS   Problems due to hyperphosphatemia are usually those due to associated renal failure, hypocalcemia, or the hypomagnesemia that is usually present.

THERAPY   Therapy is aimed at treating the underlying cause and restricting calcium phosphate intake to less than 200 mg/day. With normal renal function, phosphate excretion can be increased with saline (1 to 2 L every 4 to 6 h) and acetazolamide (500 mg every 6 h). Phosphorus absorption from the gastrointestinal tract is decreased with oral phosphate binders (i.e., aluminum carbonate or hydroxide 30 to 45 mL qid). These binders also absorb phosphate secreted into the gut lumen and are of benefit even if no oral phosphorus is given. If clinically significant hypocalcemia exists, calcium should be cautiously administered. If renal failure is present, calcium carbonate is the treatment of choice to avoid aluminum toxicity. Hemodialysis may be required.

It may take years to correct the structural changes in bone that occur secondarily to long-term hypophosphatemia.

24 DISTURBANCES OF CARDIAC RHYTHM AND CONDUCTION

Edmund Bolton

The interpretation and treatment of cardiac dysrhythmias is basic to the practice of emergency medicine. This chapter reviews the important cardiac rhythm and conduction disturbances, their clinical significance, and their emergency treatment. Discussions of defibrillation, cardioversion, and artificial cardiac pacemakers are also included.

Although emphasis is appropriately placed on drug treatment of these dysrhythmias, it is also important that underlying and reversible causes of rhythm and conduction disturbance—such as hypoxia, alkalosis, electrolyte abnormalities, and drug toxicity—be recognized and treated.

THE NORMAL CARDIAC CONDUCTING SYSTEM

The heart consists of three types of specialized tissue: (1) pacemaker cells that undergo spontaneous depolarization and can initiate an electric impulse (this property is called *automaticity*); (2) cells that conduct electrical waves more rapidly than other cardiac cells, causing a very rapid propagation of the electric impulse throughout the heart, and (3) contractile cells, which contract when electrically depolarized.

The sinus [sinoatrial (SA)] node is normally the dominant cardiac pacemaker unless disease or drugs depress its activity. The SA node is located near the junction of the superior vena cava and right atrium. Blood supply is from the sinus node artery, which arises from either the proximal few centimeters of the right coronary artery (in about 55 percent of individuals) or from the proximal few millimeters of the left circumflex artery (in the other 45 percent). Both sympathetic and parasympathetic nerves, which are the primary controls of the heart rate, innervate the SA node. The normal sinus discharge rate is 60 to 100 beats per minute.

The electric impulse generated by the SA node spreads in waves through the cardiac muscles of the atria, activating atrial contraction. Additionally, specialized atrial conduction tracts (anterior, middle, and posterior internodal tracts) serve to propagate the electric impulse through the atria and between the sinus node and the atrioventricular (AV) node.

The atria and ventricles are insulated electrically from each other by the fibrous connective tissue of the AV ring (annulus fibrosus). Normally, electric impulses from the atria can reach the ventricles only by passing through the AV node and infranodal conducting system.

The AV node is under the surface of the right atrial endocardium and directly above the insertion of the septal leaflet of the tricuspid valve. The AV node receives its blood supply from the right coronary artery as it turns to form the posterior descending artery in 90 percent of individuals and, in the other 10 percent, as it comes off the left circumflex artery. This accounts for the common occurrence of AV conduction disturbances with acute inferior myocardial infarctions. The AV node is innervated by both sympathetic and parasympathetic fibers. It has two important electrophysiologic characteristics: a slow conduction velocity and a long refractory period. The slow conduction velocity through the AV node allows time for atrial contraction to give an extra 10 percent ventricular filling, which increases stroke volume according to the Frank-Starling principle. This "atrial kick" is most important for patients with ventricular failure. The long refractory period of the AV node protects the ventricles from excessively rapid stimulation; very rapid heart rates decrease the diastolic filling period and thereby reduce cardiac output, which may cause deterioration into ventricular fibrillation or cardiac failure. Cells near the AV node have automaticity and will escape from the control of the SA node if its rate becomes too low, normally below 60 beats per minute.

Electric impulses leave the inferior pole of the AV node along the bundle of His, which travels downward along the posterior margin of the membranous portion of the intraventricular septum to reach the top of the muscular portion. The bundle of His consists of Purkinje cells, which are the most rapidly conducting cells of the heart. The common bundle is only 1 to 2 cm in length before it divides at the crest of the muscular intraventricular septum into the right and left bundle branches (RBB and LBB). The RBB is a compact group of fibers that travels down to the apex of the right ventricle before separating into smaller branches. The LBB travels 2 to 3 cm before fanning out into a virtual sheet of fibers to cover the left ventricle. There are two relatively distinct pathways to the base of the papillary muscles, the left anterior superior fascicle (LASF) and the left posterior inferior fascicle (LPIF). These fascicles are distinguished more readily by electrical means in humans than by anatomy, but they can be seen clearly in animals.

The blood supply to the RBB and LASF is from the same sources: about half the time from both the AV nodal artery and branches from the left anterior descending coronary artery and the other half from the left anterior descending artery alone. The LPIF is supplied about half the time from the AV nodal artery and the other half by both the AV nodal artery and left anterior descending artery. Infarction in the region supplied by the left anterior descending artery is capable of affecting the RBB and LASF but very rarely the LPIF.

Accessory tracts are embryologic remnants of myocardium found in the AV annulus that can transmit electric impulses between the atria and ventricles, bypassing all

or part of the AV node and infranodal system. These bypass tracts conduct at different rates and are the anatomic basis for the preexcitation syndrome.

THE NORMAL ELECTROCARDIOGRAM (ECG)

The clinical surface ECG records the potential (voltage) differences between "neutral" ground and recording electrodes. The ECG is generated by the electrical activity of the heart and depicts the net sum of this activity recorded over time. By convention, a potential difference that points toward a recording electrode is assigned a positive deflection on the ECG, and a potential that points away from the recording electrode is assigned a negative deflection. Also by convention, routine ECG recordings are obtained with paper speed at 25 mm/s (2.5 cm/s) and signal calibration of 1.0 mV/10 mm (1.0 cm).

In Fig. 24-1, depolarization starts on the left side of the ventricular septum and initially proceeds to the right; this is recorded as a small negative deflection in the recording electrode. Subsequent depolarization involves the free walls of both ventricles, and since the left side has a much larger mass, the net sum of electrical activity is directed toward the recording electrode and a tall, positive deflection is recorded.

FIG. 24-1. Ventricular depolarization recorded in lead V $_6$.

The P-QRS-T complex of the normal ECG represents electrical activity over one cardiac cycle (Fig. 24-2).

FIG. 24-2. Normal P-QRS-T ECG pattern.

The P wave is caused by atrial depolarization. The QRS complex usually obscures atrial repolarization. The normal P wave duration is less than 0.10 s (2.5 mm), and normal amplitude is less than 0.3 mV (3 mm). A P wave originating from the SA node is directed inferiorly and to the left on the frontal plane.

The PR interval is the time between the onset of depolarization in the atria and the onset of depolarization in the ventricles. It is commonly used as an estimation of AV nodal conduction time because the AV node is the most likely site for delay in conduction. For adults in sinus rhythm, the PR interval is 0.12 to 0.20 s (3 to 5 mm) at 25 mm/s.

The QRS complex indicates ventricular depolarization. In general, depolarization starts on the endocardium and spreads outward to the epicardium. Despite the large amount of myocardium that must be depolarized, the specialized conducting system makes this a rapid process and the normal QRS duration is 0.06 to 0.10 s (1.5 to 2.5 mm). Any delay in intraventricular conduction results in a wide QRS. Ectopic impulses that originate below the bundle of His or that arrive prior to repolarization of the bundle branches also result in a widened QRS because they do not use the Purkinje network.

While small negative initial deflections (Q waves) are normal, large Q waves can be due to an electrically unexcitable area just under the recording electrode. An abnormal Q wave has a width of 0.04 s or greater and a height one-third that of the QRS complex.

The ST segment represents the plateau phase of ventricular depolarization. While the ST segment is usually isoelectric, a small deviation, less than 0.1 mV (1 mm), is not always pathologic.

The T wave is caused by ventricular repolarization. Depolarization is a rapid, near-simultaneous release of stored energy (like the release of a compressed spring); repolarization is a slow, asynchronous event where the metabolic machinery of each individual cell restores the transmembrane potential. Therefore, the T-wave duration is much longer and the amplitude much lower than those of the QRS complex. In general, repolarization starts on the epicardium and spreads to the endocardium. Many factors can influence this normal repolarization sequence: (1) metabolic factors (hypoxia, fever, drugs), (2) autonomic stimuli (abdominal pain, hyperventilation), (3) myocardial hypertrophy, (4) myocardial ischemia or inflammation, and (5) abnormal depolarization (Bundle branch block).

The QT interval represents ventricular depolarization and repolarization. While QT duration is commonly between 0.33 and 0.42 s, it does vary inversely with heart rate. The corrected interval is obtained by dividing the measured QT interval (in seconds) by the square root of the R-R interval (in seconds). The normal corrected QT interval is less than 0.47 s. This corrected QT should be checked prior to giving drugs such as ibutilide (Corvert), a recently released drug for the conversion of new onset atrial fibrillation. If Corvert is given in face of a prolonged correct QT, it may cause torsades de pointes.

The U wave may be seen as a normal component of the surface ECG. It is best seen in leads V $_1$ and V$_2$. There is still some dispute as to the origin of the U wave. The classic explanation is that the U wave represents the delayed repolarization of the Purkinje network. More recent research has shown that the U wave can be seen at the same time as early afterdepolarizations (EADs) in patients with a prolonged QT interval and torsades de pointes.

CARDIAC DYSRHYTHMIAS

There are many protocols for the classification of dysrhythmias and conduction disturbances. Dysrhythmias are basically classified in relation to the rate and site of abnormality. Conduction disturbances are usually classified as to the site and degree of block.

Cardiac dysrhythmias may decrease cardiac output if the ventricular rate is too fast or slow. In an adult without cardiac disease, heart rates between 40 and 160 are usually well tolerated because physiologic adaptations are able to maintain an adequate cardiac output and blood pressure. In adults with significant heart disease, rates below 50 or above 120 may produce decreased cardiac output based on a poorly functioning ventricle because of basic myocardial cell damage, ischemic cells,

valvular disease, or a combination of these.

Mechanisms of Tachydysrhythmias

There are three accepted mechanisms for dysrhythmias: (1) increased automaticity in a normal or ectopic site, (2) reentry in a normal or accessory pathway, and (3) afterdepolarizations causing triggered rhythms. While treatment is best directed by an understanding of the underlying process, uncertainty still exists over the precise mechanism of many dysrhythmias, and therapy is still often empiric.

An ectopic focus is an area of the heart, away from the normal sinus node pacemaker, that acquires independent pacemaker activity and usurps the pacemaking role. The result can be a single extrasystole or multiple extra depolarizations. These ectopic pacemakers can be the result of (1) enhanced automaticity of subsidiary pacemaker cells (i.e., in the AV node or infranodal conduting system) or (2) abnormal automaticity of myocardial cells, which seldom possess pacemaking activity (i.e., Purkinje cells). Dysrhythmias due to an ectopic focus usually have a gradual onset ("warmup period"). The termination is also gradual, as opposed to the abrupt onset and termination seen with reentry or triggered mechanisms.

Reentry was initially described when researchers took myocardial tissue and increased the K^+ concentration in a part of the tissue. They found that when stimulated, a rhythm was sustained without further stimulation at certain K^+ concentrations. Reentry requires a temporary or permanent unidirectional block in one limb of a circuit and slower-than-normal conduction around the entire circuit. These conditions are secondary to disease, drugs, accessory pathways, or when tissue is stimulated during the partial refractory period (before full repolarization), as with premature depolarizations.

As indicated in Fig. 24-3, the inciting impulse traveling in the normal downward direction encounters the two limbs, finds limb *a* blocked, and travels down limb *b*. Upon reaching the bottom portion of the circuit where the two limbs rejoin, the impulse can then travel retrograde up limb *a* and reach the upper connection of the circuit. Normally, conduction is so rapid that the impulse would encounter limb *b* still refractory to stimulation, and no further propagation would occur. However, if conduction around the circuit were slow enough, limb *b* would be able to conduct the impulse again in the antegrade direction. With the right size circuit and conduction velocity, an electric impulse can be maintained traveling around the circuit in a cyclic manner. Each time the impulse passes the upper and lower limb connections, a depolarization occurs.
FIG. 24-3. Reentry circuit.

Reentry can occur around anatomically defined circuits, resulting in a regular rapid rhythm such as paroxysmal supraventricular tachycardia. Conversely, reentry can also occur in a disorganized and chaotic fashion through a syncytium of myocardial tissue—as seen, for example, in atrial or ventricular fibrillation.

Triggered dysrhythmias are due to the oscillations of the transmembrane potential during or after repolarization (afterpotentials). Under ideal conditions of rate, afterpotentials reach threshold and trigger a complete depolarization (afterdepolarization). Once triggered, this process may be self-sustaining. Triggered dysrhythmias associated with early afterpotentials are enhanced by slow heart rates and usually treated by accelerating the ventricular rate with positive chronotropic drugs or electrical pacing. Triggered dysrhythmias associated with delayed afterpotentials are enhanced by fast heart rates. Treatment with agents that have a negative chronotropic action is usually effective.

The urgency with which tachydysrhythmias require treatment is guided by two considerations: (1) evidence of hypoperfusion (shock, altered mental status, anginal chest pain, or pulmonary edema) and (2) the potential to degenerate into a more serious dysrhythmia or cardiac arrest. The two treatment methods most commonly used are intravenous drugs for the clinically stable patient and synchronized cardioversion or defibrillation for the unstable patient. Some tachydysrhythmias are amenable to overdrive electrical pacing but frequently require rates over 200 in order to capture the ventricle.

Mechanisms of Bradydysrhythmias

Bradydysrhythmias can be caused by two mechanisms: depression of sinus nodal activity or conduction system blocks. In both situations, subsidiary pacemakers take over and pace the heart; and provided the pacemaker is located above the bifurcation of the bundle of His, the rate is generally adequate to maintain cardiac output.

The need for emergent treatment of bradycardias is guided by two considerations: (1) evidence of hypoperfusion and (2) the potential to degenerate into a more profound bradycardia or ventricular asystole. In general, emergent treatment is not required, unless (1) the heart rate is below 50 and there is clinical evidence of hypoperfusion or (2) the bradycardia is due to structural disease of the infranodal conducting system (either transient or permanent) that has a risk of progressing to complete AV block. The first group of patients requires immediate treatment during assessment of the etiology of the bradycardia and consideration of whether internal pacing will be required. The second group of patients does not always require immediate treatment but should be monitored closely, with therapy readily available, while arrangements are made for further evaluation and possible internal cardiac pacing.

Three methods are currently available for emergent treatment of bradycardias: atropine, isoproterenol, and transcutaneous cardiac pacing.

Atropine should be the initial agent, at doses of 0.5 mg IV every 5 min until the desired response is achieved or a total vagolytic dose (about 0.05 mg/kg in humans) is given. Usually, if no response is seen by a dose of 2.0 mg, further doses are not effective. The vast majority of bradycardias due to problems of either the sinus or AV node respond to atropine. Even some patients with infranodal blocks may respond, so atropine deserves consideration in most bradycardias when emergent treatment is desired. Atropine can increase rate and myocardial oxygen consumption; therefore it has no place in an otherwise stable patient with bradycardia.

Isoproterenol can be used when atropine is ineffective, generally as a result of disease of the infranodal conducting system. Isoproterenol is given as a constant infusion, starting at a rate of around 0.5 μg/min and increasing as required to maintain a heart rate of 60. Isoproterenol increases myocardial oxygen demand, stimulates ventricular ectopy, and produces peripheral vasodilation, making it a less attractive agent than atropine. The reported response to isoproterenol is less than that observed with atropine, although isoproterenol is usually used only in patients who fail while receiving atropine. It is difficult to say how effective isoproterenol would be if used initially, and we do not suggest that.

External cardiac pacing represents a reemergence of an old concept with new electronics that make the technique more sensitive and likely to capture rhythm. This should be available in every emergency facility. The emergency physician must become familiar with the technique of applying the transcutaneous pacemaker so that it will sense and pace appropriately.

Internal pacing is the definitive treatment for progressive or persistent bradycardias. Emergent internal pacing is possible with the use of balloon-tipped flotation catheters, although, without fluoroscopic guidance, it is often technically difficult to achieve stable placement in a patient with low cardiac output.

Supraventricular Dysrhythmias

SINUS DYSRHYTHMIA   Some variation in the sinus node discharge rate is common, but if the variation exceeds 0.12 s between the longest and shortest intervals, sinus dysrhythmia is present. The ECG characteristics of sinus dysrhythmia are (1) normal sinus P waves and PR intervals, (2) 1:1 AV conduction, and (3) variation of at least 0.12 s between the shortest and longest P-P interval (Fig. 24-4).
FIG. 24-4. Sinus dysrhythmia.

Clinical Significance   Sinus dysrhythmia is frequently a normal finding in children and young adults; it tends to disappear with advancing age. Sinus dysrhythmia is most commonly a phasic (respiratory variation) variety and less commonly a nonphasic variety. In the phasic variety, the sinus node rate accelerates during inspiration and decelerates during expiration because of changes in vagal tone occurring with respiration (Bainbridge reflex). The irregularity in either the phasic or nonphasic varieties can be exaggerated by conditions that increase vagal tone. During long intervals of sinus dysrhythmia, junctional escape beats may occur.

Treatment   None is required.

SINUS BRADYCARDIA   Sinus bradycardia occurs when the sinus node rate falls below 60. The ECG characteristics of sinus bradycardia are (1) normal sinus P waves and PR intervals, (2) 1:1 AV conduction, and (3) atrial rate below 60 (Fig. 24-5).
FIG. 24-5. Sinus bradycardia, rate 44.

Clinical Significance   Sinus bradycardia represents a suppression of the sinus node discharge rate. Sinus bradycardia can be (1) physiologic (in well-conditioned athletes, during sleep, or with vagal stimulation), (2) pharmacologic (digoxin, narcotics, reserpine, b-adrenergic antagonists, calcium channel blockers, quinidine), or (3) pathologic (acute inferior myocardial infarction, increased intracranial pressure, carotid sinus hypersensitivity, hypothyroidism).

Treatment

1. Sinus bradycardia usually does not require specific treatment unless the heart rate is below 50 and there is evidence of hypoperfusion.
2. Therapy should begin with atropine as previously described. Most patients will respond to one or two doses.
3. Isoproterenol can be used if atropine is ineffective.
4. External cardiac pacing can be used in the patient refractory to atropine or isoproterenol.
5. Internal pacing is required in the patient with symptomatic recurrent or persistent sinus bradycardia.

SINUS TACHYCARDIA   Sinus tachycardia originates from acceleration of the sinus node discharge rate. The ECG characteristics of sinus tachycardia are (1) normal sinus P waves and PR intervals and (2) an atrial rate usually between 100 and 160 (Fig. 24-6).
FIG. 24-6. Sinus tachycardia, rate 176.

Clinical Significance   Sinus tachycardia represents an acceleration of the sinus node discharge rate, usually in response to three categories of stimuli: (1) physiologic (infants and children, exertion, anxiety, emotions), (2) pharmacologic (atropine, epinephrine and other sympathomimetics, alcohol, nicotine, caffeine), or (3) pathologic (fever, hypoxia, anemia, hypovolemia, pulmonary embolism). In many of these conditions, the increased heart rate is due to an effort to increase cardiac output to match increased circulatory needs.

Treatment

1. No specific treatment is usually required, but any underlying conditions should be investigated and treated.
2. Some patients with acute myocardial infarction have an "inappropriate" tachycardia and may benefit from slowing heart rate with b-adrenergic antagonists.

PREMATURE ATRIAL CONTRACTIONS (PACs)   PACs originate from ectopic pacemakers anywhere in the atrium other than the sinus node. The ECG characteristics of PACs are that (1) an ectopic P' wave appears sooner (prematurely) than the next expected sinus beat, (2) the ectopic P' wave has a different shape and axis, and (3) the ectopic P' wave may or may not be conducted through the AV node (Fig. 24-7). A PAC is not conducted through the AV node if it reaches the AV node during the absolute refractory period and is conducted with a delay (longer P'R interval) during the relative refractory period. Most PACs are conducted with typical QRS complexes, but some may be conducted aberrantly through the infranodal system if they reach a bundle branch during the refractory period. The sinus node is often depolarized and "reset," so that while the interval following the PAC is often slightly longer than the previous cycle length, the pause is less than fully compensatory.
FIG. 24-7. Premature atrial contractions (PACs). Top: ectopic P' waves (arrows). Bottom: atrial bigeminy.

Clinical Significance   PACs are common at all ages and often seen in the absence of heart disease. It is generally assumed, although it remains unproven, that stress, fatigue, alcohol, tobacco, and coffee may precipitate PACs. Frequent PACs may also be seen in chronic lung disease, ischemic heart disease, or digitalis toxicity. PACs may precipitate sustained atrial tachycardia, flutter, or fibrillation under the right circumstances.

Treatment

1. Any precipitating drugs or toxins should be discontinued.
2. Underlying disorders should be treated.
3. PACs that produce symptoms or initiate sustained tachycardias can be suppressed with quinidine, procainamide, or b-adrenergic antagonists.

MULTIFOCAL ATRIAL TACHYCARDIA (MFAT)   MFAT (also known as "chaotic atrial rhythm" or "wandering atrial pacemaker") is an irregular rhythm caused by at least three different sites of atrial ectopy. The ECG characteristics of MFAT are (1) three or more differently shaped P waves; (2) varying PP, PR, and RR intervals; and (3) atrial rhythm usually between 100 and 180 (Fig. 24-8). MFAT is frequently confused with atrial flutter or fibrillation.

FIG. 24-8. Multifocal atrial tachycardia (MFAT).

Clinical Significance   MFAT is most often found in elderly patients with decompensated chronic lung disease, but it may also complicate congestive heart failure or sepsis or be caused by methylxanthine toxicity. Digoxin toxicity is an unlikely cause of MFAT.

Treatment

1. Treatment is directed toward the underlying disorder. With decompensated lung disease, oxygen and bronchodilators improve pulmonary function and arterial oxygenation and decrease atrial ectopy. Theophylline agents have been associated with the production or exacerbation of this dysrhythmia.
2. Specific antiarrhythmic treatment is rarely indicated. Standard antiarrhythmics appear to be ineffective in suppressing these multiple sites of atrial ectopy, and toxic side effects from these agents have been reported. Likewise, attempts to slow the ventricular rate by depressing AV nodal conduction with digoxin is also difficult without producing toxic side effects. Recently, three modes of therapy have been described that may be helpful in some patients. Magnesium sulfate 2 g IV over 60 s followed by a constant infusion of 1 to 2 g/h has been shown to reduce atrial ectopy in these patients and is sometimes associated with conversion to sinus rhythm. The full antiarrhythmic effect of magnesium requires supplemental potassium to maintain serum potassium levels above 4 meq/L. Intravenous verapamil (5 to 10 mg) slows the ventricular response in most patients, decreases atrial ectopy in some patients, and is associated with conversion to sinus rhythm in many patients. The b-adrenergic antagonists esmolol, acebutolol, and metoprolol all decrease the ventricular rate in MFAT, and metoprolol is associated with conversion to sinus rhythm in a majority of patients. However, theoretically, b-adrenergic therapy may worsen bronchospasm. The value of such specific antiarrhythmic treatment in MFAT is unproven.
3. Cardioversion has no effect on these multiple sites of atrial ectopy.

ATRIAL FLUTTER   Atrial flutter usually originates from a localized area within the atria. The exact mechanism—whether reentry, automatic focus, or triggered dysrhythmia—is not yet known. Intracardiac studies demonstrate electrical activity usually originating in the inferior right atrium and propagating upward and to the left. ECG characteristics of atrial flutter are (1) regular atrial rate between 250 and 350 (most commonly 280 and 320); (2) sawtooth flutter waves directed superiorly and most visible in leads II, III, aV$_F$; and (3) AV block, usually 2:1, but occasionally greater, causing an irregular ventricular response (Fig. 24-9). One-to-one AV conduction may occur in the presence of bypass tracts or if drugs are used to slow the atrial rate to the level that the junction will be able to conduct one-to-one. If the ventricular rate is greater than 300, this should definitely be investigated with EP studies. Carotid sinus massage is a useful technique to slow the ventricular response, increase the AV block, and unmask flutter waves.
FIG. 24-9. Atrial flutter.

Clinical Significance   Atrial flutter is usually associated with heart disease. It is most commonly found in patients with ischemic heart disease or acute myocardial infarction. Less common causes include congestive cardiomyopathy, pulmonary embolus, myocarditis, blunt chest trauma, and, rarely, digoxin toxicity. Atrial flutter may be a transitional dysrhythmia between sinus rhythm and atrial fibrillation.

Treatment

1. Low-energy cardioversion (25 to 50 J) is very successful in converting more than 90 percent of cases of atrial flutter into sinus rhythm. Energies less than 10 J should be avoided, as they are more likely to convert atrial flutter into atrial fibrillation than into sinus rhythm.
2. If cardioversion is contraindicated, control of ventricular rate can be achieved with digoxin, verapamil, diltiazem, esmolol, or propranolol. If there is 1:1 conduction and the rate is 300 and above, preexcitation should be considered and procainamide may be the drug of first choice.
3. Quinidine or procainamide can be used for 1:2 conduction after ventricular rate control is achieved to chemically slow or convert atrial flutter or prevent recurrence of the dysrhythmia.
4. Intravenous esmolol will convert up to 60 percent of patients with new-onset atrial flutter to sinus rhythm.
5. Intravenous verapamil will occasionally convert atrial flutter into sinus rhythm (up to 30 percent) or atrial fibrillation (up to 20 percent).
6. Some of the newer antiarrhythmics may also have a role in the chemical conversion of atrial flutter. Ibutilide (Corvert), mentioned earlier, can convert both atrial flutter and fibrillation to normal sinus rhythm. This drug should be used in new-onset atrial flutter (AF) because of the chance of emboli if used in long-term AF. Ibutilide is very effective in the conversion of atrial flutter or atrial fibrillation; however, there is a significant chance of torsades de pointes (TdP). To reduce the chance of TdP, it is suggested that the K^+ and the corrected QT (QTc) interval be checked prior to administration of the agent. This agent should not be given in the presence of hypokalemia, prolonged QTc, or history of congestive heart failure (CHF). The chance of TdP can extend 4 to 6 h after the drug is given.

ATRIAL FIBRILLATION   Atrial fibrillation occurs when there are multiple small areas of atrial myocardium continuously discharging and contracting. There is no uniform atrial depolarization and contraction—instead, only a quivering of the atrial wall. While the atrial rate is usually above 400, the ventricular rate is limited by the refractory period of the AV node or an accessory pathway. The ECG characteristics of atrial fibrillation are (1) fibrillatory waves of atrial activity, best seen in leads V_1, V_2, V_3, and aV_F; and (2) irregular ventricular response, usually around 170 to 180 in patients with a healthy AV node (Fig. 24-10). Disease or drugs (especially digoxin) may reduce AV node conduction and markedly slow ventricular response. A more rapid ventricular response may be seen in patients with bypass tracts, and the rate in these patients has been suggested as a way of estimating the refractory period of the accessory path. Rates above 300 are possible and dangerous. In this case, since ventricular activation occurs by way of the bypass tract, the QRS complex is usually wide. The configuration of the aberrancy may vary with the site of the one or more accessory pathways.
FIG. 24-10. Atrial fibrillation.

Clinical Significance   Atrial fibrillation can occur in a paroxysmal or in a sustained manner. Predisposing factors for atrial fibrillation are increased atrial size and mass, increased vagal tone, and variation in refractory periods between different parts of atrial myocardium. Atrial fibrillation is usually found in association with four disorders: rheumatic heart disease, hypertension, ischemic heart disease, and thyrotoxicosis. Less common causes are chronic lung disease, pericarditis, acute alcoholic intoxication, or atrial septal defect.

In patients with left ventricular failure, left atrial contraction contributes significantly to cardiac output. The loss of effective atrial contraction, as in atrial fibrillation, may produce heart failure in these patients. Atrial fibrillation also predisposes to peripheral venous and atrial emboli, with the risk of pulmonary and systemic arterial embolism. Up to 15 percent of patients per year in chronic atrial fibrillation have at least one embolic episode. Conversion from chronic atrial fibrillation to sinus rhythm also carries up to a 1 to 2 percent risk of arterial embolism. Patients with chronic atrial fibrillation are frequently anticoagulated.

Treatment

1. Atrial fibrillation with a rapid ventricular response and acute hemodynamic deterioration should be treated with synchronized cardioversion. Over 60 percent of patients can be converted with 100 J and over 80 percent with 200 J. Conversion to and retention in sinus rhythm is more likely when atrial fibrillation is of short duration and the atria are not greatly dilated. If initial cardioversion is unsuccessful, procainamide should be given intravenously to facilitate further cardioversion attempts. Oral quinidine or low-dose amiodarone can enhance maintenance of sinus rhythm. Metanalysis and decision analysis of postconversion antiarrhythmic treatment has found that the benefits of maintaining sinus rhythm with antiarrhythmics is partially offset by an increase in sudden death, presumably due to the proarrhythmic properties of these drugs. In the emergency department (ED) setting, all other causes of hypotension, such as acute blood loss, must be ruled out before concluding that the rate is causing the hemodynamic deterioration.
2. In the more stable patient, the first priority is to achieve ventricular rate control. Diltiazem 10 to 20 mg (0.125 to 0.25 mg/kg) given intravenously over 2 min is extremely effective in achieving ventricular rate control, with the peak response seen in 2 to 7 min. An infusion of 10 mg/h is usually started after the initial dose to maintain control and a second dose of 25 mg (0.35 mg/kg) can be given at 15 min if rate control is not achieved. Verapamil 5 to 10 mg IV is effective in slowing the ventricular response in 60 to 70 percent of patients with atrial fibrillation and converts 10 to 15 percent into sinus rhythm. Intravenous b-adrenergic blockers (e.g., esmolol and propranolol) are effective, especially in patients with thyrotoxicosis or rheumatic mitral stenosis, but the depressive effects on myocardial contractility make them poor agents to use in patients with ventricular failure. Intravenous digoxin is an effective agent for this purpose, although the onset of action is slow, with a mean time of over 11 h to achieve ventricular rate control.
3. Once ventricular rate control has been achieved, chemical conversion can be considered with procainamide, quinidine, or verapamil. Intravenous procainamide has also been used as a single agent to chemically convert atrial fibrillation of short duration into sinus rhythm; however, ibutilide is being touted as a better agent. Because of the risk of intraatrial thrombi and arterial embolization, patients with atrial fibrillation of more than 2 days' duration should be anticoagulated

systemically for 1 to 3 weeks prior to attempts at either chemical or electrical conversion. More recent work indicates that there may be some increased risk of embolism even with AF of less than 2 days' duration. An alternative to anticoagulation is to exclude atrial thrombi by transesophageal echocardiography. Those without visible thrombi can be safely cardioverted without the need for preconversion oral anticoagulation.

4. Patients with a slow ventricular response not due to digitalis have AV node disease and probably a more generalized disorder of cardiac conduction (second- or third-degree AV block is seen in these patients when in sinus rhythm). These patients are at increased risk for profound bradycardias or asystole following cardioversion or antiarrhythmic drug therapy.

5. In some patients with a rapid ventricular response, conversion will reveal a very slow rate (tachy-brady syndrome) because of underlying disease of the pacemaker tissue (sick sinus syndrome).

SUPRAVENTRICULAR TACHYCARDIA (SVT)   Supraventricular tachycardia is a regular, rapid rhythm that arises from either reentry or an ectopic pacemaker in areas above the bifurcation of the bundle of His. The reentrant variety is clinically the most common. These patients often present with acute, symptomatic episodes termed *paroxysmal supraventricular tachycardia* (PSVT).

Ectopic SVT usually originates in the atria with an atrial rate of 100 to 250 (most commonly 140 to 200) (Fig. 24-11). The regular P waves can be mistaken for atrial flutter, or, if there is a 2:1 AV block, sinus rhythm.
FIG. 24-11. Ectopic supraventricular, tachycardia (STV) with 2:1 AV conduction.

Reentrant SVT is seen in the majority of patients with SVT: about 60 percent of these patients have reentry within the AV node and 20 percent have reentry involving a bypass tract. The remainder have reentry in other sites. In the normal heart, reentrant SVT at the typical rates of 160 to 200 is often tolerated for hours or days. However, cardiac output is usually depressed—regardless of the blood pressure—and rapid rates may produce heart failure depending upon the health of the myocardium.

Reentrant SVT within the AV node usually is initiated when an ectopic atrial impulse encounters the AV node during the partially refractory period (Fig. 24-12). There are two functionally different parallel conducting limbs within the AV node that are connected above at the atrial end and below at the ventricular end of the node. This circuit is capable of sustained reentry when properly stimulated. In AV nodal reentry, the P wave is usually buried in the QRS complex and not visible, there is 1:1 conduction, and the QRS complex is normal.
FIG. 24-12. Reentrant supraventricular tachycardia (SVT). Top: 2d (*) initiates run of PAT. Bottom: SVT, rate 286.

Patients with bypass tracts have two parallel limbs of the reentry circuit, the AV node and the bypass tract, with connections at the atrial and ventricular ends by myocardial cells. While reentry can occur in either direction, it usually occurs in a direction that goes down the AV node and up the bypass tract, producing a narrow QRS complex (orthodromic conduction). In the Wolff-Parkinson-White syndrome, about 85 percent of the reentrant SVTs have narrow QRS complexes. If the conduction is down the accessory bundle and up the AV node (antidromic conduction), the complexes are wide and are difficult to differentiate from ventricular tachycardia.

Clinical Significance   Ectopic SVT may be seen in patients with acute myocardial infarction, chronic lung disease, pneumonia, alcohol intoxication, and digoxin toxicity [where it is often associated with AV block and termed *paroxysmal atrial tachycardia* (PAT) with block]. It is commonly held that a high percentage of SVT with block, as much as 75 percent, is due to digoxin toxicity. However, not all studies have found this to be the case. In the test situation, PAT with block is still pathognomonic for digitalis toxicity. The common dysrhythmias of digoxin toxicity are listed in Table 24-1.

PVCs (60%)
  Unifocal, multifocal, bigeminy, or trigeminy
AV block (20%)
  Second degree
  Mobitz I, Mobitz II
  Third degree
Ectopic SVT (20–30%)
  Rate 70–130
  Gradual appearance and disappearance
  AV dissociation and or block
Junctional escape beats (10%)
Ventricular tachycardia (10%)
  Bidirectional ventricular tachycardia associated with high mortality
Sinus bradycardia, SA block, and sinus pause (1–10%)

TABLE 24-1   Common Dysrhythmias of Digoxin Toxicity (Approximate Incidence)

Reentrant SVT can occur in a normal heart or in association with rheumatic heart disease, acute pericarditis, myocardial infarction, mitral valve prolapse, or one of the preexcitation syndromes.

SVT often causes a sensation of palpitations and light-headedness. In patients with coronary artery disease, anginal chest pain and dyspnea may occur from the rapid heart rate. Frank heart failure and pulmonary edema may occur in patients with poor left ventricular function. The decrease in diastolic filling period and subsequent decrease in cardiac output cannot be tolerated in the patient with left ventricular failure.

Treatment Ectopic SVT due to digoxin toxicity is treated as follows:

1. Discontinuation of the digoxin.
2. As long as there is not a high-grade AV block, correction of any existing hypokalemia to bring serum potassium into the high-normal range in an effort to reduce atrial ectopy is indicated.
3. Digoxin-specific antibody fragments (Fab) should be considered for patients with hemodynamic deterioration or serious ventricular dysrhythmias due to digoxin toxicity.
4. Either phenytoin, lidocaine, or magnesium given intravenously can reduce atrial ectopy. Published reports are not methodologically adequate for determination of the response rate, risks, and benefits of each agent, so the choice is often guided by personal preference. Historically, phenytoin has been the most commonly used drug, but its response rate has not been impressive and toxic side effects are common with full loading doses (15 to 18 mg/kg IV). Lidocaine has not been considered a useful agent for this dysrhythmia, but a recent report indicates some benefit. Recent studies indicate that magnesium sulfate 1 g IV impressively reduces atrial ectopy due to digoxin toxicity, and perhaps this agent has a greater effect than phenytoin or lidocaine.
5. Cardioversion is not effective and is potentially hazardous.

Reentrant SVT can be converted by impeding conduction through one limb of the reentry circuit; sustained reentry is then impossible and extinguishes, allowing sinus rhythm to resume ventricular pacing. Since it is usually impossible to differentiate ectopic from reentrant SVT clinically, treatment should be the same.

1. Maneuvers that increase vagal tone have been shown to slow conduction and prolong the refractory period in the AV node. These maneuvers can be done by themselves or after administration of drugs.
   a. Carotid sinus massage. This attempts to massage the carotid sinus and its baroreceptors against the transverse process of C6. Massage should be done for 10 s at a time, first attempted on the side of the nondominant cerebral hemisphere, and should never be done simultaneously on both sides. In addition, bruits should be discovered prior to the procedure. Prolonged AV block during carotid massage may occur in patients with AV node disease or who are on digoxin. Patients with carotid artery stenosis may develop cerebral ischemia or infarction from overvigorous carotid massage.
   b. Facial immersion in cold water for 6 to 7 s with the nostrils held closed ("diving reflex"). This maneuver is particularly effective in infants. The parents usually have more vagal tone than the infant so this must be approached carefully.
   c. The Valsalva maneuver. Done in the supine position, it appears to be the most effective vagal maneuver for the conversion of reentrant SVT. For maximal effectiveness, the strain phase must be adequate (usually at least 10 s) with slowing or conversion seen during the release phase.
2. Administration of adenosine. An ultra-short-acting (20 s) agent, adenosine produces AV block and has been observed to convert over 90 percent of reentrant SVT. The initial dose is a 6-mg rapid IV bolus. This must be given in a large vein, preferably in the antecubital space. If no effect is seen within 2 min, a second dose of 12 mg can be given. There is no proven benefit to repeated doses or administration of more than 20 mg. Half or more of patients experience distressing albeit transient side effects of facial flushing or chest pain. This should obviously be discussed with the patient when possible. Because adenosine possesses no sustained antiarrhythmic effect, subsequent ectopic beats are able to initial the dysrhythmia again, and early recurrences of SVT are seen in up to 25 percent of patients. The major advantage of adenosine is its ultrashort effect and its lack of hypotensive or myocardial depressive activity. Adenosine is also safe and effective in unstable patients (chest pain and/or hypotension) with reentrant SVT. It is safer in pregnancy. In addition, it is not contraindicated in the presence of Wolff-Parkinson-White syndrome.
3. Verapamil, 0.075 to 0.15 mg/kg (3 to 10 mg) IV over 15 to 60 s, with a repeat dose in 30 min if necessary. Studies have found that more than 90 percent of adults with reentrant SVT will respond within 1 to 2 min to verapamil. In patients with a normal blood pressure, intravenous verapamil is almost always associated with a decrease in blood pressure, even following successful conversion of SVT. The falls in systolic and mean arterial pressures are around 20 and 10 mmHg, respectively. The drop in blood pressure due to verapamil can be prevented and/or treated with intravenous calcium without reducing the antiarrhythmic action of verapamil. While the use of different calcium doses and salts has been reported, 90 mg of elemental calcium given intravenously over 3 to 6 min appears safe and effective (90 mg elemental calcium = 10 mL calcium gluconate 10% solution = 3.3 mL calcium chloride 10% solution). Whenever verapamil is used intravenously, calcium should be readily available. Intravenous verapamil is generally considered to be contraindicated in the hypotensive patient. Studies of intravenous verapamil in hypotensive patients with SVT report an excellent conversion rate (80 percent or better), the ventricular rate almost always slows, and rarely does the systolic blood pressure decrease without a change in ventricular rate. I would consider cardioversion a better approach to the hypotensive patient with SVT.
4. Diltiazem 20 mg (0.25 mg/kg) IV over 2 min. This is reported to be 75 to 100 percent effective in converting reentrant SVT.
5. Parasympathetic tone can be increased with edrophonium. A standard treatment protocol is a 1-mg IV test dose, a wait of 3 to 5 min, followed by 5 to 10 mg IV over 60 s. Historically, edrophonium does not have the 90 percent response rate seen with verapamil. I have not used this drug for the last 12 years but have noted that, most likely, it was the profound vomiting that caused the conversion rather than the direct effect of the drug.
6. Vagal tone can be enhanced by pharmacologically evaluating blood pressure with a pure peripheral vasoconstrictor; do not use agents with b-adrenergic activity. This method should be combined with carotid sinus massage. Blood pressure should be monitored frequently, and diastolic pressure should not be allowed to exceed 130 mmHg. This method should not be used if hypertension is already present.
   a. Metaraminol 200 mg/500 mL D_5W or norepinephrine 4 mg/500 mL D_5W can be infused at rates of 1 to 2 mL/min and titrated until the rhythm converts.
   b. Methoxamine or phenylephrine 0.5 to 1.0 mg IV over 2 to 3 min, with repeat doses as required.
7. Esmolol is an intravenous b-adrenergic blocker with an ultrashort duration of activity that can be titrated to effect. This agent can be used to control the ventricular rate in most tachycardias of supraventricular origin and is capable of converting about half of reentrant SVT. Esmolol is given as a bolus dose of 300 µg/kg over 60 s, followed by an infusion starting at 50 µg/kg per min. If there is an inadequate response after 2 to 5 min, a repeat bolus of 300 µg/kg should be given and increases in the infusion rate in increments of 50 µg/kg per min. should be made. The maximal recommended infusion rate is 300 µg/kg per min., although most patients respond to rates of 200 µg/kg per min. or less. With aggressive dosing regimens, hypotension occurs in about half of patients but can be quickly reversed by halting the infusion.
8. Propranolol 0.5 to 1.0 mg IV slowly over 60 s, repeated every 5 min, until the rhythm converts or the total dose reaches 0.1 mg/kg. Overall, propranolol has about a 50 percent success rate in converting reentrant SVT: about 80 percent with AV nodal reentry and 15 to 20 percent with accessory tract retrograde reentry.
9. Digoxin 0.5 mg IV with repeat doses of 0.25 mg in 30 to 60 min until a response occurs or the total dose reaches 0.02 mg/kg. The chief drawback of digoxin has been its long onset of action and potential hazard in patients with accessory (bypass) tracts who develop either atrial fibrillation or flutter.
10. External noninvasive pacing has been used in a limited number of patients to terminate reentrant SVT. Asynchronous pacing with 2 to 10 external pulses at a rate 240 to 280 (typically 40 faster than the SVT rate) with an impulse amplitude of 120 mA is effective in young, hemodynamically stable adults. Most pacing units in the ED do not pace at 240 to 280 beats per min. Some automatic internal cardiac defibrillators (AICDs) have overdrive pacing capability.
11. Synchronized cardioversion should be done in any unstable patient with hypotension, pulmonary edema, or severe chest pain. The dose required is usually small, less than 50 J.

Junctional Dysrhythmias

Traditionally, a junctional impulse is considered to be one that arises from the AV node or bundle of His above the bifurcation. Pacemaker tissue cannot be found in the AV node of experimental animals. The question is not settled in humans. From its source, probably in the junction, the impulse spreads retrograde toward the atria and antegrade toward the ventricles. Depending on the site of origin, conduction velocity, and refractory periods, the atria may be activated before, during, or after ventricular depolarization. Atrial depolarization may not be visible if retrograde conduction is blocked or atrial activation occurs simultaneously with ventricular activation and the QRS complex obscures the P waves. AV dissociation may occur if the rate of discharge from the junctional pacemaker is faster than the sinus node rate and the junctional impulse is blocked from retrograde conduction toward the atria.

JUNCTIONAL PREMATURE CONTRACTIONS (JPCs) JPCs are due to an ectopic pacemaker within the AV node or common AV bundle. The ECG characteristics of JPCs are as follows:

1. The ectopic QRS complex is premature.
2. The ectopic P' wave has a different shape and direction (usually inverted in leads II, III, and aV$_F$).
3. The ectopic P' wave may occur before or after the QRS complex.
4. The PR interval of the ectopic beat is shorter than normal.

5. The QRS complex is usually of normal shape unless there is aberrant conduction.
6. The sinus node is usually affected and the postectopic pause is not fully compensatory (Fig. 24-13). Some JPCs do not conduct retrograde; therefore a compensatory pause may be seen.
FIG. 24-13. Junctional premature contractions (JPCs).

JPCs may be isolated, multiple (as in bigeminy or trigeminy), or multifocal.

Clinical Significance   JPCs are uncommon in healthy hearts. They occur in congestive heart failure, digoxin toxicity, ischemic heart disease, and acute myocardial infarction (especially of the inferior wall).

Treatment

1. No specific treatment is usually required.
2. Treat the underlying disorder.
3. Antiarrhythmic therapy with quinidine or procainamide may be useful if JPCs are frequent, symptomatic, or initiate more serious dysrhythmias.

JUNCTIONAL RHYTHMS   Under normal circumstances, the sinus node discharges at a faster rate than the AV junction, so the pacemaker function of the AV junction and all other slower pacemakers is suppressed (overdrive suppression). If sinus node discharges slow or fail to reach the AV junction, then junctional escape beats may occur, usually at a rate between 40 and 60, depending on the level of the pacemaker. Generally, junctional escape beats do not conduct retrograde into the atria, so a QRS complex without a P' wave is usually seen (Fig. 24-14).

FIG. 24-14. Junctional escape rhythm, rate 42.

Under other circumstances, enhanced junctional automaticity may override the sinus node and produce either an accelerated junctional rhythm (rate 60 to 100) or junctional tachycardia (rate greater than 100). Usually, the enhanced junctional pacemaker (Fig. 24-15) captures both the atria and ventricles.
FIG. 24-15. Accelerated junctiional rhythm, rate 61.

Clinical Significance   Junctional escape beats may occur whenever there is a long enough pause in the impulses reaching the AV junction: sinus bradycardia, slow phase of sinus dysrhythmia, AV block, or during the pause following premature beats. Sustained junctional escape rhythms may be seen with congestive heart failure, myocarditis, hypokalemia, or digoxin toxicity. If the ventricular rate is too slow, myocardial or cerebral ischemia may develop.

Accelerated junctional rhythm and junctional tachycardia may occur from digoxin toxicity, acute rheumatic fever, or inferior myocardial infarction. With digoxin toxicity, the rate is usually between 70 and 130. If this rhythm develops in a patient being treated with digoxin for atrial fibrillation, the ECG is characterized by regular QRS complexes superimposed on atrial fibrillatory waves. Regulation of ventricular response during digoxin therapy in a patient with atrial fibrillation should therefore raise the suspicion of digoxin toxicity.

Treatment

1. Isolated, infrequent junctional escape beats usually do not require specific treatment.
2. If sustained junctional escape rhythms are producing symptoms, the underlying cause should be treated. Atropine can be used to accelerate the sinus node discharge rate temporarily and enhance AV nodal conduction.
3. Accelerated junctional rhythm and junctional tachycardia usually do not produce significant symptoms. If the cause is digoxin toxicity, the drug should be discontinued. If the rate is fast and producing symptoms, giving supplemental potassium to increase the serum level into the high-normal range may decrease it.

Ventricular Dysrhythmias

PREMATURE VENTRICULAR CONTRACTIONS (PVCs)   PVCs are due to impulses originating from single or multiple areas in the ventricles. The ECG characteristics of PVCs are as follows:

1. There is a premature and wide QRS complex.
2. There is no preceding P wave.
3. The ST segment and T wave of the PVC are directed opposite the major QRS deflection.
4. Most PVCs do not affect the sinus node, so there is usually a fully compensatory postectopic pause or the PVC may be interpolated between two sinus beats.
5. Many PVCs have a fixed coupling interval (within 0.04 s) from the preceding sinus beat.
6. Some PVCs are conducted into the atria, producing a retrograde P wave (Fig. 24-16).

FIG. 24-16. Premature ventricular contractions (PVCs). Top: unifocal PVC. Center: interpolated PVC. Bottom: multifocal PVCs.

Occasionally, a ventricular fusion beat occurs when supraventricular and ventricular impulses depolarize the ventricles almost simultaneously. The QRS configuration of a fusion beat contains features of the individual components.

A PVC may be confused with an aberrantly conducted supraventricular beat. Several clinical and ECG criteria can be used to help distinguish aberrantly conducted supraventricular beats from PVCs; this is discussed later in this section.

Clinical Significance   PVCs are very common, even in patients without evidence of heart disease. They occur in most patients with ischemic heart disease and are universally found in patients with acute myocardial infarction (MI). Other common causes of PVCs include digoxin toxicity, congestive heart failure, hypokalemia, alkalosis, hypoxia, and sympathomimetic drugs.

While there is a correlation between the severity of underlying coronary artery disease and the degree of ventricular ectopy, there is disagreement as to whether ventricular ectopy itself is an independent risk factor for future morbidity or mortality. Most studies indicate that repetitive PVCs (two or more in a row) do have some associated independent risk in patients with coronary artery disease, but the evidence for other forms of ventricular ectopy is less convincing. Lown has made an attempt with his classification to quantitate the risks associated with chronic ventricular ectopy, but his classification is not universally accepted (Table 24-2). It must be remembered that his classification was made using patients with recent acute MIs.

Grade	ECG Characteristics
1	Uniform PVCs < 30/h
2	Uniform PVCs > 30/h
3	Multiform PVCs
4A	Couplets (2 consecutive PVCs)
4B	Triplets (3 or more consecutive PVCs)
5	R-on-T PVCs

TABLE 24-2   Lown Grading System for Ventricular Ectopy

In the setting of an acute MI, PVCs indicate the underlying electrical instability of the heart. The patients are at increased risk for the development of primary ventricular fibrillation. Current work indicates that various degrees of PVCs ("warning dysrhythmias") are not reliable predictors of subsequent ventricular fibrillation.

Although it is experimentally established that electric impulses, such as PVCs, that occur during or soon after repolarization (the so-called vulnerable period) can initiate ventricular tachycardia or fibrillation, clinical studies have found that late-coupled PVCs initiate more paroxysms of ventricular tachycardia than early-coupled PVCs (R-on-T phenomenon).

Treatment

1. Most patients with acute myocardial disease and PVCs will respond to intravenous lidocaine, although some patients may require procainamide. In the setting of acute myocardial ischemia (unstable angina or acute MI), many physicians would treat frequent or multiform PVCs with the goal of reducing deaths due to sudden ventricular tachycardia or fibrillation. While single studies have suggested benefit, pooled data and metanalyses find no reduction in mortality from either suppressive or prophylactic treatment of PVCs.
2. In patients with chronic PVCs, there is no evidence that oral antiarrthymics enhance survival. To the contrary, large, randomized studies of postinfarction patients found that treatment with encainide, flecainide, or moricizine increased the incidence of cardiac arrest or arrhythmic death, probably related to their proarrthymic effects. Before treating chronic PVCs, the physician should consider several factors:
   a. Underlying heart disease
   b. The nature of the ectopy
   c. The presence or absence of symptoms
   d. The potential side effects of oral antiarrhythmic therapy
   e. Which technique will be used to judge efficacy of therapy (continuous monitoring versus EP studies)? Oral antiarrhythmic therapy requires careful monitoring. In some patients at risk of sudden cardiac death, automatic internal cardiac defibrillators (AICDs) are used in conjunction with antiarrhythmics.

VENTRICULAR PARASYSTOLE   Parasystole occurs when an independent ectopic pacemaker is protected from the influence of outside impulses (entrance block) and competes with the dominant pacemaker to produce myocardial depolarizations. A parasystolic pacemaker can arise anywhere in the heart but is most often located in the ventricles, where it produces a rhythm that operates in competition with the sinus node. This ectopic pacemaker has an innate rate; however, not all beats depolarize the ventricle (exit block).

The ECG characteristics of ventricular parasystole are (1) variation in the coupling interval between the preceding sinus beat and the ectopic beat, (2) common

relation between the interectopic beat intervals, and (3) occurrence of fusion beats (Fig. 24-17). Usually, long rhythm strips are necessary to establish that the interectopic intervals are multiples of a common parasystolic pacemaker. Because of the difference in response to antiarrthymics, it is important to recognize and differentiate parasystolic beats from PVCs.

FIG. 24-17. The fifth and eighth ventricular complexes are premature and of similar morphology but have different coupling intervals. The second complex (marked "F") represents a fusion beat. The interectopic interval is 2.36 s. (From Heger JW, Niemann JT, Boman KG, et al: *Cardiology for the House Officer.* Baltimore, Williams & Wilkins, 1982. Used by permission.)

Clinical Significance   Ventricular parasystole is most often associated with severe ischemic heart disease, acute MI, hypertensive heart disease, or electrolyte imbalance. Parasystole is often self-limited and benign but infrequently may lead to ventricular tachycardia or fibrillation.

Treatment

1. The underlying disease should be treated.
2. Antiarrhythmics are indicated in patients with symptomatic episodes or beats that initiate ventricular tachycardia.

ACCELERATED IDIOVENTRICULAR RHYTHM (AIVR)   AIVR is an ectopic rhythm of ventricular origin occurring at a rate of 40 to 100. Even though AIVR is not a tachycardia, such terms as *idioventricular tachycardia, nonparoxysmal ventricular tachycardia,* or *slow ventricular tachycardia* are sometimes used to describe this rhythm.

The ECG characteristics of AIVR are (1) wide and regular QRS complexes, (2) a rate between 40 and 100 that is often close to the preceding sinus rate, (3) most runs of short duration (3 to 30 beats), and (4) an AIVR often beginning with a fusion beat (Fig. 24-18).
FIG. 24-18. Accelerated idioventricular rhythms (AIVR).

Clinical Significance   This condition is found most commonly in the setting of an acute MI. Reports indicate that AIVR sometimes appears during successful thrombolysis of an occluded coronary artery. AIVR and other ventricular dysrhythmias seen during this time are termed *reperfusion dysrhythmias.* AIVR may be seen infrequently in patients without organic heart disease. While there is some variable association with ventricular tachycardia, there is no apparent association with ventricular fibrillation. AIVR usually produces no symptoms itself. Sometimes the loss of atrial contraction and subsequent fall in cardiac output may produce hemodynamic deterioration.

Treatment

1. Treatment is not necessary. On occasion, AIVR may be the only functioning pacemaker, and suppression with lidocaine can lead to cardiac asystole.
2. If sustained AIVR produces symptoms secondary to a decrease in cardiac output, treatment with atrial pacing may be required.

VENTRICULAR TACHYCARDIA   Ventricular tachycardia is the occurrence of three or more depolarizations from a ventricular ectopic pacemaker at a rate greater than 100. The ECG characteristics of ventricular tachycardia are (1) wide QRS complexes; (2) rate greater than 100 (most commonly 150 to 200); (3) rhythm usually regular, although there may be some beat-to-beat variation; and (4) QRS axis usually constant (Fig. 24-19). Uncommonly (about 5 percent of episodes), ventricular tachycardia may have a narrow (<120 ms) QRS complex. In these cases, ECG criteria usually suggest a ventricular origin (see " Aberrant versus Ventricular Tachyarrhythmias," below). Ventricular tachycardia can occur in a nonsustained manner—usually short episodes, lasting seconds, with spontaneous termination—or in a sustained fashion—longer episodes that typically require treatment.
FIG. 24-19. Ventricular tachycardia.

There are several variants of ventricular tachycardia. *Ventricular flutter* is the phrase used for a regular zigzag pattern without distinguishable QRS complexes or T

waves. In *bidirectional ventricular tachycardia,* the QRS complexes alternate polarity as recorded in a single lead. In *alternating ventricular tachycardia,* the QRS complexes alternate in height (but not polarity) in a single lead. (Both bidirectional and alternating ventricular tachycardia indicate serious myocardial disease and are often due to digitalis toxicity.) In *polymorphous ventricular tachycardia,* the QRS complexes have many different shapes in one lead. *Atypical ventricular tachycardia* [torsade de pointes (TdP), or "twisting of the points"] is where the QRS axis swings from a positive to negative direction in a single lead (Fig. 24-20). This rhythm results from a triggered arrhythmic mechanism. TdP usually occurs in short runs of 5 to 15 s at a rate of 200 to 240. This form of ventricular tachycardia generally occurs in patients with serious myocardial disease who have a prolonged and uneven ventricular repolarization (prolonged QT interval) (Table 24-3).
FIG. 24-20. Two examples of short runs of atypical ventricular tachycardia showing sinusoidal variation in amplitude and direction of the QRS complexes: "Le torsade de pointes" (twisting of the points). Note that the top example is initiated by a late-occurring PVC (lead II).

TABLE 24-3 Etiologies and Associated Conditions in Torsades de Pointes

Drugs that further prolong repolarization—quinidine, disopyramide, procainamide, phenothiazines, and tricyclic antidepressants—exacerbate this dysrhythmia. Conventional treatment with lidocaine often is ineffective. To date, treatment for TdP consisted of accelerating the heart rate (thereby shortening ventricular repolarization) with isoproterenol (2 to 8 µg/min) while making arrangements for a ventricular pacemaker to overdrive the heart at rates of 90 to 120. Temporary pacing is the most effective and safest method to treat TdP and prevent its recurrence in the emergency setting. Recent reports have revealed that magnesium sulfate 1 to 2 g IV over 60 to 90 s followed by an infusion of 1 to 2 g/h is effective in abolishing these runs of TdP, although recurrences are seen despite continued infusion. A wide variety of other agents and antiarrhythmics have reported anecdotal success, but overall efficacy has been inconsistent.

Clinical Significance   Ventricular tachycardia is very rare in patients without underlying heart disease. The most common causes of ventricular tachycardia are ischemic heart disease and acute MI. Less common causes include hypertrophic cardiomyopathy, mitral valve prolapse, and toxicity from many drugs (digoxin, quinidine, procainamide, and sympathomimetics). Hypoxia, alkalosis, and electrolyte abnormalities exacerbate the tendency toward ventricular ectopy and tachycardia.

It is a common misconception that patients with ventricular tachycardia appear clinically unstable; this is the basis for the mistaken assumption that patients who appear stable with a wide complex tachycardia have SVT with aberrancy rather than ventricular tachycardia. This is definitely wrong. Ventricular tachycardia cannot be differentiated from SVT with aberrancy on the basis of clinical symptoms, blood pressure, or heart rate. Patients who are unstable should be cardioverted; this is effective for both dysrhythmias. In patients who are stable, a 12-lead ECG should be obtained first and examined for evidence favoring one dysrhythmia over another; but even then, it is often difficult to decide. Therefore, in general, it is best to treat all wide complex tachycardias as ventricular tachycardia with lidocaine or procainamide. These drugs are obviously effective in ventricular tachycardia and often surprisingly effective in SVT with aberrancy, and they carry little risk of harming the patient. Conversely, verapamil is harmful in most patients with ventricular tachycardia, accelerating the heart rate and the decreasing blood pressure without converting the rhythm. Adenosine appears to do little harm in patients with ventricular tachycardia and has potential merit for the treatment for wide QRS complex tachycardias. However, until further experience is gained with this agent, it cannot be recommended for routine use in this setting.

Treatment

1. Unstable patients or those in cardiac arrest should be treated with synchronized cardioversion. Ventricular tachycardia can be converted with energies as low as 1 J, and over 90 percent can be converted with less than 10 J. Rarely is more than 100 J needed. Current advanced cardiac life support (ACLS) guidelines recommend that pulseless ventricular tachycardia be *defibrillated* (unsynchronized cardioversion) with 200 J.
2. Clinically stable patients should be treated with intravenous antiarrhythmics.
   a. Lidocaine 75 mg (1.0 to 1.5 mg/kg) IV over 60 to 90 s, followed by a constant infusion at 1 to 4 mg/min (10 to 40 µg/kg per minute). A repeat bolus dose of 50 mg lidocaine may be required during the first 20 min to avoid a subtherapeutic dip in serum level due to the early distribution phase.
   b. Bretylium 500 mg (5 to 10 mg/kg) IV over 10 min, followed by a constant infusion at 1 to 2 mg/min.
   c. Procainamide at a rate of less than 50 mg/min IV until the dysrhythmia converts, the total dose reaches 15 to 17 mg/kg in normals (12 mg/kg in patients with congestive heart failure), or early signs of toxicity develop with hypotension or QRS prolongation. The loading dose should be followed by a maintenance infusion of 2.8 mg/kg per hour in normal subjects (1.4 mg/kg per hour in patients with renal insufficiency).
   d. A variety of other antiarrhythmics have been studied for the treatment of ventricular tachycardia. Most class I and III agents are effective for the acute termination of ventricular tachycardia when given intravenously. Recommendations concerning their routine use will have to await further studies.

VENTRICULAR FIBRILLATION   Ventricular fibrillation is the totally disorganized depolarization and contraction of small areas of ventricular myocardium—there is no effective ventricular pumping activity. The ECG of ventricular fibrillation shows a fine to coarse zigzag pattern without discernible P waves or QRS complexes (Fig. 24-21).
FIG. 24-21. Ventricular fibrillation.

A pulse or blood pressure never accompanies ventricular fibrillation. In patients who are awake and responsive, the ECG pattern of ventricular fibrillation is caused by a loose lead artifact or electrical interference.

Clinical Significance Ventricular fibrillation is most commonly seen in patients with severe ischemic heart disease, with or without an acute MI. Primary ventricular fibrillation occurs suddenly, without preceding hemodynamic deterioration, while secondary ventricular fibrillation occurs after a prolonged period of left ventricular failure and/or circulatory shock. Ventricular fibrillation may also occur from digoxin toxicity, quinidine toxicity, hypothermia, blunt chest trauma, severe electrolyte abnormality, or myocardial irritation caused by an intracardiac catheter or pacemaker electrode.

Treatment

1. Current ACLS guidelines recommend immediate electrical defibrillation with 200 J. If ventricular fibrillation persists, defibrillation should be repeated immediately with 200 to 300 J for the second attempt and increased to 360 J for the third attempt.
2. If the initial three attempts at defibrillation are unsuccessful, CPR should be initiated and, according to ACLS guidelines, further electrical defibrillations done after the administration of various intravenous drugs.

ABERRANT VERSUS VENTRICULAR TACHYDYSRHYTHMIAS

Differentiation between ectopic beats of ventricular origin and those of supraventricular origin but conducted aberrantly can be difficult, especially in sustained tachycardias with wide QRS complexes [wide complex tachycardia (WCT)]. In general, the majority of patients with WCT have ventricular tachycardia and should be approached as having ventricular tachycardia until proved otherwise. Several guidelines might help in the distinction.

1. A preceding ectopic P' wave is good evidence favoring aberrancy, although coincidental atrial and ventricular ectopic beats or retrograde conduction can occur. During a sustained run of tachycardia, AV dissociation greatly favors a ventricular origin of the dysrhythmia.
2. Postectopic pause. A fully compensatory pause is more likely after a ventricular beat, but exceptions do occur.
3. Fusion beats are good evidence for ventricular origin, but exceptions do occur.
4. A varying bundle branch block pattern suggests aberrancy.
5. Coupling intervals are usually constant with ventricular ectopic beats unless parasystole is present. Varying coupling intervals suggest aberrancy.
6. Response to carotid sinus massage or other vagal maneuvers will slow conduction through the AV node and may abolish reentrant SVT and slow the ventricular response in other supraventricular tachyarrhythmias. These maneuvers have essentially no effect on ventricular dysrhythmias.
7. A QRS duration of longer than 0.14 s is usually only found in ventricular ectopy or tachycardia.
8. QRS morphology: Wellens et al have studied patients with both ventricular tachycardia and SVT with aberrancy using His bundle electrocardiography. Several morphologic ECG criteria were found useful in differentiating between the two (Table 24-4). In the ED, these morphologic criteria are not helpful.

QRS Pattern in V₁	Favors	QRS Pattern in V₆	Favors
rSR (RBBB pattern) rR'	Aberrancy	qRS	Aberrancy
R		rS	
qR		S	
RS	Ventricular	qR or QR	Ventricular
Slurred downslope R		R qQ'	
Slurred upstroke R	Either	RS Slurred R	Either

Source: Wellens HJJ, Friss WHMB, Lie KI. *Am J Med* 64:27, 1978, with permission.

TABLE 24-4 Aberrancy versus Ventricular Ectopy

9. Historical criteria have also been found to be useful: age of the patient over 35 and/or history of MI, congestive heart failure, or coronary artery bypass graft strongly suggest ventricular tachycardia in patients with WCT.

CONDUCTION DISTURBANCES

Sinoatrial (SA) Block

The sinus node discharge must be conducted into the atria to pace the heart during sinus rhythm. If sinus node discharges are delayed or blocked in their outward propagation (exit block), then sinoatrial block is present. Sinoatrial block is divided into first-, second-, and third-degree varieties.

First-degree SA block means that the impulse is delayed in its conduction out of the sinus node into the atria—a condition that cannot be recognized on the clinical ECG.

Second-degree SA block means that some impulses get through and some are blocked. Second-degree SA block can be suspected whenever an expected P wave and the corresponding QRS complex are absent. In the variable (Wenckebach) type of second-degree SA block, the missing P wave would come after a period of progressive prolongation of the conduction time from the sinus node to the atrium, something undetectable on the clinical ECG. However, another ECG finding common to the Wenckebach phenomenon can be seen—progressive shortening of the P-P intervals prior to the missing P wave (Fig. 24-22). In the constant type of second-degree SA block, the sinoatrial conduction time remains constant before and after the blocked impulses. In this situation, the interval encompassing the missing beat is an exact or near-exact multiple of the cycle length (Fig. 24-23).
FIG. 24-22. Second-degree SA block type I (Wenckebach). (From Braunwald E: Heart Disease. *A Textbook of Cardiovascular Medicine.* Philadelphia, Saunders, 1980. Used by permission.)
FIG. 24-23. Second-degree constant SA block type II (lead V$_4$).

Third-degree SA block occurs when the sinus node discharge is completely blocked and no P wave originating from the sinus seen. There are three other causes of absent sinus P waves in addition to third-degree SA block: (1) sinus node failure, (2) a sinus node stimulus inadequate to activate the atria, and (3) atrial unresponsiveness.

CLINICAL SIGNIFICANCE   Sinoatrial block usually arises from myocardial disease (acute rheumatic fever, acute inferior MI, other causes of myocarditis) or drug toxicity (digoxin, quinidine, salicylates, b-adrenergic blockers, or calcium channel blockers). In rare individuals, vagal stimulation can produce SA block.

TREATMENT

1. Treatment depends on the underlying cause, associated dysrhythmias, and whether symptoms of hypoperfusion are present.
2. Sinus node discharge rate and sinoatrial conduction can be facilitated by atropine or isoproterenol when clinically required; however, ischemia may result from a rhythm that is accelerated.
3. Cardiac pacing is indicated for recurrent or persistent symptomatic bradycardia.

Sinus Arrest (Pause)

Sinus pause is a failure of impulse formation within the sinus node. In sinus arrest, the P-P interval has no mathematical relation to the basic sinus node discharge rate (Fig. 24-24).
FIG. 24-24. Sinus pause.

CLINICAL SIGNIFICANCE   The same conditions that produce SA block can also produce sinus arrest, especially digoxin toxicity and aging disease of the SA node, as in sick sinus syndrome, discussed below. The combination of digoxin and carotid sinus massage is well known to be able to produce prolonged sinus arrest. Brief periods of sinus arrest may occur in healthy individuals from increased vagal tone. If sinus arrest is prolonged, AV junctional escape beats often occur.

TREATMENT

1. Treatment depends on the underlying cause, associated dysrhythmias, and whether symptoms of hypoperfusion are present.
2. If sinus arrest is symptomatic, atropine will usually increase the sinus node discharge rate.
3. Cardiac pacing is indicated for recurrent or persisent symptomatic bradycardia.

Atrioventricular (AV) Dissociation

AV is a condition in which separate and independent pacemakers drive the atria and ventricles. It is not a primary rhythm disturbance but is secondary to another conduction or rhythm abnormality. There are two varieties of AV dissociation: passive (default or "escape") and active (usurpation).

Passive AV dissociation occurs when an impulse fails to reach the AV node because of sinus node failure or block. Usually an escape rhythm takes over and paces the ventricles. When the sinus node recovers, atrial activity resumes, but there may be a period during which the ventricles are still driven by the escape pacemaker and the P waves and QRS complexes occur independently of each other (Fig. 24-25).

FIG. 24-25. Passive AV dissociation, secondary to third-degree AV block.

Active AV dissociation occurs when a lower pacemaker accelerates to usurp the sinus node and captures the ventricles but the atria are still paced as before (Fig. 24-26).
FIG. 24-26. Active AV dissociation. (Arrows indicate P waves.)

In both varieties of AV dissociation, fusion beats are common. It is also common for the two pacemakers to operate with nearly identical rates, possibly as a result of mechanical or electrical influences that tend to keep them in phase with each other—a condition termed *isorhythmic dissociation.*

CLINICAL SIGNIFICANCE   Passive AV dissociation occurs when the sinus node discharge rate is slowed by sinus bradycardia, sinus dysrhythmia, SA block, or sinus pause. Common causes of this include (1) ischemic heart disease (especially acute inferior myocardial infarction), (2) myocarditis (especially acute rheumatic fever), (3) drug toxicity (especially digoxin), and (4) vagal reflexes. It may also be seen in well-conditioned athletes.

Active AV dissociation occurs when the automaticity of lower pacemakers is enhanced. Common causes include myocardial ischemia and drug toxicity (especially digoxin). This form of AV dissociation is seen only when the lower tachycardiac rhythm is not conducted to the sinus node with capture of the SA node. Ventricular tachycardia is the classic example of an active AV dissociation.

TREATMENT

1. Most occurrences of AV dissociation have an acceptable heart rate and are well tolerated.
2. Therapy, if any, is directed toward the underlying cause.

Atrioventricular (AV) Block

Clinical classification of AV block was done before the sites and mechanisms involved in impairing conduction between the atria and ventricles were understood. As a matter of fact, Wenkebach described his block prior to the development of ECGs by looking at the A and V waves in the jugular veins. Mobitz described his classification after the invention of the ECG but before His bundle recordings. This classification is too simple to categorize all the problems that may occur with AV conduction. However, this system is almost universally used in respect to their observations.

First-degree AV block is characterized by a delay in AV conduction manifest by a prolonged PR interval. Second-degree AV block is characterized by intermittent AV conduction—some atrial impulses reach the ventricles and others are blocked. Third-degree AV block is characterized by the complete interruption of AV conduction.

Precise localization of AV conduction blocks can be made with His bundle electrocardiography. Although this method is not available for use in the ED, correlations can be made between the clinical ECG, approximate location of the block, and risk of future progression.

AV blocks can also be divided into nodal and infranodal blocks. This is an important distinction because the clinical significance and prognosis vary with the site. AV nodal blocks (block at the AH area by the His bundle) are usually due to reversible depression of conduction, are often self-limited, and generally have a stable infranodal escape pacemaker pacing the ventricles. AV nodal blocks therefore do not usually have a serious prognosis. Infranodal blocks (block at the HV area by the His bundle) are usually due to organic disease of the His bundle or bundle branches; often the damage is irreversible. They generally have a slow and unstable ventricular escape rhythm pacing the ventricles, and they may have a serious prognosis depending on the clinical circumstance.

FIRST-DEGREE AV BLOCK   In first-degree AV block, each atrial impulse is conducted into the ventricles, but more slowly than normal. This is recognized by a PR interval of greater than 0.20 s (Fig. 24-27). The AV node is usually the site of conduction delay, although this may occur at any infranodal level.
FIG. 24-27. First-degree AV block (PR interval = 0.3 s).

Clinical Significance   First-degree AV block is occasionally found in normal hearts. Other common causes include increased vagal tone (whatever the cause), digoxin toxicity, acute inferior MI, and myocarditis. Patients with first-degree AV block without evidence of organic heart disease appear to have no significant difference in mortality compared with matched controls.

Treatment

1. None is usually required.
2. Prophylactic pacing in acute myocardial infarction is not indicated unless more serious infranodal conduction disturbances are present.

Second-Degree Mobitz I (Wenckebach) AV Block

In this block there is progressive prolongation of AV conduction (and the PR interval) until an atrial impulse is completely blocked (Fig. 24-28). This property of gradually increasing block until complete block is a normal property of cardiac tissue. In the face of disease, this property occurs at a much slower rate. In the electrophysiology laboratory (EP), a Wenkebach type of block is frequently seen when atrial pacing occurs at fast rates to uncover an accessory pathway. Conduction ratios are used to indicate the ratio of atrial to ventricular depolarizations: 3:2 indicates that two out of three atrial impulses are conducted into the ventricles. Usually, only a single atrial impulse is blocked. After the dropped beat, the AV conduction returns to normal and the cycle usually repeats itself with either the same conduction ratio (fixed ratio) or a different conduction ratio (variable ratio). This type of block almost always occurs at the level of the AV node and is often due to reversible depression of AV nodal conduction.
FIG. 24-28. Second-degree Mobitz I (Wenckebach) AV block 4:3 AV conduction.

The Wenckebach phenomenon involves a seeming paradox. Even though the PR intervals progressively lengthen prior to the dropped beat, the increments by which they lengthen decrease with successive beats; this produces a progressive shortening of the R-R interval prior to the dropped beat (Fig. 24-28). This sign can be used to indicate that a Wenckebach phenomenon is occurring even when the conduction delay cannot be seen, as in SA Wenckebach block.

Wenckebach block is believed to occur because each successive depolarization produces prolongation of the refractory period of the AV node. When the next atrial impulse comes upon the node, it is earlier in the relative refractory period and conduction occurs more slowly relative to the previous stimulus. This process is progressive until an atrial impulse reaches the AV node during the absolute refractory period and conduction is blocked altogether. The pause allows the AV node to recover and the process can resume.

CLINICAL SIGNIFICANCE   This block is often transient and usually associated with an acute inferior MI, digoxin toxicity, or myocarditis, or it is seen after cardiac surgery. As mentioned, Wenckebach block may also occur when a normal AV node is exposed to very rapid atrial rates.

TREATMENT

1. Specific treatment is not necessary unless slow ventricular rates produce signs of hypoperfusion.
2. 0.5 mg IV of atropine is given, repeated every 5 min as necessary, titrated to the desired effect, or until the total dose reaches 2.0 mg. Almost all patients will respond to atropine. The need for an increased rate and hopefully increased perfusion must be consistently balanced with the increased myocardial O_2 consumption in the ischemic patient.
3. Isoproterenol is hazardous in the setting of acute myocardial infarction or digoxin toxicity and its use should be avoided.
4. Transcutaneous or transvenous ventricular demand pacing should be initiated if atropine is unsuccessful. It must be confirmed that the hypoperfusion is due to the rate and not to decreased preload, as in some patients with an inferior MI.

Second-Degree Mobitz II AV Block

In this block, the PR interval remains constant before and after the nonconducted atrial beats (Fig. 24-29). One or more beats may be nonconducted at a single time.

FIG. 24-29. Top: second-degree Mobitz II AV block. Bottom: second-degree AV block with 2:1 AV conduction.

Mobitz II blocks usually occur in the infranodal conducting system, often with coexistent fascicular or bundle branch blocks, and the QRS complexes are therefore usually wide. Even if the QRS complexes are narrow, the block is generally in the infranodal system.

When second-degree AV block occurs with a fixed conduction ratio of 2:1, it is not possible to differentiate between a Mobitz type I (Wenckebach) or Mobitz type II block. If the QRS complex is narrow, then the block is in the AV node or infranodal system with about equal incidence. If the QRS complex is wide, the block is more likely to be in the infranodal system.

CLINICAL SIGNIFICANCE   Type II blocks imply structural damage to the infranodal conducting system, are usually permanent, and may progress suddenly to complete heart block—especially in the setting of an acute MI.

TREATMENT

1. Emergent treatment is required when slow ventricular rates produce symptoms of hypoperfusion. Atropine should be the first drug used, and up to 60 percent of patients will respond. Isoproterenol is effective in up to 50 percent of cases but is potentially hazardous in the setting of acute myocardial infarction or digoxin toxicity, and its use should be avoided. Transcutaneous cardiac pacing is a useful modality in patients unresponsive to atropine.
2. Most patients, especially in the setting of acute MI, will require permanent transvenous cardiac pacing.

Third-Degree (Complete) AV Block

In third-degree AV block, there is no atrioventricular conduction. The ventricles are paced by an escape pacemaker at a rate slower than the atrial rate (Fig. 24-30). Third-degree AV block can occur either at nodal or infranodal levels.
FIG. 24-30. Third-degree AV block.

When third-degree AV block occurs at the AV node, a junctional escape pacemaker takes over with a ventricular rate of 40 to 60, and—since the rhythm originates above the bifurcation of the bundle of His—the QRS complexes are narrow.

When third-degree AV block occurs at the infranodal level, the ventricles are driven by a ventricular escape rhythm at a rate of less than 40. In third-degree AV block located at the His bundle level, the escape rhythm has narrow QRS complexes about half of the time. Presumably in these cases, the escape pacemaker resides above the bifurcation of the conducting system into the separate bundle branches. Third-degree AV block located in the bundle branch or elsewhere in the Purkinje system invariably have escape rhythms with wide QRS complexes.

CLINICAL SIGNIFICANCE   Nodal third-degree AV block may develop in up to 8 percent of acute inferior MIs, where it is usually transient, although it may last for several days.

Infranodal third-degree AV blocks indicate structural damage to the infranodal conducting system, as seen with an extensive acute anterior myocardial infarction (AMI). The ventricular escape pacemaker is usually inadequate to maintain cardiac output and is unstable, with periods of ventricular asystole. When third-degree block is seen in acute AMI, mortality is increased even when rhythm is controlled with pacing.

TREATMENT

1. Nodal third-degree AV blocks should be treated like second-degree Mobitz I AV blocks with atropine or ventricular demand pacemaker as required.
2. Infranodal third-degree AV blocks require a ventricular demand pacemaker. Isoproterenol can be used temporarily to accelerate the ventricular escape rhythm, or external cardiac pacing can be performed before transvenous pacemaker placement.

FASCICULAR BLOCKS

Unifascicular Block

Unifascicular block is a conduction block that affects one of the three major infranodal conduction pathways: right bundle branch (RBB), left anterior superior fascicle (LASF), or left posterior inferior fascicle (LPIF). A wide variety of disease processes can produce conduction block in the fascicles: ischemia, cardiomyopathies, valvular (especially aortic), myocarditis, cardiac surgery, congenital conditions, and degenerative processes affecting the conduction tissue (Lenegre or Lev diseases). The RBB and the LASF are relatively small and easily affected parts of the conduction system. The LPIF is very broad and is caused by disease affecting a large area of myocardium.

In LASF block, left ventricular activation is by way of the LPIF and proceeds in an inferior-to-superior and right-to-left direction. The ECG characteristics of LASF block are (1) normal QRS duration, (2) frontal plane mean QRS axis of less than –45°, (3) R wave in lead I greater than the R waves in leads II or III, (4) a qR complex in lead AVL, and (5) deep S wave in leads II, III, and AVF (Fig. 24-31). The LASF is small and easily affected by focal lesions. Other causes of left axis deviation should be excluded—inferior MI, hyperkalemia, preexcitation syndromes, or body habitus. Left ventricular hypertrophy can cause left axis deviation as seen with LASF block; however, the axis is infrequently less than –30.
FIG. 24-31. Left anterior superior fascicular block (LASF block).

In LPIF block, left ventricular activation is by way of the LASF and proceeds in a superior-to-inferior and left-to-right direction. The ECG characteristics of LPIF block are (1) normal QRS duration, (2) frontal plane mean QRS axis greater than 110°, (3) small r and deep S waves in lead I, (4) an R wave in lead III larger than the R wave in lead II, and (5) a qR complex in lead III (Fig. 24-32). The LPIF is broad and not affected by focal lesions; its presence indicates widespread organic heart disease. Other causes of right axis deviation are chronic cor pulmonale, right ventricular hypertrophy, and lateral MI.
FIG. 24-32. Left posterior inferior fascicular block (LPIF block).

In RBB block, ventricular activation is by way of the left bundle branch, proceeding from the left to the right ventricle. The ECG characteristics of RBB block are (1) prolonged QRS duration (greater than 0.12 s); (2) triphasic QRS complexes (RSR') in lead V_1; (3) wide S waves in the lateral leads I, V_5, and V_6; and (4) normal onset of ventricular activation in lead V_6 (Fig. 24-33). The frontal plane mean QRS axis is usually not deviated to the right unless there is associated right ventricular hypertrophy or LPIF block.

FIG. 24-33. Right bundle branch block (RBB block).

Bifascicular Block

The term *bifascicular block* refers to conduction blocks over two fascicles: (1) RBB and LASF, (2) RBB and LPIF, or (3) left bundle branch (LBB) block.

In LBB block, ventricular activation is by way of the RBB and proceeds from right to left and inferior to superior. The ECG characteristics of LBB block are (1) prolonged QRS duration (greater than 0.12 s); (2) large and wide R waves in leads I, aV_L, V_5, and V_6; (3) small r wave followed by deep S wave in leads II, III, aV_F, and V_1 to V_3; and (4) no q waves in leads I, aV_F, V_5, and V_6 (Fig. 24-34).
FIG. 24-34. Left bundle branch block (LBB block).

Trifascicular Block

The term *trifascicular block* refers to a combination of conduction blocks in all three fascicles, either permanent or transient: (1) RBB and LASF with first-degree AV block, (2) RBB and LPIF with first-degree AV block, (3) LBB with first-degree AV block, or (4) alternating RBB and LBB block.

While bi- and trifascicular conduction blocks indicate advanced organic heart disease, long-term follow-up studies of ambulatory patients indicate that the risk of sudden progression to complete heart block and sudden death due to ventricular asystole is not high. Placement of a ventricular demand pacemaker is indicated only for symptoms due to documented bradyarrhythmias.

In the face of an acute myocardial infarction, the risks of complete heart block are much greater when new or preexistent bi- or trifascicular conduction blocks are present. In this setting, prophylactic placement of a ventricular demand pacemaker is indicated.

PRETERMINAL RHYTHMS

Several dysrhythmias may be seen during cardiac resuscitation. Ventricular tachycardia and fibrillation potentially are treatable and resuscitation may result in a functional survivor. The four other dysrhythmias included here have a low rate of successful resuscitation and are much less likely to yield a functional survivor.

Pulseless Electrical Activity (PEA)

PEA is the presence of electrical complexes without accompanying mechanical contraction of the heart (Fig. 24-35). In the setting of a cardiac arrest, PEA is due to a profound metabolic abnormality of the myocardium, rendering it noncontractile. At this time, there is no clearly beneficial therapy; the best that can be recommended currently is continued cardiopulmonary resuscitation and a-adrenergic agents. Although calcium has been advocated traditionally, most studies have found no consistent benefit, and there are serious biophysiologic reasons to question the use of calcium in the setting of cardiac arrest. Electrical pacing is, of course, not effective.
FIG. 24-35. Pulseless electrical activity (PEA).

Other conditions that may mimic PEA are (1) severe hypovolemia, (2) cardiac tamponade, (3) tension pneumothorax, (4) massive pulmonary embolus, and (5) rupture of the ventricular wall. The first three conditions are potentially treatable if recognized early.

Idioventricular Rhythm (IVR)

An IVR is an escape rhythm of ventricular origin with very wide QRS complexes (more than 0.16 s) and a rate less than 40 (Fig. 24-36). Effective cardiac contractions and pulses may or may not be present. Idioventricular rhythm may occur as the result of complete infranodal AV block, AMI, cardiac tamponade, or exsanguinating hemorrhage. Treatment consists of attempting to accelerate the heart rate and enhance mechanical contractility using cardiopulmonary resuscitation and a-adrenergic agents. There is no proven benefit to the use of atropine or isoproterenol to treat IVR during cardiac resuscitation.
FIG. 24-36. Idioventricular rhythm (IVR).

Agonal Ventricular Rhythm

Agonal rhythm is the occurrence of very broad and irregular ventricular complexes at a slow rate, usually without associated ventricular contractions (Fig. 24-37).
FIG. 24-37. Agonal ventricular rhythm. Top: regular. Bottom: irregular.

Cardiac Asystole (Cardiac Standstill)

Asystole is complete absence of any cardiac electrical activity. Treatment consists of attempting to stimulate electrical activity and mechanical contractions with continued cardiopulmonary resuscitation and a-adrenergic agents. Transthoracic or transvenous ventricular pacing may occasionally produce electrical capture but rarely yields effective pumping action if prior agents were unsuccessful.

TACHYCARDIA-BRADYCARDIA SYNDROME (SICK SINUS SYNDROME)

Sick sinus syndrome (SSS) is a heterogeneous disorder consisting of abnormalities of supraventricular impulse generation and conduction that produce a wide variety of intermittent supraventricular tachy- and bradydysrhythmias. The tachydysrhythmias are usually atrial fibrillation, junctional tachycardia, reentrant SVT, and atrial flutter. The bradydysrhythmias are marked sinus bradycardia, prolonged sinus arrest, and sinoatrial block, usually associated with AV nodal conduction abnormalities and inadequate AV junctional escape rhythms.

Clinical Significance

Symptoms of SSS are due to the effects of either fast or slow heart rate. Common symptoms include syncope or near-syncope, palpitations, dyspnea, chest pain, and cerebrovascular accidents.

A wide variety of cardiac diseases can affect the sinus and AV nodes, producing the dysrhythmias of SSS: ischemic and rheumatic disorders, myocarditis and pericarditis, rheumatologic disease, metastatic tumors, surgical damage, or cardiomyopathies.

Conditions such as abdominal pain, increased intracranial pressure, thyrotoxicosis, and hyperkalemia, which increase vagal tone, may exacerbate the abnormalities of SSS and cause increased symptoms. Drugs such as digoxin, quinidine, procainamide, disopyramide, nicotine, b-adrenergic antagonists, or calcium channel blockers also cause increased symptoms.

Ambulatory ECG monitoring or EP studies are usually necessary for the diagnosis of SSS, since a routine ECG will not normally demonstrate the intermittent

dysrhythmias common in this syndrome. The demonstration of increased sensitivity of the sinus node to carotid sinus massage, the Valsalva maneuver, or atropine suggests sinus node dysfunction but is not conclusive proof for the diagnosis of SSS.

Treatment

1. SSS is the most common indication for a permanent pacemaker. This disease of the SA and AV nodes accounts for 48 percent of primary pacemaker implants. Retrospective analysis indicates that a reduction in mortality and in the incidence of CHF, AF, and thromboembolism occurs in patients with atrial pacing (AAI or DDD) compared to ventricular pacing (VVI).
2. Treatment of atrial tachyarrhythmias with digoxin, quinidine, disopyramide, procainamide, propranolol, or verapamil carries the risk of aggravating preexisting AV block or sinus arrest. Therefore, most patients should have pacemaker implantation before drug therapy is begun.

PREEXCITATION SYNDROMES

Preexcitation occurs when the ventricles are activated by an impulse from the atria sooner than would be expected if the impulse were transmitted down the normal conducting pathway (the AV node). Several different forms of preexcitation have been described, based on anatomic, clinical, electrocardiographic, and electrophysiologic abnormalities. All forms of preexcitation are felt to be due to accessory tracts that bypass all or part of the normal conducting system. These bypass tracts have specific names (Fig. 24-38).
FIG. 24-38. Anatomic sites of bypass tracts.

James fibers (atriohisian connection) are a continuation of the posterior internodal tract and connect the atrium and proximal His bundle. Atrial impulses can therefore completely bypass the AV node to activate the ventricles. On ECG, this appears as (1) a short PR interval because the usual delay in the AV node is bypassed and (2) a normal QRS because James fibers insert directly into the infranodal conducting system and the ventricles are activated normally. When this is associated with reentrant SVT, the clinical condition is termed the Lown-Ganong-Levine (LGL) syndrome.

Mahaim bundles are composed of myogenic tissue; they originate from either the AV node, His bundle, or bundle branches and insert into the ventricles in the septal region. Atrial impulses pass through the AV node but then bypass all or part of the infranodal conducting system to activate the ventricles. Ventricular activation then occurs from two sources, the bypass tract and the normal conducting system, and the QRS complex represents a fusion of the two. The initial depolarization starts at the ventricular insertion of the bypass tract and is spread slowly by cell-to-cell transmission of the impulse. Subsequent depolarization by way of the faster normal conducting system then overtakes the initial depolarization and activates the bulk of ventricular myocardium. The QRS complex is basically normal with a slurred and distorted initial portion termed a *delta wave.* On ECG, this appears as a normal PR interval, and an initial distortion of ventricular depolarization (delta wave).

Kent bundles are composed of myogenic tissue and directly link the atria to the ventricles, completely bypassing the AV node and infranodal system. This is the most common form of preexcitation and is the anatomic basis for the Wolff-Parkinson-White (WPW) syndrome. On ECG, this appears as a shortened PR interval and with an initial distortion of ventricular activation (delta wave). Sometimes the bypass tract does not conduct an atrial impulse in the antegrade direction and the QRS complex is entirely normal. However, these concealed bypass tracts may conduct retrograde and be able to sustain reentrant SVT.

The WPW syndrome has been divided into types, depending on the direction of the initial delta wave on the surface ECG. This, in turn, is determined by where the bypass tract (bundle of Kent) inserts into the ventricles and which portion of the ventricles is activated first. In reality, accessory tracts can insert anywhere around the AV annulus; the three types are just the most common locations.

In type A WPW, ventricular activation first occurs in the inferior-posterior region of the left ventricle and the delta wave is directed anteriorly. A positive initial deflection with a dominant R wave is seen in lead V$_1$. Q waves in leads II, III, and aV$_F$ are common (Fig. 24-39).
FIG. 24-39. Type A Wolff-Parkinson-White syndrome.

In type B WPW, ventricular activation first occurs in the inferior-posterior region of the right ventricle and the delta wave is directed posteriorly and to the left. A negative initial deflection and rS or QS pattern are seen in lead V$_1$ (Fig. 24-40).

FIG. 24-40. Type B Wolff-Parkinson-White syndrome.

In type C WPW, ventricular activation first occurs in the posterior-lateral region of the left ventricle and the delta wave is directed to the right, superiorly, and anteriorly. A positive delta wave is seen in lead V_1, with a negative or isoelectric delta wave in leads V_5 and V_6.

Because there is altered depolarization, repolarization is often abnormal, with changes in the ST segments and T waves. The ECG changes of WPW may mimic changes seen with myocardial ischemia, infarction, or ventricular hypertrophy. Type A WPW may imitate as a posterior MI, and type B WPW may imitate an inferior MI.

Clinical Significance

There is a high incidence of tachyarrhythmias in patients with WPW. Atrial flutter occurs in about 5 percent, atrial fibrillation in 10 to 20 percent, and paroxysmal reentrant SVT in 40 to 80 percent.

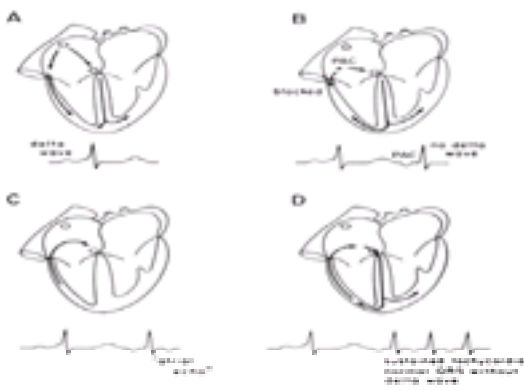
Reentrant SVT occurs when an impulse is sustained around a loop composed of the bypass tract and the AV conducting system, the impulse traveling down one and up the other. Whether the QRS complex is wide or narrow depends on which limb of the circuit is used as the downward pathway to activate the ventricles. About 80 to 95 percent of the time, reentrant SVT occurs with the impulse being conducted down the normal AV conducting system and up the bypass tract [orthodromic AV reciprocating tachycardia (OAVRT)]. In this situation, ventricular activation occurs entirely over the normal system, the QRS complex is normal, and no delta wave is seen. Because the entire heart is used as the reentrant pathway, these arrythmias are easily converted. Conversely, 5 to 10 percent of the time, the impulse is conducted down the bypass tract and retrograde up the AV node [antidromic AV reciprocating tachycardia (AAVRT)]. In this case, the QRS complex is wide, and in the ED setting, this arrythmia is treated as ventricular tachycardia. Reentry is usually initiated by a premature atrial contraction that encounters a bypass tract which still is refractory from the previous sinus beat, but the AV node has recovered partially and conducts the impulse more slowly than normal (Fig. 24-41). In some patients, the bypass tract does not conduct antegrade during sinus rhythm and so no delta wave is seen, but it does conduct retrograde so reentrant SVT occurs. Patients with concealed bypass tracts account for about 20 percent of all patients with reentrant SVT.


FIG. 24-41. Onset of reentrant SVT in Wolff-Parkinson-White syndrome.

If patients with WPW develop atrial flutter or fibrillation, impulses can reach the ventricles via the accessory tract, the normal conducting system, or both. Which pathway is used depends on the refractory period of each. Most patients with WPW have longer refractory periods in their accessory tracts than in the AV node, but a minority have the opposite. In patients with short refractory periods in their accessory tracts, more atrial impulses can be conducted through the accessory tract than the AV node, so most of the QRS complexes will be wide. In atrial flutter, 1:1 AV conduction is possible with ventricular rates of 300 (Fig. 24-42). In atrial fibrillation, very rapid and irregular ventricular rates are possible. These rapid rhythms may resemble ventricular tachycardia, and excessive stimulation of the ventricles may precipitate ventricular fibrillation. Any patient with a ventricular rate of over 300 should raise the suspicion of preexcitation syndrome.
FIG. 24-42. Atrial fibrillation in Wolff-Parkinson-White syndrome.

Treatment

1. Reentrant SVT (OAVRT, narrow QRS complex) in the WPW syndrome can be treated like other cases of reentrant SVT. Since the AV node is involved in the reentry circuit, any maneuver or drug that slows conduction through the AV node is usually effective. Verapamil in the patient who is not hypotensive or in CHF is by some accounts the optimal drug. Adenosine is very successful at terminating this dysrhythmia in patients with WPW; however, there is some proclivity to increase atrial vulnerability to AF and to ectopic atrial activity, which may reinitiate the dysrhythmia.
2. Antidromic tachycardia (AAVRT, wide QRS complex) is usually associated with a short refractory period in the bypass tract, and such patients are at risk for rapid ventricular rates and degeneration into ventricular fibrillation. Stable patients should be treated with intravenous procainamide and unstable patients should be cardioverted. b-adrenergic agents, adenosine, and calcium channel blockers should be avoided.
3. Atrial flutter or fibrillation with a rapid ventricular response is best treated with cardioversion. As an alternative, agents that prolong the refractory period of the accessory tract—such as intravenous procainamide—can be used. Lidocaine may have some utility, and experimental studies with intravenous flecainide have shown promise. In general, phenytoin, esmolol, propranolol, or verapamil should not be used because of their variable effect on accessory conduction. Digoxin is contraindicated, as it may shorten the refractory period and enhance conduction over the bypass tract.

DEFIBRILLATION AND SYNCHRONIZED CARDIOVERSION

Defibrillation and cardioversion is the technique of passing a short burst (about 5 ms) of direct electric current across the thorax to terminate tachyarrhythmias. The electric current simultaneously depolarizes all excitable cardiac tissue and terminates any areas of reentry by halting further propagation of the impulse around the reentry loop. This places all cardiac cells in the same depolarized state, and a dominant pacemaker (usually the sinus node) paces the heart in a regular manner.

Defibrillation or cardioversion uses the same type of equipment. A device stores a known quantity of electrical energy in a storage capacitor and, on command, discharges it through two paddles placed on the chest wall. Usually, a rhythm monitor and a synchronizer circuit are built into the device. Paddle placement can be either anterior-posterior or apex–right parasternal. While some authors found a lower energy requirement for conversion using anterior-posterior paddles, others have not. For emergencies, paddle placement probably does not matter.

To reduce transthorax electrical impedance and increase the amount of current passing through the heart, certain techniques are important at the paddle–chest wall interface. Electrode paste, gel, or saline pads are applied to the surface of the paddles. Firm pressure of 10 to 12.5 kg/cm^2 (20 to 25 lb/in.^{2}) is used to achieve good electrical contact. Larger paddles or defibrillator pads, within reason, have a reduced impedance, but this does not appear to significantly influence the energy required for conversion.

Older devices had significant internal energy losses and delivered as little as 40 percent of the stored energy to the patient. This is not a problem with modern defibrillators, as they deliver very close to the stored amount.

Defibrillation should be done as soon as ventricular fibrillation is diagnosed. The longer ventricular fibrillation persists, the less likely it is that resuscitation will be successful. Current ACLS guidelines recommend 200 J for the first attempt, 200 to 300 J for the second attempt, and 360 J for subsequent defibrillations. Several studies have found that most patients can be defibrillated with 160 to 200 J. Recommendations for children are 2 J/kg (1 J/lb) in the initial attempt and 4 J/kg on subsequent attempts.

Synchronized cardioversion applies the electric current at a time during the cardiac cycle well away from the vulnerable period when there is little chance of inducing ventricular fibrillation—usually about 10 ms after the peak of the R wave. On most machines, the synchronizer circuit must be turned on each time an impulse is desired. Many devices also display by the monitor screen or a flashing light that the synchronizer circuit is detecting properly the QRS complex. Cable leads, rather than the paddles, should be used to monitor the cardiac rhythm to avoid any movement artifact that could be misinterpreted by the synchronizer circuit as the QRS complex.

Complications of defibrillation or cardioversion include the following:

1. Direct myocardial damage: unusual unless there are repeated shocks at high energy (more than 325 J).
2. Ventricular fibrillation: incidence is less than 5 percent with a synchronized discharge but probably greater in the presence of digoxin or quinidine toxicity, hypokalemia, or AMI. However, patients on maintenance digoxin therapy can be safely cardioverted using low energies (less than 50 J).
3. Systemic emboli: about 1.2 to 1.5 percent in patients with chronic atrial fibrillation.
4. ST segment changes: transient elevations or depressions, usually resolving within 5 min.
5. Bradycardias: more common in patients with inferior MIs and those requiring multiple defibrillations-cardioversions. Bradycardias are usually evident during the first 5 s after shock and may occasionally persist for longer than 20 s and require external or internal pacing.
6. Tachycardias: usually sinus tachycardia, occasionally atrial flutter or fibrillation, and usually resolving spontaneously within 5 min.
7. Atrial, junctional, or ventricular ectopy: usually transient and benign.
8. Pulmonary edema: uncommon but may occur in patients with mitral or aortic valvular disease or left ventricular failure.
9. Hypotension: rare, inexplicable, and may last for several hours before spontaneously resolving.
10. Muscle damage: elevated levels of creatine phosphokinase and lactate dehydrogenase are common, but other more specific indicators (CPK-MB and troponin) are rarely abnormal.

CARDIAC PACEMAKERS

Artificial cardiac pacemakers have two components: a power source (battery with pulse generator) and an electrode that delivers current to the heart (transvenous, epicardial, transthoracic, and transcutaneous). In permanent pacemaker placement, the power source is implanted subcutaneously, and the electrodes are run through the veins to inside the heart or through the subcutaneous tissue to the epicardial surface. In temporary pacemaker placement, the power source is external to the body, and electrodes are placed in one of two ways: (1) transvenously to an intracardiac location or (2) transcutaneously with electrodes placed on the thoracic skin. The pulse generator can be designated to operate in either a fixed-rate mode (asynchronous or competitive) or a demand mode (synchronous or noncompetitive). In the fixed-rate mode, the pulse generator produces an electrical signal at the preset rate regardless of the patient's own intrinsic cardiac rhythm. Serious dysrhythmias or ventricular fibrillation may occur if the pacemaker discharges during the vulnerable period (T wave); for this reason, fixed-rate pacing is rarely done.

In the demand mode, the pulse generator has a sensing circuit that detects spontaneous cardiac activity and will discharge only if no cardiac depolarization is detected for a preset interval. Demand pacemakers may have two response modes, either inhibited or triggered. Pacemakers set to be inhibited have a pulse generator that is inhibited by the sensed cardiac activity and do not generate an impulse. In the triggered response mode, the pacemaker detects the patient's intrinsic cardiac activity and then discharges during the absolute refractory period. On ECG, this appears as pacing spikes following each intrinsic QRS complex.

The latest five-letter code system is shown in Table 24-5. This coding system has added antitachyarrhythmic and shocking capabilities of the latest pacemakers. Many patients carry cards indicating the type of pacemaker they have. The simplest type of pacemaker used—the ventricular-demand inhibited-response pacemaker—would be designated as VVI.

TABLE 24-5   NASPE/BPEG Generic (NBG) Pacemaker Code*

The modern permanent pacemaker is powered by a lithium battery that has an approximate lifetime of 8 to 12 years. Most units are preset for rates around 70, with a pacing interval of 0.84 s. The demand pacemaker has a built-in refractory period (0.2 to 0.4 s) during which it will not sense. This prevents it from being inhibited by its own stimulus. Most demand pacemakers have a magnetic switch, which temporarily converts the pulse generator from the demand mode to the fixed-rate mode when a magnet is held over the unit. In this way, the pacing rate can be quickly determined, but the magnet should be applied for only short periods to avoid initiating tachyarrhythmias. The rate and stimulus strength can be reset by noninvasive means in programmable pacemakers. Some of the more sophisticated pacemakers can be interrogated to indicate events such as tachyarrhythmias and conversions. Since pacemaker complexity varies, the manufacturer supplies an identification card with each unit that patients should carry.

Temporary pacemakers are powered by 9-V radio-type batteries. On these pacemakers, there are settings for the mode (fixed or demand), rate (40 to 140), and stimulus strength (0.2 to 20 mA). During emergency pacing, initial settings should be in the demand mode with a rate around 70 and stimulus strength around 3.0 mA. The negative terminal should be connected to the distal electrode.

The transvenous intracardiac electrode may be either unipolar or bipolar. The unipolar setup has the negative electrode within the heart and the positive electrode in

the chest wall. Permanent pacemakers using the unipolar setup have the positive electrode in their surface covering. Temporary pacemakers using the unipolar setup have their positive electrode connected to a needle implanted in the skin of the anterior thorax. With the bipolar setup, both electrodes are within a few millimeters of each other and both lie within the heart. Transvenous electrodes are placed most commonly into the apex of the right ventricle. This causes an LBBB pattern when pacing. Different catheters are used depending on the clinical situation. Semirigid catheters (6 or 7 Fr) are inserted through a venous puncture or cutdown. They usually require fluoroscopy for correct placement. Semifloating (3 or 4 Fr) or flexible balloon-tipped catheters (3 or 5 Fr) can be introduced and directed into the right ventricle without fluoroscopy, using blood flow. Flexible catheters can become dislodged by patient or cardiac movement and are usually replaced with semirigid catheters within 24 h.

Transthoracic cardiac pacing has been largely replaced by transcutaneous pacing. Transthoracic pacing is fraught with many complications, including coronary artery laceration and cardiac tamponade in addition to pneumothorax (Fig. 24-43).
FIG. 24-43. Ventricular capture with transthoracic pacing.

Transcutaneous electrodes are self-adhesive pads that are usually placed with the negative electrode over the left anterior precordium and the positive electrode over the left infrascapular area. Transcutaneous pacing is then initiated by using the lowest current setting, which is increased until electrical capture is achieved. Most patients can be paced with 100 mA, but some may require up to 200 mA. The newer pacemakers cause much less discomfort, can be applied faster, and combine defibrillator and pacing functions from the same pads.

Indications for Emergency Pacing

Emergency cardiac pacing is indicated either therapeutically (for symptomatic bradyarrhythmias) or prophylactically (for conduction defects that pose a high risk of sudden complete heart block or asystole).

As noted before, symptomatic bradyarrhythmias should be treated with atropine and/or isoproterenol as a temporary measure to support cardiac rhythm prior to pacemaker placement. Some patients may respond adequately to atropine alone and do not require pacemaker insertion.

Most authors would recommend prophylactic placement of a pacemaker in any patient with acute myocardial infarction who has a new or age-indeterminant bi- or trifascicular block. In addition, second-degree Mobitz II and, of course, third-degree AV blocks are also indications for pacemaker insertion or transcutaneous pacer pads. Despite successful pacing, many patients with acute myocardial infarction and these serious conduction blocks have extensive left ventricular damage and a high mortality from pump failure.

Pacemaker Malfunction

Malfunction of a permanent pacemaker can be categorized as either (1) failure to sense, (2) failure to pace, (3) oversensing, or (4) combinations of the first three. With current lithium batteries and reliable circuitry, most pacemaker malfunctions are due to problems with the electrodes and not the result of battery exhaustion or pulse-generator failure.

Failure to sense may occur when the voltages of the patient's own intrinsic QRS complex is too low to be detected by the sensing circuit of the pacemaker. Changing from a bipolar to a unipolar setup (if possible) may help the pacemaker sense the intrinsic cardiac activity. Failure to sense may cause the pacemaker to become a fixed-rate pacemaker, discharge during the T wave, and trigger serious dysrhythmias.

Failure to pace may occur when tissue reaction around the electrode makes the myocardium insensitive to the electric discharge that is generated by the pacemaker. It is common for the pacing threshold to increase during the first few weeks after insertion, but further rises are infrequent.

Failure to both sense and pace may be due to battery exhaustion, fracture of the wires in the catheter, or displacement of the electrodes. Battery exhaustion is indicated when the pacing rate slowly decreases. With lithium batteries, such decreases usually occur years before actual battery exhaustion. Greater than a 10 percent change from the initial rate is an urgent indication for replacement. Catheter wire fracture may cause either sustained or intermittent interruption in electrical conductivity. Sudden onset of symptoms and/or bradyarrhythmias suggests catheter fracture. Catheter fractures are rarely seen on routine chest radiographs. The transvenous electrode is usually positioned in the right ventricular apex, with a characteristic appearance on the chest radiograph and ECG. Displacement can be suggested when changes on radiographs or ECG occur.

Oversensing is used to describe the situation where the pacemaker senses electrical activity not associated with atrial or ventricular depolarizations; it is thus inhibited and generation of the pacemaker impulse is suppressed. Causes of oversensing include physiologic electrical activity (T waves, muscle potentials), external electromagnetic interference, and signals generated by the interaction of different portions of the pacing system. Unipolar electrodes are more sensitive to physiologic electrical activity and electromagnetic interference than bipolar electrodes.

Under certain conditions, pacemakers may initiate tachyarrhythmias despite functioning as designed; this usually results from an intrinsic depolarization occurring during the pacemaker refractory period, therefore not being sensed, and the pacemaker firing soon thereafter and initiating a reentrant tachycardia. In this setting, maintenance of the dysrhythmia does not require further participation of the pacemaker. Dual-chamber pacemakers can also induce and sustain dysrhythmias. In this situation, emergent treatment requires reprogramming the pacemaker, if possible, or converting to synchronous mode by placing a magnet over the pulse generator.

EVALUATION OF PALPITATIONS

Palpitations are common symptoms that may be due to an dysrhythmia. Frequently, palpitations are no longer present when the patient presents to the emergency department. The term is nonspecific, but certain descriptions may be helpful in pointing toward certain types of rhythm disturbances. Premature atrial or ventricular contractions followed by a compensatory pause are often described as a flip-flopping in the chest. Atrial or ventricular dysrhythmias can cause a fluttering feeling. Pounding in the neck can be felt when atrial and ventricular contractions are dissociated as in supraventricular or junctional tachycardias. Inappropriate sinus tachycardia is also in the differential diagnosis.

History taking should include questions regarding prescribed medications, including herbals; recreational drugs, and use of caffeine-containing beverages. History suggestive of endocrine disorders such as hyperthyroidism should also be sought. If the clinical presentation suggests potassium abnormality, electrolytes can be checked.

Palpitations associated with dizziness, syncope, or presyncope should be assumed to be associated with ventricular tachycardia until proven otherwise. While panic

attack is often assumed to be associated with palpitations; this diagnosis cannot be established in the ED.

The ECG should be examined for evidence of dysrhythmia, bypass tracts, and QT-interval prolongation. Patients with a family history of sudden death, syncope, or dysrhythmia, those with any evidence of organic heart disease, and those with presyncope, syncope, or dizziness can be admitted or placed in an observation unit for monitoring and electrophysiologic testing. Patients felt to be at lower risk can be discharged and ambulatory monitoring arranged by the continuing care physician.

25 PHARMACOLOGY OF ANTIDYSRHYTHMIC AND VASOACTIVE MEDICATIONS

Teresa M. Carlin

To understand antidysrhythmic therapy, one must be familiar with the cardiac cycle. The action potential is made up of four phases, with phase 4 representing diastole. During diastole, pacemaker cells slowly depolarize (automaticity) while all other myocytes are electrically quiescent. Once the pacemaker reaches threshold, through propagation of an action potential, myocardial cells rapidly depolarize in coordinated fashion because of influx of sodium through voltage-dependent sodium channels (phase 0). The efflux of potassium down its concentration gradient initiates repolarization (phase 1). The phase 2 plateau occurs when ion fluxes across membranes are in equilibrium—namely, calcium influx via slow calcium channels and potassium efflux. The influx of calcium allows the heart to contract. During phase 3, the calcium channels close and potassium permeability increases, which permits rapid repolarization. The beginning of phase 0 (rapid depolarization) until midway through phase 3 (rapid repolarization) represents the absolute refractory period. During the effective refractory period (ERP), a second action potential cannot be elicited. (Fig. 25-1).
FIG. 25-1. Ventricular myocardial cell transmembrane action potential.

The Vaughan Williams classification of antidysrhythmics groups drugs based on their ability to block sodium channels (class I), block calcium channels (class IV), block beta-adrenergic receptors (class II), or prolong the refractory period (class III) (Table 25-1). Digoxin and adenosine do not fit into this scheme.

TABLE 25-1   Electrophysiologic Actions of Antidysrhythmic Agents

ANTIDYSRHYTHMIC AGENTS

Class I Antidysrhythmic Agents

PROCAINAMIDE   Procainamide is useful as an antidysrhythmic agent in the treatment of various ventricular and supraventricular dysrrhythmias. Procainamide was developed after the antidysrhythmic effects of the local anesthetic agent procaine were realized. However, procaine's short duration of action and its prominent central nervous system (CNS) effects rule it out for its clinical use.

Like all class I agents, procainamide blocks sodium channels and depresses the speed of impulse conduction (phase 0) of the cardiac action potential. It prolongs the duration of the action potential and the effective refractory period. This is reflected on the electrocardiogram (ECG) as QRS, QT, and PR interval prolongation. These effects directly depress myocardial conduction, suppress fibrillatory activity in the atria and ventricles, and prevent ectopic or reentrant dysrhythmias. These electrophysic effects of procainamide are more pronounced at faster heart rates.

Procainamide suppresses automaticity (phase 4), especially of ectopic pacemakers, secondary to its anticholinergic properties. The effects on AV node conduction are variable. Sodium channel blockade slows AV node conduction time. However, anticholinergic stimulation tends to speed AV node conduction. The antimuscarinic effects are dose dependent. Large doses of procainamide will provide extensive anticholinergic effects and may even increase automaticity (inducing a prodysrhythmic effect). Unlike quinidine, procainamide produces more local anesthetic effects but less vagolytic effects. Procainamide is less depressing to cardiac contractility than quinidine; negative inotropy is most pronounced in ischemic tissue.

Pharmacokinetics   The onset of action of procainamide is 5 to 10 min following intravenous administration and 15 to 60 min following intramuscular injection. Procainamide has an elimination half-life of 2.5 to 4.7 h (in normal renal function) and an apparent volume of distribution (Vd) of 2 L/kg. However, in patients with congestive heart failure (CHF) and renal dysfunction, the elimination half-life may increase and the Vd may decrease (i.e., requiring smaller doses). Procainamide is metabolized to an active compound, Λ-acetyl procainamide (NAPA), in the liver via Λ-acetyltransferase. This active metabolite has an average half-life of 7 h in patients with normal renal function. Rapid acetylators convert greater amounts of procainamide to NAPA than do slow acetylators. Plasma procainamide levels of approximately 4 to 10 mg/mL are usually required to suppress ventricular dysrhythmias. Refractory dysrhythmias may require levels up to 20 mg/mL (usually 10 to 15

mg/mL). Adverse effects often appear with levels greater than 12 mg/mL.

Common Emergency Department (ED) Indications   Procainamide is a second-line agent generally used to treat and prevent recurrence of ventricular dysrhythmias, specifically stable ventricular tachycardia (VT) and premature ventricular contractions (PVCs) that are unresponsive to lidocaine. It is infrequently used in ventricular fibrillation (VF) or pulseless VT because it takes so long to achieve therapeutic concentrations. Procainamide may also be used for slowing or converting supraventricular tachycardias (SVT) including atrial flutter and fibrillation [especially in Wolff-Parkinson-White (WPW) syndrome], paroxysmal supraventricular tachycardia (PSVT), paroxysmal atrial tachycardia (PAT), and paroxysmal atrioventricular (AV) junctional rhythm. Contraindications include complete AV heart block, second- or third-degree heart block (without an electrical pacemaker present), long QT intervals, and torsades de pointes. The drug should be used cautiously in patients with systemic lupus erythematosus, CHF, and hepatic or renal disease and avoided in those with allergies to procaine or amide-type drugs.

Dosing and Administration   In the past, the recommendation for intravenous loading of procainamide for treating ventricular dysrhythmias was as a bolus injection. However, a continuous infusion has been shown to be safer (fewer adverse effects) than a bolus injection until the dysrhythmia is controlled, hypotension develops, the QRS complex widens more than 50 percent, prolongation of the QT interval develops, or a total of 17 mg/kg (1.2 g for a 70-kg patient) has been given. The recommended infusion rate is 20 mg/min; in urgent situations, however, 30 mg/min may be given cautiously. Blood pressure and QRS complex must be monitored during intravenous administration. If procainamide suppresses the VT, initiate a continuous infusion at 1 to 4 mg/min to maintain the suppression. Lower doses are generally necessary for patients with CHF, hypotensive states, and hepatic or renal failure. Measurement of daily serum levels of procainamide or NAPA should be considered in patients with risk factors for impaired clearance.

Alternatively, oral therapy may be started after intravenous loading with procainamide (375 to 500 mg PO q3–4h) or a sustained-release preparation may be used (Procan SR or Pronestyl-SR in a dose of between 500 and 1000 mg q6–8h).

Adverse-Effects Profile   The most serious adverse effects of procainamide are from myocardial depression. ECG changes may include prolongation of the QRS and QT intervals, impairment of AV conduction, VF, and torsades de pointes. High doses or rapid infusion can cause severe hypotension. It should be initiated cautiously in patients with acute myocardial infarction (AMI) owing to its potential prodysrhythmic effect. Procainamide and NAPA levels should be monitored in the following patients: (1) those on procainamide longer than 24 h, (2) those on a maintenance infusion of 3 mg/min or higher, and (3) those with acute CHF or renal failure. Symptoms of systemic lupus erythematosus (SLE) have been reported with chronic administration. Hypersensitivity reactions—characterized by angioedema, acute bronchoconstriction, vascular collapse, febrile episodes, and respiratory arrest—may occur. In addition, idiosyncratic reactions—including agranulocytosis, hepatomegaly, confusion, nausea, vomiting, urticaria, fever, maculopapular eruptions, and thrombocytopenia—may develop with procainamide.

QUINIDINE (GLUCONATE OR SULFATE)   **Actions**   Quinidine is a class IA antidysrhythmic agent with essentially the same mechanism of action as procainamide. However, anticholinergic effects are more pronounced with quinidine. These anticholinergic effects may facilitate conduction across the AV node.

Pharmacokinetics   Onset of action following intravenous administration is within minutes, whereas the onset for the intramuscular and oral routes usually occurs in 1 to 3 h. Therapeutic cardiovascular effects last for the half-life of the drug, 6 to 8 h. The oral sustained-release gluconate preparation, however, can last up to 12 h. Therapeutic serum levels range between 2 and 7 mg/mL. Quinidine has an average Vd of 2 L/kg in healthy adults. It is metabolized in the liver to two active metabolites. Approximately 10 to 50 percent of a dose is excreted as unchanged drug in the urine within 24 h.

Common ED Indications   Quinidine is effective in the treatment of atrial and ventricular dysrhythmias and thus has the same indications as procainamide. It is not commonly used parentally in the ED, since other agents such as procainamide are safer alternatives.

Dosing and Administration   The oral route is preferred in administering quinidine. Oral quinidine is available in three salts: sulfate (83 percent active drug), gluconate (62 percent active drug), and polygalacturonate (60 percent active drug). Only the gluconate and sulfate salts are available for parenteral use. Intramuscular administration is effective in acute but not in critical dysrhythmias. Intravenous administration is now rarely used. The dosage of quinidine varies, depending on the indication and salt used. For example, the adult dosage for suppressing atrial, AV junctional, and ventricular complexes is 324 to 600 mg PO of extended-release quinidine gluconate q8–12h, while the dosage for quinidine sulfate to maintain sinus rhythm after conversion is 200 to 400 mg three or four times daily. The initial IM dose is 600 mg PO of quinidine gluconate, then 400 mg PO as often as q2h until desired effects are seen. Generally, the intravenous dosage required to abolish ventricular dysrhythmias is 300 mg or less; however, 500 to 750 mg may be needed. The rate of infusion should not exceed 16 mg/min, and the ECG and blood pressure should be continuously monitored to gauge the efficacy and safety of treatment.

Adverse-Effects Profile   The adverse-effect profile of quinidine is similar to that of procainamide (including a prodysrhythmic effect) and includes QT prolongation, torsades de pointes, SLE, and hypersensitivity reactions. Toxicity usually impairs therapeutic effectiveness. High serum levels of quinidine may result in cinchonism, which includes tinnitus, blurred vision, headache, nausea, and deafness. Severe cases may lead to delirium and psychosis. Quinidine may also cause SA or AV nodal block and decrease cardiac contractility. It is also associated with acute hemolytic hemolysis, thrombocytopenia, and hepatitis. Hypotension, heart failure, and hepatic disease decrease clearance. Quinidine has also been implicated in raising serum digoxin levels two- to threefold.

Class IB Agents

LIDOCAINE   **Actions**   Lidocaine is the prototype of a class IB agent. It is a first-line agent in the treatment of serious ventricular dysrhythmias. It preferentially depresses the automaticity (phase 4) of the distal conduction system of depolarized and ischemic tissue; it does not affect normal myocardium. It has greater activity at faster heart rates. Lidocaine is not effective against atrial dysrhythmias because it preferentially acts on the His-Purkinje and more distal conduction system. Unlike class IA and IC agents, lidocaine only minimally depresses phase 0 (conduction). The refractory period is essentially unchanged, since the shortening of the action potential duration is offset by the relative lengthening of the effective refractory period.

Lidocaine has local anesthetic effects that stabilize membranes, elevate the ventricular fibrillation threshold, and suppress ventricular ectopy in tissues during acute myocardial ischemia. However, lidocaine is no longer routinely recommended for prophylaxis after myocardial infarction (MI). Although it reduces the incidence of ventricular ectopy and fibrillation after MI, it may increase mortality secondary to asystole, which may occur if ventricular escape rhythms are abolished.

The benefits of lidocaine include its rapid onset of action, its short time to recovery from sodium channel blockade, and its relative lack of adverse hemodynamic effects. It is protein-bound and undergoes hepatic metabolism. Given the extensive first-pass effect, it is not available as an oral medication.

Pharmacokinetics   The onset of action is 30 to 90 s following intravenous administration and 10 min following an intramuscular dose. Subsequent bolus doses are generally required to attain therapeutic plasma levels early in treatment; maintenance infusions started without an initial bolus dose will not attain therapeutic levels for up to 30 min to several hours (based on disease state). Lidocaine has an approximate Vd of 1.3 L/kg in normal patients and 0.9 L/kg in patients with liver disease or CHF or in those who are hypotensive. The drug is available for intravenous use only because of its lack of gastrointestinal (GI) absorption and its high first-pass metabolism. Less than 10 percent is excreted unchanged in the urine. The major metabolites, monoethylglycinexylidide (MEGX) and glycinexylidide (GX), possess antidysrhythmic and neurotoxic actions and are excreted renally.

Lidocaine has a short distribution half-life of 7 to 8 min following an intravenous bolus and 12 to 28 min following intramuscular administration. This short distribution half-life accounts for the short duration of action after a bolus injection. The elimination half-life in healthy patients ranges from 80 to 108 min, but this may increase up to 7 h in patients with CHF or liver disease and is also greatly prolonged in cardiac arrest. Renal dysfunction does not alter kinetics. Therapeutic serum levels range from 1.5 to 6 mg/mL; serum levels greater than 5 mg/mL may cause CNS toxicity. It readily crosses the blood brain barrier, which accounts for its CNS effects. Not all patients require maximum serum levels.

Common ED Indications   Lidocaine is the drug of choice for the suppression of ventricular dysrhythmias and ventricular ectopy (frequent multifocal PVCs, couplets, salvos, and especially long runs of VT) in suspected acute myocardial ischemia or unstable angina. [1] Although once popular, the prophylactic routine use of lidocaine during acute MI is generally not recommended. Such therapy has not been shown to reduce mortality following AMI. In addition, lidocaine should not be used to treat chronic PVC that occur in an asymptomatic patient, as it does not prevent VF. The drug is indicated for control of VT and VF refractory to defibrillation and epinephrine. Lidocaine should be given following successful conversion of ventricular tachydysrhythmias to normal sinus rhythm. It is also indicated for ventricular dysrhythmias associated with cardiac arrest, myocardial infarction, and unstable angina. Lidocaine can be an adjunct to procainamide for the treatment of wide-complex supraventricular dysrhythmias of uncertain type (e.g., WPW syndrome).

Dosing and Administration   Lidocaine is given as an initial bolus dose of 1.0 to 1.5 mg/kg followed by additional bolus doses of 0.5 to 0.75 mg/kg q5–10 min as needed up to a cumulative dose of 3 mg/kg. An alternative method is to give 1.5 mg/kg initially followed by 50-mg bolus doses every 5 min up to a total dose of 225 mg or 3 mg/kg. When VF is present and defibrillation and epinephrine have failed, an initial bolus of 1.5 mg/kg is recommended for all patients. Conscious patients should receive lidocaine at a rate not exceeding 50 mg/min to minimize adverse CNS effects (< 25 mg/min if infused through a central line). However, in pulseless VT or VF, lidocaine can be given by rapid intravenous push. When intravenous lines are not available, the drug may be instilled endotracheally, in which case 2 to $2\frac{1}{2}$ times the intravenous dose diluted with normal saline solution to a total volume of 10 mL is recommended for optimal drug absorption.

VF and pulseless VT should be managed only with intravenous bolus doses. Maintenance infusions should be started at 2 mg/min and titrated up to 4 mg/min as needed (30 to 50 mg/kg per minute) only upon return of perfusion (poor perfusion will hamper the drug's elimination).

Patients more than 70 years of age as well as those with CHF, liver disease, or impaired hepatic blood flow should have their loading dose and maintenance infusion rate lowered by 50 percent. Drug interactions that can prolong the half-life of lidocaine or increase toxicity include those that potentiate neurologic effects (e.g., procainamide, tubocurarine), drugs that undergo metabolism in the liver and increase lidocaine levels (e.g., cimetidine, propranolol), and drugs that can produce excessive cardiac depression (e.g., phenytoin). Septic shock will also produce increased cardiac depression. Since the half-life of lidocaine can be increased after 24 to 48 h in any of the above, serum levels should be obtained and infusions adjusted if therapy is used for longer than 24 h. Lidocaine toxicity may also develop in patients with renal dysfunction because of accumulation of the metabolites. Patients should be switched over to oral antidysrhythmics within the first 24 h.

Adverse-Effects Profile   Adverse effects from lidocaine usually occur when the drug is administered too rapidly in a conscious patient, when excessive doses are administered, or when a drug interaction potentiates toxicity. Symptoms of mild lidocaine toxicity that correlate with levels greater than 5 mg/mL include slurred speech, drowsiness, confusion, nausea, vertigo, ataxia, tinnitus, paresthesias, muscle twitching and tremor. An abrupt change in mental status is classic for lidocaine toxicity and may indicate that an excessive dose was administered or that the rate of administration was excessive. Serious symptoms occurring at plasma levels greater than 9 mg/mL may include psychosis, seizures, and respiratory depression. Lidocaine is contraindicated in patients with known sensitivities to amide-type local anesthetics and those with high degrees of sinoatrial (SA) or AV block. Lidocaine should be used cautiously in sulfite-allergic patients.

PHENYTOIN   Phenytoin also a class IB agent, is used to treat ventricular and supraventricular dysrhythmias associated with digitalis intoxication because of its ability to increase AV nodal conduction time. Unlike lidocaine, phenytoin increases AV nodal conduction. Additionally, it has central sympatholytic activity which is responsible for some of its antidysrhythmic effects. The dose for digoxin-induced dysrhythmias is 100 mg IV q5 min to a total of 1000 to 1500 mg. With parental administration, hypotension can occur secondary to the phenol carrier. Toxic serum levels can result in CNS changes. A further general discussion of phenytoin appears in Chap. 172.

Class IC Antidysrhythmic Agents

Encainide and flecainide are prototypical class IC agents. They have no effect on the duration of the action potential or the refractory period. They cause marked depression of automaticity (phase 4) of pacemaker cells and slow conduction velocity (phase 0). These agents are not used in the ED setting because of associated prodysrhythmic effects. They were earlier thought helpful for the treatment of atrial fibrillation and refractory VT. However, the Cardiac Arrhythmia Suppression Trial (CAST) demonstrated an increased mortality associated with class IC agents when used to suppress ventricular ectopy in patients with a history of a recent MI and LV dysfunction.[2] In fact, encainide was voluntarily taken off the market because of its prodysrhythmic tendencies. It is available only on a limited basis.

Class II Antidysrhythmic Agents: b Blockers

There are numerous b blockers, each being an effective antidysrhythmic because it prevents circulating catecholamines from binding to beta receptors. However, specific to each drug is its degree of cardioselectivity, intrinsic sympathomimetic activity, a-adrenergic blockade, and quinidine-like membrane stabilization. The metabolic effects (such as alterations in glycogen metabolism) and pharmacokinetics (relative potency, route of elimination, distribution in fat and brain, and duration of action) of each agent are also unique.

Two types of beta receptors exist in the body. b_1 receptors are chiefly found in the heart (also kidney and eye), whereas b_2 receptors are primarily extracardiac. The cardiovascular response to b_1 stimulation includes increased inotropy, increased chronotropy, and increased dromotropy. Therefore b_1 blockade reduces cardiac contractility and myocardial oxygen consumption, decreases heart rate and blood pressure, and slows cardiac conduction velocity.

b_2 receptors are primarily in respiratory, uterine, and vascular smooth muscles as well as in the human liver. b_2 stimulation promotes smooth muscle relaxation and glycogenolysis while b_2 blockade is associated with bronchoconstriction and alterations in glucose metabolism, namely hypoglycemia.

Metoprolol, atenolol, and esmolol are b_1-cardioselective drugs. They are better choices for use in patients with a history of asthma, chronic obstructive pulmonary disease (COPD), and diabetes, since the blockade of b_2 receptors may result in adverse outcomes. At high doses, some agents lose their cardioselectivity; the exact dose at which this occurs, however, has not been clearly established.

Propranolol is a noncardioselective b-blocker prototype since it inhibits both the b_1- and b_2-receptor response. It reduces the incidence of sudden cardiac death after MI. Labetalol is a noncardioselective b blocker with a $_1$-adrenergic blocking effects. The b-blocking effects of intravenous labetalol are approximately seven times more potent than the a-blocking effects. Sotalol is a class III antidysrhythmic that has b-antagonistic properties. It is discussed later in the chapter.

Cardioselective b blockers with intrinsic sympathomimetic activity (Table 25-2), such as acebutol, occupy the b receptor and produce low-level stimulation. Despite this stimulation, the receptor is functionally blocked to high sympathetic tone. Theoretically, these drugs would be safer to use in patients with low cardiac output states because of their intrinsic ability to stimulate the heart. This ability may prevent acute drug-induced heart failure, but this has not been proven in clinical trials.

TABLE 25-2   Summary of Dosing and Administration of Common Antidysrhythmic Agents*

b antagonists have a wide spectrum of clinical usefulness. This discussion is limited to acute cardiovascular indications. b blockers slow conduction through the AV node and are therefore useful in slowing the ventricular response in SVT, atrial fibrillation, and atrial flutter. They are particularly useful when these dysrhythmias are dependent on catecholamine stimulation or occur in the setting of an acute myocardial infarction. They are used for rate control but not chemical cardioversion.

b blockers are negative inotropic agents that decrease myocardial oxygen tension. They are therefore useful adjuncts to the treatment of angina and acute myocardial infarction. b blockers limit infarct size, decrease the risk of reinfarction, and reduce mortality in the setting of an AMI. Specifically, propranolol, metoprolol, and atenolol can decrease mortality in AMI patients. This is particularly true if administered early in the course of an AMI (within 6 h of onset), or during an acute anterior infarct. In

low-risk patients receiving thrombolytics, b blockade may reduce mortality and recurrent MI if administered within 2 h of symptom onset and it can lower the rate of nonfatal reinfarction and recurrent ischemia if used within 4 h.

Patients with hypertrophic cardiomyopathy develop diastolic dysfunction. b blockers are first-line therapy for ischemic chest pain associated with diastolic dysfunction and may be used very cautiously in CHF associated with this condition. b blockers help reduce shearing forces in patients with dissecting thoracoabdominal aneurysms. Catecholamine excess such as thyroid storm and hypertensive crisis are successfully treated with b antagonist. Symptoms associated with alcohol withdrawal and with mitral valve prolapse are also ameliorated with b blockers.

Mechanism of Action   Some b-receptor antagonists have quinidine-like membrane stabilization properties. They depress all phases of the cardiac action potential. Specifically, they depress automaticity (phase 4) and conduction velocity (phase 3) and prolong the refractory period (phase 0). Sinus node discharge and AV conduction velocity are both slowed. Heart rate, blood pressure, and contractility are reduced because of the negative inotropic and negative chromotropic effects. The net result is decreased myocardial oxygen consumption.

Adverse-Effects Profiles   The adverse-effects profiles of all b blockers are remarkably similar. Bronchospasm secondary to b_2 blockade is particularly exaggerated in individuals with asthma or COPD. Therefore, these agents are avoided in the severe COPD/asthma population. However, if a clear indication for b blockade exists in the mild COPD/asthma patient, a cardioselective drug may be used. Cardioselective b agonists are less likely to cause bronchoconstriction than are noncardioselective agents. Bradycardia, hypotension, and heart block can occur. Therefore, patients receiving parental medication should be placed on a cardiac monitor with frequent blood pressure assessments. b blockers may precipitate CHF in patients with LV dysfunction secondary to negative inotropic effects. Hypoglycemia and hyperglycemia may occur. Hypoglycemia needs to be considered, since b blockers may mask signs and symptoms of low blood sugar. Other general side effects include nausea, vomiting, diarrhea, dizziness, lassitude, weakness, and sexual dysfunction.

These drugs are generally contraindicated in patients with heart block greater than first degree, CHF, and cardiogenic shock. However, b blockers may provide some relief when CHF is secondary to diastolic dysfunction or tachycardia. They must be used cautiously in patients with asthma, COPD, and diabetes. Cardioselective drugs cause less bronchospasm and glucose abnormalities than nonselective agents. b blockers are pregnancy class C drugs but can be given when benefits outweigh the risks.

PROPRANOLOL   **Actions**   In therapeutic doses, the major effect of propranolol is its b-adrenergic blocking activity. The drug blocks the effects of catecholamines on b receptors, inhibiting chronotropic, inotropic, and vasodilator responses to b-adrenergic stimulation. Propranolol slows the sinus rate, depresses AV conduction, decreases cardiac output, reduces blood pressure on exercise, and reduces both supine and standing blood pressures. In addition, propranolol decreases renin release and myocardial oxygen demand and protects against sudden cardiac death.

Pharmacokinetics   The onset of action of propranolol following intravenous administration is within 1 min, with a half-life of elimination that varies with duration of therapy. In short-term treatment, the elimination half-life approximates 2 to 3 h; in chronic treatment, however, the elimination half-life is 4 h. Propranolol is widely distributed throughout the body, undergoes extensive first-pass metabolism by the liver, and is also significantly bound to sites within the liver. For these reasons, propranolol has a low bioavailability when taken orally as compared to intravenous administration, requiring the intravenous dose to be approximately 10 times smaller than the oral dose. Several metabolites have been discovered; they are primarily excreted in the urine and feces. In significant renal impairment, the proportion of metabolites excreted by the feces will increase. No dosage adjustments are required in patients with kidney disease. Propranolol has the highest lipid solubility of all b blockers as well as the highest protein binding (93 percent).

Common ED Indications   Propranolol is indicated for a wide variety of supraventricular dysrhythmias. These include paroxysmal atrial tachycardia, particularly those dysrhythmias induced by digoxin or catecholamines or associated with the WPW syndrome; refractory sinus tachycardia; atrial flutter or fibrillation refractory to digoxin; persistent atrial extrasystoles that do not respond to conventional therapy; and tachydysrhythmias associated with thyrotoxicosis.[1] Propranolol is less effective for ventricular than for supraventricular dysrhythmias, but it can be used for ventricular tachycardias or ectopic beats due to digoxin or catecholamine toxicity.

Other indications for propranolol include the management of angina and acute myocardial ischemia or infarction because it decreases myocardial oxygen demands; management of all chronic types of hypertension, either alone or in combination with other antihypertensive agents (propranolol is not indicated for hypertensive emergencies); the treatment of idiopathic hypertrophic subaortic stenosis; prophylaxis for common migraine headaches; management of familial or hereditary essential tremor; and as an adjunctive drug following an a-adrenergic blocker in controlling tachycardia due to pheochromocytoma.

Dosing and Administration   For life-threatening dysrhythmias, the intravenous dose of propranolol is 0.5 to 1 mg given as an intravenous bolus up to 5 mg at a rate not exceeding 1 mg/min. The dose may be repeated in 2 min. Since significant myocardial depression can occur when doses greater than 3 mg are given, caution should be used if additional doses are necessary. Intravenous esmolol infusion has been as effective as intravenous propranolol in reducing heart rate and has resulted in a more rapid reversal of b blockade as compared with propranolol.

Adverse-Effects Profile   The adverse-effects profile of propranolol is similar to that of other nonselective b blockers. The drug is generally not given to patients with asthma or allergic rhinitis and is contraindicated in those with sinus bradycardia or advanced SA or AV block. Propranolol should also not be used in CHF or cardiogenic shock unless these conditions are due to tachydysrhythmias. Following an AMI with the presence of heart failure, "cardiac asthma" can be aggravated with propranolol, but less so with cardioselective agents (e.g., esmolol, metoprolol, and atenolol).

ESMOLOL   **Actions**   Esmolol possesses cardioselective b-adrenergic blocking properties. It selectively blocks the b_1 receptor. As with other b blockers, this drug exhibits both negative inotropic and negative chronotropic effects. Esmolol prevents excessive adrenergic stimulation on the myocardium by blocking the b_1 receptors, thus producing an increase in sinus cycle length, prolongation of SA nodal recovery time, and a prolongation in conduction through the AV node. Esmolol is effective for treating SVT and also possesses antihypertensive effects. These may be due to its ability to decrease cardiac output, sympathetic outflow, and renin release from the kidneys, or perhaps from the direct vasodilatory action of the drug.

Pharmacokinetics   Within 1 to 4 min of intravenous loading with esmolol, both the heart rate and blood pressure decline and the PR interval becomes prolonged on the ECG. Of all the available b-blocking agents, esmolol has the shortest duration of action. The elimination half-life is approximately 9 min, and effects of the drug completely reverse within 30 min after cessation of intravenous therapy. This feature makes intravenous esmolol a useful agent for the treatment of acute and unstable SVT, since the adverse or toxic effects disappear quickly upon discontinuation of the drug. The short duration of action also allows the drug to be titrated to effect. Although 90 percent of an administered dose is excreted renally as metabolites, the metabolites possess minimal if any b-blocking effects. Dosing adjustments are thus not required in patients suffering from hepatic or renal insufficiency. At high doses, esmolol loses its cardioselectivity.

Common ED Indications   Esmolol is currently indicated to control ventricular rate for the short term when the termination of SVT is desired. It prevents and treats SVT resulting from increased sympathetic tone during or following surgical procedures. Intravenous esmolol may also be used during surgery as replacement b-blocker therapy to prevent rebound hypertension in patients who have been receiving long-term b-blocker treatment. Esmolol can also be used to maintain normal sinus rhythm (NSR) in post-AMI patients who cannot tolerate oral medications. Esmolol is not indicated for long-term management of SVT.

Dosing and Administration   A loading dose of esmolol is given as an IV bolus of 500 μg/kg over 1 min, followed by IV infusion starting at 50 μg/kg per min infused over 4 min. Assess for therapeutic and adverse effects immediately following the infusion. If there is no response, give another loading dose over 1 min and increase the infusion rate to 100 μg/kg per min for 4 min. If there is still no response, repeat this procedure, using the same bolus dose each time and increasing the infusion rate by increments of 50 μg/kg per min until the rate of infusion reaches 200 μg/kg per min, the desired response is achieved, or adverse effects appear. The majority of patients will respond within this dosage range. A dose-dependent action is noticed, however, and doses above 200 μg/kg per min are usually of no greater benefit. Once adequate therapeutic response is obtained, it is advisable to change infusion rates by no more than 25 μg/kg per min and not use a bolus dose. Also, avoid concentrations greater than 10 μg/mL. The use of esmolol infusions up to 24 h has been well documented. Limited data indicate that esmolol is well tolerated up to 48 h. After achieving a desired hemodynamic response, transition to alternative antidysrhythmic agents should be considered. Wean the patient off esmolol gradually.

The majority of patients will respond within this dosage range. A dose-dependent action is noticed, however, and doses above 200 μg/kg per min are usually of no greater benefit. Once adequate therapeutic response is obtained, it is advisable to change infusion rates by no more than 25 μg/kg per min and not use a bolus dose. Also, avoid concentrations greater than 10 μg/mL. The use of esmolol infusions up to 24 h has been well documented. Limited data indicate that esmolol is well tolerated up to 48 h. After a desired hemodynamic response is achieved, transition to alternative antidysrhythmic agents should be considered. Wean the patient off

esmolol gradually.

Adverse-Effects Profile   Esmolol shares the same toxic potential and adverse effect profile as the other b-blocking agents. The most common adverse effect associated with esmolol use is hypotension, which occurs in approximately 20 to 50 percent of patients being treated for SVT. This usually occurs within 30 min of the initiation of therapy. Other common adverse effects include dizziness, somnolence, and nausea.

LABETALOL   **Actions**   Labetalol possesses membrane-stabilizing effects and thus has some antidysrhythmic action; however, the drug is often used as an antihypertensive agent because it blocks both a- and b-adrenergic receptors. The b-adrenergic blocking effects are nonselective, while the a-blocking effects are selective for the a_1 receptor. The b-blocking effects of labetalol are much greater than its a-blocking effects, in a ratio between 3:1 for oral and 7:1 for intravenous administration. Labetalol possesses some ability to stimulate rather than block the b_2 receptors.

The mechanisms by which labetalol elicits its antihypertensive effects may include any or all of the following: (1) synergistic effects resulting in hypotension when both a_1 and b_1 receptors are blocked, (2) b_2-receptor stimulation, and (3) direct vasodilatory action. Labetalol decreases heart rate, contractility, cardiac output, cardiac work, and total peripheral resistance.

Pharmacokinetics   Labetalol is primarily eliminated by the liver and undergoes extensive first-pass metabolism, with approximately 30 percent of the drug reaching circulation following oral administration. It is excreted in the urine and feces. Very little crosses the blood-brain barrier. Geriatric patients and those with liver disease, however, may have a greater bioavailability. The onset of action of intravenous labetalol is within 2 to 5 min; it peaks in 10 to 15 min and lasts 2 to 4 h. Oral labetalol acts within 20 min to 2 h, peaks within 1 to 4 h, and lasts 8 to 24 h. The elimination half-life is approximately 3 to 8 h in normal individuals. Only 5 percent of the drug is excreted unchanged.

Common ED Indications   Labetalol is used in emergency medicine primarily for its antihypertensive actions. Intravenous labetalol rapidly and effectively reduces elevated pressures, causing only minimal alterations in heart rate and cardiac output. It is a good alternative for treating the hypertensive patient with myocardial ischemia. Oral labetalol may be substituted once control of blood pressure has been established. Intravenous labetalol can be used in pregnancy as long as benefits outweigh risks. It is a class C drug in pregnancy.

Dosing and Administration   Labetalol can be administered intravenously via multiple intravenous boluses or a continuous infusion. When initiating an intravenous bolus, the clinician should start with 20 mg (0.25 mg/kg in an 80-kg patient) and repeat with 40 mg to 160 mg every 10 min until the desired effect is reached or until a total cumulative dose of 300 mg has been given. It is best to double the previous dose every 10 min, thus allowing a gradual dosage increase. A smaller alternative dosage would be 10 to 15 mg given every 15 min. Alternatively, labetalol may be given via continuous infusion at a rate of 0.5 to 2 mg/min until the desired response or a total cumulative dose of 300 mg has been reached. There are reports where labetalol has been used as a continuous drip over a 24-h period in severe and refractory cases. Patients receiving labetalol via the intravenous route should be placed in a supine position and remain supine for approximately 3 h after receiving any intravenous doses, since symptomatic orthostatic hypotension may occur. Following patient stabilization, labetalol may be given orally up to 2400 mg per day in two to four divided doses. Acute dosing of intravenous labetalol can lead to a "cumulative effect," as each dose will persist for 2 to 4 h. These patients must be under diligent observation to avoid hypotensive episodes.

Adverse-Effects Profile   Labetalol has the same adverse-effects profile as the other b- and a$_1$-blocking agents. The most common adverse effect is orthostatic hypotension, which occurs most frequently upon initial therapy. Syncope has been reported following both intravenous and oral administration. Symptomatic heart failure may also occur. Adverse CNS effects that may occur include light-headedness, drowsiness, dizziness, fatigue, lethargy, and vivid nightmares. Tingling of the scalp and skin may occur with the initiation of therapy. Occasionally, reversible elevation of the hepatic enzymes may lead to jaundice and hepatitis. Other effects include lupus-like complaints, elevated renal function tests, blood dyscrasias, and allergic reactions. There is synergism between labetalol and halothane anesthesia.

Class III Antidysrhythmic Agents

The Cardiac Arrhythmia Suppression Trial illustrated the prodysrhythmic effects and increased mortality of certain Class I sodium channel blocking agents. Class III antidysrhythmics serve as an alternative to the sodium channel blocking drugs.[3] They are a heterogenous group of antifibrillatory agents that lack negative hemodynamic effects. Class III drugs are characterized by prolongation of the effective refractory period by a mechanism other than or in addition to sodium blockade. Amiodarone, bretylium, and sotalol are discussed below.

AMIODARONE   The parental formulation of amiodarone was recently approved by the FDA for the treatment of life-threatening ventricular dysrhythmia refractory to standard first-line therapy. Amiodarone lacks significant hemodynamic effects, making it useful in patients with severe LV dysfunction.

Action   Amiodarone is classified as a class III antidysrhythmic; it has a complex pharmacodynamic profile that also includes class I, class II, and class IV properties. It is a noncompetitive a- and b-receptor blocking agent, which is responsible for its negative inotropic and chronotropic effects. The negative inotropic response is countered by the decreased SVR; therefore cardiac output and ejection fraction are unchanged. Calcium channel blockade contributes to the peripheral vasodilatory response and decreased SVR. Amiodarone also weakly inhibits sodium channels, which depresses the myocardial conduction velocity by slowing the upstroke of phase 0. It is therefore a negative dromotropic agent. Last, amiodarone directly depresses the automaticity of the SA and AV nodes. It modifies the automaticity of spontaneously firing fibers in the Purkinje system and prolongs the refractory period in accessory pathways (e.g., WPW syndrome).

The hallmark of class III antifibrillatory drugs is prolongation of the action potential duration and the refractory period. The antifibrillatory effect of amiodarone is caused by inhibition of potassium ion fluxes that normally occur during phases 2 and 3 of the cardiac cycle. Amiodarone interferes with thyroid metabolism, which may also contribute to its antidysrhythmic properties. Repolarization time is lengthened as reflected by the prolonged QT interval on ECG. Although amiodarone prolongs the QT interval, torsades de pointes rarely occurs.

Hypotension can occur with the intravenous formulation secondary to its rapid vasodilatory effects. The ECG may show sinus bradycardia, PR and QT interval prolongation, and U waves.

Pharmacokinetics   Amiodarone hydrochloride is slowly and variably absorbed following oral administration. Systemic absorption ranges from 22 to 86 percent (average, 50 percent). The drug is approximately 96 percent plasma protein–bound. The effect of food on absorption has not been determined. The Vd is 1.3 to 12 L/kg allowing the drug to be extensively distributed. Peak serum concentrations may occur from 2 to 12 h (average, 3 to 7 h) after oral administration. The half-life appears to be substantially prolonged following multiple rather than single doses. The terminal elimination half-life is 28 to 107 days. Because of the drug's slow elimination, discontinuance of the drug will still allow therapeutic levels to be maintained for weeks.

After parenteral administration, amiodarone has rapid distribution to various sites, particularly adipose tissue and highly perfused organs such as the liver, spleen, and lungs. Serum levels correlate poorly with clinical efficacy. Each individual responds differently to the initial intravenous infusion; thus supplemental dosages are frequently needed for breakthrough dysrhythmias.

Amiodarone is metabolized in the liver by cytochrome P-450 enzyme and is eliminated by biliary excretion. Enterohepatic recirculation occurs. Negligible amounts are found in the urine, and it is not dialyzable.

Common ED Indications   Labeled uses for parenteral and oral therapy include treatment and suppression of VF/pulseless VT refractory to other medications. Unlabeled uses include the treatment and suppression of refractory PSVT, paroxysmal atrial fibrillation, symptomatic atrial flutter, and suppression of ventricular dysrhythmias in patients with cardiomyopathy.

Oral amiodarone appears to be effective in the management of a wide variety of ventricular and supraventricular dysrhythmias. However, due to the severe potential adverse effects, it is used only if alternative drug and electrical therapy is ineffective or contraindicated.

Dosing and Administration   The initial parental dose of amiodarone is 150 mg over 10 min. This is followed by an infusion of 1 mg/min for 6 h, after which 0.5 mg/min is infused as maintenance. Rebolus of 150 mg over 10 min is given for breakthrough VT or VF. The recommended dose for supraventricular dysrhythmias is

the same.

Amiodarone is a highly toxic drug; therefore the lowest effective dosage should be used to minimize the risk and occurrence of adverse effects. The dosage of amiodarone must be carefully adjusted according to individual requirements and response, patient tolerance, and the general condition and cardiovascular status of the patient. The oral loading-dose phase of therapy should be performed only where close monitoring is available, especially until the risk of recurrent VT or VF has abated. All other antidysrhythmic agents should be gradually discontinued, if possible, before oral amiodarone therapy is initiated. In addition, ophthalmologic and pulmonary tests should be performed to obtain a baseline before amiodarone is started.

In adults, oral daily loading dosages of 800 to 1600 mg are generally required for 1 to 3 weeks (occasionally longer) until an initial therapeutic response is seen. Recommended oral doses of amiodarone to treat ventricular dysrhythmias are administered once daily. However, when doses of 1 g or more are administered (e.g., during the loading-dose phase of therapy) or when intolerable adverse effects (usually GI effects) occur, a twice-daily regimen with meals is suggested. Dosage reduction is essential when there is adequate control of the ventricular dysrhythmias or if adverse effects become a problem. Dosages can be gradually titrated down to 600 to 800 mg daily for about 1 month and then again to the lowest effective maintenance dose. Typically, 400 to 600 mg/day is an adequate maintenance dose.

Adverse-Effects Profile With parenteral use, hypotension is the most common side effect; it usually presents within the first few hours of therapy. Bradycardia may also occur. Hypotension and bradycardia should be treated by slowing or stopping the intravenous infusion. Refractory bradycardia may require pacemaker placement.

The most serious noncardiac side effects of amiodarone is pulmonary toxicity. Pneumonitis should be suspected in any patient who presents with fever, cough, and progressive shortness of breath. Steroids and dose reduction or discontinuation of amiodarone may prove beneficial. Asymptomatic rise in liver function tests may occur, but cirrhosis is rare. QT prolongation occurs hours after initiation of therapy, but dysrhythmias do not occur for a few days.

Oral therapy is associated with several serious and potentially fatal toxicities, including pulmonary toxicity, prodysrhythmic effects, and, rarely, hepatic toxicity. The likelihood of most adverse reactions appears to increase after the first 6 months of therapy and remains relatively constant beyond 1 year of therapy. With chronic administration, corneal microdeposits are reported in all patients. Additional adverse effects may include rash, skin discoloration, photosensitivity, serious neurologic effects, constipation and other GI symptoms, and others. These effects may persist for weeks or months after discontinuance. Also, thyroid function tests may appear falsely elevated or decreased.

For a variety of medications, concomitant administration of amiodarone may result in either increased levels and/or potential toxicities; such medications include digoxin, procainamide, quinidine, calcium channel blockers, b-adrenergic blocking agents, other antidysrhythmics, anticoagulants, theophylline, and thyroid medications. Amiodarone should not be used in patients with marked sinus bradycardia or second- and third-degree AV block unless emerging pacing is available.

BRETYLIUM **Actions** Bretylium is a class III drug with a biphasic cardiovascular response. There is an appreciable increase in heart rate, blood pressure, and cardiac output after intravenous infusion. This effect lasts approximately 20 min. Next, there is a sympatholytic response with subsequent reduction in heart rate, blood pressure, and systemic vascular resistance. The biphasic response is due to the initial release of norepinephrine from the sympathetic ganglia and the postganglionic nerve terminals, results in increased adrenergic tone. Subsequently bretylium blocks further release of norepinephrine by depressing the excitability of adrenergic nerve terminals after sympathetic stimulation. This results in a sympatholytic effect that can cause orthostatic hypotension.

Like all class III agents, bretylium prolongs the action potential duration and the effective refractory period in the ventricular myocardium. Modulation of fluxes across potassium channels is responsible for this action. Additionally, bretylium reduces the disparity of the length of the action potential duration and the effective refractory period between ischemic and normal myocardium. It is also likely that bretylium increases the fibrillatory threshold. These additive effects contribute to bretylium's antifibrillatory action. Lidocaine is still considered first-line treatment of VF/unstable VT since bretylium is associated with more adverse hemodynamic outcomes during cardiopulmonary resuscitation (CPR). However, some studies suggest a synergistic response when lidocaine is used with bretylium.

In ischemic myocardium, the resting membrane potential (phase 4) is depressed. Bretylium transiently restores the phase 4 membrane potential toward normal. Curiously, bretylium has no effect on the resting membrane potential in normal myocardium.

Pharmacokinetics The onset of action for intravenous bretylium in VF is within minutes, but it may take from 20 min up to 2 h when used for other ventricular dysrhythmias. Peak effects occur in 1.5 to 6 h and last 6 to 12 h following a single dose. Bretylium is well absorbed following intramuscular injection, but this should be avoided in cardiac arrest and shock. Bretylium is eliminated primarily as unchanged drug via the kidney (70 to 85 percent) and thus may have a prolonged duration of action in patients with renal dysfunction.

Common ED Indications Bretylium is indicated for the treatment of refractory VF/pulseless VT unresponsive to repeated countershocks, epinephrine, and lidocaine. It is also indicated for the treatment of sustained VT with a pulse resistant to lidocaine and procainamide. [1] Last, bretylium may convert a wide complex tachycardia of uncertain origin unresponsive to adenosine and lidocaine. Bretylium is considered first-line therapy when lidocaine and procainamide are contraindicated (i.e., hypersensitivity reactions).

Dosing and Administration The initial dose of bretylium for VF or pulseless VT is 5 mg/kg (500 mg = 1 ampule) administered by rapid intravenous push. If VF persists, the dose can be increased to 10 mg/kg and repeated at 15- to 30-min intervals up to a maximum dose of 35 mg/kg. Undiluted drug may be given for life-threatening emergencies, otherwise diluted drug should be used. If a peripheral line is used, the bolus is followed with a 20-mL flush. For recurrent or refractory ventricular tachydysrhythmias with a pulse, 5 to 10 mg/kg of drug should be infused over a period of 8 to 10 min. Nausea, vomiting, and hypotension can occur with a more rapid infusion. If these dysrhythmias persist, repeated boluses of 5 to 10 mg/kg can be given q1–2h as necessary.

For maintenance, give 1 to 2 mg/min by continuous intravenous infusion. Alternatively, give 5 to 10 mg/kg over 10 min every 6–8 h. If the intramuscular route is used, no more than 5 mL should be injected at any one site, and injection sites should be rotated. Consider short-term use when possible (e.g., <24 h).

Adverse-Effects Profile Transient hypertension, tachycardia, and increased frequency of dysrhythmias secondary to ventricular irritability may follow drug injection secondary to the initial release of catecholamine. Nonspecific symptoms such as nausea, vomiting, vertigo, and light-headedness can occur following rapid injection. Bretylium should be avoided, if possible, in the setting of digoxin toxicity, since catecholamines are believed to exacerbate the toxic effects of digoxin.

Postural hypotension is the most common adverse reaction and may occur within 15 to 30 min in as many as 60 percent of patients. If this occurs, the patient should be placed in a supine or Trendelenburg position and be resuscitated with crystalloid fluids. If hypotension persists, vasopressors may be employed, but note that these agents will increase automaticity and may negate bretylium's effects.

Avoid bretylium in patients with renal failure, since the drug is excreted principally unchanged in the urine. Use cautiously in patients with fixed cardiac output, such as aortic stenosis, since severe hypotension may occur.

SOTALOL **Actions** Sotalol (Betapace) is a class III antidysrhythmic with noncardioselective b-blocking activity (class II) without intrinsic sympathomimetic or local anesthetic activity. It prolongs repolarization, like other class III drugs, through modulation of potassium currents. As a result, the action potential duration and the effective refractory period are prolonged. This is reflected on the ECG as QT prolongation, which is more pronounced at lower heart rates. Sotalol is approved for use in life-threatening ventricular dysrhythmias only.

Pharmacokinetics Sotalol is rapidly and completely absorbed from the GI tract. Food reduces its bioavailability. It is hydrophilic and does not accumulate in the brain. Sotalol does not bind to plasma proteins, forms no metabolites, and is eliminated mainly in the urine. The elimination half-life of the drug is about 12 h. Peak concentrations are reached at 2.5 to 4 h after oral dosing. Unlike many drugs, sotalol does not interact with the pharmacokinetics of other cardiac drugs (e.g., digoxin, warfarin).

Common ED Indications Sotalol effectively suppresses life-threatening ventricular dysrhythmias refractory to other conventional antidysrhythmic agents but is associated with a 2 percent incidence of torsades de pointes, VT, or VF. While sotalol can suppress SVT and atrial fibrillation, it is not approved for this use.

Dosing and Administration Only the oral formula is approved for usage in the United States. The usual initial oral dosage is 80 mg bid, which can be increased to

240 or 320 mg/day; a therapeutic response is usually obtained at a total daily dose of 160 to 320 mg/day. There should be 2 to 3 days with QT monitoring allowed between increments. The maximum dosage is 480 to 640 mg/day; however, this should be used only when the potential benefit outweighs the increased risk of adverse effects. The dosing interval should be extended for renal insufficiency. Dose escalations in these patients should be done after administration of at least five to six doses and be based on the creatinine clearance. If the creatinine clearance is 30 to 60 mL/min, the dosing interval should be q24h; at 10 to 30 mL/min, adjust the dosing interval to 36 to 48 h; and when the clearance is <10 mL/min, the dose should be individualized.

Adverse-Effects Profile   Sotalol is well tolerated and many adverse effects are dose-related; the most common are related to nonselective b blockade. Sotalol can also have prodysrhythmic effects, particularly in those who are taking high doses of the drug or those with torsades de pointes, prolonged QTc intervals, hypokalemia, or bradycardia. Torsades de pointes, secondary to prolonged QT interval, is the most common dysrhythmia.

Class IV Antidysrhythmic Agents

By blocking the calcium-dependent slow channel response, calcium channel blockers slow myocardial conduction velocity, relax vascular smooth muscle, and depress cardiac contractility. They are indicated for the treatment of cardiac dysrrhythmias, hypertension, Prinzmetal angina, migraine headache, and recent subarachnoid hemorrhage (SAH). The use of calcium channel blockers (CCBs) in AMI is controversial. Some studies suggest an increased risk of adverse cardiovascular events, particularly in the presence of left ventricular dysfunction;[4] other studies dispute these findings.[5] Currently, the American College of Cardiology/American Heart Association (ACC/AHA) Guidelines for the Management of Acute Myocardial Infarction do not recommend calcium channel blockers for routine use in AMI since b-adrenergic blocking agents are generally a more appropriate choice. However, if b blockers are ineffective or contraindicated, verapamil or diltiazem may be given in patients with AMI without evidence of congestive heart failure, left ventricular dysfunction, or AV block. Nifedipine is generally contraindicated.

Class IV antidysrhythmics block calcium-dependent slow channels in vascular smooth muscle, contractile cells, and the conduction system. Specifically, they prevent the influx of calcium through the suprahisian (SA and AV nodes) conduction tissue, which is involved in the propagation of the action potential. Therefore, the conduction velocity is slowed, particularly in the AV node.

Calcium is responsible for myocardial excitation-contraction coupling. Class 4 agents block slow calcium channels in cardiac muscle, which depress excitation-contraction coupling and myocardial contractile function. As a result, CCBs exert a negative inotropic effect. Slow channels also exist in smooth muscle. By interfering with the excitation-contraction coupling in vascular smooth muscle, CCBs promote vasodilatation.

Each agent has variable effects on AVN conduction, SVR, and contractile function. For example, verapamil causes moderate prolongation of atrioventricular conduction and moderate negative inotropic effects, while nifedipine has negligible effects on each. Conversely, nifedipine causes a moderate reduction of systemic vascular resistance, while the effects of verapamil on SVR are much less pronounced. The spectrum of action of diltiazem is midway between those of verapamil and nifedipine. Only diltiazem and verapamil are used as antidysrhythmic drugs.

VERAPAMIL   **Actions**   Verapamil (Isoptin, Calan), a calcium channel blocking agent, is a class IV antidysrhythmic agent. In diseased tissue, verapamil decreases conduction velocity, prolongs the refractory period in the AV node, and decreases the discharge rate in the SA node. It interrupts the AV node reentrant pathway associated with PSVT, thus causing the myocardium to return to normal sinus rhythm (NSR). In addition, verapamil can slow ventricular response in patients with atrial fibrillation and/or flutter by its action on the AV node. A decrease in heart rate and/or SA nodal block may occur in patients with SA nodal disease. Verapamil has minimal effects on normal conduction tissue.

Although verapamil has negative inotropic effects, they are often offset by the decrease in afterload. Thus, the hemodynamic effects are negligible in normal myocardium. Those with severe heart failure, however, may experience a decrease in ejection fraction.

Most patients with PSVT and WPW syndrome demonstrate narrow QRS complexes of tachycardias. This indicates antegrade conduction through the AV node, with retrograde conduction over the bypass tract completing the circuit. Verapamil is safe and effective in patients with narrow-complex PSVT, even in the presence of WPW syndrome, because of the pronounced negative dromotropic effects of verapamil on the AV node. If antegrade conduction occurs over the accessory pathway, the QRS complex widens. Verapamil may decrease the refractory period of an accessory tract. Therefore, verapamil is contraindicated for atrial fibrillation or flutter due to WPW syndrome and in any type of wide-complex tachycardia, since it can increase rather than decrease the ventricular rate. In addition, in many cases, wide complex tachycardia can represent VT. In this case, verapamil could worsen hemodynamics because of vasodilatory and negative inotropic effects.

By inhibiting the influx of calcium, verapamil impairs the contractile processes that calcium normally activates, thereby causing dilatation of coronary and systemic arteries. Dilatation of coronary arteries improves oxygen delivery, while dilatation of the systemic arteries decreases oxygen consumption by decreasing afterload. These effects provide the myocardium with a beneficial oxygen balance in patients with vasospastic, unstable, and chronic stable angina.

Pharmacokinetics   Verapamil elicits its hemodynamic effects within 3 to 5 min following intravenous administration, with effects lasting approximately 30 min. Effects on conduction begin within 1 to 2 min, peak in 10 to 15 min, and persist for 1 to 6 h. The Vd of verapamil is 4.5 to 7.1 L/kg. Verapamil undergoes first-pass metabolism in the liver and is metabolized to several metabolites. Norverapamil, an active metabolite, appears in the greatest amount. The elimination half-life of verapamil is 2 to 8 h, increasing to 4 to 12 h after 1 to 2 days of therapy.

Common ED Indications   Verapamil is as effective as adenosine and diltiazem for terminating narrow-complex PSVT and for controlling the ventricular rate in atrial fibrillation/flutter. Avoid verapamil in patients with WPW syndrome who present in atrial fibrillation/flutter since ventricular fibrillation may occur. [6,7 and 8] Similarly, it is best avoided in patients with wide complex PSVT. It should also be avoided in patients with wide complex tachycardias. Diagnosis of PSVT should be confirmed by 12-lead ECG and managed with vasovagal maneuvers prior to administering verapamil whenever possible. Oral verapamil can be used for the management of vasospastic, chronic stable, and unstable angina and may also be used for the prophylaxis of PSVT. It is also used for essential hypertension.

Dosing and Administration   For PSVT, many recommend an initial intravenous dose of 2.5 mg given over 2 to 3 min and repeated in 15 to 30 min if the response is inadequate. Others are more aggressive, particularly if the blood pressure is elevated and the patient is known to respond to a higher dose. In such cases, 5 mg may be slowly infused and repeated every 5 min. The blood pressure should be checked immediately before and after the drug has been given. Lower initial doses of verapamil and slower administration techniques should be considered in older patients and those with hepatic dysfunction. Pretreatment with calcium chloride, gluconate, or gluceptate (500 to 1000 mg) can be given before or after verapamil infusion to prevent or reverse hypotension. Reports using calcium with verapamil have been largely anecdotal, but such use may be most efficacious in patients whose hemodynamic status is borderline (i.e., systolic blood pressure <90 mmHg). Administration of calcium may also be considered for intentional overdose or accidentally poisoned patients who demonstrate severe bradydysrhythmias.

For the prevention of recurrent PSVT, oral administration of verapamil, 240 to 480 mg daily, should be given in three to four divided doses. Control of ventricular rate in digitalized adults with chronic atrial fibrillation and/or flutter is 240 to 320 mg daily in three or four divided doses. Maximum antidysrhythmic effects are generally seen within 48 h after initiating a verapamil dose. For the treatment of vasospastic, unstable, or chronic stable angina, oral doses of verapamil can be given (80 mg q6–8h), with doses titrated up or down to desired clinical response. In patients with hypertension, verapamil is initiated with 80 mg three times daily and titrated to blood pressure response. Patients who are elderly or of small stature can be started on 40 mg three times daily. Although doses of 480 mg/day have been used, efficacy with doses greater than 360 mg/day has not conclusively been proven.

The only current recommended use for Verapamil SR is for hypertension. When switching from immediate-release tablets, the total daily dose (in milligrams) may remain the same. Breaking the sustained-release (SR) tablet does not affect the therapeutic effect of verapamil SR. The SR tablets, as an initial dose of 240 mg every morning, may be used for hypertension. Titration may be accomplished with 120-mg (one-half SR tablet) increments added in the evening. Antihypertensive effects are evident within the first week.

Adverse-Effects Profile   The majority of adverse effects secondary to verapamil are related to its pharmacologic action. The incidence is increased in patients with severe heart failure, hypertrophic cardiomyopathy, and conduction disturbances. The incidence of hypotension is 5 to 10 percent with intravenous administration and may rarely require treatment with intravenous calcium salts or vasopressors. Conduction disturbances such as bradycardia, AV block, and bundle branch block occur in approximately 2 percent or fewer of patients and usually respond to a dosage reduction or discontinuation of the drug; rarely, use of atropine, cautious use of isoproterenol, or cardiac pacing may be necessary. In addition, approximately 2 percent may develop acute pulmonary edema secondary to the negative inotropic

effects of verapamil. Verapamil may increase serum digoxin concentrations. Avoid the concomitant use of intravenous b blockers.

Noncardiac side effects with verapamil include constipation, dizziness, headache, and nausea. Other side effects, occurring in fewer than 1 percent of patients, include sleep disturbances, blurred vision, shakiness, drowsiness, confusion, dry mouth, rash, urticaria, bruising, flushing, polyuria, sexual difficulties, apnea, and muscle cramps. Several cases of hepatocellular injury accompanied by clinical signs of hepatotoxicity have also been reported. Verapamil should be given with caution to patients who are receiving agents such as b blockers, digoxin, antihypertensives, and antidysrhythmics, since their effects may be additive. Cimetidine may reduce hepatic metabolism. Do not use verapamil in children younger than 1 year old, since its use is associated with sudden circulatory collapse.

DILTIAZEM **Actions** The actions of diltiazem (Cardizem) on the coronary and systemic arteries resemble those of verapamil. Diltiazem, also a calcium antagonist, is a less potent vasodilator than nifedipine. Vasodilation is predominant in the coronary arteries, allowing improved oxygen delivery and thus benefiting patients with vasospastic angina. Systemic arterial dilation also reduces afterload, resulting in decreased oxygen consumption and improvement in oxygen balance in those with chronic stable angina. Diltiazem slows AV nodal conduction time and prolongs AV nodal refractoriness. It may selectively reduce the heart rate during tachycardias involving the AV node with little or no effect on normal AV nodal conduction at normal heart rates. The ventricular rate is slowed in patients with a rapid ventricular response during atrial fibrillation or atrial flutter. PSVT is converted to NSR by interrupting the reentry circuit in AV nodal reentrant tachycardias and reciprocating tachycardias (e.g., WPW syndrome). Diltiazem has no effects on sinus node recovery or the sinoatrial conduction time in patients without SA nodal dysfunction.

Pharmacokinetics An intravenous bolus dose appears to follow linear pharmacokinetics over a dosage range of 10.5 to 21.0 mg. The apparent Vd is 305 L. The plasma elimination of diltiazem is approximately 3 to 7 h. The drug is extensively metabolized in the liver with a systemic clearance of 65 L/h. After a continuous intravenous infusion, one study cited development of nonlinear pharmacokinetics over an infusion range of 4.8 to 13.2 mg/h for 24 h. As the dose is increased over this infusion range, systemic clearance decreases from 64 to 48 L/h and the apparent Vd remains unchanged (360 to 391 L). Generally, systemic clearance averaged 42 and 31 L/h in patients given continuous infusions of diltiazem at 10 to 15 mg/h, respectively, for 24 h. However, in comparison with healthy volunteers, patients with atrial fibrillation or atrial flutter had decreased systemic clearance.

Oral doses also have a 40 percent bioavailability due to first-pass effect. Oral bioavailability does increase as doses increase. The onset of action of conventional tablets is 30 to 60 min, with the peak effect occurring in 2 to 4 h. SR tablets, however, have a gradual onset of action, with a peak effect occurring in 6 to 11 h. Comparable products, with a 24-h controlled drug delivery system (Cardizem-CD; Dilacor-XR), have similar absorption throughout the dosing intervals, and peak serum levels occur generally between 10 and 14 h.

Diltiazem is 70 to 80 percent protein-bound; 35 to 40 percent is bound to albumin and is metabolized in the liver to one active and several inactive metabolites. Approximately one-third of diltiazem is metabolized to desacetyldiltiazem, a metabolite with 25 to 50 percent of the coronary vasodilating activity of diltiazem. Diltiazem and its metabolites are excreted via glucuronide and/or sulfate conjugation.

Common ED Indications Intravenous diltiazem is as effective as verapamil and adenosine for rapid conversion of PSVT to NSR and to slow ventricular rate in atrial fibrillation or atrial flutter. It should not be used in patients with a wide complex tachydysrhythmia suggesting an accessory bypass tract (e.g., WPW syndrome).

Oral diltiazem is indicated for the treatment of vasospastic and chronic stable angina and is considered one of the drugs of choice for vasospastic angina. In patients with chronic stable angina, diltiazem is thought to be as effective as b-blocking agents and/or nitrates but is usually reserved for those who fail therapy with these agents.

Oral diltiazem is also approved for the treatment of hypertension either alone or in combination with other agents. An additive effect is commonly seen when thiazide diuretics are added to diltiazem therapy. Like other calcium channel blockers, diltiazem may be especially useful in hypertensive patients with low renin levels, those who have angina, or in African Americans.

Dosing and Administration The intravenous bolus dose for control of PSVT, atrial fibrillation, or atrial flutter is 0.25 mg/kg using actual body weight (average adult dose is 20 mg) over a 2-min period. If a further response is desired, a second intravenous bolus of 0.35 mg/kg actual body weight can be given at the same rate (average adult dose, 35 mg). Subsequent bolus dosing should be individualized on a milligram-per-kilogram basis. It should be noted that some patients may not need an initial dose greater than 0.15 mg/kg, yet duration of action may be shorter. For continued reduction of the heart rate (up to 24 h) in atrial fibrillation or atrial flutter, a diltiazem maintenance infusion may be started immediately following the bolus dose(s). The recommended initial rate is 10 mg/h, yet some patients may respond to a 5-mg/h dose. If needed, subsequent increases can be in 5-mg/h increments up to 15 mg/h. The infusion may be maintained for up to 24 h. Patients should have continuous ECG monitoring and frequent blood pressure checks. For patients being converted from intravenous to oral diltiazem, the following suggestions are based on oral steady state: 5 mg/h or approximately 180 mg/day; 7 mg/h or approximately 240 mg/day; 11 mg/h or approximately 360 mg/day. The oral doses and dosing intervals are variable, based on the indication and the product selected. For the treatment of vasospastic or chronic stable angina, the usual initial diltiazem dose is 30 mg before meals and at bedtime (four times daily). Most patients can be controlled with 180 to 360 mg/day in divided doses. Sustained release tablets are indicated for the control of hypertension and chronic stable angina. Angina episodes and weekly nitroglycerin consumption decreases with the use of extended release diltiazem. SR products start at 60 to 120 mg/day, with optimum dosage 240 to 360 mg/day.

For patients with hypertension, diltiazem is usually given as the extended-release tablet in 60- or 120-mg doses twice daily. Maintenance doses are usually 240 to 360 mg/day. Doses should be titrated to clinical response in each of the above situations. Additionally, patients with hepatic and/or renal dysfunction should be dosed cautiously and may require dosage adjustments. The Cardizem-CD and the Dilacor-XR products offer 180 and 240 mg with once-daily dosing. Cardizem-CD is also available in a 300-mg strength. SR products use 60- to 120-mg strengths and are started with 120 or 180 mg daily. Some patients may respond to higher doses of up to 480 mg/day. As necessary, the optimum dose for hypertension can be titrated over a 7- to 14-day period.

Adverse-Effects Profile Many of the adverse effects associated with diltiazem are an extension of its pharmacologic profile. Cardiovascular effects may include angina, bradycardia, asystole, CHF, AV block (first, second, or third degree), bundle-branch block, PVC, flushing, decreased blood pressure, palpitations, and peripheral edema.

Noncardiac side effects include headache (2 to 10 percent), dizziness (1 to 7 percent), asthenia (2 to 5 percent), nausea (1 to 3 percent), constipation (1 to 2 percent), rash (1 to 2 percent), vomiting, diarrhea, dry mouth, pruritus, nervousness, somnolence, insomnia, tinnitus, abnormal dreams, depression, sexual difficulties, bruising, polyuria, hyperglycemia, epistaxis, alopecia, and photosensitivity.

Diltiazem may cause a transient increase in liver function test values (e.g., AST, ALT, LDH), which may resolve despite continued therapy. However, hepatocellular toxicity has been reported in some patients. Patients receiving digoxin or b blockers may experience additive conduction disturbances. Cimetidine may increase diltiazem levels secondary to inhibition of metabolism.

OTHER CALCIUM CHANNEL BLOCKERS *Nifedipine* and the other dihydropyridines (e.g., amlodipine, felodipine, nicardipine, nimodipine, and nisoldipine) lower blood pressure by blocking calcium influx into vascular smooth muscle. This prohibits excitation-contraction coupling, which lowers systemic vascular resistance and dilates the coronary arteries. The coronary artery dilatation results in improved oxygen delivery, benefiting patients with vasospastic angina. Systemic arterial dilatation results in decreased afterload, leading to decreased oxygen consumption in patients with chronic stable angina. A reflex increase in heart rate and an increase in cardiac output may be seen with nifedipine. Unlike verapamil and diltiazem, nifedipine has little effect on the SA and AV nodal conduction clinically. Nifedipine may, however, result in a decrease in left ventricular end diastolic pressure (LVEDP) or left ventricular end diastolic volume (LVEDV) in patients with moderate to severely impaired LV function, thereby worsening their condition.

Approved indications for nifedipine include management of vasospastic and chronic stable angina. Nifedipine, either alone or in combination with other antihypertensives, is indicated for the management of essential hypertension. In comparison to other classes of antihypertensives (i.e., angiotensin-converting enzyme inhibitors and b blockers), nifedipine may benefit patients with low-renin hypertension, coexisting angina, or peripheral vascular disease. Nifedipine is also used for hypertensive urgencies. Sublingual administration and chewing should be avoided as this may result in a precipitous fall in blood pressure.

Nimodipine (Nimotop) is a calcium channel blocker structurally similar to nifedipine. Like other calcium channel blockers, it inhibits the influx of calcium across the transmembrane channels, thereby inhibiting the contractile activity in the cell. The inhibition of calcium influx is seen in myocardial muscle, vascular smooth muscle, and neuronal cells. Nimodipine has a relative selectivity for vascular smooth muscle—as opposed to the myocardium—and therefore has minimal effects on the conduction and inotropy of the myocardium. Its greatest affinity is for the CNS vasculature. It increases cerebral blood flow and may shunt blood to ischemic areas.

Although inhibition of cerebral vasospasm (which often occurs following SAH) was initially thought to be responsible for the beneficial effects of nimodipine in SAH, angiography has not proven this. Improved collateral blood flow and prevention of large calcium influxes into neurons (causing cell destruction) may be of greater importance.

Nimodipine is indicated for the treatment of recent (within 96 h) SAH from ruptured congenital intracranial aneurysm in patients whose postictal neurologic condition is good (e.g., Hunt and Hess grades I to III), where it can decrease the degree of morbidity and mortality. Patients with more severe disability (Hunt and Hess grades IV to V) do not seem to benefit and may become worse with nimodipine.

Nicardipine (Cardene) is a dihydropyridine calcium channel blocker structurally related to nifedine. Like nifedipine, nicardipine inhibits the transmembrane flux of calcium into cardiac and vascular smooth muscle. The inhibition results in a decrease in the contractile activity within the myocardium and vascular smooth muscle. This agent provides selective activity on the vasculature as opposed to the myocardium. Nicardipine possesses both systemic and peripheral vasodilatory action primarily through a decrease in peripheral vascular resistance. Increases in cardiac output and cardiac index can be seen in a dose-dependent manner with nicardipine. It does not have demonstrable effects on renal blood flow or glomerular filtration rate.

Intravenous nicardipine decreases systemic vascular resistance, improves coronary artery perfusion, and increases cardiac index without raising myocardial oxygen demand or left ventricular filling pressure. Despite systemic and hemodynamic effects (hypotension and tachycardia), intravenous nicardipine does not have a depressant effect on the myocardium or a negative action on right or left ventricular filling pressure in patients with uncomplicated MI. However, it has been shown to produce a decrease in contractility in patients with severe heart failure.

Intravenous nicardipine is indicated for the short-term treatment of hypertension when oral therapy is not feasible or desirable. Oral nicardipine (Cardene) is indicated for chronic stable angina and essential hypertension. It is as effective as nifedipine in treating chronic stable angina and hypertension.

Other Antidysrhythmic Agents

ADENOSINE   Adenosine (Adenocard) is an endogenous nucleoside produced by the dephosphorylation of adenosine triphosphate (ATP) and is contained in every cell of the body. Cardiac adenosine receptors are concentrated in the coronary arteries, the SA node, the AV node, and the atrial myocytes. [9] A1 adenosine receptor stimulation alters potassium channels. The increase in K^+ conductance hyperpolarizes the cell membrane and shortens the action potential of supraventricular cells. Therefore, the threshold of the SA and AV nodes to trigger another action potential is increased. This results in the long sinus pause on the rhythm strip following adenosine administration.

The positive inotropic, chronotropic, and dromotropic response of catecholamines depends on cAMP. Adenosine exerts antiadrenergic effects by inhibiting the adenyl cyclase/cAMP pathway. Therefore, adenosine antagonizes the effect of catecholamines on supraventricular and ventricular myocardium. This may explain why some wide complex tachycardias of ventricular origin are terminated with adenosine.

In summary, the modulation of K^+ currents and the blunting of catecholamine response are responsible for the antidysrhythmic properties of adenosine.

Action   Adenosine exerts negative chronotropic and negative dromotropic actions on the SA and AV nodal tissue secondary to its influence on potassium conductance. Adenosine terminates PSVT primarily via blockade of the AV node without altering conduction through accessory pathways, as is seen with the WPW syndrome. Reentrant SVTs not involving the AV node are not terminated by adenosine. Adenosine is a potent vasodilator; however, there is no change in systemic blood pressure following its administration because it is rapidly metabolized by circulating adenosine deaminase and undergoes rapid sequestration by vascular endothelial cells.

Pharmacokinetics   Onset of action is within approximately 30 s, with a duration of 60 to 90 s. The drug is rapidly metabolized in the blood, with a half-life less than 7 s. The primary routes of elimination are cellular uptake and simple or facilitated diffusion by a nucleoside transport system, metabolism to various by-products, and renal excretion of these metabolic products. The predominant final metabolite of adenosine is uric acid. Specific pharmacokinetic parameters—such as Vd, therapeutic plasma concentrations, and clearance—are difficult to assess due to the extremely short half-life of the drug.

Common ED Indications   Adenosine is the drug of first choice to convert PSVT involving the AV node into sinus rhythm. It is as efficacious as intravenous verapamil and diltiazem in terminating the dysrhythmia. Its ultrashort action and its lack of serious side effects make it the preferred drug. While it is extremely effective in the initial conversion of reentrant PSVTs, recurrence of the dysrhythmia (within minutes after the initial conversion) may occur. Although repeat doses of adenosine are effective, consideration of a longer-acting antidysrhythmic agent will often be necessary.

Adenosine causes transient AV block in narrow complex tachycardias of unknown origin. Adenosine will not convert atrial fibrillation or atrial flutter to normal sinus rhythm. However, it may expose the underlying atrial rhythm (atrial fibrillation, atrial flutter, or some other atrial tachycardias), so that therapy may be appropriately initiated. Adenosine may also detect a previously latent accessory pathway.

It is often difficult to differentiate between SVT with aberrancy and ventricular tachycardia in the ED setting. Adenosine will convert SVT with aberrancy to normal sinus rhythm or reveal the underlying atrial mechanism. Adenosine will not terminate VT (unless the dysrhythmia is dependent on adrenergic drive), nor does it block conduction over accessory pathways.

This drug is the preferred agent for treatment of PSVT in infants, children, and pregnant women. Because adenosine shortens the action potential duration and slows the heart rate, it is contraindicated in second- or third-degree AV heart block or sick sinus syndrome. Adenosine is not effective in converting atrial tachydysrhythmias (e.g., atrial fibrillation or flutter) or VT to NSR. However, it has been shown to be safe to administer in situations where VT and SVT cannot be differentiated. [10]

Dosing and Administration   The initial dose for the treatment of acute PSVT is 6 mg (6 mg/2 mL) given as a *rapid* intravenous bolus over 1 to 2 s directly into the vein or into the most proximal port of the intravenous tubing on the peripheral intravenous site. When the latter method is used, the bolus should be followed by a 20-mL saline flush and the arm immediately elevated. This method will expedite travel of the drug to the heart and lessen the amount of drug getting caught in the intravenous tubing, where it rapidly breaks down. If the heart rate does not decrease within 2 min, a second bolus injection of 12 mg should be given in the same manner. A final, third bolus dose may be given in 1 to 2 min if the dysrhythmia persists. It is imperative that adenosine be administered *fast;* if it is infused too slowly, systemic vasodilation may occur, which can result in reflex tachycardia.

Adverse-Effects Profile   When adverse effects due to adenosine occur, they are minor and well tolerated because they last less than 1 min, owing to the drug's short half-life. The most common are dyspnea, cough, syncope, vertigo, paresthesias, numbness, nausea, and metallic taste. Cardiovascular adverse effects may include facial flushing, headache, diaphoresis, palpitations, retrosternal chest pain, sinus bradydysrhythmias (i.e., bradycardia, sinus arrest, AV block), atrial tachydysrhythmias (i.e., atrial fibrillation or flutter), PVCs, and hypotension. These adverse effects rarely require specific management. Dipyridamole and carbamazepine have been shown to enhance the negative chronotropic and dromotropic effects of adenosine and may increase the degree of toxicity. Methylxanthines and caffeine, on the other hand, compete for adenosine receptors. Therefore, asthmatics or those who drink large amounts of coffee may require a higher dose of adenosine to achieve a therapeutic effect. The induction of atrial fibrillation and/or flutter is problematic in patients with an accessory pathway as in WPW syndrome, since adenosine does not block conduction over accessory pathways. For reentrant pathways, adenosine will only block conduction of the antegrade AV loop. Adenosine has been shown to be safe in the setting of hypotension and CHF. [10]

DIGOXIN   Intravenous digoxin is an effective inotropic agent with weak AV blocking effects. It exerts ventricular rate control through vagal tonic effects, which may take several hours to become clinically apparent.

Actions   Digoxin has three basic actions: (1) it increases the force, strength, and velocity of cardiac contractions (positive inotropic effects); (2) it slows the heart rate (negative chronotropic effects); and (3) it slows conduction velocity through the AV node.

Digoxin exerts its direct inotropic and electrophysiologic effects by binding to and inhibiting the sodium and potassium ATPase pump in the cell membrane. This action results in higher intracellular levels of sodium and causes calcium to move intracellularly in exchange for sodium. The elevated intracellular calcium concentration

allows more calcium to be available to increase the rate and force of cardiac contractions.

Digoxin increases the refractory period and decreases the conduction velocity of both the SA and AV nodes but shortens the refractory period and increases conduction velocity in the atrial muscles (including atrial bypass tracts, as present in WPW syndrome). The primary effect on SA and AV nodal conduction is secondary to direct enhancement of parasympathomimetic tone. ECG changes include PR interval prolongation and QT interval shortening. High doses of digoxin enhance ventricular automaticity.

Slowing of the heart results in a prolonged diastolic period, allowing a greater period for improving coronary blood and myocardial perfusion. A decrease in oxygen demand may also occur secondary to the decrease in heart rate.

Pharmacokinetics   The onset of action is about 5 to 30 min following intravenous administration and 30 to 120 min for oral tablets, while peak effects occur in 1 to 4 h and 2 to 6 h, respectively. The onset of action following parenteral therapy varies based upon the rate at which digoxin is administered. In oral dosing, however, patient variability is the primary cause of variation. The large variation in peak effect can be explained by the fact that digoxin has a large Vd of 5.6 L/kg. Digoxin crosses the blood-brain barrier and the placenta, and high concentrations are found in the liver, heart, kidney, and intestines. Digoxin may also be given by oral tablets, elixir, and capsules, the bioavailability being approximately 70, 80, and 90 percent, respectively. Digoxin is inactivated by hepatic degradation and excreted unchanged in the urine. The half-life of digoxin in patients with normal renal function is 30 to 40 h and can extend to 4 to 6 days in anuric patients. Because digoxin concentrates in the tissues, serum levels of digoxin may not accurately reflect the amount of drug in the body, making procedures such as dialysis or exchange transfusion ineffective.

Common ED Indications   Digoxin is indicated to improve cardiac output in CHF and to control heart rate in atrial fibrillation, atrial flutter, and paroxysmal atrial tachycardia (PAT). Use of digoxin in the treatment of CHF should be considered only when diuretics and vasodilators fail to improve cardiac output. Digoxin may be particularly effective in providing beneficial hemodynamic and symptomatic improvement in heart failure patients presenting with an S $_3$ gallop or "low-output" heart failure associated with depressed ventricular function. Digoxin is less effective with "high-output" heart failure, which occurs in patients with bronchopulmonary insufficiency, anemia, infection, hyperthyroidism, or arteriovenous fistulas.

Dosing and Administration   Digoxin can be administered by the oral or intravenous route. The latter is preferred when a more rapid onset of action and peak effect is desired. The intravenous dose is 20 to 30 percent less than an oral dose. Digoxin should not be administered by intramuscular injection, since this route offers no advantages and can cause severe pain at the injection site.

For control of SVT, digoxin should be administered intravenously in a dose of 10 to 15 mg/kg (up to a total of 0.75 to 1.5 mg given over the first 24 h). This dose should be divided, with 0.25 to 0.5 mg given as the initial dose and 0.125 to 0.25 mg q2–6h as subsequent doses until the entire dose is administered or the heart rate is sufficiently lowered. The dose for patients with CHF without atrial fibrillation is generally lower (8 to 12 mg/kg) but can be given in a similar fashion as above until an appropriate response has been achieved. Higher doses are often required to control the ventricular response to atrial fibrillation or flutter, but higher doses have more adverse effects. Loading doses should be calculated using lean body weight, since this method generally provides therapeutic effects with minimal risk of toxicity. Intravenous loading doses should be administered slowly over a 5-min period or longer, undiluted or diluted, to a fourfold or greater volume. Serum digoxin levels should not be obtained earlier than 6 to 8 h after loading because of the slow distribution of the drug. Dosing in infants and children must be extremely careful. The small amounts given to children can easily be miscalculated.

Maintenance therapy should be adjusted according to clinical response or to maintain a serum digoxin concentration between 0.8 to 2.0 ng/mL. Dosage adjustments are necessary in renal failure, dehydration, hypokalemia, hypercalcemia, hypomagnesemia, and hypothyroidism. Drugs that interact with digoxin to cause increases in serum digoxin levels include amiodarone, verapamil, nifedipine, hydroxychloroquine, propafenone, quinidine, erythromycin, tetracycline, and anticholinergic agents. In contrast, the use of cholestyramine, metoclopramide, kaolin-pectin, penicillamine, and dietary fiber has resulted in lower serum digoxin concentrations.

Adverse-Effects Profile   When digoxin toxicity is suspected, the drug should be stopped and a serum level obtained. Toxicity may actually occur in some patients with low serum levels, since it is often the myocardial tissue level rather than the serum level that determines the degree of toxicity. Symptoms of digoxin toxicity include mental depression, confusion, headache, drowsiness, anorexia, nausea, vomiting, weakness, visual disturbances (green or yellow vision and/or halo effects), delirium, electroencephalographic (EEG) abnormalities, and seizures. Patients may also present with diarrhea and abdominal discomfort. Almost any type of dysrhythmia may manifest in digoxin toxicity. The most common dysrhythmias include an increased number of unifocal or multiform PVCs, VT, junctional tachycardia, high-degree AV block, PSVT with block, and sinus arrest. Atrial fibrillation, bradycardia, and ventricular fibrillation may also occur. Other adverse effects may include gynecomastia, skin rash, eosinophilia, and thrombocytopenia. See Chap. 168 for a detailed discussion of digitalis toxicity.

While hypokalemia increases the risk of digoxin toxicity, significant digoxin toxicity itself may produce hyperkalemia due to paralysis of the transmembrane sodium-potassium pump. However, when hypokalemia develops in less severe cases of toxicity, potassium can be replaced by intravenous infusion provided that there is no evidence of high-degree AV conduction block. When digoxin toxicity is associated with hyperkalemia, a corresponding intracellular deficiency of potassium exists, which may be the causative factor of subsequent dysrhythmias. Treatment in this circumstance is controversial. It is not clear whether measures should be taken to decrease the total body supply of potassium (at the risk of increasing intracellular hypokalemia), to increase the total body potassium in the face of extracellular hyperkalemia, or to use measures that would ordinarily encourage movement of potassium back into cells (e.g., use of bicarbonate, glucose, and insulin). These methods may all prove useless in the absence of a functioning transmembrane sodium-potassium pump.

Lidocaine and phenytoin are antidysrhythmics that have classically been used in digoxin toxicity, but their efficacy has not been proven. Atropine and electrical pacing have been tried in cases of bradydysrhythmias, but these too have had limited success. Hemodialysis and resin hemoperfusion have been attempted in some cases of severe digoxin poisoning but have generally been unsuccessful because of the large volume of distribution of digoxin. Digoxin antibody fragments, otherwise known as digoxin immune FAB (fragmented antibodies) or Digibind (Burroughs-Wellcome), is available for use in treating life-threatening digoxin toxicity. This antidote is indicated for life-threatening ventricular tachydysrhythmias, sinus bradydysrhythmias, or severe AV blocks resulting from overdose or accidental pediatric ingestion of digoxin and digitalis-like glycosides that are unresponsive to conventional therapy. An additional indication for FAB, by the manufacturer, is in patients experiencing severe digoxin toxicity who have serum potassium levels greater than 5 meq/mL. See Chap. 168 for more information.

MAGNESIUM   **Actions**   Magnesium affects skeletal and smooth muscle contractility, vasomotor tone, and neuronal transmission directly via the Na $^+$, K $^+$-ATPase pump and indirectly via calcium blocking activity. It increases membrane potential, prolongs AV conduction, and increases the absolute refractory period. Hypomagnesemia can precipitate life-threatening cardiac dysrhythmias, symptoms of cardiac insufficiency, and sudden cardiac death after an AMI. Resupplementation of magnesium helps to replenish intracellular potassium in hypomagnesemic, hypokalemic patients, blocks calcium to cause vasodilation, and reduces platelet aggregation. Magnesium also decreases myocardial sensitivity to catecholamines as well as their release, which can lead to an excessive adrenergic surge. This surge can lead to dysrhythmias, hypertension, and increased myocardial oxygen consumption.

Common ED Indications   The national council on CPR classified magnesium as usually indicated, always acceptable, and considered useful and effective in each of the following situations: treatment of torsades de pointes, cardiac arrest with suspected magnesium deficiency, and AMI with suspected magnesium deficiency. Suspect magnesium deficiency if a patient has a history of diuretic use, chronic illness, or malnutrition (including chronic alcoholism).

Some studies have suggested that magnesium therapy reduces the incidence of serious dysrhythmia as well as mortality in AMI. However, routine use of magnesium in AMI is not currently advocated by the ACC/AHA Task Force on Practice Guidelines. [11] Conflicting data exists for its usefulness. The second Leicester Intravenous Magnesium Infusion Trial (LIMIT-2) showed decreased mortality post-MI at 28 days. [12] However, the Fourth International Study of Infarct Survival (ISIS-4) did not demonstrate any benefit to magnesium therapy. [13] In fact, it was associated with an increased incidence of heart failure. Timing of administration of magnesium therapy may account for the conflicting results. Magnesium is recommended if there is a documented or suspected magnesium deficiency or if thrombolytics are contraindicated. If magnesium is used, it should be given as soon as possible.

Magnesium is indicated for ventricular fibrillation and sustained ventricular tachycardia refractory to standard therapy regardless of serum magnesium levels. [14] Polymorphic ventricular tachycardia will probably not respond to magnesium therapy if the QT interval is normal. Magnesium may reduce the frequency of PVCs, since this dysrhythmia is associated with low serum levels. Several studies indicate the usefulness of magnesium for the treatment of multifocal atrial tachycardia. [14] Its mechanism of action may be inhibition of after-depolarizations. Magnesium also proves helpful in digoxin toxic dysrhythmias, which often occur in hypomagnesemic states. Magnesium may also terminate PSVT by prolonging atrioventricular nodal conduction. Other uses for parenteral magnesium sulfate include seizures associated with toxemia/eclampsia/nephritis, hypomagnesemia (mild to severe), and hyperalimentation. Unlabelled uses include the termination of preterm labor and

bronchodilation in a subset of asthma patients.

Pharmacokinetics   When magnesium sulfate is given intravenously, its onset of action is immediate and the duration of action is about 30 min. Following intramuscular administration, the time to onset of action is about 1 h and the duration is 3 to 4 h. Magnesium is excreted by the kidney at a variable rate directly proportional to the serum concentration and the glomerular filtration rate.

Dosing and Administration   An intravenous loading dose of magnesium sulfate is administered as 1 to 2 g (8 to 16 meq), mixed in 50 or 100 mL D$_5$W, using either the 10% (100 mg/mL) or 50% (500 mg/mL) solutions. In cardiac arrest scenarios, the intravenous dose can be injected over 1 to 2 min. However, if time permits, a safer method is to administer 2 to 4 g as an intravenous infusion over 20 to 60 min. The rate of infusion should be slowed or stopped if hypotension develops. Several trials recommend the routine use of magnesium at doses of 8 to 12 g/24 h for AMI or suspected MI in the face of magnesium deficiency. While most recommendations suggest that an intravenous maintenance infusion at 0.5 to 1 g/h (4 to 8 meq) should follow for up to 24 h, the rate and duration of infusion should be based on the clinical situation and the degree of hypomagnesemia.

Adverse-Effects Profile   Hypotension is the predominant adverse effect, yet it is surprisingly uncommon, even when a 1- to 2-g IV push is given over a few minutes. Other signs of hypermagnesemia, which may begin at serum concentrations of 4 meq/mL, include flushing, sweating, CNS depression, depression of reflexes, flaccid paralysis, hypotension, circulatory collapse, hypothermia, and fatal respiratory paralysis. Depression of reflexes usually precedes respiratory collapse.

VASOACTIVE DRUGS

Vasoactive drugs have two functions: (1) to improve cardiac perfusion pressure during cardiac arrest and (2) to support the circulation during hemodynamic compromise. During cardiac arrest, the myocardium needs to be perfused with adequately oxygenated blood before the return of spontaneous circulation can occur. Since a-adrenergic stimulation is responsible for improved coronary perfusion pressure, for this reason as well as others, adrenergic agents are used. Epinephrine is the agent most frequently employed. Currently, no evidence exists to support the superiority of an alternative agent although many have been tested in animal models.

Adrenergic agents are divided into pure a agents (phenylephrine), mixed a and b agents (epinephrine, norepinephrine, dopamine), and pure b or primarily b agonists (isoproterenol, dobutamine). The a receptors are found primarily in blood vessels, where a stimulation causes vasoconstriction. The b agonists work primarily on the heart and promote increased heart rate, increased contractility, and increased myocardial oxygen consumption. The b$_2$ receptors are found in smooth muscle of the bronchi, blood vessels, and uterus; stimulation causes bronchodilatation, vasodilatation, and uterine relaxation. If the etiology of the hemodynamic compromise is identified (e.g., cardiogenic, vasogenic, hypovolemic, or septic shock, etc.), then the judicious selection of a sympathomimetic agent can be achieved. See Table 25-3, Table 25-4, and Table 25-5 for details.

Receptor Type	Cardiovascular Actions	Signal Pathway
α_1	Vasoconstriction	Activation of phospholipase C
α_2	Decreased central sympathetic outflow; feedback inhibition of norepinephrine release; vasoconstriction	Inhibition of adenyl cyclase
β_1	Increased heart rate, contractility, and conduction velocity	Activation of adenyl cyclase
β_2	Vasodilation	Activation of adenyl cyclase
Dopamine	Vasodilation	Activation of adenyl cyclase

TABLE 25-3   Cardiovascular Actions and Signal Transduction Pathways Initiated by Adrenergic Receptor Activation

	Receptor Type			
	α	β_1	β_2	Dopamine
Phenylephrine	++/+++	–	–	
Norepinephrine	++++	++++	+/++	
Epinephrine	+++	++++	+++

TABLE 25-5   Vasopressor Agents

EPINEPHRINE   **Actions**   Epinephrine is a potent, nonselective a- and b-adrenergic agonist. It is first-line therapy for cardiac arrest. The myocardium needs to be perfused before return of spontaneous circulation can occur. The a-adrenergic properties of epinephrine increase coronary artery perfusion pressure, which improves myocardial blood flow. Epinephrine is also a potent vasoconstrictor and increases mean arterial pressure by stimulating a-adrenergic receptors. This effect causes vasoconstriction of arterioles in the skin, mucosa, and mesenteric vasculature, redistributing blood to the heart and brain, and in turn results in improved cardiac and cerebral perfusion during resuscitation. However, its b-adrenergic qualities can have deleterious effects in the patient with myocardial ischemic or coronary artery disease. The b agonists increase heart rate, improve myocardial contractility, and therefore increase myocardial oxygen demand.

The b$_2$ adrenergic effects of epinephrine cause bronchodilation and antagonize the effects of histamine. Therefore, epinephrine is a useful adjunct for the treatment of

severe bronchospasm and severe hypersensitivity reaction.

Pharmacokinetics Both the onset and the duration of action of epinephrine are relatively short: 1 to 2 min and 2 to 10 min, respectively. The drug quickly becomes fixed in the tissues and is rapidly inactivated via oxidation by monoamine oxidase (MAO) and via methylation by catechol-O-methyltransferase (COMT). Subsequent metabolites are excreted in the urine as sulfates and glucuronides.

Common ED Indications Epinephrine is considered a first-line agent in the treatment of cardiac arrest and may be used in pulseless VT/VF that has not responded to electrical countershock, asystole, and pulseless electrical activity (PEA). The drug has also been purported to "coarsen" fine ventricular fibrillation, but there is no documented evidence that this is true. Epinephrine does, however, increase the likelihood of continued hemodynamic stability in animals that have been successfully defibrillated. This has been attributed to the effect of epinephrine on systemic vascular resistance. Historically, the standard 1-mg dose came from the operating room practice of intracardiac injections, which were effective in restarting the arrested heart. But when studies showed that 1 to 3 mg of intracardiac epinephrine seemed to be more effective, higher dosages were adopted. Further animal studies were performed, and their dose-response curves demonstrated that vasoactive effects of epinephrine were dose-dependent. The lower doses favored b-adrenergic effects (cardiac stimulation), while higher doses revealed a-agonist effects (vasoconstriction). Over the years, it was assumed that 1 mg of epinephrine administered intravenously was equivalent and would be useful for all body weights. The dose-response curve was studied in the 1980s and early 1990s, revealing that higher doses of epinephrine (ranging from 0.045 to 0.2 mg/kg) were required to improve hemodynamics and demonstrate increased rates of return of spontaneous circulation (ROSC). However, trials failed to demonstrate significant improvement in survival rates to hospital discharge compared with the standard epinephrine doses (see "Dosing and Administration," below). Experience with "high-dose" epinephrine resulted in increased numbers of patients with ROSC admitted to intensive care settings, who previously would likely have failed resuscitation. While these results were initially exciting, the routine practice of administering high-dose epinephrine has waned as clinicians have come to appreciate the poor outcomes and needless consumption of precious medical resources.

Epinephrine is also used as an antidote to reverse bronchospasm due to anaphylactic and hypersensitivity reactions. It can be used as a vasopressor to increase blood pressure in septic shock. It should be employed as second-line therapy after norepinephrine. Be aware of its b-agonist properties, namely cardiac stimulation, which can increase the risk of dysrhythmias.

Dosing and Administration Current AHA guidelines recommend that epinephrine in a 1-mg (1:10,000) IV bolus continue to be the initial dose in cardiac arrest. It is now recommended that the dosing frequency be increased to 3 to 5 min from a 5-min interval. The AHA recognizes that higher doses of epinephrine are acceptable but can neither recommend nor discourage their use; however, they do say higher doses should be used only after the 1-mg dose has failed. The intermediate epinephrine dose suggestion is 2 to 5 mg IV push, also given every 3 to 5 min; the escalating regimen is 1 mg to 3 mg to 5 mg IV push, 3 min apart; the high dose reflects use of a bolus of 0.1 mg/kg every 3 to 5 min.

Epinephrine may be given by peripheral vein, central line, or endotracheally. The optimal dose for endotracheal drug delivery is unknown; however, a dose that is at least 2 to $2\frac{1}{2}$ times the peripheral intravenous dose may be needed. Endotracheal (ET) administration is performed by placing 10 mL of a 1:10,000 solution (preload syringe) down the ET tube and then performing several rapid ventilations to disperse the drug throughout the airways for maximal absorption. If the more concentrated epinephrine vial is used (30 mg/30 mL, 1:1000), the dose should be diluted to 10 mL.

Intracardiac administration should be used only during open cardiac massage so as to avoid the risk of pneumothorax, coronary artery laceration, and cardiac tamponade. Transthoracic intracardiac injections will interrupt ventilations and closed chest compressions and are thus no longer recommended.

Although ephinephrine is not the first choice, a continuous epinephrine infusion can be used to elicit the vasopressor response in patients who are not in cardiac arrest. The initial dose should begin at 1 mg/min (range 2 to 10 mg/min) and be titrated to a desired hemodynamic response. Continuous intravenous infusions of epinephrine should be administered by central venous access to ensure prompt transport to the heart and reduce the risk of extravasation.

Adverse-Effects Profile Adverse effects are of minimal importance in the setting of cardiac arrest. Epinephrine does increase myocardial oxygen consumption significantly and thus can exacerbate ventricular irritability in the setting of myocardial ischemia. The a-adrenergic activity of epinephrine produces an increase in systemic vascular resistance, which could conceivably be detrimental to a failing myocardium in that increased afterload can significantly decrease cardiac output. Also, if the patient is resuscitated, hypertension, tachycardia, and dysrhythmias should be anticipated. Because epinephrine causes renal artery vasoconstriction, it may cause a detrimental decrease in the glomerular filtration rate (GFR). Epinephrine is not compatible with alkaline solutions (e.g., sodium bicarbonate) in the same intravenous line, as some studies show slow inactivation of catecholamine.

DOPAMINE **Actions** Dopamine (Intropin), an endogenous catecholamine and the precursor of endogenous norepinephrine, acts on dopaminergic, b_1 and a receptors. In low doses (1 to 3 µg/kg per min), dopamine acts on dopaminergic receptors, causing vasodilation of the renal, mesenteric, coronary, and intracerebral vascular beds. This effect improves organ perfusion and increases urine output. At moderate doses (3 to 10 µg/kg per min), dopamine acts on its b_1-adrenergic receptors, exerting inotropic and chronotropic effects and increasing cardiac output without marked increases in pulmonary wedge pressure. Stimulation of a receptors increases peripheral resistance, increases pulmonary wedge pressure, and decreases blood flow to the kidney. The a effects begin at 10 µg/kg per min and predominate above 15 µg/kg per min.

Pharmacokinetics Dopamine has an onset of action within 2 to 4 min and a duration of action of less than 10 min. It is used only as an intravenous infusion. Renal response may take 20 to 30 min. Dopamine is metabolized primarily (75 percent) to homovanillic acid and other metabolites (including norepinephrine) by MAO and COMT and is subsequently excreted in the urine. Only a fraction of the dose eliminated by the kidneys is unchanged dopamine.

Common ED Indications Dopamine is used to treat hemodynamic compromise associated with MI, heart failure, septic shock, and renal failure. It is indicated for reversing hemodynamically significant hypotension due to MI, overt heart failure, renal failure, and chronic CHF when fluid resuscitation is unsuccessful (using the appropriate crystalloid or colloid solution) or not appropriate. It is also used to improve renal blood flow and to increase urine output, especially in the patient with septic shock. It is a preferred agent for treatment of cardiogenic shock.

Dopamine can be used in septic shock, especially if the primary goal is improvement in myocardial contractility. At high a-adrenergic doses (>10 µg/kg per min), dopamine can effectively raise the blood pressure in the fluid-resuscitated patient with septic shock. However, cardiac stimulation also occurs at high doses, which increases the risk of dysrhythmias. Often low-dose dopamine is used in combination with a more pure a vasoconstrictor to treat septic shock. Dopamine should be avoided in trauma until the patient has been adequately fluid-resuscitated.

Dosing and Administration The range for low-dose dopamine is 1 to 3 µg/kg per min, while the moderate dose is 3 to 10 µg/kg per min. High-dose dopamine begins at 10 µg/kg per min and should be titrated to adequate blood pressure response. These three levels of dosage are also referred to as "renal," "cardiac," and "vasopressor," respectively, in recognition of the different physiologic effects at different doses. Renal dose dopamine improves renal blood flow and urine output. Cardiac dose dopamine improves myocardial contractility and increases heart rate secondary to b_1-adrenergic effects. Peripheral arterial and venous vasoconstriction caused by a-adrenergic stimulation occurs with vasopressor dose dopamine. As with all vasoactive infusions, dopamine should be discontinued by tapering the dosage. Most patients can be managed on 20 µg/kg per min or less. If higher doses are needed for septic shock, an intravenous norepinephrine infusion should be added. The combination of dopamine and dobutamine improves cardiac performance during cardiogenic shock.

Adverse-Effects Profile Dopamine may produce dose-dependent adverse effects, including hypotension at low infusion rates, hypertension at high infusion rates, ectopic beats, headache, nausea, vomiting, angina pectoris, and tachycardia. Necrosis may occur if the infusion extravasates. Gangrene of the extremities has occurred in patients with occlusive vascular disease or diabetes as well as in those who received prolonged high-dose infusions. Monoamine oxidase inhibitors, halogen anesthetics, sympathomimetics, and phosphodiesterase inhibitors will prolong and intensify the effects of dopamine, possibly causing hypertensive and dysrhythmogenic activity. Phenytoin may interact with dopamine and cause hypotension, seizures, and bradycardia. Dopamine is contraindicated in pheochromocytoma. Like epinephrine, dopamine should not be mixed with alkaline solutions in the same line.

DOBUTAMINE **Actions** Dobutamine (Dobutrex) is a synthetic sympathomimetic agent that exerts potent inotropic and mild chronotropic activity by directly stimulating b-adrenergic receptors. Dobutamine also has mild a_1-agonist activity, but the effects are balanced by the more potent b_2-agonist effects, cumulatively resulting in mild vasodilation. Dobutamine has potent b_1 effects, which make it an excellent inotrope, but it lacks the a vasoconstricting activity of dopamine. Doses of 2 to 20 µg/kg per min increase cardiac output, induce peripheral vasodilation, and decrease pulmonary occlusive pressures, causing minimal increase in heart rate.

However, higher doses of dobutamine will accelerate the heart rate and induce dysrhythmogenic effects. An increased cardiac output usually results in increased renal and mesenteric blood flow.

Pharmacokinetics   Dobutamine has an onset of action of 1 to 2 min, but peak plasma levels may not be reached for 10 min. Its duration of action is 10 to 15 min. The plasma half-life is 2 min. Dobutamine is metabolized in the liver and other tissues by COMT and glucuronic acid, and over two-thirds of a dose is excreted as metabolites in the urine within 48 h.

Common ED Indications   Dobutamine is used to increase inotropic activity in the short-term management of cardiac decompensation due to depressed contractility resulting either from organic heart disease or from cardiac surgical procedures. The drug should be used to increase cardiac output in patients with chronic CHF when standard therapy (diuretics, vasodilators, and digoxin) fails to improve symptoms and/or in the patient with pulmonary congestion and low cardiac output.

Dosing and Administration   Dobutamine is administered only by intravenous infusion. The dosage range is 2 to 20 µg/kg per min; however, most patients can be maintained on 10 µg/kg per min or less. In some cases, very low doses (0.5 µg/kg per min) may be effective. Conversely, infusions up to 40 µg/kg per min have been used, but doses greater than 20 µg/kg per min should be used with caution because of increased risks of tachydysrhythmias. To assess the effectiveness of the drug correctly, patients should be monitored with a Swan-Ganz catheter.

Adverse-Effects Profile   The primary adverse effects of dobutamine are increased heart rate (increases greater than 5 to 15 beats per minute are uncommon), blood pressure (increases greater than 10 to 20 mmHg are uncommon), and ectopic dysrhythmias (escape beats, unifocal and multifocal ventricular ectopic beats, and ventricular bigeminy). Less common effects include headache, paresthesias, tremors, nausea, angina, and dyspnea. Increases in heart rate greater than 10 percent may induce or exacerbate myocardial ischemia.

NOREPINEPHRINE   **Actions**   Norepinephrine bitartrate (Levophed) is identical to the endogenous catecholamine synthesized in the adrenal medulla and sympathetic nervous tissue. Norepinephrine acts primarily on a receptors, inducing powerful vasoconstrictor actions on arterial and venous beds (i.e., renal and mesenteric vasoconstriction). It is particularly useful in patients with dopamine refractory septic shock. The drug also has direct action on b_1 receptors, thus inducing inotropic and chronotropic effects. Paradoxical decreases in heart rate may result from reflex increases in parasympathetic tone. Norepinephrine therefore produces less tachycardia than dopamine. It differs from epinephrine in that it has little effect on b_2 receptors.

Pharmacokinetics   Norepinephrine is administered only as intravenous infusion. The pressor effect has an onset of action within 1 to 3 min and stops within 5 to 10 min of discontinuation of the infusion. The primary elimination of norepinephrine is via uptake by adrenergic neurons and metabolism in the liver and other tissues, mainly by COMT and to a lesser extent by MAO. Norepinephrine metabolites are excreted in the urine as sulfate and glucuronate conjugates.

Common ED Indications   Norepinephrine is used primarily as a vasopressor for the treatment of severe hypotension refractory to fluids and other pressor agents, specifically dopamine. Norepinephrine may be particularly effective when endogenous norepinephrine stores are low. This scenario may arise in patients who have been on prolonged infusions of dopamine. To a certain degree, norepinephrine increases inotropic activity and may be indicated in severe hypotension occurring during an AMI. However, norepinephrine is a potent vasoconstrictor that increases afterload and may impede cardiac output. Therefore norepinephrine should be employed in cardiogenic shock only after more traditional therapy has failed. Other specific uses for norepinephrine include controlling hypotensive states during poliomyelitis, treating drug overdose (various phenothiazines and tricyclic antidepressants), and for spinal anesthesia, pheochromocytomectomy, and sympathectomy. Its potent a effects make it a good choice to treat septic shock.

Dosing and Administration   Norepinephrine should be used only as an intravenous infusion. The initial adult dose is 0.5 to 1 µg/min. Rates must be titrated carefully, increasing by 1 to 2 µg/min q3–5 min until a systolic blood pressure of 80 to 100 mmHg is attained. The drug should be infused at the lowest effective dose for the shortest period of time possible. Occasionally, high doses of norepinephrine may be necessary to reverse hypotension (e.g., 8 to 30 mg/min). Usually, the maintenance dose is 2 to 4 µg/min. Adjust the rate of flow q3–5 min to maintain blood pressure. Once the blood pressure is adequate, the infusion may be gradually titrated down. Abrupt withdrawal may result in acute hypotension.

Adverse-Effects Profile   Large doses of norepinephrine may result in ventricular irritability, cardiac depression, decreased renal blood flow, and a reflex bradycardia. Acute hypertension may result in patients on MAO inhibitors or tricyclic antidepressants. Use norepinephrine with extreme caution in these patients. Use as large a vein as possible to minimize the risk of extravasation. If extravasation occurs, phentolamine, 5 to 10 mg in 10 to 15 mL of normal saline solution, should be infiltrated as soon as possible to prevent necrosis and sloughing. Check frequently for intravenous extravasation if a small vein is used. Norepinephrine is contraindicated in patients with hypotension resulting from cyclopropane or halogenated hydrocarbon anesthesia or uncorrected blood volume deficits as well as in mesenteric or peripheral vascular thrombosis. Norepinephrine must be used with caution in patients with known or suspected pulmonary hypertension, since norepinephrine is a potent vasoconstrictor of the pulmonary vasculature.

PHENYLEPHRINE   **Actions**   Phenylephrine is an a-adrenergic agent that possesses few b-adrenergic effects. It is useful for the treatment of septic shock, particularly if further cardiac stimulation is to be avoided. However, phenylephrine lacks the vasoconstrictor potency of epinephrine and norepinephrine.

Pharmacokinetics   The vasoconstrictor activity of phenylephrine lasts approximately 20 min after intravenous infusion, 1 to 2 h after an intramuscular dose, and 50 min after subcutaneous administration. It is associated with reflex bradycardia, which is blocked by atropine. The sympathomimetic effects are potentiated by MAO inhibitors.

Common ED Indications   Phenylephrine is a powerful a-receptor stimulant. It causes peripheral vasoconstriction, which causes an elevation of the systolic and diastolic blood pressure and reflex bradycardia. Unlike epinephrine and norepinephrine, phenylephrine lacks cardiac stimulant b effects. Therefore cardiac complications are rarely seen. It is useful in shock states caused by sepsis and by some drug toxicities. Patients with cardiogenic shock and left ventricular dysfunction require more b-inotropic support. Phenylephrine should be avoided in this patient population.

Dosing and Administration   Phenylephrine can be administered intravenously or as a continuous infusion. In shock, the initial dose is 100 to 180 µg/kg as an intravenous infusion. Once the blood pressure is stable, the infusion can be decreased to 40 to 60 µg/kg. An alternate regimen is 0.1 to 0.5 mg intravenously q15 min. Do not exceed an individual dose of 0.5 mg IV. This should elevate the blood pressure for at least 15 min. Clinical response to the continuous infusion occurs between 40 to 180 µg/min. Blood pressure should be monitored continuously for both routes and hypertension avoided.

Adverse-Effects Profile   Phenylephrine is associated with headache and restlessness. Reflex bradycardia commonly occurs. Since phenylephrine is pure a stimulant, cardiac dysrhythmias are rare. The a receptors are located in large coronary arteries but not commonly found in the small coronary arteries. Vasoconstriction of the large coronary arteries is particularly dangerous in the elderly, in those with severe atherosclerosis, and in patients with a history of MI. Extravasation of the drug is associated with sloughing and tissue necrosis, often requiring surgical debridement. Phentolamine, an a-adrenergic blocking agent, may prevent necrosis. (Dilute 10 mg of phentolamine in normal saline solution to a volume of 15 mL. Infiltrate the "at risk" area.)

ISOPROTERENOL   **Actions**   Isoproterenol is a synthetic sympathomimetic with strong b_1 and b_2-adrenergic-agonist properties; it increases the myocardial oxygen consumption. b_1 actions increase the inotropic and chronotropic activity of cardiac muscle, resulting in increased cardiac output despite a reduction in the mean blood pressure. The drop in blood pressure can be attributed to the b_2-adrenergic relaxation of smooth muscle in the splanchnic vascular bed and alimentary tract, the lungs, and skeletal muscle, which causes peripheral vasodilation and venous pooling. Therefore, isoproterenol is not a vasopressor agent and should not be used in shock.

Pharmacokinetics   After intravenous administration, isoproterenol has an onset of action within 1 to 5 min and a duration of action lasting 1 to 2 h. Some 50 percent of the drug is eliminated unchanged in the urine, while 25 to 35 percent is metabolized primarily to 3-O-methylisoproterenol (which has been reported to have weak b-adrenergic blocking activity) by COMT in the lung, liver, and other body tissues and then excreted unchanged or as a sulfate conjugate.

Common ED Indications   Isoproterenol is now indicated only for refractory torsades de pointes and immediate temporary management of hemodynamically significant bradycardias in the denervated heart of patients at or and after heart transplantation. Isoproterenol is not considered the drug of choice for either of these conditions; it should be considered only as a temporary measure until pacemaker therapy is instituted. For hemodynamically unstable bradydysrhythmias transcutaneous pacing (TCP) is the definitive treatment, since it provides better control and is a safer mode of therapy. Other agents that should be considered before

isoproterenol are intravenous fluid challenge, atropine, and a dopamine or epinephrine infusion. The vasodilator effects of isoproterenol have been shown to lower coronary perfusion pressure during cardiac arrest and to increase the mortality rate in experimental animals; the drug has not been shown to be efficacious in cardiac arrest or for use in hypotension.

Dosing and Administration   Isoproterenol should be administered only via intravenous infusion. The initial infusion rate, 2 to 10 μg/min, should be titrated to the desired heart rate. The drug has been shown to be more helpful at low doses rather than high doses.

Adverse-Effects Profile   It must be emphasized that the b_1-agonist action of isoproterenol will cause an increase in chronotropic effect. This effect raises myocardial oxygen requirements and can possibly precipitate or exacerbate myocardial ischemia, inducing serious dysrhythmias (e.g., VT and VF). Other adverse effects include anxiety, mild tremors, and anginal pain in patients with previously reported angina pectoris. Therefore, the drug should be avoided in patients with preexisting ischemic heart disease. Isoproterenol may also induce tachydysrhythmias in hypokalemic and digoxin-toxic patients. The primary adverse effects from b_2-adrenergic actions are facial flushing, headache, and hypotension.

AMRINONE   **Actions**   Amrinone is thought to be a positive inotropic agent not related to digitalis glycosides, catecholamines (e.g., epinephrine, dopamine, and norepinephrine), or synthetic b_1-adrenergic agonists (e.g., dobutamine and isoproterenol); it possesses potent vasodilator activity. While its true mechanism is not known, amrinone is believed to act by inhibiting cyclic adenosine monophosphate (cAMP) phosphodiesterase activity, which results in increased levels of cellular cAMP. Increased levels of cAMP are thought to increase calcium availability to the myocardial contractile components. These actions increase myocardial contractility and force of contractions (i.e., positive inotropic effect) without significant increases in heart rate and blood pressure. Some believe that the vasodilator action is the primary mechanism responsible for increasing myocardial performance. Vasodilation with amrinone may be the result of direct action by the drug on the vessels or may be caused by a reflex withdrawal of sympathetic tone following the improvement of myocardial function. Nonetheless, the primary effect of amrinone is an increase in myocardial contractility and stroke volume with a reduction in preload and afterload.

Pharmacokinetics   Cardiovascular effects usually begin within 2 to 5 min and generally peak within 10 min at all doses. The duration of effect is dose-related. Following a 0.75-mg/kg bolus dose, the duration is about 30 min, while a 3-mg/kg dose will last approximately 2 h. Amrinone is metabolized in the liver, excreted in the urine, and has a Vd of 1.2 L/kg. In patients with normal renal function, amrinone has an elimination half-life of 3.6 h. In patients with CHF and/or hepatic or renal dysfunction, amrinone has a prolonged elimination half-life (average 5.8 h).

Common ED Indications   Amrinone is indicated for increasing myocardial performance in the short-term management of CHF. Because of its adverse-effects profile, the drug should be used only when other therapies, such as diuretics, digoxin, and vasodilators, have failed. Amrinone has been studied in class III and IV CHF. It may serve as an alternative or adjunctive agent to dobutamine in the treatment of cardiogenic shock.

Dosing and Administration   The initial dose is 0.75 mg/kg followed by a maintenance infusion at 5 to 10 μg/kg per min. Amrinone should be administered as a slow direct intravenous injection (undiluted) over 2 to 3 min or as a continuous infusion diluted in 0.9 or 0.45% saline. Dextrose-containing solutions may result in a loss of the drug's activity. The total daily dose should not exceed 10 mg/kg. A second intravenous bolus injection may be given 30 min following the first dose if desired effects have not been achieved. Adjustments in the maintenance infusion should be titrated to clinical response.

Adverse-Effects Profile   The most common adverse effects are thrombocytopenia (<100,000/mm^3, in 2.4 percent), ventricular and supraventricular dysrhythmias (3 percent), hypotension (1.3 percent), and nausea (1.7 percent). Other adverse effects, which occur in fewer than 1 percent of patients, include vomiting, anorexia, fever, chest pain, and burning at the site of injection. Although rare, hepatotoxicity with amrinone has been reported. Acute marked elevations of hepatic enzymes along with clinical symptoms may suggest a hypersensitivity reaction, which would require prompt discontinuation of the drug.

MILRINONE   Milrinone is a phosphodiesterase inhibitor with positive inotropic and vasodilator effects. It is similar to amrinone in its spectrum of action. Milrinone has a lower incidence of thrombocytopenia but a higher risk of cardiac dysrhythmias as compared with amrinone. Milrinone minimally slows AV node conduction time, which may speed the ventricular response in patients with atrial fibrillation or atrial flutter. Ventricular ectopy, ventricular dysrhythmias, and supraventricular dysrhythmias may also occur with milrinone, especially in high-risk patients.

Milrinone inhibits cAMP phosphodiesterase activity. Like amrinone, cAMP mediated increases in intracellular calcium permit the cardiac muscle to contract with increased force. Milrinone promotes improved diastolic function and vascular muscle relaxation. It is indicated for the treatment of CHF. The loading dose is 50 μg/kg administered over 10 min, then a maintenance infusion at 0.375 to 0.75 μg/kg per min (standard is 0.5 μg/kg per min).

ATROPINE   **Actions**   Atropine sulfate, an antimuscarinic agent, enhances sinus node automaticity and AV conduction by blocking vagal activity; thus it has been termed a parasympatholytic drug. It has anticholinergic properties.

Pharmacokinetics   The onset of action of atropine following intravenous, intramuscular, and endotracheal administration is rapid, with peak increases in heart rate occurring within 5 min. The half-life of atropine is 2 to 4 h or longer. Well absorbed and distributed throughout the body, atropine is metabolized in the liver and excreted in the urine.

Common ED Indications   Atropine is the treatment of choice for increasing heart rate in hemodynamically unstable bradycardias (e.g., decreased heart rate with hypotension, altered mental status, "escape beats," and chest pain). Higher doses have been used in asystolic cardiac arrest, specifically if it is associated with increased vagal tone. It improves AV node conduction time in first degree and type I second degree AV block. Caution should be exercised with type II second degree and third degree AV block, since atropine may be associated with paradoxical slowing of the heart rate. The drug reverses cholinergic medications and toxins that cause a decrease in systemic vascular resistance, heart rate, and blood pressure. Additionally, atropine may reduce nausea and vomiting that occur as a result of morphine administration.

Dosing and Administration   The dose of atropine for hemodynamically unstable bradycardia is 0.5–1.0 mg by rapid IV push, repealed q3–5 min until a desired heart rate is achieved or symptoms resolve. Do not administer less than 0.5 mg since lower doses are associated with paradoxical bradycardia. Bolus doses of 1 mg can be given for asystole and repeated once if necessary. A total dose of 3 mg (0.04 mg/kg) results in full vagolytic blockade in humans. It has been conventional practice to stop atropine administration when the total "vagolytic dose" has been given as outlined in standard ACLS teaching. This practice is appropriate when there is no response to atropine; further doses are unlikely to be effective. However, if a response is seen, there is no proscription to exceeding the "vagolytic" dose, if further dosing maintains the desired effect.

Atropine can be administered by intravenous push, intramuscularly, and via endotracheal tube. If given via the endotracheal tube, recommendations include a bolus of at least 1 mg at a time. No dilution is necessary when a preload syringe (1 mg/10 mL) is used. However, if the 1-mg/mL ampules are used, dilution with up to 10 mL of normal saline is recommended. It appears that absorption across tracheobronchial structure is good and substantial atropine levels are achieved within 10 min of dosing. The pediatric dose is 0.02 mg/kg with a minimum dose of 0.1 mg. Do not administer less than 0.1 mg since lower doses are associated with paradoxical bradycardia.

Adverse-Effects Profile   Atropine is not indicated for bradycardia in hemodynamically stable patients. If it is administered, marked increases in heart rate can increase myocardial oxygen consumption, possibly inducing ischemia and precipitating ventricular tachydysrhythmias (including VT and VF). This is particularly true with doses greater than 0.5 mg. Doses less than 0.5 mg along with a therapeutic dose administered slowly can cause paradoxical bradycardia. This may be due to a central reflex stimulation of the vagus or a peripheral parasympathomimetic effect on the heart. There is concern by some about using atropine in AV block at the His-Purkinje level (type II AV block and third-degree block with new wide QRS complexes). Other effects that may occur include anticholinergic symptoms (e.g., blurred vision, dry mouth, CNS stimulation, hallucinations, mydriasis, tachycardia).

Vasodilator Agents

NITROGLYCERIN   **Actions**   Although the mechanism of action of nitroglycerin is not fully understood, its therapeutic benefit appears to be due to its actions on the peripheral circulation and the coronary blood flow. Nitroglycerin is a direct vasodilator that induces venodilation at low doses (<100 mg/min) and arteriolar vasodilation at high doses (>200 mg/min). Coronary artery dilation occurs throughout the dosage range.

Pharmacokinetics Table 25-6 describes the onset and duration of action of various nitroglycerin products. Nitroglycerin has a plasma half-life of 1 to 4 min and is metabolized in the liver. Oral doses undergo an extensive first-pass metabolism.

TABLE 25-6   Nitroglycerine Chart

Common ED Indications Nitroglycerin is approved for the prophylaxis, treatment, and management of angina pectoris. Intravenous nitroglycerin is used to control hypertension associated with surgery and also in CHF associated with AMI.

Dosing and Administration Refer to Table 25-6 for dosing details of specific nitrates used in clinical practice. Nitroglycerin can be administered sublingually, lingually, intrabuccally, orally, topically, or by intravenous infusion. The sublingual and intrabuccal tablets should not be swallowed, and the extended-release buccal tablets (transmucosal) should not be chewed or swallowed. Patients should be in a sitting or supine position immediately following sublingual, lingual, or intrabuccal administration.

An intravenous infusion of nitroglycerin (Tridil) should be administered by a controlled-infusion device. Since data on the incompatibility of nitroglycerin with other parenteral agents are unclear, a separate intravenous site for a nitroglycerin infusion should be used. Infusions should not be suddenly discontinued, since abrupt withdrawal reactions (including angina pectoris or MI) may result. Attempts should be made to gradually wean down the infusion. Specific dosing regimens are shown in Table 25-6. There is no specific upper limit to the dose. Although most patients will be managed below 200 µg/min or even 100 µg/min, a few patients may require a dose several fold higher. The dose of nitroglycerin for each patient should be titrated to individual response, using the smallest effective dose.

Adverse-Effects Profile Most adverse effects are related to the cardiovascular actions induced by nitroglycerin. These effects include headache, dizziness, weakness, syncope, flushing, hypotension, reflex tachycardia, and occasionally bradycardia. Use in patients concomitantly using alcohol may potentiate hypotension. Nitroglycerin has been shown to decrease the anticoagulant effects of heparin. Also, rash has been reported with topical nitroglycerin use.

Caution is advised when nitroglycerin is used in patients who are hemodynamically unstable (including those who are volume-depleted) or who have increased intracranial pressure or severe anemia. The drug should also be used cautiously in cases of constrictive pericarditis, pericardial tamponade, and hypertrophic cardiomyopathy. Also, there have been reports of associated brief increases in intraocular pressure in patients with glaucoma. Extended-release preparations of nitroglycerin should be avoided in patients with GI hypermotility or malabsorption syndromes.

Transdermal patches and topical ointment must be removed prior to attempting defibrillation or synchronized cardioversion. Topical nitroglycerin products alter electrical conductivity and enhance the potential for electrical arcing. To avoid excessive dosing, topical products should also be removed if additional nitroglycerin is given for acute symptoms.

NITROPRUSSIDE Sodium nitroprusside (Nipride) is another potent arterial and venous dilator used to treat the full spectrum of hypertensive emergencies. A full discussion of nitroprusside is found in Chap. 53.

Pediatric Considerations

Children, unlike adults, seldom have primary ventricular dysrhythmias in the absence of congenital heart disease. Rather, pediatric arrest is usually secondary to severe respiratory insufficiency. Bradydysrhythmias are the most common rhythms seen in pediatric arrest. Table 25-7 shows the drugs most commonly used in pediatric advanced life support. Pediatric resuscitation is discussed in depth in Chap. 10.

26 APPROACH TO THE PATIENT IN SHOCK

Emanuel P. Rivers
Mohamed Y. Rady
Robert Bilkovski

EPIDEMIOLOGY

Over 1 million cases of shock present to the emergency department (ED) each year; the presentation may be cryptic or obvious as in the ultimate shock state of cardiac arrest. The definition and treatment of shock continue to evolve because of new understanding and technologies, some of which are now available for ED use. With a contemporary understanding of shock, the emergency physician can initiate expert and timely intervention. Regardless of the specific precipitating events, modifying circumstances, and variable presentations, common principles apply concerning the general approach to a patient in the initial stages of shock.

THE RATIONALE FOR EARLY INTERVENTION

The "golden hour" is the tenet of early intervention in surgical resuscitation. Due to inpatient crowding, this "golden hour" can frequently be *hours* in hospitals, requiring the provision of critical care in the ED. [1,2] The benefit of ED care in nontraumatic critical illness has not been adequately studied. Using a measure of illness severity that also predicts mortality (APACHE II), a study of critically ill patients admitted to the medical critical care unit demonstrated that ED intervention significantly decreased the incidence of organ failure by 25 percent and predicted mortality by 12.5 percent. [3] This study, and others like it, provide evidence that expert and timely ED care reduces morbidity and mortality in patients with nontraumatic critical illness.

PATHOPHYSIOLOGY

Shock is now defined as circulatory insufficiency that creates an imbalance between tissue oxygen supply and oxygen demand. Global tissue hypoperfusion is associated with a decreased venous oxygen content and metabolic acidosis (lactic acidosis). Shock is classified into four categories by etiology: (1) hypovolemic (due to inadequate circulating volume), (2) cardiogenic (due to inadequate cardiac pump function), (3) distributive (maldistribution of blood flow), and (4) obstructive (extracardiac obstruction to blood flow). Clinically, shock may have a predominant cause, but as the shock state persists or progresses, other pathophysiologic mechanisms become operative.

Knowledge of the principles of oxygen transport and consumption is important to the understanding of shock. A maximum of four molecules of oxygen is loaded onto each molecule of hemoglobin as it passes through the lungs. If all available oxygen sites are occupied (four per molecule of hemoglobin), Sa_{O_2} is 100 percent (see Table 26-1 for abbreviation definitions). The Ca_{O_2} is the amount of oxygen bound to hemoglobin plus a small amount dissolved in plasma (Table 26-2). Oxygen is delivered to the tissues by the pumping function of the heart. The D_{O_2} is the product of the Ca_{O_2} and CO.

TABLE 26-1   Definitions of Abbreviations

TABLE 26-2   Oxygen Transport and Utilization Components

D_{O_2} and V_{O_2} comprise a sensitive balance of supply and demand. Normally, 25 percent of the oxygen carried on hemoglobin is consumed by the tissues, and venous blood returning to the right heart is normally 75 percent saturated. When oxygen supply is insufficient to meet demands, the first compensatory mechanism is an increase in CO. If the increase in CO is insufficient, the amount of oxygen extracted from hemoglobin by the tissues increases, which decreases Smv_{O_2}.

When compensatory mechanisms have failed to correct the imbalance between tissue supply and demand, anaerobic metabolism occurs, resulting in the formation of lactic acid. Elevated lactic acid levels are associated with an Smv_{O_2} of less than 50 percent. Most cases of lactic acidosis are due to inadequate oxygen delivery, as in cardiogenic shock, but lactic acidosis occasionally can develop from an excessively high oxygen demand (abnormally elevated V_{O_2}), for example, status epilepticus. Sometimes, lactic acidosis can occur because of an impairment of tissue oxygen utilization, as in septic shock and postresuscitation from cardiac arrest. [4] Elevated lactic acid and normal Smv_{O_2} in the presence of adequate delivery indicate an impairment of tissue oxygen utilization. Lactic acid levels are markers of the severity of the tissue oxygen supply-to-demand imbalance and can be used in the triage, diagnosis, therapy, and prognosis of critically ill patients.

In addition to lactic acid, Smv_{O_2} can be used as a measure of tissue oxygen supply and demand imbalance. Smv_{O_2} is usually obtained from the pulmonary artery catheter, but similar information can be obtained by sampling the central venous blood through an internal jugular or subclavian catheter (Scv_{O_2}), which has been shown to correlate with Smv_{O_2} and can be more easily obtained in the ED.

Shock is usually, but not always, associated with arterial hypotension: systolic blood pressure less than 80 or 90 mmHg. Since the product of flow and resistance determines pressure, blood pressure may not fall if, along with a marked reduction in flow, there is a corresponding increase in peripheral vascular resistance. MAP, CO, and SVR are related by the equation: MAP = CO × SVR. A marked reduction in CO may not be reflected by a decrease in MAP if SVR increases as a compensatory response. In this situation, the result will be global tissue hypoperfusion. The insensitivity of blood pressure to detect global tissue hypoperfusion has been repeatedly confirmed.[5] Thus, shock may occur with a normal blood pressure, and hypotension may occur without shock.

The onset of shock induces autonomic responses, many which serve to maintain perfusion pressure to vital organs. Stimulation of the carotid baroreceptor stretch reflex activates the sympathetic nervous system leading to (1) arteriolar vasoconstriction, which overcomes local autoregulation and redistributes blood volume from the skin, skeletal muscle, kidneys, and splanchnic viscera; (2) an increase in heart rate and contractility that increases cardiac output; (3) constriction of venous capacitance vessels, which augments venous return; (4) release of the vasoactive hormones epinephrine, norepinephrine, dopamine, and cortisol to maintain arteriolar and venoconstriction; and (5) release of antidiuretic hormone and activation of the renin-angiotensin axis to enhance water and sodium conservation to maintain intravascular volume. These compensatory mechanisms attempt to maintain D_{O_2} to the most critical organs: the coronary and cerebral circulation. In this process, blood flow to other organs such as the kidney and gastrointestinal tract may be compromised.

The cellular response to decreased D_{O_2} is adenosine triphosphate depletion leading to ion-pump dysfunction, an influx of sodium, an efflux of potassium, and a reduction in membrane resting potential. Cellular edema occurs secondary to increased intracellular sodium while cellular membrane receptors become poorly responsive to the stress hormones insulin, glucagon, cortisol, and catecholamines. As shock progresses, lysosomal enzymes are released into the cells with subsequent hydrolysis of membranes, deoxyribonucleic acid, ribonucleic acid, and phosphate esters. As the cascade of shock continues, the loss of cellular integrity and the breakdown in cellular homeostasis result in cellular death. These pathologic events give rise to the clinical features of hyperkalemia, hyponatremia, metabolic acidosis, hyperglycemia, and lactic acidosis.

In the early phases of shock, these physiologic changes produce SIRS, defined as the presence of two or more of the following features: (1) temperature greater than 38°C or less than 36°C; (2) heart rate faster than 90 beats per minute; (3) respiratory rate faster than 20 breaths per minute; and (4) white blood cell count greater than 12.0×10^9/L, less than 4.0×10^9/L, or with greater than 10 percent immature forms or bands.[6] If shock progresses, SIRS may be accompanied by MODS manifested by myocardial depression, adult respiratory distress syndrome, disseminated intravascular coagulation, hepatic failure, or renal failure. Inflammatory mediators or cytokines, which arise from endothelial cell disruption, have a significant pathogenic role in the progression from SIRS to MODS. How fulminant the progression is from SIRS to MODS is determined by the balance of these anti-inflammatory and proinflammatory mediators (Fig. 26-1).[7]

FIG. 26-1. The pathophysiology of shock, SIRS, and MODS.

Global tissue hypoperfusion alone can independently activate SIRS or serve as a comorbid variable in the pathogenesis of other forms of shock. The progression from SIRS to MODS is frequently accompanied by cardiovascular insufficiency.[8] The failure to diagnose and treat global tissue hypoperfusion in a timely manner leads to an accumulation of an oxygen debt; the magnitude of which correlates with increased mortality. [9]

CLINICAL FEATURES

History

Often the presence of shock will be instantly apparent along with the underlying cause, such as acute myocardial infarction, anaphylaxis, or hemorrhage. Some patients may be in shock with few symptoms other than generalized weakness, lethargy, or altered mental status. Symptoms that suggest volume depletion include bleeding, vomiting, diarrhea, excessive urination, insensible losses due to fever, or orthostatic light-headedness. A history of cardiovascular disease is important, particularly episodes of chest pain or symptoms of congestive heart failure. Prior neurologic diseases can render patients more susceptible to complications from hypovolemia. Drug use, both prescribed and nonprescribed, is important. Some drugs will cause volume depletion (e.g., diuretics) whereas others depress myocardial contractility (e.g., b blockers). The possibility of an anaphylactic reaction to a new medication or cardiovascular depression due to drug toxicity should be considered.[10]

Physical Examination

The clinical presentation of shock can be dramatic, as in profound hypotension caused by hemorrhage from a gunshot wound. Or shock can be subtle, as in heart failure or, even paradoxically, hypertensive crisis. [11,12] No single vital sign or value is diagnostic of shock; all vital signs are insensitive in detecting and assessing the severity of shock. Measurement of blood pressure can be particularly difficult due to peripheral vascular disease, tachycardia with a small pulse pressure, and irregular rhythms such as atrial fibrillation. Although not specific, physical findings taken as a composite are useful in the assessment of patients in shock (Table 26-3).

TABLE 26-3 Physical Examination

DIAGNOSIS

Ancillary Studies

The clinical presentation and the presumptive etiology of shock will dictate the use of ancillary studies. A battery of standard hematologic, coagulation, and biochemical tests usually provides an assessment of a patient's general physiologic condition and occasionally detects an abnormality that requires specific treatment (Table 26-4). A wide range of laboratory abnormalities may be encountered in shock, but most abnormal values merely point to the particular organ system that is either contributing to or being affected by the shock state. No single laboratory value is sensitive or specific for shock.

TABLE 26-4 Ancillary Studies

Hemodynamic monitoring is important in the assessment of patients in shock and following response to treatment. Monitoring capabilities will vary from institution to institution, but basic capabilities should include electrocardiographic monitoring, continuous noninvasive but preferably intraarterial blood pressure monitoring, pulse oximetry, end-tidal CO_2 monitoring, and CVP monitoring.

A variety of tubes and catheters are used to monitor patients or prevent complications: nasogastric tube, continuous rectal or esophageal temperature, and bladder catheterization. A pulmonary artery catheter, although impractical in the ED, is useful in monitoring mixed venous oxygen saturation, cardiac output, and left ventricular filling pressure. The benefit of monitoring patients with a pulmonary artery catheter is subject to debate.[13] Because hemodynamic measurements are physiologic values, they should be used to answer specific physiologic questions rather than to serve as end points themselves.

TREATMENT

Initial Treatment

The tenets of shock resuscitation are *A*irway establishment, control the work of *B*reathing, optimization of the *C*irculation, preventing inappropriate oxygen *C*onsumption, assuring adequate oxygen *D*elivery and tissue oxygen *E*xtraction.

Airway Control

Airway control is best obtained through endotracheal intubation for airway *p*rotection, *p*ositive *p*ressure ventilation (oxygenation), *p*atency, and *p*ulmonary toilet. Sedatives, which are frequently used to facilitate intubation, can exacerbate hypotension through arterial vasodilatation, venodilation, and myocardial suppression. Furthermore, positive pressure ventilation reduces preload and cardiac output. The combination of these interventions can lead to hemodynamic collapse. Volume resuscitation or application of vasoactive agents may be required prior to intubation.

Control of the Work of Breathing

Control of breathing is required when tachypnea accompanies shock. Respiratory muscles are significant consumers of precious D_{O_2} during shock and contribute to lactic acid production. Mechanical ventilation and sedation and decrease the work of breathing in shock and have been shown to improve survival. In the absence of a full shock picture, arterial blood-gas analysis can assist in the decision to perform intubation and mechanical ventilation. Sa_{O_2} should be restored to greater than 93 percent and ventilation controlled to maintain a Pa_{CO_2} of 35 to 40 mmHg. Attempts to normalize pH above 7.3 by hyperventilation are not beneficial. Mechanical ventilation not only provides oxygenation and corrects hypercapnia, but assists, controls, and synchronizes ventilation, which ultimately decreases the work of breathing.

Circulatory Stabilization

Circulatory or hemodynamic stabilization begins with adequate intravenous access. For fluid resuscitation, large-bore peripheral lines are equally as effective as central venous access, thus peripheral venous access should be the procedure of choice if peripheral veins are available. Trendelenburg positioning does not significantly improve cardiopulmonary performance compared with the supine position. Trendelenburg positioning may also worsen pulmonary gas exchange and enhance aspiration of vomitus. If a volume challenge is felt to be urgent, rather than using the Trendelenburg position, a compromise would be to raise the patient's legs above the level of the heart with the patient supine. Central venous access will aid in assessing volume status (CVP) and monitoring Scv_{O_2}. It is a preferred route for the long-term administration of vasopressor therapy, and provides rapid access to the heart if pacemaker placement is required.

Fluid resuscitation begins with isotonic crystalloid: the amount and rate are determined by an estimate of the hemodynamic abnormalities. Most patients in shock have either an absolute or relative volume deficit. The one exception is cardiogenic shock with pulmonary edema. Fluid is given rapidly, in set quantities (e.g., 500 to 1000 mL), with reassessment of the patient after each amount. Patients with modest degrees of hypovolemia usually require about 20 mL/kg of isotonic crystalloid; much more may be required with profound volume deficits.

The colloid-versus-crystalloid resuscitation controversy remains despite evidence that there is a slight increase in mortality when colloids are used for volume replacement in critically ill patients.[14] Some studies have found a lower incidence of pulmonary edema and possibly greater benefit in elderly patients with colloid

resuscitation, although survival is not statistically improved.

Without invasive hemodynamic monitoring, noncardiogenic pulmonary edema may be difficult to differentiate from cardiogenic pulmonary edema in the ED. Even though the former may respond to fluids, fluids should be minimized until appropriate monitoring can be placed.

Vasopressor agents are usually used when there has been an inadequate response to volume resuscitation or when a patient has contraindications to volume infusion. Vasopressors are most effective when the vascular space is "full" and least effective when the vascular space is depleted. However, vasopressors may be necessary early in the treatment of shock, before volume resuscitation is complete, in order to prevent potentially lethal consequences of prolonged systemic arterial hypotension. This is especially important in elderly patients with significant coronary and cerebrovascular disease. Rapidly restoring the MAP to 60 mmHg or systolic pressure to 90 mmHg may avoid the coronary and cerebral complications of decreased blood flow. Vasopressor agents are based on the catecholamine molecule and have variable effects on the a- and b-adrenergic receptors (Table 26-5).

TABLE 26-5   Commonly Used Vasoactive Agents

The use of vasopressors is a double-edged sword. While improving perfusion pressure in the large vessels, they may decrease capillary blood flow in certain tissue beds. Vasopressors also may alter the relationship between volume and pressure measurements through their effect on the pulmonary and peripheral vascular beds. In other words, vasopressors will falsely elevate CVP and pulmonary artery occlusion pressure. They should be used judiciously, generally only after volume resuscitation. When multiple vasopressors are used, they should be simplified as soon as the most therapeutic vasopressor is identified. Volume resuscitation and intravascular volume assessment should be a dynamic process. This will increase the opportunity for the earliest possible discontinuation of vasopressor.

Control of Oxygen Consumption

The control of V_{O_2} is important in restoring the balance of oxygen supply and demand to tissues. A hyperadrenergic state results from the compensatory response to shock, physiologic stress, pain, and anxiety. Shivering frequently results when a patient is unclothed for examination and then left inadequately covered in a cold resuscitation room. The combination of these variables increases systemic oxygen consumption. Pain further suppresses myocardial function, thus impairing D_{O_2} and V_{O_2}.[15] Providing analgesia, muscle relaxation, warm covering, anxiolytics, and even paralytic agents, when appropriate, decreases this inappropriate V_{O_2}. It is also important to provide appropriate anesthesia/analgesia for invasive procedures, since this is many times inappropriately forgotten in the haste of expedient intervention.

Oxygen Delivery

Once blood pressure is stabilized through optimization of preload and afterload, D_{O_2} can be assessed and further manipulated. Arterial saturation should be returned to physiologic levels (93 to 95 percent) and hemoglobin maintained above 10 g/dL. [16] If cardiac output can be assessed, it should be increased using volume infusion and inotropic agents in incremental amounts until the Smv_{O_2} and lactic acid are normalized.

Oxygen Extraction

Tissue oxygen extraction assesses adequacy of the resuscitation in meeting the oxygen needs of the tissues. Sequential examination of lactic acid and Scv_{O_2} or Smv_{O_2} is a method to assess adequacy of tissue oxygen extraction. Continuous measurement of Scv_{O_2} through fiberoptic technology can be used in the ED. [17] Other technologies have potential to assess D_{O_2} during the resuscitation of shock in the ED (Table 26-6).

TABLE 26-6   Adjuncts in Assessing Tissue Perfusion

Resuscitation End Points

Traditional end points have been normalization of blood pressure, heart rate, and urine output. Since these underestimate the degree of remaining hypoperfusion and oxygen debt, more physiologic end points have been investigated [16] (Table 26-7 and Table 26-8). No therapeutic end point is universally effective, and only a few have been tested in prospective trials, with mixed results. [18,19] The goal of resuscitation is to maximize survival and minimize morbidity using objective hemodynamic and physiologic values to guide therapy.

Traditional: normalization of blood pressure, pulse, and urine output		
Restoration of circulating volume		
Restoration of all fluid compartments		
Vascular space is "full"		
Hemodynamic parameters are "normalized"		
Tissue oxygen delivery is maximized		
Restoration of aerobic metabolism, elimination of tissue acidosis, and repayment of oxygen debt		

TABLE 26-7   End Points of Resuscitation

	Modality	Goals
Preload	CVP PAOP	10–12 mmHg 12–18 mmHg
Afterload	MAP SVR = (MAP – CVP/CO)(80)	90–100 mmHg 800–1400 dyne·s/cm⁵
Contractility	CO CI SV = CO/heart rate	5.0 L/min 2.5–4.5 L/min/m² 50–60 mL/min
Heart rate	60–100 bpm	Avoid >100 bpm; this will decrease SV and increase myocardial oxygen consumption
Coronary perfusion pressure	CPP = DBP – CVP (or PAOP)	>60 mmHg
Tissue oxygenation	Scvo₂ or Smvo₂ Lactic acid	>70% <2 mM/L

Note: See Table 26-1 for abbreviation definitions.

TABLE 26-8   Hemodynamic Resuscitation End Points

Troubleshooting a Persistently Hypotensive Patient

Treatment of a persistently hypotensive patient after maximal therapy can be a harrowing experience in the ED. The patient who has obvious trauma with ongoing hemorrhage, the reason is usually apparent, and the outcome is dismal if uncorrected. In medical cases of shock or in cases without ongoing hemorrhage, potential pitfalls should be rapidly reviewed. Is the patient appropriately monitored? Is there malfunctioning arterial blood pressure monitoring, such as dampening of the arterial line or disconnection from the transducer? Is the patient adequately volume resuscitated? The early use of vasopressor will falsely elevate CVP and disguise hypovolemia. Is the intravenous tubing into which the vasopressors are running connected appropriately? Are the vasopressor infusion pumps working? Are the vasopressors mixed adequately? Does the patient have a pneumothorax after that CVP placement? Has the patient been adequately assessed for an occult penetrating injury (a bullet hole or stab wound)? Is there hidden bleeding from a ruptured spleen or ectopic pregnancy? Does the patient have adrenal insufficiency? The incidence of adrenal dysfunction can be as high as 30 percent in this subset of patients. [20] Is the patient allergic to the medication just given (e.g., penicillin) or taken before arrival? Is the renal failure or cancer patient in cardiac tamponade?

Bicarbonate Use in Shock

The primary treatment of acidosis in shock is to reverse the underlying cause. Because this goal is not rapidly attainable, intravenous bicarbonate is often administered. The rationale for giving bicarbonate is that it will diminish myocardial depression and counteract the insensitivity to endogenous catecholamines attributed to acidosis, but experimental data indicate that exogenous bicarbonate can actually worsen intracellular acidosis, and prospective studies have not shown benefit. [21] Bicarbonate also shifts the oxygen-hemoglobin dissociation curve to the left and impairs tissue unloading of hemoglobin-bound oxygen. However, many clinicians remain uncomfortable withholding bicarbonate, which has created disparate opinions in the medical literature. [22] A middle ground to correct the metabolic acidosis partially over time is as follows: calculate the bicarbonate deficit, which is equal to (normal HCO_3^- minus the patient's HCO_3^-) × 0.4 × body weight (kilograms), with one-half of this amount infused slowly and the remainder over 6 to 8 h to a pH of no greater than 7.25.

DISPOSITION

Transition to the Intensive Care Unit

Documentation and communication are important. Resuscitation in the ED is commonly performed in "ordered chaos" and, even though resuscitation is systematic and thoughtful, miscommunication with the intensivist or subspecialist accepting the patient can undo the benefits of initial treatment. A system-oriented problem list with an assessment and plan, including all procedures and complications, should be verbally communicated, written, or dictated prior to transfer. For prolonged ED stays, notations regarding patient status, diagnostic and therapeutic intervention, and sentinel events should be provided frequently, if possible.

Prognosis

Outcome prediction at ED disposition has not been fully studied, however, some clinical variables are associated with poor outcome: severity of shock, temporal duration, underlying cause, preexisting vital organ dysfunction, and reversibility. Direct noninvasive measurement of V_{O_2} has been shown to be predictive of outcome in patients who developed cardiogenic shock secondary to myocardial infarction and after cardiac arrest. [4,23] Serial elevated lactic acid levels have been shown to be predictive in trauma, septic shock, and after cardiac arrest. [4,24] Base-deficit correction has also been correlated with the development of multisystem organ failure in trauma.[25] Outcome predictions using physiologic scoring systems in the ED are currently being studied. 27 FLUID AND BLOOD RESUSCITATION

Steven C. Dronen
Eileen M. K. Bobek

Fluid resuscitation is the mainstay of therapy of hemorrhagic shock in the emergency department (ED) setting, with the goal of restoring or maintaining tissue oxygenation despite ongoing blood loss. Considerable research has been devoted to identifying the optimal resuscitation fluid, as well as its rate of delivery. Despite significant advances, questions regarding the ideal resuscitation agent and the timing and endpoints of resuscitation remain unanswered. Recently, the standard practice of rapidly infusing crystalloid during resuscitation of hypotensive trauma victims has been called into question. Ultimately, the ability to answer these questions and optimize the care of the shock victim will require a better understanding of the physiologic and biochemical events that characterize acute hemorrhage.

PATHOPHYSIOLOGY

Acute hemorrhage is defined as a rapid blood loss that may accompany a wide variety of medical and surgical conditions. The most common causes of significant hemorrhage include trauma, disorders of the gastrointestinal and reproductive tracts, and vascular disease (Table 27-1). Hemorrhagic shock occurs when blood loss is of sufficient magnitude to overcome normal physiologic compensatory responses and compromise tissue perfusion and oxygenation.

TABLE 27-1   Etiologic Classification of Acute Hemorrhage

Acute hemorrhage triggers a series of physiologic responses involving the cardiovascular, respiratory, renal, hematologic, and neuroendocrine systems. The net effect of these responses is an increase in cardiac rate and contractility, a redistribution of blood flow to preserve vital organ function, conservation of water and sodium, and control of blood loss at the site of injury.

Cardiovascular

One of the very first responses observed in animal studies of acute hemorrhage is a fall in blood pressure that cannot be accounted for simply by the initial reduction in intravascular volume.[1] It is likely that the fall in blood pressure is caused by a sudden reduction in systemic vascular resistance, although the mechanism has not been explained. The fall in blood pressure is sensed by both high-pressure baroreceptors in the carotid artery sinus and the aortic arch as well as low-pressure baroreceptors in the left atrium and pulmonary veins. Stimulation of these baroreceptors, in turn, causes disinhibition of the medullary vasomotor center, a subsequent decrease in vagal tone, and an increase in the secretion of norepinephrine (NE). Decreased vagal tone increases heart rate and cardiac output. NE increases heart rate and myocardial contractility, stimulates renin secretion, and causes intense vasoconstriction, especially of splanchnic and musculoskeletal blood vessels. Such vasoconstriction provides a functional reservoir that can be used to compensate for acute blood loss, since 20 to 30 percent of the circulating blood volume resides in the splanchnic bed.

Cardiac output typically falls during hemorrhage, due to a decrease in atrial filling or preload, despite increases in myocardial rate and contractility. It is commonly taught that afterload rises during acute hemorrhage in order to maintain blood pressure. In fact, there is little evidence to support this claim. It is more likely that, early in the course of hemorrhage, total systemic vascular resistance falls or remains at near-normal levels in order to facilitate flow to vital organs. There are, however, increases in regional resistance that cause redistribution of blood flow away from skin, muscle, and gut to favor the brain, heart, and kidneys.

Endocrine and Humoral

Conservation of sodium and water during hemorrhage is mediated by an increase in the levels of aldosterone and antidiuretic hormone. Stretch receptors in the afferent arterial walls of the juxtaglomerular apparatus (JGA) respond to a drop in blood pressure by stimulating an increase in renin secretion. Renin converts angiotensinogen to angiotensin I, which is then converted in the lung and liver to angiotensin II. The effects of angiotensin II include intense vasoconstriction of arteriolar smooth muscle and stimulation of aldosterone secretion by the adrenal cortex. Aldosterone is also secreted in response to elevation of potassium and adrenocorticotropic hormone (ACTH) levels, both of which occur during acute hemorrhage. Aldosterone increases the reabsorption of sodium and the excretion of potassium in the distal convoluted tubule. Water passively follows sodium and is therefore reabsorbed and conserved. Aldosterone also stimulates the secretion of hydrogen ions, thus decreasing acidosis.

Osmo- and baroreceptors also regulate the release of arginine vasopressin or antidiuretic hormone (ADH), which is synthesized in the hypothalamus and stored in the posterior pituitary. Release of ADH occurs in response to both a fall in blood pressure and a decrease in sodium concentration. ADH increases the permeability of the renal distal tubule collecting ducts, and loop of Henle to NaCl and water, with the net result being fluid and salt retention. In higher concentrations, ADH also acts as a vasoconstrictor.

Acute hemorrhage causes local activation of the coagulation system. In response to injury, affected blood vessels contract, and activated platelets rapidly adhere to

the edges of the damaged vessels. Platelets release thromboxane A$_2$, which is a potent local vasoconstrictor and further platelet activator. Platelets form an unstable jelly-like plug during the first 20 min after injury. Control of hemorrhage during this period depends upon a regional reduction in flow caused by systemic hypotension and local vasoconstriction. Vessel injury exposes collagen and releases tissue thromboplastin, causing fibrin deposition in the platelet plug and gradual formation of a stable clot. The entire process for complete fibrinous transformation takes approximately 24 h.

Compensatory Limitations

The compensatory mechanisms described above are quite effective at maintaining critical organ perfusion even in the face of severe hemorrhage. Animal studies demonstrate complete recovery without intervention in animals bled as much as 40 percent of their estimated blood volumes. However, if the hemorrhage is not controlled, a vicious cycle of increased myocardial work and decreased perfusion eventually develops. Progressive increases in heart rate shorten diastole, with a resultant decrease in myocardial perfusion and oxygenation as well as cardiac filling and output. The low perfusion state increases acidemia, which in turn decreases myocardial contractility.

Eventually, cardiac output becomes inadequate to maintain cellular oxygen delivery, and characteristic changes occur. The first cellular response to hypoperfusion is an attenuation of the cell membrane and an increase in sodium influx. Adenosine triphosphate (ATP) is utilized to maintain function of the sodium-potassium pump; during periods of low flow, however, it cannot be regenerated in sufficient quantities through the normal oxygen-dependent pathways. As the supply of oxygen and high-energy substrates diminishes, the cells revert to anaerobic metabolism to generate ATP, resulting in the accumulation of lactic acid. As ATP availability decreases, sodium continues to enter the cells, causing progressive swelling first of the cytoplasm, then the endoplasmic reticulum, and finally the mitochondria. Eventually the cells undergo clumping of mitochondria, loss of membrane integrity, and death.

There appears to be a point of no return for individual cells as well as for the overall organism in shock. Although this point is well defined for the cell, the clinician caring for patients in shock is less able to identify this landmark. It has been suggested that a sudden and substantial decrease in oxygen consumption may be a reliable marker of irreversible shock.

CLINICAL FEATURES

Factors that affect the clinical presentation of acute hemorrhage include the etiology, duration, and severity of hemorrhage and the patient's age and underlying medical condition. Acute hemorrhage most often accompanies blunt or penetrating trauma and is generally the presumed cause of shock in the trauma patient. Hemorrhage must be differentiated from other causes of shock associated with trauma, including cardiac tamponade (distinguished by elevated central venous pressure), tension pneumothorax (distinguished by unilaterally diminished breath sounds), and spinal cord injury (distinguished by the presence of neurologic deficits, warm skin, and a lower than expected pulse rate).

Hemorrhage not associated with trauma may present with a myriad of complaints depending upon the primary organ system involved. Nausea and vomiting; dizziness; syncope; pain in the chest, abdomen, or back; and rectal or vaginal bleeding are some common chief complaints associated with bleeding from those organ systems.

The classic clinical features of acute hemorrhage include tachycardia; tachypnea; a narrow pulse pressure; decreased urine output; cool, clammy skin; poor capillary refill; low central venous pressure; and, in the later stages, hypotension and altered mentation. Elderly patients and those with preexisting cardiac disease may show more severe signs and symptoms with less blood loss. Medications such as b blockers can mask some of the early signs and symptoms of hemorrhage. On the other hand, young, athletic patients can lose considerable amounts of blood before they appear ill. Up to a third of patients who sustain intraabdominal hemorrhage severe enough to develop hypotension [systolic blood pressure (BP) <90 mmHg] will not develop a tachycardia (heart rate >100), presumably due to vagal simulation from blood in the peritoneal cavity.

In general, however, there is a somewhat predictable and orderly progression of pathophysiologic events through which the patient passes as organ and cellular perfusion deteriorate and shock develops. Blood loss of less than 20 percent of circulating blood volume causes cool, clammy skin, delayed capillary refill, and decreased pulse pressure. Tachycardia may be present, and generally the blood pressure is normal, although the pulse pressure may be narrow. As hemorrhage progresses, with blood loss of 20 to 40 percent, patients are tachycardic and tachypneic, have postural changes in blood pressure, and may be confused or agitated. If the patient is not resuscitated and the bleeding continues, hypotension and oliguria develop, respirations quicken and become deeper, tachycardia worsens, and the skin becomes mottled. With hemorrhage exceeding 40 percent of the circulating blood volume, patients commonly demonstrate tachycardia, profound hypotension, either tachypnea or irregular respirations, markedly decreased urine output, decreased or absent peripheral pulses, pallor, and lethargy and obtundation. Death from severe hemorrhage is generally marked by respiratory arrest prior to circulatory arrest due to fatigue of the respiratory musculature and, sometimes, bradyasystolic rhythms.

MANAGEMENT

There are two goals in the treatment of hemorrhagic shock: control of hemorrhage and maintenance of oxygen delivery. The definitive therapy of hemorrhage is control of the source of bleeding; this often requires operative intervention. Thus, for most patients with hemodynamic instability secondary to hemorrhage, prompt surgical consultation and intervention are mandatory.

Oxygenation and Ventilation

Maintenance of tissue oxygen delivery requires, first and foremost, an assessment of the adequacy of oxygenation and ventilation. Items requiring immediate evaluation include airway patency, skin color, depth and rate of respiration, as well as the presence of any mechanical obstruction to ventilation including pneumothorax, hemothorax, or flail chest. Supplemental oxygen should be administered to all patients in shock and to most patients who are bleeding acutely. Many patients will require endotracheal intubation and ventilatory support. Respiratory arrest caused by fatigue of the intercostal muscles and diaphragm commonly precedes cardiac arrest as a terminal event in hemorrhagic shock; therefore it is essential that liberal guidelines for ventilatory support be used.

Intravenous Access

Tissue oxygenation also requires restoration of circulating blood volume, and it is routine to place at least two large-bore intravenous lines for infusion of crystalloid and potentially blood. A practical limitation during fluid resuscitation is sometimes the size of the intravenous access, which limits the rate of infusion (Table 27-2). The largest-bore catheter possible should be used in patients who may require aggressive fluid administration. All patients should be placed on a continuous cardiac monitor and pulse oximeter. As the intravenous lines are placed, initial blood samples should be drawn for type and cross matching, coagulation studies [prothrombin time (PT), partial thromboplastin time (PTT), platelet count] and a baseline complete blood count (CBC). All women of childbearing age need a pregnancy test. An immediate serum glucose assessment is critical in the patient with a depressed level of consciousness. A baseline metabolic assessment requires more extensive laboratory study, including serum electrolytes, blood urea nitrogen (BUN), creatinine, and liver function tests. An arterial blood gas (ABG) provides crucial information about the patient's acid-base, oxygenation, and ventilatory status and, if available on the blood gas analyzer, data regarding the patient's hematocrit and bicarbonate level. An initial electrocardiogram (ECG) is also indicated in adult patients. All patients should have a Foley catheter placed, as urine output is believed to reflect underlying renal perfusion.

IV Catheter Size	Gravity 80 cm height	Pressure 300 mmHg
18 g IV	50–60 mL/min	120–180 mL/min
16 g IV	90–125 mL/min	200–250 mL/min
14 g IV	125–160 mL/min	250–300 mL/min
8.5 Fr introducer	200 mL/min	400–500 mL/min

TABLE 27-2   Approximate Maximal Infusion Rates of Normal Saline or Ringer's Lactate

Standard Monitoring

Parameters that should be routinely monitored during resuscitation of acute hemorrhage include vital signs, mentation, skin temperature, capillary refill, oxygen saturation of arterial blood, and urine output. There is a tendency to follow BP quite closely and to gauge the adequacy of therapy by the extent to which BP returns to normal levels. It is important to recognize, however, that BP is not precisely correlated with cardiac output and provides a poor assessment of the state of cellular metabolism.[2] Also, as noted below, restoration of normotension in the presence of a vascular injury may merely increase the severity of hemorrhage. Central venous pressure (CVP) monitoring may be of some value in confirming the diagnosis of hypovolemia and judging the response to therapy. A low CVP (<5 cmH$_2$O) supports the diagnosis of hypovolemia; probably more useful, a failure of the CVP to increase after fluid infusion suggests persistent hypovolemia and indicates the need for further fluid. Swan-Ganz catheterization is usually not necessary in the acute setting except in elderly patients or those with respiratory or cardiac disease.

Prehospital Treatment

There have been many debates in recent years over the extent to which patients should be resuscitated prior to operative intervention, both in the prehospital setting and the ED. The concept of field stabilization of trauma victims has been discredited for those with hemorrhagic shock. The prehospital interventions that improve survival include attention to the airway, ventilation, immobilization, and rapid transport; not fluid resuscitation. [3] Standard prehospital interventions directed at restoring blood pressure, such as application of a pneumatic antishock garment (PASG) and infusion of intravenous fluids, have not been shown to improve survival. [4,5]

The PASG became standard prehospital treatment in the late 1970s based on anecdotal reports of efficacy and its extensive use during the Vietnam War. While there is no doubt that application of the PASG often raises blood pressure, most likely through a rise in systemic vascular resistance, there is no evidence that use of the PASG to achieve such a result actually improves outcome. Several controlled trials have failed to prove that any significant benefit is derived from its use in trauma victims.[4,6,7] In fact, in the presence of shock and chest trauma, PASG use may actually increase the severity of hemorrhage and also mortality. [8] Thus, enthusiasm for the PASG has begun to wane except for patients with unstable pelvic fractures, for whom it may stabilize the fractures and potentially tamponade retroperitoneal hemorrhage. The PASG may also prove useful for splinting of multiple lower extremity fractures and control of soft tissue bleeding from lower extremities.

There has also been debate over the efficacy of prehospital line placement and fluid resuscitation. Proponents of field resuscitation state that skilled paramedics are able to place intravenous lines with little or no delays in transport. [9] Opponents state that since blood loss cannot be controlled in the field, any delay in definitive treatment is excessive. Clinical studies have shown that the amount of fluid infused en route is usually minimal as compared with the total fluid requirement, and one randomized study of victims of penetrating trauma has failed to show any benefit associated with preoperative fluid therapy. [10] Prehospital fluid therapy probably does not affect outcome in the vast majority of cases, but it may be valuable given a specific combination of hemorrhage severity and distance from the hospital. Until conclusive data for a particular position can be obtained, it is reasonable to place intravenous lines once en route to the hospital whenever possible. This practice avoids potentially lethal delays in the field and grants patients the potential benefits of prehospital fluid therapy.

Fluid Resuscitation

It should be noted, however, that the benefits of early and aggressive fluid replacement in victims with ongoing hemorrhage, whether given in the prehospital setting or the ED, remain unproven. Many animal studies have shown that raising the blood pressure with either vasopressors or fluid also worsens mortality, sometimes dramatically.[11] Such findings were recently validated in a prospective clinical study of hypotensive patients with penetrating torso injuries in which improved outcome was demonstrated for those whose fluid resuscitation was delayed until the start of operative intervention. [10] These studies indicate that resuscitation to normotension is harmful because it exacerbates continued hemorrhage and that some degree of "underresuscitation" may be beneficial. [12] Conversely, to purposefully withhold resuscitation as the patient exsanguinates is also wrong.

Both animal and human studies continue in an attempt to determine the ideal rate and volume of fluid administration as well as the appropriate therapeutic end point of resuscitation. [13] The traditional end point of isotonic fluid resuscitation has been clinical assessment of the adequacy of tissue perfusion. In addition, the use of red cells was generally identified as a hemoglobin of 10 g/dL or a hematocrit of 30 percent as the "transfusion trigger." However, such a guideline is not reliable in an actively hemorrhaging patient, particularly in the setting of trauma. At the present time, the amount and type of volume expander used depends primarily on the clinical status of the patient and to a lesser extent on individual institutional preference. In most hospitals, isotonic crystalloid—either 0.9% NaCl [normal saline (NS)] or Ringer's lactate (RL)—is the agent of choice for the initial management of acute hemorrhage. Standard therapy of the hemodynamically unstable patient is rapid infusion of 20 to 40 mL/kg as fast as possible, typically over 10 to 20 min. Since, at best, only about 30% of infused isotonic crystalloid stays intravascular, blood volume restoration with NS or RL requires a volume approximately three times that of the lost blood (Table 27-3).[14] An isotonic infusion of 30 mL/kg can be expected to expand blood volume by about 10 mL/kg, roughly one-seventh of the estimated blood volume of 70 mL/kg. Thus, if an adult patient continues to show signs of impaired perfusion after a total of 30 mL/kg (roughly 2 L), it is likely that blood loss exceeds 15 percent of the total blood volume.

Fluid Space	VOLUME EXPANSION		
	Intracellular	Interstitial	Plasma
D5W	660 mL	255 mL	85 mL
NS or RL	−100 mL	825 mL	275 mL
7.5% NaCl	~2950 mL	2960 mL	990 mL
5% Albumin	0	500 mL	500 mL
Whole blood	0	0	1000 mL

TABLE 27-3   Representative Volume Properties of 1 L of Intravenous Fluid

Blood Transfusion

At this point, it is appropriate to begin red cell transfusions, particularly if blood loss has not been controlled. If the patient appears to be stable, it usually is possible to wait for fully cross-matched blood, but that decision must be individualized, based on the assessment of ongoing blood loss and the efficiency of the local blood bank. When in doubt, it is advisable to use type-specific blood. Several studies have shown this to be a very safe practice, and delays in providing needed oxygen-carrying capacity are potentially more harmful to the patient. Early blood therapy is particularly important in the elderly and in those with significant respiratory and cardiac disease, as their ability to tolerate a decrease in oxygen-carrying capacity is significantly reduced.

More aggressive therapy is mandated in the hemorrhaging patient exhibiting any degree of hemodynamic instability or signs of end-organ hypoperfusion. These patients almost always require blood transfusions, and it is appropriate to begin type-specific blood early unless there is a prompt and persistent improvement in perfusion with saline solution alone. Type-specific blood is indicated in patients who are profoundly hypotensive on initial presentation, those who remain in shock after crystalloid infusion, and those who demonstrate rapid ongoing hemorrhage. Continued administration of crystalloid without blood may result in profound dilution of the remaining red blood cell mass, platelets, and coagulation factors. It may also disrupt clot formation in the injured vessels. Volume restored at the expense of oxygen-carrying capacity and hemostasis is of questionable therapeutic value.

The moribund patient requires even more prompt restoration of circulating red blood cell mass. In this case, type O blood should be used immediately if it is available. Type O Rh-negative blood should be given to females of childbearing age. In most other situations Type O Rh-positive blood is preferred because of its greater availability. A sample for type and cross match should always be drawn and sent before administration of type O blood.

Autologous whole blood may be given if the hemorrhage is intrathoracic and the capabilities for autotransfusion exist (Fig. 27-1). Autotransfusion decreases the risk of transmission of diseases such as acquired immunodeficiency syndrome (AIDS) and hepatitis, and it also decreases the demand on the blood bank. There has been some discussion concerning autotransfusion in patients with intraabdominal injuries. It can be difficult to determine, especially in the ED, if there is fecal contamination of intraabdominal blood. Transfusion of contaminated blood has not been shown to be safe, and it may be prudent to autotransfuse blood from intraabdominal injuries only in the operating suite, after the source of blood has been discovered and the risk of transfusing contaminated blood is known.

Colloid Resuscitation

Although isotonic saline solution is most commonly used in the initial management of hemorrhagic shock, debate continues over the value of adding colloid to the resuscitation regimen. Albumin has fallen into disfavor, but purified protein fraction (PPF) and fresh frozen plasma (FFP) continue to be recommended and used. Central to the issue are the effects of fluid resuscitation on the pulmonary interstitium. [15] Proponents of protein replacement argue that saline resuscitation of hemorrhage results in a fall in intravascular oncotic pressure and a reversal of the normal gradient favoring intravascular fluid retention. Theoretically, this may lead to pulmonary edema and impaired tissue oxygenation. Colloid administration is advocated because it raises oncotic pressure in the pulmonary capillary bed. This argument ignores the fact that the pulmonary capillary endothelium permits considerable flow of fluids, including plasma proteins, between the capillaries and the interstitium. A fall in intravascular oncotic pressure is compensated for by a fall in pulmonary interstitial oncotic pressure, thereby minimizing changes in the pressure gradient. It appears likely that pulmonary capillary hydrostatic pressure [measured as pulmonary artery (occlusion) wedge pressure] is far more important than pulmonary capillary oncotic pressure in determining the amount of fluid flowing to the interstitium. Maintenance of the pulmonary artery occlusion pressure below 15 mmHg is probably the most important factor in preventing pulmonary edema. Systematic reviews of clinical studies have found no clear benefit to colloid resuscitation compared with crystalloid resuscitation. [16] Clinicians inclined to use albumin, PPF, or FFP in the resuscitation of hemorrhagic shock should question whether the undocumented benefits of this therapy are worth the substantial increase in cost or, in the case of FFP, the risk of disease transmission.

Alternatives to the use of naturally occurring colloid preparations include synthetic colloid solutions such as hydroxyethyl starch (HES) and dextran 70. The volume-expanding properties of HES are equivalent to those of 5% albumin. These agents differ significantly from albumin, however, in that they remain predominantly in the intravascular space because of their high molecular weight and branched structure. Their plasma-expanding effects are more prolonged than those of albumin, and interstitial edema is not a significant concern. Their inability to restore oxygen-carrying capacity, however, is a significant disadvantage shared by all crystalloid and colloid solutions with the exception of blood.

Oxygen-Carrying Resuscitation Fluids

Blood remains, from a physiologic perspective, the ideal resuscitation agent, but there are substantial practical limitations to its routine use. Although the potential for disease transmission has been significantly reduced by modern donor screening techniques, it has not been completely eliminated. [17] Other concerns include the limited availability of blood products; the cost of collection, storage and transfusion; a limited shelf-life; and the existence of religious prohibitions against the transfusion of blood products. These issues have led researchers to search for alternative agents that can safely and effectively deliver oxygen to the cells. [18] To date the use of stoma-free hemoglobin as well as pyridoxalated-hemoglobin-polyoxyethylene (PHP) conjugate represent examples of hemoglobin-based substitutes under investigation. Hemoglobin solutions became of interest during World War II owing to practical difficulties of blood storage and compatibility testing on the battlefield. Their use was ultimately rejected due to their short half-lives and the frequent occurrence of significant hypotension. Subsequent research was directed at the modification of these solutions to eliminate side effects such as renal failure and bleeding abnormalities. Currently, although some modified hemoglobin solutions may be effective at restoring blood pressure and cardiac index, their clinical efficacy remains limited by their short half-lives and potential toxic effects. [19] Hemoglobin has been identified as a neurotoxin and has been shown to promote vasoconstriction, platelet adhesion, and free radical damage.

Perfluorocarbons (PFCs) have also been investigated as possible blood substitute candidates because of their high oxygen solubility. Unfortunately, new PFC emulsions produce toxic effects on the lung in a dose-dependent fashion, thereby severely limiting their ability to improve oxygen-carrying capacity. Because of these problems, blood substitutes are not currently recommended as an alternative to blood transfusion in the treatment of hemorrhagic shock. The importance of developing a safe and effective blood substitute is not diminished, however, and this remains a fertile area for future research.

Hypertonic Resuscitation Fluids

Hypertonic saline (HS) has been recommended as a possible alternative fluid resuscitation therapy based upon impressive hemodynamic effects in numerous animal studies of acute hemorrhage. Given in small amounts and often in combination with 6% dextran 70, HS caused a prompt and sustained shift of fluid from the interstitial to the intravascular compartment. Based upon these studies, HS was once promoted as an ideal agent for the prehospital resuscitation of hemorrhage. Thus far, clinical studies have not demonstrated overall improvement in survival in victims of hypotensive trauma given HS. [20,21] However, there was a trend toward improved outcome in some subpopulations of hypotensive trauma victims given HS. There may be particular injury patterns (such as combined hypovolemia and head injury) in which a benefit exists. Given the absence of a demonstrated benefit in the general population of hemorrhage patients, the widespread use of HS cannot be recommended because of uncommon but potentially significant complications. These include confusion, seizures, and central pontine myelinolysis. The addition of dextran also presents disadvantages, as it may induce anaphylactic reactions and coagulopathies.

End Points to Resuscitation

Perhaps one of the greatest challenges in shock management facing both clinicians and researchers today is the identification of valid and reliable shock parameters to assess the severity of hemorrhage and the adequacy of resuscitation. [2,13] In the past, gross physiologic indices such as heart rate, blood pressure, capillary refill, urine output, and central venous pressure have been used to assess the severity of hemorrhage. Despite a long history of frequent clinical use, these parameters have repeatedly been shown to be unreliable. More reliable indicators include mixed venous oxygen saturation and serum lactate concentrations, both of which may reflect the presence of hypoperfusion, even in the face of normal vital signs. [13,22]

Several different parameters have been introduced as potential markers for the end point of resuscitation, including supernormal oxygen transport variables, mixed

venous oxygen saturation (Smvo$_2$), central venous oxygen saturation (Scvo$_2$), gastric intramucosal pH, end-tidal CO$_2$, serum lactate, and base deficit.[13] Oxygen transport variables of particular interest include cardiac index (CI), oxygen delivery (D$_{O2}$), and oxygen consumption(V$_{O2}$). It has been proposed that the measurement of such indices would supply an accurate reflection of oxygen debt and therefore tissue perfusion. Adjusting therapeutic interventions in an effort to achieve supernormal values would therefore presumably be indicative of an adequate level of resuscitation. Studies have demonstrated, however, that although attainment of supernormal oxygen transport variables may have some prognostic significance, it is not an appropriate resuscitation end point.[13] This may also be true for Smvo$_2$. Although it also provides a measure of tissue oxygen extraction, it does not provide information about regional hypoperfusion, and normal or elevated values do not necessarily imply the absence of shock, particularly in the face of sepsis.

The measurement of oxygen transport variables and mixed venous oxygen saturation requires the placement of a pulmonary artery catheter, a procedure that is both time-consuming and has inherent risks. Central venous oxygen saturation monitoring has therefore been proposed as an alternative, since Scv$_{O2}$ measurements have been shown to correlate with Smvo$_2$. Although it still requires invasive monitoring and its use is limited by similar factors as Smv$_{O2}$ measurements, placement is certainly less time-consuming. Until prospective studies demonstrate its validity as a potential guide for resuscitation though, its use cannot be unequivocally advocated.

Gastric intramucosal pH (pHi) has been investigated as a potential minimally invasive marker of regional perfusion. The splanchnic bed is particularly sensitive to hypoperfusion states because blood is shunted from its mucosa to preserve flow to the brain, heart, and kidneys. Theoretically, restoration of splanchnic perfusion should indicate adequacy of resuscitation. To date though, studies evaluating gastric intramucosal pH have been limited and do not demonstrate a reliable correlation with indices of global hypoperfusion, such as serum lactate and base deficit.

End-tidal CO$_2$ monitoring has also been recommended as a noninvasive monitoring tool during shock.[23] The reduction in cardiac output and pulmonary blood flow should be accompanied by reduced production of CO$_2$ and reflected in low end-tidal CO$_2$ measurements. Similarly, restoration of normal flow should be accompanied by increased end-tidal CO$_2$ measurements. Preliminary studies have shown that persistently low end-tidal CO$_2$ measurements are associated with poor outcome, but no prospective trials exist evaluating its contribution to clinical decision making.

Serum lactate concentrations have gained prominence as an indirect measure of tissue perfusion and oxygenation, because shock ultimately results in a shift from aerobic to anaerobic metabolism and increased production of lactate. Elevated serum lactate levels have been shown to correlate with both the severity of shock and the adequacy of resuscitative measures. In addition, changes in serial lactate values during resuscitation have provided prognostic information about patients in shock.[22] Although the use of lactate has been limited by its lack of real-time availability, the development of accurate bedside lactate analyzers may eliminate this disadvantage in the future.

Base deficit has also been utilized as a measure of global tissue acidosis due to inadequate tissue perfusion. Base deficit is defined as the amount of base, in millimoles, required to titrate 1 L of whole arterial blood to a pH of 7.40, with the sample fully saturated with O$_2$ at 37° and a P$_{CO2}$ of 40 mmHg. Although some studies have found a correlation between serum lactate and base excess, the relationship is not always predictable.[24]

One element that is certainly common to all potential markers for the end points of resuscitation is that isolated values in time have significantly less importance than the identification of a trend. It is clear that both the development and resuscitation of a shock state are dynamic processes and in many respects remain elusive ones to monitor.

COMPLICATIONS

The overwhelming bulk of clinical and scientific data indicate that the infusion of resuscitation fluids is an extraordinarily safe procedure but still with risk for complications. The overall percentage of interventions that lead to complications is quite low, but given the frequency with which fluid resuscitation occurs, complications arise regularly. This is particularly true when blood products are infused and especially when they are infused in massive quantities. Although there is no strict criteria, massive transfusion is generally defined as the transfusion of the equivalent of one blood volume (70 to 80 mL/kg in an adult) within 24 h. Clotting abnormalities are commonly noted after massive transfusion owing to dilutional thrombocytopenia and the effects of storage on coagulation factors and platelet number and function. Previous guidelines recommended the routine transfusion of FFP and platelets based upon the number of units of red cells transfused. It has been demonstrated, however, that the occurrence of bleeding diathesis in trauma correlates not just with the number of red cell transfusions, but also with the duration of the shock state and the type and severity of injury sustained. Therefore it is recommended that transfusion of FFP and platelets be based on clinical evidence of impaired hemostasis and frequent monitoring of coagulation parameters.[25] Platelets are indicated in the actively bleeding trauma patient with a platelet count of 50,000 or less. FFP is indicated if the PT is prolonged more than 1.5 times normal (usually 18). When an underlying coagulation disorder is suspected, as in patients taking warfarin or with evidence of severe liver disease, it may be appropriate to administer FFP without waiting for laboratory confirmation.

Other potential complications of massive transfusion include electrolyte abnormalities. Hypocalcemia and hypomagnesemia may occur due to citrate toxicity, particularly in neonates, patients transfused with whole blood and those with preexisting liver disease. Reductions in these electrolytes may precipitate cardiac dysrhythmias; therefore careful monitoring of their levels is essential. Empiric therapy with calcium and magnesium is not recommended. Treatment, when indicated, includes administration of calcium or magnesium solutions as the chloride salts.

Potassium levels also require close monitoring, because massive transfusion may precipitate both hyperkalemia, due to leakage of potassium from stored cells, and hypokalemia, due to hepatic conversion of transfused citrate and lactate to bicarbonate, with resultant metabolic alkalosis. Theoretically, massive transfusion of banked blood may also precipitate the development of a metabolic acidosis, as banked blood is relatively acidic owing to its citrate and lactate content. It cannot be overstated however, that the presence of ongoing acidosis in the patient in shock should not be attributed to massive transfusion but to ongoing hemorrhage. Although persistent acidosis is ominous, bicarbonate administration is not routinely recommended unless pH remains persistently at or below 7.1 despite aggressive resuscitative measures.

Many trauma patients arrive in the ED with a lower than normal temperature, possibly due to prolonged exposure as well as the shock state. In the face of massive transfusion, hypothermia may contribute to the development of platelet dysfunction and cardiac dysrhythmias. Whenever possible, therefore, blood warmers should be utilized throughout the course of resuscitation.

At the extremes of age, trauma patients have limited cardiovascular reserve to tolerate the large shifts of fluid that occur during massive transfusion. One potential consequence of such physiologic restrictions is the development of signs and symptoms of congestive heart failure and potentially adult respiratory distress syndrome (ARDS). At such times, aggressive fluid administration may paradoxically defeat efforts to improve a patient's oxygenation status.

Perhaps the most feared consequences of transfusion are hemolytic transfusion mediated reactions and transfusion-transmitted disease. The most common cause of hemolytic transfusion reactions is ABO incompatibility, accounting for a mortality of 1/100,000 units transfused. The viruses of most concern are hepatitis B virus (HBV), hepatitis C virus (HCV), human immunodeficiency virus (HIV), and human T-cell lymphotrophic virus (HTLV).[17] Recently, the risk of donating blood during an infectious window period were estimated as 1 in 63,000 for HBV; 1 in 103,000 for HCV; 1 in 493,000 for HIV; and 1 in 641,000 for HTLV.[17] Although modern screening techniques have substantially reduced the risk of blood-borne infection, the potential risk must always be considered when transfusion is contemplated.

28 SEPTIC SHOCK

Jonathan Jui

Sepsis is a heterogenous clinical syndrome that can be caused by any class of microorganism. Although both gram-negative and gram-positive bacteria account for the majority of sepsis cases, fungi, mycobacteria, rickettsia, viruses, or protozoans can cause similar presentations. Microbial blood invasion is not essential to the development of sepsis.

EPIDEMIOLOGY

It is commonly believed that the incidence of sepsis has continued to rise over the last 3 decades, but most figures, including the often quoted 300,000 to 500,000 patients developing sepsis every year in the U.S., are largely estimations. A study from 8 academic medical centers reported an incidence of 2 cases of sepsis per 100 hospital admissions. Of these cases, 55 percent occurred in the ICU, 12 percent in the emergency department, and 33 percent in a non-ICU patient care unit. Up to half of sepsis patients develop shock with an overall mortality rate of about 45 percent, but with a wide range of 20 to 80 percent depending on the host. In 1991, sepsis was the thirteenth leading cause of death in the United States with approximately two-thirds of the cases occurring in hospitalized patients. Recent clinical studies in patients with bacteremia indicate that gram-positive and gram-negative bacteria are the etiology of the sepsis in 35 to 40 percent and 55 to 60 percent of the episodes, respectively. The most frequent sites of infection are the lungs, abdomen, and the urinary tract. Factors that predispose to gram-negative bacteremia include diabetes mellitus, lymphoproliferative diseases, cirrhosis of the liver, burns, invasive procedures or devices, and chemotherapy. Major gram-positive bacteremia risk factors include vascular catheters, indwelling mechanical devices, burns, and intravenous drug injection. Fungemia most often occurs in immunocompromised patients.

While there is no reason to suspect that the occurrence of septic shock would vary according to the patient's sex, two large-scale prospective studies have found a slightly higher incidence of systemic inflammatory response syndrome (SIRS) and sepsis syndrome in men; 60 percent and 56 percent, respectively. This slight difference may reflect a higher rate of preceding surgical procedures in men as opposed to women. Sepsis is more common in older adults; the mean age reported is 55 to 60 years. Older patients are more likely to have conditions that predispose to bacterial infection, such as diabetes, surgical procedures, and cancer.

DEFINITIONS AND RISK CATEGORIZATION

In 1991, the American College of Chest Physicians and the Society of Critical Care proposed a set of definitions that could be applied to patients with sepsis and its sequelae. These definitions are contained in Table 28-1. The primary goals of this classification were to provide a conceptual and practical framework of the systemic inflammatory response to infection; to improve the ability of clinicians to make early bedside detection of sepsis, thus allowing early therapeutic intervention; and to standardize the definition which would allow better comparison and analysis of research protocols.

TABLE 28-1   Definitions

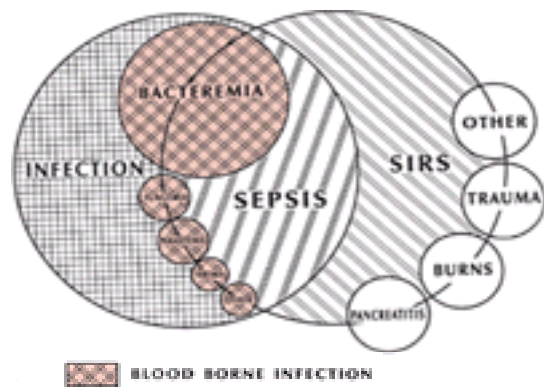
The identification of SIRS does not confirm a diagnosis of infection or sepsis because the features of SIRS can be seen in many other conditions such as trauma, pancreatitis, burns, or infection (Fig. 28-1). SIRS is not a diagnosis nor is it a good indicator of outcome. Its presence, however, must be explained adequately.


FIG. 28-1. The interrelationship between systemic inflammatory response syndrome (SIRS), sepsis, and infection. (From *Chest* 101:6, 1992.)

The SIRS criteria may be seen as a crude stratification for patients with systemic inflammation. In a recent prospective study of the epidemiology of SIRS in medical and surgical patients, mortality was 3 percent in patients without SIRS, 6 percent in those with two criteria, 10 percent in those with three positive criteria, and 17 percent in those meeting all four criteria. Death rates were similar for patients with culture-negative SIRS and those with culture-positive SIRS. Other investigators propose a complementary method of classification of sepsis based primarily on physiologic abnormalities such as the APACHE III acuity system. These investigators found that multivariate analysis using initial APACHE score, etiology of sepsis (urosepsis or other), and treatment location prior to ICU admission provided the greatest degree of discrimination of patients by risk of hospital death.

PATHOPHYSIOLOGY

Sepsis starts as a focus of infection (urinary tract infection, pneumonia, cellulitis, abscess, or indwelling prosthetic device) resulting in either blood stream invasion or a proliferation of organisms at the infected site (Fig. 28-2). These growing organisms release a large amount of exogenous toxins consisting of endotoxins, exotoxins, and other components of the organism's structural components. The host's reaction to these toxins results in the release of endogenous mediators and other humoral defense mechanisms including complement, kinins, and coagulation factors. Among the most prominent of the endogenous mediators are the cytokines (tumor necrosis factor, interleukins), platelet activating factor (PAF), arachidonic acid metabolites, and myocardial depressant substances (MDS). Release of MDS results in the depression of myocardial function, dilation of the ventricles, and vasodilation. These vascular and myocardial abnormalities combine to result in generalized cardiovascular insufficiency leading to refractory hypotension and multiple organ system failure, and death.

FIG. 28-2. Pathogenic sequence of the events in septic shock.
*TSST-1 denotes toxic shock syndrome toxin 1.
†Toxin A is *Pseudomonas aeruginosa* toxin A.

One of the most important of the vasoactive mediators is nitric oxide. Nitric oxide is a low-molecular weight membrane-permeable gas with both harmful and beneficial effects in shock. Under normal conditions, this gas is produced in the endothelium by a calcium and calmodulin-dependent nitric oxide synthase (NOS) which converts L-arginine and O_2 to L-citrulline and nitric oxide. This pathway is normally well regulated by signal transduction pathways linked to cell-surface receptors for vasodilators such as acetylcholine and histamine. However, inflammatory mediators induce a calcium-independent form of nitric oxide synthase that is not controlled by this mechanism. This form may rise to abnormal amounts of nitric oxide in septic patients and patients given IL-2 for cancer treatment.

Three distinct NOS enzyme complexes have been described. The first, neuronal nitric oxide synthase (nNOS) is found in central nervous system cells and is thought to support a neurotransmitter function. The second, constitutive NOS (cNOS) is found in endothelial cells and is thought to play a role in the maintenance of normal vascular tone. The third, a high output inducible enzyme called inducible NOS (iNOS) is found in many cell types including, endothelial cells, vascular smooth muscle cells and macrophages.

Nitric oxide actions include functioning as a neurotransmitter; regulating vascular tone; and inhibiting platelet aggregation and leukocyte adhesion. At higher doses, nitric oxide has antitumor and antimicrobial activity. Nitric oxide is thought to have a beneficial role in sepsis. It is important in maintaining visceral and microvascular blood flow acting as a counter-regulatory mechanism to the vasoconstriction mediators (thromboxane and endothelin-1) released in inflammation. It is thought to be an important free radical scavenger that prevents microvascular stasis and thrombosis by blocking platelet aggregation and leukocyte adhesion.

Nitric oxide may have several harmful effects in sepsis. Nitric oxide has been implicated as a major mediator for vasodilation and hypotension in septic shock. The inducible form of nitric oxide synthase is stimulated by inflammatory mediators (including TNFa and interleukin-1), which leads to increased release of nitric oxide from endothelial cells, vascular smooth muscle cells, and macrophages. Once induced, iNOS is likely to persist for many hours to days. Peroxynitrite, which is formed from the reaction between superoxide radicals and nitric oxide, may cause direct cellular injury. Nitric oxide may also contribute to the myocardial depression and increased permeability seen in septic shock.

Anti-inflammatory substances are also released. These include endogenous steroids and catecholamines, interleukin-10 (IL-10), interleukin-4 (IL-4), prostaglandin E$_2$, interleukin-1 receptor antagonists, and tumor necrosis factor receptors. All of these substances alter immune function, which leads to a period of immune depression after the initial shock episode.

Molecular Pathophysiology of Sepsis

There is now compelling evidence that septic shock and its morbid consequences are the direct result of endogenous proteins and phospholipid mediators secreted by the infected individual. Molecular pathophysiology of sepsis can be divided into 3 phases: induction of cytokine synthesis, cytokine synthesis and secretion, and cascade phase of sepsis.

The induction of cytokine synthesis involves the interaction of certain microbial molecules that, when recognized by the host, results in the production of mediators that amplify and transmit the microbial signal to other cells and tissues.

Of currently available models, the pathophysiology of gram-negative infection is best understood. An individual suffering from a gram-negative infection is not only exposed to membrane bound lipopolysaccharides (LPS) at the site of infection, but is also systemically exposed to the free endotoxin on fragments of bacterial outer membrane commonly shed during bacterial growth and replication. LPS binds to LPS-binding protein forming an LPS-LPS-binding protein complex. This complex is

1000-fold more potent than LPS alone in inducing TNF production by macrophages. The receptor for this complex is known to be the CD14 molecule that is found on monocytes, macrophages, and neutrophils. The peptidoglycan and lipoteichoic acids of gram-positive bacteria, certain polysaccharides, extracellular enzymes, and toxins induce cytokine synthesis in animals similar to those of LPS.

The phase of cytokine synthesis and secretion involves several regulated steps. These steps include transcription (synthesis of messenger RNA from the DNA template), translation of mRNA into protein, post-translational processing, and secretion of protein. An example is when LPS-LPS-binding protein complex interacts with the CD14, transcription of TNF gene in vitro increases threefold with levels of TNF mRNA increasing 100-fold. Biosynthesis and secretion of TNF, however, increase over 10,000-fold; this is primarily due to increased translational efficiency of preformed TNF mRNA as well as efficient translation of newly transcribed TNF mRNA.

The cascade portion of sepsis results from the activation and release of a central mediator (TNF, IL-1), which results in the secretion of various secondary mediators (IL-1, IL-6, IL-8, PAF, prostaglandins, leukotrienes); the activation of neutrophils, the complement system, and vascular endothelial cells; and synthesis of acute phase reactants. LPS and TNF probably promote intravascular coagulation initially by inducing blood monocytes to express tissue factor, by initiating the release of plasminogen activator inhibitor-1 (PAI-1) and inhibiting the expression of thrombomodulin and plasminogen activator by vascular endothelial cells. TNF, IL-1, and IL-6 are cytokines that have been detected in increased concentrations in the serum of patients with septic shock. The physiologic outcome of this complex cascade comprises the SIRS.

Parallel to SIRS is the body's intrinsic anti-inflammatory response. This response "compensatory anti-inflammatory response syndrome (CARS)" attempts to downregulate the SIRS response. Agents identified as participating in CARS include interleukins (IL-4, -10, -11, -13), transforming growth factor-b (TGF-b), colony-stimulating factor (CSF), soluble receptors to tumor necrosis factor (sTNFR), and antagonists to tumor necrosis factor (TNFra) and IL-1 (IL-1ra) receptors. These mediators inhibit T and B lymphocyte activity, as well as decrease antigen-presenting activity on the monocyte. The body normally maintains a delicate balance between SIRS and CARS. Uncontrolled sepsis and SIRS lead to profound hypotension, inadequate perfusion, and death. If the CARS reaction is severe, it will manifest clinically as anergy and increase susceptibility to infection.

CLINICAL FEATURES

Constitutional

Hyperthermia or hypothermia, tachycardia, wide pulse pressure, tachypnea, and mental status changes are early systemic signs of infection and septic shock. Endotoxin, TNF, IL-1, and interferon-a have all been shown to elicit febrile responses in humans. Acute hyperventilation with respiratory alkalosis (Pa CO_2 £30 mmHg) is common in sepsis. The etiological mechanism of this tachypnea is thought to be due either to the direct effects of endotoxins or secondary to kallikreins, bradykinin, prostaglandins, or complement activation.

The most frequent mental status change in sepsis is mental obtundation. The neurological findings are nonfocal and range from mild disorientation to confusion, lethargy, agitation, and coma. The pathophysiology is still unknown; an altered state of amino acid metabolism producing a state similar to portosystemic encephalopathy or decreased cerebral blood flow with secondary disruption of the blood-brain barrier are proposed mechanisms.

Cardiovascular

In the early stages of septic shock, the vasodilatory mediators predominate, and patients present with warm extremities. Cardiac output and stroke volume are usually well maintained. Frequently, cardiac output is increased concomitantly with tachycardia. Hemodynamic measurements during the first 24 hours show that the characteristic pattern of septic shock consists of an initial decrease in left and right ventricular ejection fractions (RVEF, LVEF) with an increase in both end-diastolic and end-systolic volume indices, normal stroke volume and decreased peripheral vascular resistance. In survivors, the changes are reversible, and the ventricular function and size return to normal by 7 to 10 days after septic shock onset. Patients with septic shock have been shown to have markedly diminished cardiac response to volume administration with only minor increments in both end-diastolic volume index (EDVI) and left ventricular stroke work index (LVSWI). Hemodynamic factors that are significant predictors of survival are an initial heart rate of <106 beats per minute, a 24-h heart rate of <95 beats per minute, or a systemic vascular resistance of >1529 dyne/s/cm^{-5}), and a change over the initial 24-h heart rate with a decrease in heart rate >18 beats per minute or a decrease in cardiac index by >0.5 L/min/m^2.

Myocardial depression is present in early septic shock. Studies show that the perfusion of the coronary arteries in patients with septic shock are equal to or greater than controls. This data strongly argues against the hypothesis that coronary hypoperfusion with secondary ischemic myocardial dysfunction is the cause of the myocardial depression. Significant evidence points towards the existence of several active circulating myocardial depressant substances.

Substances that have demonstrated myocardial depressant activity include TNFa (when IL-1b is present), nitric oxide, and IL-1b (when TNF is present), PAF, oxygen free radicals, interferon-g, and arachidonic acid metabolites. The compounds that have received the most scrutiny are the combination of TNFa and IL-1b as well as nitric oxide. TNFa, in the presence of IL-1b, has been shown to produce significant myocardial depression in vitro. Another major contributor to the prolonged myocardial depression is cytokine-mediated nitric oxide. Nitric oxide can be produced in cardiac tissue, as in the vasculature, by two distinct pathways. Constitutive NOS (cNOS) appears to be involved in the physiologic regulation of myocardial contractility through the interaction between endothelial cells and cardiac myocytes. cNOS is stimulated by cytokines such as TNF, IL-1, and possibly IL-2, and activated macrophages. This inflammatory stimulus of sepsis is sustained at higher capacity through iNOS, which is responsible for the larger portion of the prolonged myocardial depression in sepsis.

Pulmonary

Sepsis remains the most common condition associated with adult respiratory distress syndrome (ARDS). ARDS is a physiologic syndrome characterized acutely by lung edema resulting from increased alveolar-capillary permeability. Recently, the concept of global microcirculatory injury has won favor with many investigators. In the setting of trauma and sepsis, ARDS affects capillary beds throughout the body concurrently. The lung is a conspicuous organ because when increased microvascular permeability develops in the lung, alveolar flooding occurs, causing dyspnea, hypoxemia, and abnormal opacities on chest x-ray. The appearance of ARDS varies from minutes to hours after the onset of sepsis. Although there are no specific and sensitive markers for ARDS, diagnostic criteria for ARDS include bilateral pulmonary infiltrates, pulmonary capillary wedge pressure (PCWP) <18 mmHg, Pa o_2/PAo$_2$ ratio <0.2, and static compliance <40 mL/cm H_2O. Clinically, severe refractory hypoxemia, noncompliant "heavy" lungs, and a chest radiograph showing bilateral pulmonary alveolar infiltrates should suggest the presence of ARDS. The hypoxemia is due to perfusion of the underventilated alveoli; right-to-left shunting has been reported as high as 30 to 50 percent in this syndrome. Pathogenic factors implicated in the global microcirculatory injury are endotoxin, TNFa, IL-1, IL-6, IL-8, and bacterial permeability increasing protein.

Renal

Renal manifestations of septic shock include acute renal failure (ARF) with azotemia, oliguria, and active urinary sediment. Factors associated with the development of ARF in septic shock include hypotension, dehydration, aminoglycoside administration, and pigmenturia. Within the kidney, both vasoconstrictive and vasodilator mediators are generated and their balance dictates renal hemodynamics. If renal hypoperfusion predominates, renal ischemic injury occurs. Renal hypoperfusion is considered to be a major factor in the pathogenesis of ARF in sepsis. Toxic products resulting from neutrophil-endothelial interactions, endothelial damage by various mediators, reperfusion injury, and microvascular thrombosis in the kidney also contribute to renal dysfunction. In patients without septic shock, renal insufficiency may occur as a consequence of glomerulonephritis or interstitial nephritis. Glomerular disease in the setting of sepsis has been reported in subacute bacterial endocarditis, pyogenic visceral abscesses, and infections at other sites. Urine sediment in glomerular disease contains red blood cells, casts (red, white, or pigmented), and protein. Renal biopsy usually shows proliferative changes. Immune complex deposition with glomerular deposits of IgG, IgM, C3, bacterial antigens, and antibodies to these antigens has been reported. Tubulointerstitial disease has been associated with *Streptococcus pneumoniae, Staphylococcus pyogenes, Legionella pneumophila,* salmonellosis, brucellosis, and diphtheria infections. Acute interstitial nephritis secondary to allergic reaction to antibiotics (most commonly, methicillin) has also been reported; eosinophilia and eosinophiluria are usually present in this setting.

Hepatic

Liver dysfunction is frequently seen in patients with sepsis. The most frequent presentation is cholestatic jaundice. Increases in transaminase, alkaline phosphatase

(one to three times normal) and bilirubin concentrations (usually not >10 mg/dL) are frequently noted. The proposed mechanism for bilirubin elevation involves hemolysis of red blood cells and hepatocellular dysfunction due to endotoxin, cytokines, or immune complex disease. Prolonged or severe hypotension may induce acute hepatic injury or ischemic bowel necrosis.

Hematologic

Major blood loss secondary to upper gastrointestinal bleeding occurs in only a small percentage of patients with sepsis. However, minor blood loss within 24 h of developing a severe infection is common as patients develop painless 1- to 2-mm erosions in the mucosal layer of the stomach and/or duodenum. Proposed mechanisms for these ulcerations include decrease in the blood flow, hypoxia of the mucosal cells, interruption of the gastric mucosal barrier, and release of mucosal lysozyme.

The most frequent hematologic changes in the septic patient are neutropenia or neutrophilia, thrombocytopenia, and disseminated intravascular coagulation (DIC). Sepsis most frequently produces a neutrophilic leukocytosis with a "left shift." These early changes result from demargination and release of less-mature granulocytes from the marrow storage pools. One proposed mechanism for demargination and bone marrow release is the presence of endotoxin or other similar substances and activation by complement (C3a) causing the release of a neutrophil-releasing substance. The sustained neutrophilia that accompanies chronic infection is thought to be secondary to colony stimulating factors. These glycoproteins increase granulocyte production by activating committed stem cells. Infection increases the colony-stimulating factor elaboration by macrophages, lymphocytes, and other tissues. In certain cases of sepsis, leukemoid reactions with leukocyte counts of 50,000 to 100,000 cells/μL have been reported.

Neutropenia, occurring rarely, is associated with an increase in mortality. The etiology of this neutropenia includes increased peripheral utilization of neutrophils, damage to neutrophils by bacterial byproducts, or depression of marrow granulocyte production by inflammatory mediators. Both morphologic and functional changes to neutrophils have been reported in sepsis. The most commonly reported morphologic changes include the presence of toxic granulations, Dohle bodies, and vacuolization. Functional changes reported in sepsis include increased phagocytic and cytotoxic activities. Eosinophilia occurring in the presence of sepsis has been attributed to the effect of margination or migration of these cells from the vascular space, inhibition of bone marrow release, and a decrease in marrow production. Activated complement C5a has been implicated.

Red cell number and morphologic characteristics are not usually affected by sepsis. However, red cell production and survival are decreased during sepsis. Decreased production and survival do not usually cause anemia unless the infection is prolonged. Septic patients generally possess low serum iron concentrations. Sepsis and its intermediaries cause a rapid iron flux into the liver and other parts of the reticuloendothelial cells, with the serum iron concentration decreasing by 50 percent or more within a period of hours. This effect may last days. An attractive hypothesis is that this represents a host defense mechanism. The addition of iron to normal human serum enhances the growth of organisms. Also, iron in the reticuloendothelial system may be beneficial to the host cells in detoxifying bacterial activity.

Thrombocytopenia most frequently arises as a consequence of DIC, although isolated thrombocytopenia is present in over 30 percent of cases of sepsis. Thrombocytopenia may be an early clue to bacteremia and may also be useful in observing patient's response to therapy. The proposed mechanisms for the thrombocytopenia include inhibition of thrombopoiesis, increased platelet turnover, increased endothelial adherence, and increased destruction secondary to immunologic mechanisms.

DIC is a condition in which the clotting and/or fibrinolytic system are systemically activated, leading to the consumption of many coagulation factors and platelets. DIC, with disseminated fibrin depositions in the microcirculation of various organ systems, is a frequent finding in patients with septic shock. The activation of the hemostatic (clotting) system is due primarily to the activation of the extrinsic pathway of clotting. This cascade is triggered by multiple sources including bacteria (gram-negative and gram-positive), viruses, fungi, endotoxins, and exotoxins (see Fig. 28-2). Gram-negative infections precipitate DIC more readily than does gram-positive bacteremia. The fibrinolytic system is also activated in sepsis and plays an important role in the regulation of fibrin deposition in the microcirculation. Several studies of septic patients have demonstrated the release of tissue type plasminogen activator, which activates the fibrinolytic system, at least initially in sepsis. As sepsis progresses, there is an increased release of plasminogen activator inhibitor type 1 (PAI-1), which blocks plasmin generation and thus contributes to fibrin deposition in the microcirculation and subsequent multiple-organ failure.

DIC can be categorized into two forms. The compensated form of DIC is characterized by a "slower" generalized activation of the hemostatic system. Although platelets and coagulation factors are consumed more rapidly than normal, bleeding is prevented by increasing coagulation factor production in the liver, by the release of the platelets from reserve storage sites, and by the synthesis of inhibitors at an accelerated rate. Patients with decompensated DIC will have clinical bleeding and/or thrombosis. Laboratory studies suggesting the presence of DIC include thrombocytopenia, prolonged prothrombin and activated partial thromboplastin values, decreased fibrinogen and antithrombin III levels, and increased fibrin monomer, fibrin split products, and D-dimer values.

Endocrine

Hyperglycemia may suggest the presence of sepsis in diabetic patients. Proposed pathogeneses include increased amounts of catecholamines, increased cortisol and glucagon in the circulation, peripheral insulin resistance, impaired glucose utilization, and decreased insulin secretion. Hypoglycemia with glucose levels as low as 10 to 20 mg/dL has been reported but is a relatively uncommon manifestation of sepsis. Bacterial infections associated with hypoglycemia include *S. aureus, S. pyogenes, S. pneumoniae, Listeria monocytogenes, Haemophilus influenzae, Neisseria meningitidis,* and *Enterobacteriaceae*. The proposed pathogenesis of hypoglycemia includes the depletion of hepatitic glycogen and inhibition of gluconeogeneses.

Acid-Base

Blood gas analysis performed early in the course of septic shock usually finds respiratory alkalosis. Relative or absolute hypoxemia is often present due to ventilation perfusion mismatches. The development of metabolic acidosis reflects inadequate tissue perfusion and increased glycolysis in peripheral tissues, along with impaired hepatic clearance of lactate and pyruvate. As perfusion worsens and continues, tissue hypoxia generates more lactic acid and metabolic acidosis worsens.

Cutaneous

Cutaneous lesions that occur as a result of sepsis can be divided into three categories: direct bacterial involvement of the skin and underlying soft tissues (cellulitis, erysipelas, and fasciitis); lesions that occur as a consequence of sepsis, hypotension, and/or DIC (acrocyanosis and necrosis of peripheral tissues); and lesions secondary to infective endocarditis (microemboli and/or immune complex vasculitis).

DIAGNOSIS

Septic shock should be suspected in any individual with temperature >38°C or <36°C and a systolic blood pressure of <90 mmHg with evidence of inadequate organ perfusion. The hypotension should not reverse with rapid volume replacement of at least 1 L of isotonic crystalloid. Frequently, the diagnosis is straightforward with the patient presenting with hypotension or inadequate perfusion and complaints attributable to a serious infection such as pneumonia, acute pyelonephritis, or an acute abdomen. Other early clinical features of sepsis include mental obtundation; hyperventilation; hot, flushed skin; and a widened pulse pressure. In the elderly, very young, or immunocompromised patient, the clinical presentation may be atypical with no fever or localizable source of infection.

The differential diagnosis of septic shock includes the other nonseptic causes of shock such as cardiogenic, hypovolemic, anaphylactic, neurogenic, obstructive (pulmonary embolism, tamponade), and endocrinal (adrenal insufficiency, thyroid storm) causes.

History and physical examination with some basic laboratory or radiologic investigations are usually successful in the initial assessment and identification of a presumptive source of sepsis. Particular attention should be focused on infections in these organ systems: central nervous system; pulmonary; intra-abdominal; skin and soft tissue.

Acute bacterial meningitis is the CNS infection that is most commonly associated with shock. Community-acquired meningitis with shock is usually due to *S. pneumoniae* or *N. meningitidis*. The majority of patients present with nuchal rigidity and a depressed level of consciousness. Chest radiographs may show a pneumonia with secondary bacteremia due to *S. pneumoniae*. Disseminated meningococcemia may present only with shock without meningismus. Frequently, these patients possess a "new petechial rash," which is the major clue to the etiology of shock. Brain abscesses, subdural or epidural empyemas, and viral CNS infections

are seldom associated with shock on the initial presentation. Shock is also unusual in neurosurgical patients with *S. aureus* or enteric gram-negative meningitis secondary to neurosurgical procedure or skull fracture.

The major pulmonary entity commonly leading to septic shock is acute bacterial pneumonia. The most frequent organisms are *S. pneumoniae, S. aureus,* gram-negative bacilli, and *L. pneumophila.* The physical examination and chest radiograph almost always suggest the presence of pneumonia.

Intraabdominal processes are the source of infection leading to septic shock in the largest proportion of patients. Acute pancreatitis with or without infection can result in a presentation identical to septic shock. Suppurative cholangitis and empyema of the gallbladder are the primary considerations for the biliary tree. In women of childbearing age, septic abortion and postpartum endometritis/myometritis are the dominating presenting infections leading to septic shock. Acute pyelonephritis secondary to gram-negative enteric bacteria or enterococci can occasionally present with shock. Ureteric obstruction is often present in these syndromes.

The most common skin and soft tissue infection associated with septic shock is cellulitis due to *S. aureus* or *S. pyogenes.* Soft tissue infections secondary to gram-negative organisms are indistinguishable from those due to primary infection by staphylococci or streptococci. Shock associated with soft tissue infections is clinically obvious and frequently associated with bacteremia. Shock associated with a generalized erythematous macular rash may represent toxic shock syndrome. Necrotizing soft tissue infections are suspect in infections in immunocompromised patients or in patients with history of poor vascular circulation. Populations at risk for necrotizing infections are diabetics and individuals with peripheral vascular disease.

Individuals without obvious source of septic shock may have a primary bacteremia, or endocarditis. The most prevalent etiologies of primary bacteremias in outpatients are *S. aureus, S. pneumoniae,* and *N. meningitidis.* Encapsulated species such as *Salmonella* or *H. influenzae* are important pathogens in individuals who are asplenic. *Pseudomonas aeruginosa* and other gram-negative bacteria are occasionally etiologies of bacteremia and endocarditis in intravenous drug users.

Ancillary Studies

While there is no specific laboratory test for the diagnosis of septic shock, tests are useful because they (1) assess the general hematologic and metabolic state of the patient, (2) provide results that suggest the potential for occult bacterial infection, and (3) detect a specific microbial etiology for infection. Basic laboratory studies should include a complete blood count including platelet count; DIC panel (prothrombin time, activated partial thromboplastin time, fibrinogen, D-dimer, antithrombin III concentration); serum electrolytes (including magnesium, calcium, phosphate, and serum glucose); liver function panel (bilirubin, alkaline phosphate, and ALT); renal function panel (blood urea nitrogen and creatinine); arterial blood gas analysis; and urinalysis. Blood should be typed and crossed if low hematocrit is suspected. A chest radiograph should also be a part of the basic evaluation. Flat and upright abdominal films are helpful in patients in which there is a potential abdominal source of infection and should be considered in every patient except individuals with a completely benign abdomen or an obvious alternate source. Any patient with a clinical presentation compatible with a CNS source of infection should undergo a lumbar puncture with CSF collected for analysis. This should be performed without delay in the emergency department. In individuals with papilledema, focal neurologic deficits, or with potential for brain abscess or epidural or subdural empyema, the LP should be deferred until an imaging study is performed. However, if meningitis is an important consideration, empiric antimicrobial therapy should be initiated prior to the study.

Bacterial cultures of blood and urine should be obtained on all septic patients. At least two separate sets of blood cultures from different venipuncture sites should be obtained. Gram's stain and culture of secretions from any potential site of infection should be performed. A Gram's stain or other means of rapid identification of microbial etiologies are generally the only immediately available tests useful in selection of antimicrobial therapy.

TREATMENT

Airway and Respiratory Management

Immediate assessment of oxygenation and ventilation status is the first priority in the management. Oxygen by mask and consideration of endotracheal intubation should be done immediately if the patient's airway is not secure or if respirations are inadequate. In addition, patients with hypotension not responding acutely to rapid fluid resuscitation should be intubated to avoid respiratory arrest from fatigue of the respiratory muscles due to inadequate perfusion of these muscles. There is no consensus as to acceptable levels of oxygen saturation or tensions; however, most experts recommend maintaining oxygen saturations above 90 percent in a septic patient.

Hemodynamic Stabilization

FLUID ADMINISTRATION   Correction or stabilization of hypotension and inadequate perfusion is the second goal of resuscitation. Rapid fluid administration at a rate of 0.5 L (20 mL/kg in children) of normal saline or similar isotonic crystalloid should be administered every 5 to 10 min as needed; it is not unusual for the patient to require 4 to 6 L (60 mL/kg in children) or more of crystalloid in the initial phase of resuscitation. Stabilization of the patient's mentation, blood pressure, respiration, pulse rate, skin perfusion, and central venous pressure, with urine output greater than 30 mL/h (1 mL/kg/h in pediatric patients) are useful clinical parameters in monitoring the response to fluid administration.

INOTROPIC SUPPORT   If no response to the fluid infusion is noted after 3 to 4 L of fluid, or if there are signs of fluid overload (elevated central venous pressure or pulmonary edema), an infusion of dopamine can be started. If the patient has a pulmonary artery catheter in place during this resuscitation, dopamine should be added in the setting of a PCWP of 15 to 18 mmHg or if there are marked increases of the PCWP with additional fluids. Doses of dopamine often required are 5 to 20 μg/kg/min resulting in both b-adrenergic inotropic and a-adrenergic vasopressor activity. If the patient is still unresponsive above a rate of 20 μg/kg/min of dopamine infusion, norepinephrine should be started with the goal of keeping the mean blood pressure at least 60 mmHg. Although previous investigations have raised doubts concerning the efficacy of norepinephrine in these cases, recent studies have demonstrated that norepinephrine can reverse septic shock in patients unresponsive to fluid administration and dopamine. Once the blood pressure and perfusion have been stabilized by norepinephrine, the lowest dosage that maintains blood pressure should be utilized to minimize the complications of vasoconstriction. Additionally, data from the canine model has suggested the use of low-dose dopamine (1 to 4 μg/kg/min) in patients on norepinephrine results in significantly higher renal blood flow and reduced renal vascular resistance. In one series, the norepinephrine survival group approached 40 percent. Vasodilators are rarely used in the emergency department, but they have been used in the intensive care units in situations of severe myocardial depression, increased system vascular resistance, and adequate blood pressure.

HEMODYNAMIC ENDPOINTS   Most authorities recommend that the optimal hematocrit should be maintained between 30 and 35 percent to maximize oxygen transport capacity. A number of studies have suggested that increased global oxygen delivery has improved survival in critically ill patients. However, a recent multicenter trial involving more than 10,000 patients in 56 intensive care units suggested that hemodynamic therapy aimed at achieving supranormal values for cardiac index, with normal values of mixed venous oxygenation, failed to reduce morbidity or mortality in critically ill patients when compared to a control group that was supported to normal cardiac index levels.

Empiric Antimicrobial Therapy

All patients with septic shock should receive empiric antimicrobial therapy as soon as possible. Whenever possible, samples of blood or fluids from potential sites of infection should be obtained prior to the initiation of antimicrobial therapy. Selection of antibiotics should be based upon the adequate coverage of all potential pathogens of the potential infection sites as well as the anticipated antimicrobial susceptibility patterns of the bacterial isolate(s).

Empiric therapy should be effective against gram-positive organisms (*Streptococcus spp.* and *Staphylococcus spp.*) and gram-negative bacteria. The route of administration should be intravenous in the maximum doses allowed. In neonates, a regimen of ampicillin plus cefotaxime is recommended. For infants one to three months of age, the combination of ampicillin with cefotaxime or ceftriaxone is recommended. In nonimmunocompromised children three months or older, cefotaxime or ceftriaxone is the drug of choice. In adults (non-neutropenic) without an obvious source of infection, a third-generation cephalosporin or an antipseudomonal b-lactamase-susceptible penicillin is recommended. Some experts advise the addition of an aminoglycoside (tobramycin, gentamicin, or amikacin) to this regimen. Alternatively, imipenem or meropenem alone is acceptable. In neutropenic children and adults, ceftazidime, imipenem, or meropenem alone is acceptable. Alternatively, the combination of an antipseudomonal aminoglycoside plus ceftazidime or antipseudomonal b-lactamase-susceptible penicillin is acceptable. In patients with high probability of a gram-positive etiology (history of illicit drug abuse), nafcillin or vancomycin should be added to the regimen. If an anaerobic source is suspected (intraabdominal, biliary, female genital tract, necrotizing cellulitis, aspiration pneumonia, odontogenic infection, or an anaerobic soft tissue infection) metronidazole or clindamycin should be added to the regimen. In patients with potential for *Legionella* species infection, the addition of erythromycin to the regimen is

recommended. In patients with indwelling vascular devices, vancomycin should be added to the regimen.

Removal of Source of Infection

If a focal source of sepsis is identified, removal of the nidus of infection is absolutely mandatory for successful treatment. Indwelling intravenous catheters should be removed and replaced. The tip should be sent for quantitative culture. Foley catheters should be replaced if obstructed. Intraabdominal or soft tissue sites of pus require urgent drainage.

Initial Baseline Assessment

Hemodynamic and laboratory monitoring is critical to the resuscitation of a patient in septic shock. Some clinicians advocate following the serum lactate as a monitor of response to therapy. Arterial blood gas should be repeated to monitor adequacy of ventilation and perfusion. Septic shock patients should have at least two large-bore intravenous catheters for administration of fluids and vasoactive drugs. Early placement of a central venous catheter (ideally with a 8.5-Fr catheter introducer) may help in the monitoring of fluid resuscitation. Placement of a flow-directed thermal-dilution pulmonary artery wedge-pressure catheter should be considered in patients requiring vasoactive therapy, where there is difficulty in assessing volume status, or ongoing hemodynamic instability is present. Generally, the placement of this catheter can wait until the patient is in the intensive care unit.

New noninvasive methods of patient monitoring are currently under investigation. Clinical studies have shown that only the measurement of gastric pH has a significant impact on the treatment and prognosis of patients with sepsis. Among the most promising of the newer techniques being investigated are near-infrared spectroscopy and transcranial Doppler measurements. Near-infrared spectroscopy (NIRS) enables the assessment of intracerebral oxygenation and may be suitable for monitoring critically ill patients. Investigations in patients with sepsis have suggested that NIRS detected evidence of impaired vasoregulation. Its clinical use is limited by its only giving relative values and no critical values of tissue perfusion can be given. Currently, NIRS is used for the cerebral monitoring of newborn infants and patients undergoing cardiopulmonary bypass or operations involving the carotid artery.

Transcranial Doppler measurements enable the noninvasive evaluation of blood flow velocities of some cerebral arteries. Investigations have suggested that the monitoring cerebral blood flow is vital in critically ill patients. In particular, the risks of cerebral vasoconstriction induced by hyperventilation, and the sepsis-induced nonhomogenous cerebral blood flow seen in some patients with sepsis, may place certain patients at risk for cerebral ischemia.

Other Therapies

BICARBONATE   Some investigators advocate the administration of bicarbonate for individuals with severe acidosis (pH <7.2). The efficacy of this intervention is not established.

THERAPY OF DIC   The management of the patient in DIC has three basic approaches: elimination of the underlying disorder or source of infection; substitution of coagulation constituents lost in the clotting process; and arrest of the intravascular clotting process. If the patient is actively bleeding and decompensated DIC is present, urgent replacement of the components of the coagulation and fibrinolytic systems is indicated with the rapid infusion of fresh-frozen plasma and/or platelets. Reasonable guidelines in the actively bleeding patient with DIC include the transfusion of platelets to maintain a concentration of 50 to 100 × 10^3/μL and fresh-frozen plasma to keep the coagulation parameters (prothrombin time and activated prothrombin time) less than twice normal.

Interruption of the activated hemostatic system has been attempted by a number of investigators. Heparin has been used (primarily outside the United States) with mixed results. Currently, no conclusive evidence is available to suggest that heparin therapy reduces morbidity or mortality in septic patients with DIC. Administration of a natural anticoagulant, such as antithrombin III (ATIII) may arrest clotting without concomitant risk of bleeding. ATIII is a single-chain glycopeptide that is produced by the liver. ATIII is an important regulator of hemostasis by inhibiting several serine proteases of the coagulation system, predominately thrombin and factor Xa. Plasma ATIII levels decrease in septic patients with DIC. In healthy individuals, the half-life of ATIII is approximately 60 h. In patients with sepsis and septic shock, this may be reduced to as little as 4 to 6 h. The possibility that replacement of ATIII neutralizes excess thrombin and dampens the intravascular coagulation process has prompted several experimental and clinical studies. In several animal models of DIC, infusion of ATIII concentrates shortened the duration of DIC and reduced multiple organ failure and mortality. Results of human clinical studies have been mixed. These investigations have suggested either a trend towards efficacy or no significant difference between patients who received ATIII and controls. Until a definitive study is available, some experts recommend that patients with DIC secondary to a septic process should receive replacement of ATIII to a level of 70 to 80 percent of normal. Other investigators suggest that a much higher level of ATIII (140 to 150 percent) is required for efficacy.

ANTI-INFLAMMATORIES   Although some animal models have shown that high-dose corticosteroid therapy was effective, large clinical trials have shown no differences in mortality between corticosteroid treated patients and control patients. These studies also have documented the occurrence of superinfection in corticosteroid treated patients. Thus the primary role of steroids is in patients with suspected or documented adrenal insufficiency. Adrenal insufficiency should be considered in septic patients with fulminant *N. meningitidis* bacteremia, disseminated tuberculosis, AIDS, prior glucocorticoid use, or with refractory hypotension. The use of inhibitors to metabolites elaborated in sepsis (inhibitors include ibuprofen, naloxone, eicosanoids, or antihistamines) has not proven to be effective in the management of septic shock.

NEW AGENTS IN THE TREATMENT OF SEPSIS

Recent advances in molecular biology and immunology suggest that the host's inflammatory response to infection contributes substantially to the development of septic shock. Standard sepsis treatment strategies include the use of life support procedures, antibiotics to kill invading bacteria, and surgical procedures to eradicate the nidus of infection. Despite these aggressive measures, the mortality rate of septic shock remains high. The development of new interventions is based on the premise that neutralizing bacterial toxins and the potentially harmful host mediators could stop or slow this syndrome. Researchers have targeted interventions at all three phases of the host's inflammatory responses. Interventions targeting the induction phase include all those against the endotoxin's lipopolysaccharide molecule. This category includes E5 and HA-1A therapy monoclonal antibodies. Therapies targeting cytokine synthesis include pentoxifylline, b-agonists (amrinone and dobutamine), and corticosteroids. Therapies directed against the cascade phase of sepsis include monoclonal antibodies to TNF- and IL-1-receptor antagonist, monoclonal antibodies against the neutrophil CD11/18 adhesion complex, nitric oxide synthase inhibitors, and cyclooxygenase inhibitors.

Currently, none of the therapies aimed at single targets in the inflammatory cascade has been proven to be effective in the treatment of septic shock in humans. In the cases of interventions that are directed at endogenous inflammatory mediators, none of the studies has produced unequivocal benefit in the treatment of sepsis. Great potential danger exists in altering the natural balance of inflammatory mediators. These mediators perform important functions, such as clearing bacterial toxins and the mobilization of the host defenses that control the infection. Attempting to block the harmful effect of inflammatory mediators may compromise host defenses and ultimately worsen the outcome. Successful therapeutic approaches may depend on determining which inflammatory mediators should be inhibited or augmented and when to do so. In almost all the animal models, anti-LPS therapy is only effective if given before or simultaneously with LPS challenge. Thus, it is very unlikely that anti-LPS treatment alone will change outcome in patients in shock and with organ failure. The situations in which these agents may be the most effective are those in which the patients are in early gram-negative sepsis or as a prophylaxis for high-risk patients.

Anti-Endotoxin Antibodies

The most studied exogenous mediator is endotoxin. This macromolecule is found in gram-negative bacteria as one of the integral components of the outer bacterial lipopolysaccharide cell wall. The molecule can be functionally divided into 3 parts: a highly variable O-polysaccharide side-chain that provides the heat-stable serologic specificity of gram-negative bacteria and is the basis for the O (somatic) antigen type scheme; an oligosaccharide or R-core region composed of approximately 10 monosaccharides; and a lipid backbone referred to as lipid A. The lipid A portion of endotoxin is responsible for the majority of the molecule's toxicity; this portion is also highly conserved and is essentially invariable and ubiquitous.

Experimental studies of the administration of endotoxin have produced in physiologic changes paralleling those of septic shock. Administration of endotoxin in dogs results in severe hypotension. Administration of endotoxin in humans produces an increase in heart rate and cardiac index, and a decrease in peripheral vascular resistance. Later hemodynamic changes include a depressed cardiac state with a dilated left ventricle. Endotoxin administration in rabbits produces DIC and bilateral renal cortical necrosis. Endotoxin administration in both animals and humans results in fever.

Endotoxin (otherwise known as lipopolysaccharide) alone can induce septic shock. Recently, scientists have discovered a major cellular basis for the pathophysiologic response to LPS. Endotoxin (LPS), lipopolysaccharide-binding protein (LBP), and CD14 (a protein found on the surface of monocytes and macrophages) form a complex that is critical for macrophage and neutrophil activation by LPS. LBP is present in the circulation and concentrations are increased in the response to inflammatory stimuli. LBP binds LPS and this LPS-LBP complex then interacts with CD14. CD14 is thought to act as a carrier molecule presenting LPS to a signaling receptor. It is the LPS-sCD14 complex that is thought to be the major module that binds to endothelial cells and triggers the cascade of events leading to septic shock.

Many strategies have been developed to manipulate this complex, including enhanced LPS clearance (anti-LPS antibodies, direct removal of LPS via filtration and use of hemoglobin); direct neutralization of circulating LPS (anti-LPS antibodies, LPS neutralizing proteins); inhibition of LPS-LBP; and removal of both endotoxin and cytokines by hemofiltration, hemadsorption, or hemodialysis. Limited information from using continuous veno-venous hemofiltration (CVVH) on patients with sepsis and oliguric renal failure has suggested that CVVH may increase the predominance of circulating anti-inflammatory cytokines over pro-inflammatory cytokines. This change is thought to be beneficial. However, there are no randomized trial data to support the routine use of plasma filtration or hemodialysis in sepsis. Other interventions include the use of LPS-sCD14 complex modifiers (lipid A analogues, anti-LBP antibodies, anti-CD14 antibodies); blocking cellular LPS receptors (lipid A analogues, anti-CD14 antibodies); and inhibition of cell signal transduction via tryosine kinase or protein kinase C inhibitors.

J5 (POLYCLONAL ANTI-ENDOTOXIN ANTIBODY)   Despite initial promise, five subsequent clinical trials using either J5 antiserum, immune plasma, or intravenous immunoglobulin have not improved survival in sepsis or septic shock.

E5 (MONOCLONAL ANTI-ENDOTOXIN ANTIBODY)   Monoclonal antibodies were developed to produce a more specific anti-endotoxin therapy with less risk for transmission of infection. E5 is an IgM antiendotoxin monoclonal antibody produced by immunizing mice with the core lipopolysaccharide antigen of the E5 mutant of *E. coli.* E5 is manufactured by an antibody-producing hybridoma created by the fusion of mouse spleen cells with a murine myeloma cell line. Preliminary animal studies suggested potential efficacy in septic shock. Double-blind, placebo-controlled investigations of patients in sepsis and septic shock have produced mixed results. Overall mortality has not been consistently reduced in either sepsis or septic shock. The only consistent benefit appears to be a more rapid resolution of organ failure in patients with gram-negative sepsis without hypotension or shock. Allergic reactions to the murine antibody were minimal, and adverse effects were minimal. Overall, the benefits of E5 are too limited to justify the expense of routine use.

HA-1A (HUMAN-HYBRID MONOCLONAL ANTI-ENDOTOXIN ANTIBODY)   While the hybridoma that produces HA-1A is about 80% murine, the antibody itself is predominately human. Studies of HA-1A in animals have met with varied results; some models showing benefit and others showing harm. The first human study with HA-1A originally reported a decrease in mortality and a more rapid resolution of organ system failure in patients with gram-negative bacteremia. HA-1A treatment did not improve survival in patients who had non-bacteremic gram-negative infections and in patients without gram-negative infections. Despite these favorable results, significant concerns were raised, and when the data were analyzed using the original analytic plan, HA-1A did not show a significant effect on survival. In the second placebo-controlled study with HA-1A, mortality in patients with gram-negative bacteremia was unaffected and mortality in patients without gram-negative bacteremia was actually worsened. Further development of HA-1A for the treatment of septic shock was halted.

T88 (MONOCLONAL ANTIBODY)   This is an antibody to a common enterobacterial antigen that has shown promise in animal studies. A phase III trial of patients with sepsis has recently been completed and preliminary data suggest that no overall benefit resulted from the administration of this medication.

LPS-NEUTRALIZING PROTEIN   A number of lipopolysaccharide-neutralizing proteins has been described of which BPI has been most extensively studied and is currently in clinical trials for gram-negative sepsis. BPI is a 55 to 60 kDa neutrophil primary granule protein with 45 percent sequence homology to LBP. BPI has a higher affinity for LPS than LBP and therefore displaces LPS from the LPS-LBP complex. In addition, BPI is cytotoxic for many gram-negative bacteria. Phase II and phase III clinical studies of BPI_{23} are in progress including a multicenter trial of patients with meningococcemia.

LIPID A ANALOGUES   Inhibition of the LPS-LBP interaction is an attractive and potential method of intervention. Analogues based upon the structure of lipid A display reduced or absent cellular toxicity. The most attractive of these compounds is E5331. This compound has been shown to block endotoxin binding to cells, to inhibit LPS-induced TNFa release, and to protect mice from *E. coli* challenge. E5331 inhibits endotoxin-induced cytokine release in human volunteers in response to low-dose endotoxin infusion and phase I/II studies are in progress.

A number of conclusions can be made. Antiendotoxin core-directed antibodies have not shown a reproducible survival benefit for patients with sepsis in 10 clinical trials. However, both E5 and HA1A may have beneficial roles in a subgroup of patients presenting with sepsis. Further investigations are needed to determine if monoclonal antibody to endotoxin is an appropriate therapeutic modality for treatment of septic shock.

The setting where antiendotoxin antibody therapy is therapeutic and cost-effective remains to be defined. Neither E5 nor HA-1A benefited the approximately 30 percent of individuals who did not have a gram-negative infection. Separating patients with gram-positive sepsis from those with gram-negative sepsis based upon clinical symptoms and presenting signs alone is difficult. Early laboratory diagnosis of gram-negative bacteremia or endotoxemia is not currently available. The rapid identification of the presence of gram-negative organisms from potential sites of infection (UTI; pneumonia; abdominal infection; CNS infections; soft tissue infections; decubitus or cellulitis in the setting of diabetes or peripheral vascular disease) is critical for interventions and antiendotoxin antibody therapy. Gram's stain and other rapid assays remain the most valuable tests for rapid identification of gram-negative organisms in clinical specimens.

Anticytokine Therapy

Cytokines are peptides that function as cellular signals to regulate the amplitude and duration the host's inflammatory response. TNF, IL-1, and other cytokines play protective roles in the host's immune response to infection. The host's response to these cytokines consists of recruited and activated neutrophils, macrophages and lymphocytes, increased gene expression, and release of granulocyte colony-stimulating factors. Two cytokines, TNF and IL-1, have been studied extensively in patients with sepsis.

TUMOR NECROSIS FACTOR   Tumor necrosis factor is a polypeptide hormone that can stimulate the release of other mediators including IL-1, IL-6, and PAF. TNF also promotes the metabolism of arachidonic acid, leading to eicosanoid formation. TNF is directly toxic to endothelial cells, increases the adhesion of polymorphonuclear leukocytes to the endothelial cells, and enhances the phagocytic activity of these cells. Finally, TNF reduces the transmembrane potential of muscle cells, depresses myocardial function, and activates coagulation.

Administration of TNF to experimental animals and healthy human subjects duplicates many of the signs and symptoms of sepsis. Injection of TNF into animals results in hemodynamic collapse, multiple-organ injury, and a life-threatening vascular leak syndrome. In humans, injection of TNF produces hypotension, chills, fever, headache, and malaise synchronously with the time of the peak serum TNF level. In addition, rapid and sustained activation of the common pathway of the coagulation system occurs.

Numerous studies have reported a positive correlation between level of serum concentrations of TNF and clinical outcome in patients with sepsis. Significantly higher levels of TNF were found in nonsurvivors of meningococcemia, sepsis, children with infectious purpura, and adult respiratory distress syndrome. Close association of the presence of TNF and septic shock has been demonstrated. Absolute TNF levels were a significant predictive factor for morbidity and mortality in patients with septic shock.

The most compelling evidence that TNF is a causal rather than an associative factor are animal studies demonstrating that antibodies to TNF enhance survival and reduce physiologic derangements after challenge with endotoxin or live bacteria.

Human studies on the feasibility of monoclonal antibodies are currently underway. Two phase I and one phase II trials have reported that administration of monoclonal anti-TNF antibodies was well tolerated and that the serum half-life ranged from 40 to 54 h in septic patients. Unfortunately, the multicenter North American trial of 478 patients with septic shock and the multicenter European trial of 420 patients with sepsis found no reduction in either the 3-day or 28-day mortality. Further analysis suggested significantly more rapid reversal of shock and a decreased incidence of multiorgan failure with anti-TNF antibody administration.

Investigators have attempted to "trap and eliminate" TNF. There are two major types of TNFa receptors that exist in surface-bound and circulating forms. Researchers have developed a recombinant human TNF receptor termed p75. Hypothetically, this receptor should act as a matrix for removal of TNF from the circulation but

preliminary human study found the 28-day mortality was unchanged.

INTERLEUKIN-1   Interleukin-1b is also present in the blood of patients with septic shock. Both TNF and IL-1b induce hypotension, and a combination of the two cytokines is a more potent inducer of shock than either cytokine alone. Both cytokines induce IL-6, a nonlethal cytokine, that serves as an excellent marker of cytokine activity in patients with sepsis. An interleukin-1 receptor antagonist (IL-1ra) has been shown to block the hemodynamic consequences of *E. coli* endotoxin and heat-killed *S. epidermidis* in experimental animals. Human recombinant IL-1ra decreased the mortality rate of endotoxin-induced shock in rabbits and lethal *E. coli*-induced septic shock in primates. In addition, IL-1ra attenuated the decrease in mean artery blood pressure and cardiac output in the primate model.

Results are available from three human studies on the efficacy of IL-1ra in patients with septic syndrome. Reduction in 28-day mortality has been in the two smaller studies but not the largest study with 696 patients.

In summary, most investigators believe that TNF is a key and perhaps central mediator in sepsis. To date, anti-TNF and anti-IL-1 agents have not been shown to consistently improve outcome in the treatment of septic patients.

The Neutrophil

Evidence suggests that the neutrophil has both beneficial and harmful effects in sepsis and septic shock. The neutrophil is a key component of the host defense. Data from neutropenic animals and humans suggest that augmented neutrophil count and function reduce the risk of infection. Conversely, studies have also shown that the neutrophil and its toxic byproducts produce tissue injury and organ dysfunction in sepsis and septic shock.

One area of intense interest is the leukocyte endothelium interaction. This interaction appears to be a crucial step in the inflammatory cascade during sepsis. A membrane glycoprotein complex termed CD11/18 has been suggested as the primary adhesion receptor site on endothelial cells and leukocytes for this interaction, and has been the target of many investigators. This complex is a cell-surface receptor that regulates neutrophil-endothelial cell adhesion, the first step in the neutrophil migration to sites of infection or inflammation.

Researchers have developed monoclonal antibodies against the CD11/18 complex. These antibodies, both in vitro and in vivo, prevent endotoxin, TNF, and complement-induced neutrophil adhesion; injury to endothelial cells; and neutrophil extravascular migration. In some animal models of sepsis and meningitis, monoclonal anti-CD 11/18 antibodies improved mortality rates, decreased adverse hemodynamic parameters, and decreased meningeal inflammation. In a study of dogs pretreated with CD11/18 monoclonal antibody and challenged with TNF, animals treated with CD11/18 had a reduced mortality rate and better arterial oxygenation in the first 24 hours; but this effect was not sustained and the overall survival between the two groups was not significantly different. In a subsequent study in dogs using a similar design but challenged with *E. coli,* investigators found that the CD11/18 monoclonal antibody worsened cardiovascular instability and decreased tissue perfusion during sepsis. In conclusion, studies to date suggest that efforts to inhibit neutrophil function may lead to more tissue injury and more adverse outcomes.

Nitric Oxide

There is good evidence from a large number of studies that humans suffering from sepsis syndrome also have increased systemic nitric oxide production. The higher the nitric oxide level, the more pronounced the septic hypotension seems to be.

Animal studies using nitric oxide synthase inhibitors have mixed results. Researchers have reported that nitric oxide synthase inhibitors restored the responsiveness of septic vasculature to catecholamines and improved survival in endotoxin-challenged animals. Other investigators have reported opposite and harmful effects. These investigators found that the administration of a nitric oxide synthase inhibitor increased systemic and renal vascular resistance, decreased renal blood flow, increased capillary leak, decreased cardiac output, and increased mortality.

Only a handful of studies using an iNOS antagonist, such as arginine analogues, in septic patients has been published. In a small placebo-controlled study with 12 individuals, an arginine analogue was shown to be an effective pressor but was associated with diminished cardiac output and continued high mortality rates. Other limited, uncontrolled studies have shown that the septic patients treated with nitric oxide inhibitors demonstrated transient improvements in blood pressure but no effect on overall mortality. The role of nitric oxide in septic shock warrants further investigation. To date, only nonselective nitric oxide synthetase inhibitors that block both forms of nitric oxide synthase inhibitors have been extensively studied. Future research is most likely to be performed with highly selective inhibitors.

Other Agents

PENTOXIFYLLINE   Pentoxifylline, a methylxanthine derivative, inhibits cytokine activation of neutrophils and the production of TNF by endotoxin-exposed monocytes. This prevents the adherence of neutrophils to endothelium and the release of toxic degranulation products. The mechanism of this action is believed to be via increasing cyclic adenosine monophosphate concentrations. Animal experiments suggest that treatment with pentoxifylline decreases mortality rate and prevents lung injury by inhibiting migration of neutrophils through the pulmonary capillary endothelium. Also, better survival rates and lower meningeal inflammation have been observed in animals with experimental bacterial meningitis. In healthy human volunteers, pentoxifylline inhibits the rise in TNF induced by endotoxin.

CYCLOOXYGENASE INHIBITORS   Two principal pathways of arachidonic acid metabolism exist. The lipoxygenase pathway leads to the production of leukotrienes. Leukotrienes are potent leukocyte chemoattractants. The cyclooxygenase pathway results in the release of thromboxanes and prostaglandins that are important regulators of vascular tone.

Ibuprofen is a cyclooxygenase inhibitor. In animal models of endotoxin shock and shock from peritoneal implantation or intravenous infusion of bacteria, ibuprofen decreases mortality, reverses hemodynamic, metabolic, and blood coagulation abnormalities, improves pulmonary gas exchange, and attenuates the development of increase in microvascular permeability. These results are seen with ibuprofen when administered before and after the septic insult. In preliminary human studies, treatment with ibuprofen attenuates flu-like symptoms and reduces fever, tachycardia, and metabolic rate in volunteers exposed to endotoxin. Recently, the Ibuprofen Sepsis Study Group published its findings of a randomized, double-blind, placebo-controlled trial of intravenous ibuprofen (10 mg/kg per body weight given every 6 h for a total of 8 doses) in 455 patients who had sepsis. It found that the ibuprofen-treated group had significant declines in temperature, heart rate, oxygen consumption, lactic acidosis, and urinary levels of prostacyclin and thromboxane. However, ibuprofen did not reduce the incidence or duration of shock or ARDS, and did not significantly improve the rate of survival at 30 days (mortality, 37 percent with ibuprofen versus 40 percent with placebo). No increase in adverse events (renal dysfunction, gastrointestinal bleeding) was noted in the ibuprofen group. No definitive conclusions can be made from any of the studies regarding the efficacy of ibuprofen in sepsis. However, both human and animal studies to date have suggested that ibuprofen results in decreased metabolic demand on patients with sepsis.

29 CARDIOGENIC SHOCK

Raymond E. Jackson

The syndrome of cardiogenic shock results from an impairment of the heart's pumping action to the degree that there is insufficient blood flow to the tissues to meet resting metabolic demands. Cardiogenic shock is usually caused by contractile failure of the myocardium, although other processes may impair cardiac output enough to produce shock (Table 29-1). Cardiogenic shock is a true emergency requiring rapid recognition and aggressive interventions to avert the extremely high mortality.[1,2,3,4,5] and [6]

TABLE 29-1   Etiology of Cardiogenic Shock

EPIDEMIOLOGY

Cardiogenic shock is the most frequent cause of in-hospital death from acute myocardial infarction (AMI), resulting in 50,000 to 70,000 deaths per year in the United States alone. The reported incidence in recent studies of cardiogenic shock after AMI is about 5 to 7 percent. Since the mid-1980s, the incidence seems to be decreasing, possibly secondary to early reperfusion, invasive monitoring, and rapid correction of hypovolemia. Cardiogenic shock typically occurs early in the course of an AMI, with a median time of about 7 h from the onset after symptoms to the recognition of shock. Although a small minority may present to the emergency department in shock, it is more likely that a patient may develop signs of shock while in the department. Some factors have been identified as independent predictors of the risk for developing cardiogenic shock after AMI: advanced age, female gender, large myocardial infarction as indicated by marked increases in creatinine kinase (CK), an anterior wall infarction, previous MI, previous congestive heart failure (CHF), multivessel disease, proximal occlusion of the left anterior descending coronary artery, and diabetes mellitus.[7] Increased numbers of risk factors convey greater risk and indirectly reflect a unifying principle: The greater the amount of myocardium at risk, the greater is the probability of developing shock. Early identification of patients at increased risk may reduce the incidence of shock with aggressive strategies for reperfusion. Despite recent major advances in the treatment of acute cardiac conditions and heart failure, the mortality from cardiogenic shock remains 70 to 90 percent with medical treatment alone.

PATHOPHYSIOLOGY

Although there are many etiologies for cardiogenic shock, most occur from acute left ventricular (LV) infarction (see Table 29-1). While some degree of LV dysfunction occurs with most acute infarcts, once 40 percent of the LV mass is akinetic, clinical evidence of shock is likely to ensue. This amount of LV mass loss need not have occurred with the current AMI, since there may be preexisting impairment from previous infarcts. Therefore, a patient with a past history of infarction may develop cardiogenic shock with a relatively small new MI.

In cases of cardiogenic shock after AMI, the infarct border zone appears irregular with evidence of marginal infarct extension. Myocytes in this border zone demonstrate evidence of various stages of cell death, probably due to inadequate collateral blood flow, which is exacerbated further by hypotension. Areas of focal necrosis develop throughout the right and left ventricles, suggesting widespread coronary vascular pathology and perfusion insufficiency. Resulting hypotension leads to further reduction in coronary perfusion pressure, exacerbating already compromised myocardial oxygen delivery and leading to additional loss of myocardium, additional loss of contractility, additional hypotension, and so on. This process leads to a progressive and rapid cycle of deterioration into irreversible shock. If the patient develops pulmonary edema, the hypoxia and acidosis further diminish contractility.

The severe reduction in cardiac output and the subsequent compensatory mechanisms result in acute oliguria, hepatic failure, gastrointestinal ischemia, anaerobic metabolism, lactic acidosis, and hypoxia. All these further impair myocardial contractility. Salvage of myocardium by preventing infarct extension into the border zone can prevent development of shock. Although loss of LV mass is the major predictor of shock, disease in other coronary arteries, diastolic dysfunction, and arrhythmias can amplify the negative effects of loss of LV mass and produce shock with a loss of myocardium of less than 40 percent.

Many compensatory mechanisms are recruited in the face of an AMI in an effort to maintain cardiac output and tissue perfusion. Initially, the sympathetic nervous system is activated, leading to an increased heart rate and arterial and venoconstriction. The sympathetic activity increases myocardial contractility, which can be visualized as compensatory hyperkinesis in the uninvolved myocardium by echocardiography. When the uninvolved myocardium is fibrotic or blood flow is compromised due to diffuse coronary disease, this compensatory hyperkinesis does not occur. Lack of compensatory hyperkinesis results in increased end-systolic LV volume, increasing the probability of cardiogenic shock. The renin-angiotensin system is activated by the sympathetic stimulation of renal nerves and the inadequate perfusion pressure. Increased angiotensin II activity leads to peripheral vasoconstriction and aldosterone synthesis, causing sodium and water retention and increasing blood volume. When these compensatory actions are inadequate or overwhelmed, shock may ensue.

Right ventricular (RV) infarction can occur in up to 50 percent of inferior wall infarctions. Although hypotension is not uncommon with RV infarction, shock is much less common, accounting for only 3 to 4 percent of the cases of cardiogenic shock. The major determinate of shock with RV infarction is the presence of concomitant LV dysfunction. With decreased LV contractility, the normal systolic septal function of aiding the RV to perfuse the pulmonary bed is impaired. This leads to loss of LV preload, hypotension, and a further decrease in coronary perfusion pressure.

Hemodynamic assessment of patients with AMI has disclosed four profiles based on measurement of cardiac output (either decreased or not) and LV preload (either elevated or not):

Class I: Normal cardiac output and LV preload. Infarction is tolerated without significant hemodynamic impairment; the prognosis is very good, with about a 3 percent mortality rate.

Class II: Normal cardiac output but elevated LV preload. Pulmonary edema is usually evident on clinical examination. Vasodilation and diuresis result in clinical improvement. Overall mortality is approximately 9 percent.

Class III: Decreased cardiac output but normal LV preload. There is relative or absolute volume deficiency. Cardiac output can be improved by volume infusions that

increase stroke volume utilizing the Frank-Starling relationship. Overall mortality is about 23 percent.

Class IV: Decreased cardiac output and an elevated LV preload. Clinical shock is present. Overall mortality is 50 percent or greater.

Patients with occult cardiogenic shock may be clinically indistinguishable from those with stable end-stage CHF. [8] Patients at risk appear to be those with CHF duration greater than 3 months and known decreased ejection fraction of less than 30 percent.

CLINICAL FEATURES

The patient with evolving cardiogenic shock often will exhibit a rapid progression of findings indicating poor perfusion. Clinical evaluation, diagnostic testing, and treatment are initiated simultaneously. History from the patient is often blunted by the severity of the patient's condition, so family, EMS personnel, and medical records should supplement the patient's history. Key information includes current medications, allergies, and past history of MI, CHF, diabetes mellitus, and renal failure. Although the patient may experience chest pain, ischemic equivalents include profound weakness, shortness of breath, or a feeling of impending doom.

The hallmark of shock is hypoperfusion, often, but not always, accompanied by hypotension. The systolic blood pressure is typically less than 90 mmHg, although it may be within a "normal" range, especially if the patient has preexisting hypertension. Another blood pressure parameter that may be more sensitive is a 30 mmHg decrease in mean blood pressure or a pulse pressure (systolic-diastolic) of less than 20 mmHg. Although a compensatory sinus tachycardia is common and does not require specific treatment, excessively high or low heart rates do require immediate therapy. Compensatory sympathetic stimulation leads to cool and clammy skin. Oliguria reflects development of poor renal perfusion. Diminishing cerebral perfusion and hypoxemia lead to anxiety and confusion.

Signs of acute LV failure accompanied by pulmonary edema are tachypnea, rales, wheezing, and frothy sputum. The presence of jugular venous distension in the face of hypotension without signs of pulmonary edema suggest acute RV failure, from either RV infarction, tamponade, or pulmonary embolus. Careful cardiac examination is needed to identify an S_3 or S_4. Mitral regurgitation due to chordae tendinae rupture will exhibit a soft holosystolic murmur at the apex radiating to the axilla, although the murmur is often obscured by rales. Mitral regurgitation due to papillary muscle dysfunction usually will not be completely holosystolic. It starts with the first heart sound but terminates before the second. Acute septal rupture (acute ventricular septal defect) initially will have a loud parasternal ejection murmur, often with a palpable thrill, that decreases in intensity as the intraventricular pressures equalize.

DIAGNOSIS

Although the diagnosis of cardiogenic shock can be suspected from the initial history and physical examination, ancillary tests are essential for confirmation, to define the specific causes, and to direct therapy. Findings of an AMI on the standard 12-lead electrocardiograph (ECG) support the diagnosis of cardiogenic shock. In cases of an inferior wall infarction, patients at risk to develop cardiogenic shock will have ST-segment elevation in the right-sided precordial leads, ST-segment depression in the left precordial leads, or third-degree heart block. Diffuse ST-T changes can be seen with acute myocarditis. The absence of ECG changes consistent with AMI suggests alternate causes of shock, such as aortic dissection, pulmonary embolus, pericardial tamponade, acute valvular insufficiency, hemorrhage, or sepsis.

The chest radiograph (usually an anteroposterior view obtained with a portable machine) should be inspected for evidence of pulmonary vascular congestion: Kerley-B lines, cephalization, interstitial edema, or frank pulmonary edema. A large heart size suggests prior CHF, and a globular cardiac shape provides a clue for chronic pericardial effusion. A wide mediastinum may indicate aortic dissection.

Baseline laboratory studies are of little immediate diagnostic value but provide a hematologic and metabolic assessment of the patient. The severity of tissue hypoperfusion is reflected in the degree of metabolic acidosis, as measured by arterial blood gases, serum bicarbonate, or serum lactate. Serum markers of myocardial injury support the clinical and ECG evidence: CK-MB, troponin I, and troponin T.

The best bedside diagnostic tool available for differentiating the causes of cardiogenic shock is the two-dimensional transthoracic echocardiogram (TTE). This imaging modality can reveal signs of myocardial pump failure by detecting regional hypokinetic, akinetic, or dyskinetic abnormalities. The TTE can detect early signs of distress by visualizing lack of compensatory hyperkinesis in uninvolved segments, which can alert the clinician to take steps to prevent further loss of myocardium, initiate inotropic support, and consult the invasive cardiologist. The TTE also can evaluate other causes of decreased cardiac output. The presence of acute RV dilatation, tricuspid insufficiency, paradoxical systolic septal motion, and high estimated pulmonary artery and right ventricular pressures suggest pulmonary hypertension, often seen with acute pulmonary embolus. Loss of RV contractility, RV dilatation, and normal estimated pulmonary pressures are observed more commonly with RV infarction. Use of the color flow Doppler can easily diagnose acute valvular stenosis or insufficiency, as well as septal and free wall rupture. Pericardial effusion with collapse of the right atrium or diastolic right ventricle collapse indicates cardiac tamponade. Although not the best imaging modality for aortic dissection, TTE sometimes can visualize dissection of the aortic root.

Although more often done in the intensive care unit than in the emergency department, invasive hemodynamic monitoring with a pulmonary artery catheter can provide confirmatory information and guide treatment. As noted earlier, patients with cardiogenic shock have decreased cardiac output (defined as a cardiac index <2.2 L/min/m^2) and elevated LV preload (defined as a pulmonary artery occlusion or wedge pressure >18 mmHg). Because of impaired tissue oxygen delivery with continued metabolic need, there is an elevated oxygen extraction (arterial-venous oxygen content difference >5.5 mL/dL), and blood returning back to the heart is low in oxygen (pulmonary artery oxygen saturation <60 percent or partial pressure less than 30 mmHg). Continuous hemodynamic monitoring and treatment are facilitated by using both (1) a balloon-tipped pulmonary artery catheter with continuous oximetry and cardiac output monitoring and (2) an arterial catheter for pressure measurements. There is a fair correlation between clinical and hemodynamic assessments of cardiac output and LV preload during an AMI, but the overlaps between the different classes limit therapy based solely on clinical criteria.

Noninvasive hemodynamic monitoring by a variety of techniques shows promise, but the currently available devices lack sufficient accuracy for clinical use where important therapeutic decisions require precise measurement.

TREATMENT

In the prehospital setting, the medical control physician should consider directing the patient suspected to be in cardiogenic shock to a facility that has an intraaortic balloon pump, 24-h emergency percutaneous transluminal coronary angioplasty (PTCA), and emergent coronary artery bypass graft (CABG) capabilities.

In both the prehospital and emergency department setting, monitoring should begin immediately: oxygen, intravenous access, cardiac monitor, and continuous pulse oximetry. When detected, hypoxia, hypovolemia, rhythm disturbances, electrolyte abnormalities, and acid-base alterations should be corrected. In the setting of an AMI, aspirin should be given unless the patient is allergic or has an absolute contraindication. Pain control can be attempted judiciously using intravenous nitroglycerin or morphine sulfate with attentive concern for maintaining the systemic blood pressure. In the absence of evidence for pulmonary edema, careful boluses of normal saline (100–250 mL) should be administered. As noted earlier, some patients with AMI and hypotension have a degree of relative or absolute volume deficiency and benefit from fluid administration. In a RV infarct with hypotension, fluid support is the first action. Oral tracheal intubation is often necessary to maintain oxygenation and ventilation, but the change to positive-pressure ventilation may further decrease preload and cardiac output. Alternatively, continuous positive airway pressure can be used in selected patients with a reduction in the need for intubation and a trend toward decreased mortality. [9]

In the absence of profound hypotension, dobutamine is a mainstay of initial pharmacologic treatment. [10,11] This sympathomimetic agent improves myocardial contractility and augments diastolic coronary blood flow without inducing excessive tachycardia. Usually, cardiac output increases and LV filling pressures decrease. Infusions should be started at 2.5 to 5.0 µg/kg per minute, titrating at 2.5 µg/kg per minute increments to achieve the desired effect. Increases should be stopped at 15 µg/kg per minute. With profound hypotension (systolic pressure <70 mmHg), dopamine is preferred, either as a single agent or in combination with dobutamine. Dopamine is started at 2.5 to 5.0 µg/kg per minute and titrated to desired effect. The lowest possible dose of dopamine should be used because this agent can produce excessive tachycardia, increase myocardial oxygen demands, and induce arrhythmias. When shock persists despite use of these agents, mechanical inotropic support with an intraaortic balloon pump is required. [12,13]

The intraaortic balloon pump can temporarily stabilize the hemodynamics in cardiogenic shock. [12,13] It decreases afterload and augments diastolic pressure and coronary perfusion, resulting in decreased myocardial work. It is only temporizing and does not improve survival without successful revascularization of the culprit coronary artery or surgical correction of an acute mechanical catastrophe. [13,14] If a patient requires transfer for surgical therapy, the balloon pump can be used to

support the patient during transport.

Limiting infarction size with reperfusion is the key to successful therapy of cardiogenic shock. Although early use of fibrinolytic therapy in AMI has been shown to markedly decrease morbidity and mortality, once cardiogenic shock has developed, the mortality rate remains high, at about 75 percent. One reason for the high mortality despite the use of fibrinolytics is that documented clot lysis in the infarct-related artery and reperfusion in cases of cardiogenic shock is only 40 to 50 percent with these agents. Another reason is that shock combined with the existence of multivessel disease limits the effectiveness of these agents. Thus, while fibrinolytic agents are successful in preventing cardiogenic shock in AMI, they have much less benefit once shock has developed.

A number of nonrandomized trials have reported relatively good mortality rates as low as 30 percent with primary PTCA in conjunction with balloon pump support for patients in cardiogenic shock. Although these results await confirmation by randomized trials, PTCA, if available within 60 minutes, appears to be the reperfusion modality of choice for patients who present with or develop cardiogenic shock in the emergency department. [5,13] Conversely, in hospitals without PCTA immediately available, fibrinolytics should be administered as soon as possible.

Emergent CABG also has been reported to decrease mortality in cardiogenic shock. However, the extensive surgical and medical resources required, as well as the operative risk for these seriously ill patients, have limited its use. For patients who develop a mechanical complication of infarction (e.g., ventricular septal rupture or acute mitral insufficiency) with cardiogenic shock, temporary inotropic support with the intraaortic balloon pump followed by early surgical repair produces the best outcome.

Acute RV failure leading to cardiogenic shock may occur with RV infarction. Although attempts to reverse hypotension should begin with rapid infusion of normal saline, dobutamine should be started if no improvement is observed after 1 L. As with LV infarction, early reperfusion is essential.

Acute mitral valve insufficiency accounts for about 8 percent of cases of cardiogenic shock and can be suspected at the bedside in the face of sudden hypotension, pulmonary edema, and a holosystolic apical murmur. Hemodynamic support can be initiated with dobutamine and nitroprusside to support contractility and provide afterload reduction to promote forward systemic blood flow. The intraaortic balloon pump is also beneficial for temporary support. Acute septal rupture accounts for about 4 percent of cases of cardiogenic shock and is treated with dobutamine, nitroprusside, and the intraaortic balloon pump. Confirmatory evidence for these emergent conditions with two-dimensional echocardiography should be sought concomitant with emergency notification of the cardiac surgical team.

Clearly, not all patients may benefit from aggressive care. The decision to perform or withhold therapies should be made in light of the patient's desires and wishes. Factors that may influence the decision to pursue aggressive therapy include advanced age, diminished functional status, and comorbid conditions.

30 ANAPHYLAXIS AND ACUTE ALLERGIC REACTIONS

Shaheed I. Koury
Lee U. Herfel

Anaphylaxis, a term used inconsistently in the literature, is a severe systemic hypersensitivity reaction characterized by either hypotension or airway compromise that is potentially life threatening in nature and that is caused by chemical and IgE mediators released from mast cells. *Anaphylactoia* was coined to describe responses clinically identical to anaphylaxis that were found to be non-IgE mediated and that did not require a sensitizing exposure.[1] Recent work has shown that the final pathway in "classic" anaphylactic and anaphylactoid reactions is identical, and *anaphylaxis* is now used to refer to both IgE and non-IgE reactions.[2] Hypersensitivity is an exaggerated immune system response to presented antigens. Anaphylaxis lies at one end of a gradient of hypersensitivity reactions, and it is important to keep in mind that even apparently mild allergic reactions may progress to severe anaphylaxis.

EPIDEMIOLOGY

Neither age, occupation, race, gender, nor geographic factors have been shown to increase the risk of anaphylaxis.[3] Most studies indicate that atopic individuals (sufferers of asthma, allergic rhinitis, atopic dermatitis, etc.) are at no greater risk for anaphylaxis from insect stings or drugs reactions than are nonatopic individuals.[1] Atopy is a risk factor, however, for idiopathic anaphylaxis.[4] The only other factors known to increase the risk of anaphylaxis are a previous exposure to a sensitizing antigen and a previous anaphylactic reaction. Notably, anaphylaxis recurrence risks are not 100 percent for reexposure. The reoccurrence rate is 40 to 60 percent for insect stings, 20 to 40 percent for radiocontrast agents, and 10 to 20 percent for penicillin.[1]

Limited data are available on the incidence and prevalence of anaphylaxis. The rate of fatal anaphylaxis is approximately 4 deaths per 10 million people per year.[5] The incidence of allergic reactions and anaphylaxis in one study at a university hospital emergency department was 0.5 percent (5 per 1000) and 0.02 percent (2 per 10,000) of the total emergency department population, respectively.[6] The most common causes of serious anaphylaxis are antibiotics, such as penicillin, and radiocontrast agents.[1] Penicillin is estimated to cause 100 to 500 deaths in the United States annually, with a systemic allergic reaction occurring in 1 per 10,000 exposures.[3] *Hymenoptera* stings constitute the next most common cause of anaphylaxis, with fewer than 100 deaths in the United States annually.[1] Table 30-1 contains a partial list of some of the more common causative agents.

DRUGS
Penicillin and related antibiotics
Aspirin
Trimethoprim-sulfamethoxazole
Vancomycin
Nonsteroidal anti-inflammatory agents

FOODS AND ADDITIVES
Shellfish
Soybeans
Nuts
Wheat
Milk
Eggs
Monosodium glutamate
Nitrates and nitrites
Tartrazine dyes

OTHER
Hymenoptera stings
Insect parts and molds
Radiographic contrast material

TABLE 30-1   Common Causes of Anaphylaxis and Anaphylactoid and Allergic Reactions

PATHOPHYSIOLOGY

Allergic or hypersensitivity reactions vary from localized pruritus to anaphylactic shock and death. The basic mechanism underlying allergic reactions is mast cell degranulation and mediator release.[7] The causes of mast cell degranulation include IgE cross-linking, complement activation, nonimmunologic or direct activation, modulation of arachadonic acid metabolism, exercise, catamenial effects, and idiopathic causes.[7,8]

Hypersensitivity has traditionally been divided into four types by Coombs and Gell. Type I hypersensitivity is mediated by IgE and IgG and involves cross-linking of two adjacent IgE molecules on a mast cell or basophil. Type II hypersensitivity is the reaction of IgG and IgM to cell-surface antigens, resulting in complement activation and killer-cell phagocytosis. Type III involves soluble antigen-antibody complexes that activate the complement system. Type IV is mediated by activated T lymphocytes and has not been mentioned in the literature in relation to anaphylaxis.[9] Research has shown that there is much overlapping among the types and has identified mechanisms that do not fit into the system. Therefore, the classification is for the most part not used in the current literature.

The "classic" anaphylaxis (type I hypersensitivity) pathway involves the production of IgE and requires two separate exposures to either an antigen or a hapten-protein antigenic complex. An antigen is a molecule, usually a protein, that can stimulate the immune system. Haptens are molecules, such as penicillin, that are too small to stimulate the immune system unless they are bound to endogenous proteins (e.g., albumin), resulting in an antigenic complex large enough to be recognized.[9]

Antigens are internalized by antigen-presenting (macrophages and dendritic cells), processed, and then presented externally on the cell surface bound to the major histocompatibility (MHC) 2 complex. T-helper cells recognize the antigen-MHC 2 complex and subsequently induce specific B lymphocytes to undergo proliferation and differentiation to plasma cells. These plasma cells produce and release IgE antibody into the bloodstream. The IgE antibody (like all antibodies) has a variable and a constant region. The variable region is specific for the antigen that initiated the immune response, and the constant region binds to IgE receptors present in vast quantities on mast cells (and basophils), resulting in mast cells covered with antigen-specific IgE molecules. This sensitizing process takes days to weeks, resulting in a latent period during which no clinical response to antigen occurs. After the latent period, on antigen reexposure the variable regions on the IgE bind the antigen, resulting in bridging of adjacent IgE molecules on the mast cell surface. This IgE-antigen-IgE bridging results in activation of serine proteases, a rise in intracellular cyclic AMP and calcium levels, new mediator synthesis, and mast cell degranulation with release of preformed chemical mediators.[3] Examples of IgE-mediated reaction triggers include antibiotics, foods, and *Hymenoptera* stings.

Complement-mediated anaphylactic reactions occur after the administration of blood products secondary to the formation of immune complexes. Immune complex formation results in activation of the complement pathway and formation of the anaphylatoxins C3a and C5a, which cause mast-cell and basophil degranulation.[7,8] Immune complexes include IgG aggregates and IgA-IgG from human immunoglobin therapy, and IgE-IgA complexes formed in selective IgA-deficient patients (1:600

people) who have been given blood products repeatedly.[7] Administration of mismatched blood also causes complement activation secondary to the production of IgG and IgM antibodies against transfused red blood cells, resulting in cell lysis, agglutination, anaphylatoxin generation, and subsequent anaphylaxis. This is an example of a cytotoxic type II reaction.[7]

Nonimmunologic anaphylaxis occurs when an exogenous substance results in mast-cell degranulation either by direct stimulation of the mast cell or by unknown mechanisms. These reactions have been referred to as anaphylactoid reactions.[1,7] Substances that cause anaphylactoid reactions include radiocontrast dyes, muscular depolarizing drugs, narcotics, and dextrans. The mechanism of radiocontrast reactions is uncertain but is believed to be caused by the activation of the complement, contact, and coagulation systems. Since the advent of nonionic contrast dyes, the incidence of reactions has decreased. Narcotics and neuromuscular depolarizing drugs cause direct release of mediators from mast cells, although there is little documentation of generalized reactions.[7]

Aspirin and other nonsteroidal drugs cause anaphylactic symptoms by a non-mast-cell process. The mechanism is not precisely known but is thought to involve modulation of the cyclooxygenase-arachidonic acid metabolism pathway. Five to 10 percent of asthmatics have these reactions, which include bronchospasm, bronchorrhea, rhinorrhea, and, rarely, hypotension. Nonasthmatics may experience urticaria, angioedema, and hypotension.[7]

Idiopathic anaphylaxis is by definition of unknown cause. Patients suffer recurrent attacks, with no trigger identified after extensive evaluation by an allergist. They often need prolonged treatment with alternate-day prednisone to maintain remission from attacks.[4] A rare subset of anaphylaxis is catamenial, or menstrual, anaphylaxis. The patient has repeated attacks, often coinciding with the luteal phase of menstruation due to hypersensitivity to endogenous progesterone. Treatment is with medical ovarian suppression by either luteinizing-hormone-releasing-hormone agonists or oophorectomy.

Concurrent use of b-blocking drugs by the patient is a risk factor for severe prolonged anaphylaxis. In one study, three out of five patients who had severe protracted reactions were being treated with b-blocking drugs. Furthermore, they were the only patients in the study who were taking b blockers out of the 67 anaphylactic patients in the study.[6] Use of epinephrine in patients taking b blockers may result in severe hypertension secondary to unopposed a-adrenergic stimulation.[1] b blockers should be discontinued in any patient with new-onset anaphylaxis and should not be prescribed for any patient with a history of anaphylaxis.[3] As would be expected, asthmatics are often more refractory to the treatment of allergic bronchospasm.[1]

CLINICAL FEATURES

Anaphylaxis is the most severe life-threatening form of a systemic allergic reaction involving respiratory or cardiovascular compromise. The clinician must keep in mind that even mild, localized urticaria can progress to full anaphylaxis and death. The clinical signs of systemic allergic reactions include urticaria, angioedema, abdominal pain or cramping, nausea, vomiting, diarrhea, bronchospasm, rhinorrhea, conjunctivitis, dysrhythmias, and/or hypotension.[3] Anaphylaxis can include any combination of these signs along with hypotension or airway compromise. Dermatologic manifestations of pruritus and urticaria are the most common initial symptoms. The "classic" presentation of anaphylaxis begins with pruritus, cutaneous flushing, and urticaria. These symptoms are followed by a sense of fullness in the throat, anxiety, a sensation of chest tightness, shortness of breath, lightheadedness, and finally loss of consciousness.[5] A complaint of a "lump in the throat" and hoarseness heralds life-threatening laryngeal edema in a patient with symptoms of anaphylaxis.

In the vast majority of patients, signs and symptoms begin within 60 min after exposure. In general, the faster the onset of symptoms, the more severe the reaction, as evidenced by the fact that one-half of anaphylactic fatalities occur within the first hour.[10] After the initial signs and symptoms have abated, patients are at risk for a recurrence of symptoms. This biphasic phenomenon occurs in 3 to 20 percent of patients.[6] The effect is caused by a second phase of mediator release, peaking 4 to 8 h after the initial exposure and exhibiting itself clinically 3 to 4 h after the initial clinical manifestations have cleared. The pathophysiology of this phenomenon is poorly understood.[6]

DIAGNOSIS

The diagnosis of anaphylaxis is by history and physical examination, and is easily made with a clear history of exposure, such as a bee sting, shortly followed by the multisystemic signs and symptoms described above. Unfortunately, diagnosis is not always so evident. Symptom onset is delayed over an hour in a small percentage of cases.[3] Often, such as in food allergy, the inciting substance may not be known. The differential diagnosis of anaphylactic reactions is extensive, including vasovagal reactions, myocardial ischemia, arrhythmias, status asthmaticus, seizure, epiglottitis, hereditary angioedema, foreign-body airway obstruction, carcinoid, mastocytosis, and drug reactions.[1] The most common anaphylaxis imitator is a vasovagal reaction, which is characterized by hypotension, pallor, bradycardia, diaphoresis, weakness, and sometimes syncope.[3]

Laboratory values have essentially no role in making the diagnosis. Histamine levels are elevated for 5 to 30 min postreaction and thus are usually in decline by presentation to the emergency department.[3] Tryptase is a neutral protease of unknown function in anaphylaxis that is found only in mast-cell granules and is released with degranulation. Serum tryptase levels are elevated for several hours and are useful for research purposes for later confirmation of an anaphylactic episode.[1]

TREATMENT

Emergency Treatment

The patient having an anaphylactic reaction, as defined by airway compromise or hypotension, is a true medical emergency and must be rapidly assessed and treated. Exposure to the causative agent, if identified, must be terminated if ongoing. Vital signs, intravenous (IV) access, oxygen, cardiac monitoring, and pulse oximetry measurements should be ordered immediately. Securing the airway is the first priority. The airway should be examined for angioedema. If angioedema is producing respiratory distress, the patient should be intubated immediately, since delay may result in complete airway obstruction secondary to progression of angioedema. An endotracheal tube one or more sizes smaller than normal may be needed.[10] The patient should be given sufficient oxygen to maintain a pulse oximetry value greater than 92%. Intubation is indicated if hypoxemia is refractory to 100% oxygen therapy.

Epinephrine is the cornerstone of treatment for anaphylactic reactions. If the patient has severe bronchospasm, laryngeal edema, signs of upper airway obstruction, respiratory arrest, or signs of shock, IV epinephrine is indicated.[10] Initially, 100 µg of IV epinephrine should be given in a 1:100,000 dilution. This can be done by placing 0.1 mL of 1:1000 epinephrine in 10 mL of normal saline solution (NS) and infusing it over 5 to 10 min (a rate of 1 to 2 mL/min).[2,11] If the patient is refractory to the initial bolus, then an epinephrine infusion can be started, according to the 1997 Advanced Cardiac Life Support (ACLS) guidelines, by placing 1 mg of 1:1000 epinephrine in 500 mL of dextrose in water (D_5W) or NS and running at a rate of 1 to 4 µg/min (0.5 to 2 mL/min), titrating to effect. The pediatric epinephrine infusion rate starts at 0.1 µg/kg/min and can be increased up to 1.5 µg/kg/min.[11] If hypotension is present, the patient should receive a NS bolus of 1 to 2 L concurrently with the epinephrine infusion. For hypotension refractory to 2 L NS infusion and epinephrine, colloid infusion should be considered. Physicians are often hesitant to give IV epinephrine due to its side effects. It should be stressed that the initial adult dose is 100 µg (0.1 mg) IV of 1:100,000 dilution given over 5 to 10 min and that the dose can be stopped immediately if arrhythmias or chest pain occurs.

For less severe signs, such as decreasing blood pressure without hypotension [systolic blood pressure (SBP) > 90 mmHg], symptomatic dyspnea, abdominal cramps, and urticaria, subcutaneous (SC) epinephrine can be given.[10] The dose is 0.3 to 0.5 mL of 1:000 epinephrine (pediatric dose 0.01 mL/kg 1:1000) SC, repeated every 5 to 10 min according to response. If the patient is refractory to treatment despite repeated SC epinephrine, then IV epinephrine infusion should be instituted.

The first-line therapies for anaphylaxis are epinephrine, IV fluids, and oxygen, which have immediate effect during the acute stage of anaphylaxis. The second-line drugs are antihistamines, corticosteroids, glucagon, albuterol, and aminophylline. These drugs are used to prevent recurrences and treat anaphylaxis refractory to the first-line treatments. All patients with anaphylaxis should receive corticosteroids and antihistamines. Methylprednisolone 125 mg IV and a histamine $_1$ (H_1) blocker, such as diphenhydramine 25 to 50 mg IV, should be given.[2] Since the histamine$_2$ (H_2) blockers have been shown to be effective in shock refractory to epinephrine, fluids, steroids, and H_1 blockers, it is recommended that H_2 antihistamines be given as well.[2,7] It is the authors' opinion that an H_2 blocker other than cimetidine should be used in anaphylaxis. Cimetidine prolongs metabolism of b blockers, resulting in a possible prolongation of the anaphylactic state in patients who take b blockers. Cimetidine likewise interferes with the metabolism of many other drugs, including aminophylline, which may be used in refractory bronchospasm. After the initial IV dose of steroids and antihistamines, the patient may be switched to oral medication (Table 30-2).

TABLE 30-2 Anaphylaxis and Allergic Reactions Drug Dosing

If wheezing or tightness is part of the patient's presentation, a bronchodilator, such as a continuous albuterol nebulizer, should be instituted. For severe bronchospasm refractory to the above-mentioned treatments, aminophylline can be added. The dose should be 5 mg/kg IV over 30 min, with a lower rate for elderly patients, patients taking cimetidine or erythromycin, and patients with cardiac or liver failure. [2]

For patients taking b blockers with hypotension refractory to fluids and epinephrine, glucagon should be used in a dose of 1 mg IV every 5 min until hypotension resolves, followed by an infusion of 5 to 15 µg/min. [2] The side effects of glucagon include nausea, vomiting, hypokalemia, dizziness, and hyperglycemia.

For minor allergic reactions that do not involve hypotension or respiratory symptoms, epinephrine is not needed. The causative agent should be identified and discontinued. The patient may be given oral (PO), intramuscular (IM), or IV diphenhydramine 25 to 50 mg and observed for a response for at least 1 h. [10] If the patient is stable, he or she can be discharged on an antihistamine and prednisone 20 mg bid or 40 mg qd for 4 days. [2]

DISPOSITION

Admission

An unstable patient with anaphylaxis refractory to treatment should be admitted to the intensive care unit. All patients who receive epinephrine should be observed for a minimum of 6 h. If the patient remains symptom free during this time, he or she may be discharged home.[2] Factors to consider in discharge planning include distance from medical care, whether the patient lives alone, significant comorbidity, age, past history of severe reaction, and the use of b-blocking agents. [6]

Outpatient Care

For all allergic reactions, the patient should be instructed on how to eliminate exposure to the causative agent. This may be difficult, especially in the case of food allergy. An adult or pediatric Epi-Pen prescription should be given with clear instructions for serious allergic reactions or anaphylaxis when the risk of another reaction is judged to be substantial. The patient should be referred to an allergist for in-depth preventive management and attempts at allergen identification. [12] Patients with anaphylactic reactions should be encouraged to wear Medic-Alert bracelets. Any anaphylactic patient on a b blocker should be switched to another antihypertensive drug.[1] The patient should be instructed to return immediately if there is any recurrence of symptoms.

URTICARIA AND ANGIOEDEMA

Urticaria, or hives, is a cutaneous IgE-mediated reaction marked by the development of pruritic, erythemic wheals of varying size that generally disappear quickly. Erythema multiforme is a more pronounced urticarial variant, characterized by typical target lesions. Angioedema is believed to be an IgE-mediated reaction characterized by edema formation in the dermis, most generally involving the face and neck. These manifestations may accompany many allergic reactions. As with all allergic manifestations, a detailed history of exposures, ingestions, medications, and infections and a family history should be obtained. If an etiologic agent can be identified, future reactions may be avoided. Treatment of these reactions is generally supportive and symptomatic, with attempts to identify and remove the offending agent. Epinephrine, antihistamines, and steroids are most often tried. Oral antihistamines and steroids for several days may be beneficial. The addition of an H$_2$ receptor blocker, such as ranitidine, may also be useful in more severe cases. Cold compresses may be soothing to affected areas. Referral to an allergy specialist is indicated.[13]

Angioedema of the tongue, lips, and face occurs in 0.1 to 0.2 percent of patients taking angiotensin-converting enzyme (ACE) inhibitor antihypertensives. Fortunately, most cases are mild and transient. Management is supportive, with special attention to the airway, which can become occluded rapidly and unpredictably. One must anticipate and be prepared for airway problems in any patient who presents with angioedema. Typical allergic-reaction drugs, such as antihistamines and steroids, are not proven to be beneficial due to the pathophysiology of ACE-inhibitor angioedema. Normally, ACE inactivates bradykinin, a potent vasodilator, and converts angiotensin I to angiotensin II, a potent vasoconstrictor. ACE inhibitors therefore allow accumulation of bradykinin and angiotensin I, which leads to vasodilation, hypotension, and angioedema. Also, ACE inhibitor angioedema is not associated with an increase in IgE. For this reason, angioedema is usually refractory to standard medical therapy. Epinephrine, antihistamines, and steroids are still used; however, their benefits have not been clearly demonstrated in the literature. Immediate withdrawal from the ACE inhibitor is indicated, and another antihypertensive should be prescribed as needed. Patients with mild swelling and no evidence of airway obstruction can be observed in the emergency department and discharged if swelling diminishes. Rebound or recurrent swelling will not occur unless the patient takes an ACE inhibitor again. Patients with moderate-to-severe swelling, dysphagia, or respiratory distress are best admitted for close observation. [14,15]

Hereditary angioedema is an autosomal dominant disorder with a characteristic complement pathway deficiency: low levels of C1 esterase inhibitor or elevated levels of dysfunctional C1 esterase inhibitor with low levels of C4 between acute attacks. Reactions often involve the upper respiratory tract and gastrointestinal tract. Attacks can last from a few hours to 1 to 2 days. Minor trauma often precipitates a reaction. Many of the typical treatments of allergic problems, such as epinephrine, steroids, and antihistamines, have been tried, but their effectiveness is not clearly demonstrated. [13] Prophylaxis of acute attacks is possible with attenuated adrogens, such as stanozolol 2 mg/d or danazol 200 mg/d.[16] Acute attacks can be shortened by C1 esterase inhibitor replacement, either by a concentrate or fresh-frozen plasma infusion.[17] Treatment of patients is complex and best done in coordination with the appropriate specialist.

OTHER COMMON ALLERGIC PROBLEMS

Food Allergy

Hypersensitivity reactions to ingested foods are generally due to IgE-mediated reactions to food components or additives. IgE-coated mast cells lining the gastrointestinal tract react to presented allergens in ingested foods and produce clinical findings associated with the release of biologic mediators, as previously described. Non-IgE-mediated food allergy reactions have also been described. Dairy products, eggs, and nuts are some of the most commonly implicated foods.

A detailed history will provide the best clues to food allergy, with particular attention to other allergic history and prior reactions. Diagnosis is often difficult, since the offending food or foods may only occasionally produce symptoms, depending on the amount ingested and other foods present.

Symptoms of food allergy include swelling and itching of the lips, mouth, and pharynx; nausea; abdominal cramps; vomiting; and diarrhea. Cutaneous manifestations, such as angioedema and urticaria, as well as anaphylaxis, can occur. Treatment for mild reactions is supportive, with the administration of antihistamines to lessen symptoms. More severe reactions or anaphylaxis are managed as previously described. Referral to an allergy specialist is indicated. [3,7,13]

Insect Sting Allergy

Insect stings can produce significant and sometimes fatal reactions, particularly in sensitized patients. Approximately 100 patients die annually from insect sting reactions, making insect sting the second most common cause of fatal anaphylaxis. True stinging insects belong to the order *Hymenoptera,* which includes three families: *Apoidea* (honeybee), *Formicoidea* (fire ants), and *Vespidae* (wasps, yellow jackets, and hornets). The venoms of each family are unique, although all have similar types of components, mostly proteins. This difference accounts for the limited cross-reactivity seen. The usual reaction to these stings includes localized pain, pruritus, swelling, and redness. Sensitized individuals may have exaggerated local reactions with or without systemic manifestations. Systemic reactions run from mild nausea and malaise to urticaria, angioedema, or anaphylaxis.

Diagnosis depends on clinical history, with particular attention to past reactions, and an examination to locate the site of the sting. Occasionally, the site of envenomization is overlooked, and predominance of reaction in one organ system can lead to misdiagnosis.

Treatment is symptomatic and supportive. Mild local reactions can be managed with application of ice and oral antihistamines. More generalized reactions or local reactions of the head and neck may benefit from a short steroid course. Severe reactions are managed as outlined under "Treatment" above. Patients with severe reactions should be advised to carry self-administered epinephrine and antihistamines. A referral to an allergy specialist is indicated. [1,3,7,13]

Drug Allergy

Although adverse reactions to drugs are a common clinical problem, true immunologically mediated hypersensitivity reactions probably account for less than 10 percent of these problems. Since most drugs are small organic molecules, they are generally unable to stimulate the immune system alone. However, when a drug or metabolite becomes protein bound, either in serum or on cell surfaces, the drug-protein complex can become an allergen and stimulate immune system responses. Thus, the ability of a drug or its metabolites to sensitize the immune system depends on the ability to be bound to tissue proteins. Approximately 100 to 500 patients die yearly of anaphylactic drug reactions. Penicillin is the drug most commonly implicated in eliciting true allergic reactions and accounts for approximately 90 percent of all allergic drug reactions. Of those patients who had fatal anaphylactic drug reactions, over 95 percent reacted to penicillin. Only about 25 percent of patients who die of penicillin anaphylaxis had exhibited allergic reactions during previous courses of the drug. Parenterally administered penicillin was more than twice as likely to produce fatal allergic reactions as orally administered penicillin. [3,13]

The clinical manifestations of drug allergy are widely varied and can involve all four types of hypersensitivity reactions. A generalized reaction similar to immune-complex or serum-sickness reactions is very common. Beginning usually in the first or second week after the administration of the drug, this reaction may take many weeks to subside after drug withdrawal. Generalized malaise, arthralgias, pruritus, urticarial eruptions, and fever are common. Drug fever may occur without other associated clinical findings and may also occur without an immunologic basis. Circulating immune complexes are probably responsible for the lupus-like reactions caused by some drugs. Cytotoxic reactions, such as penicillin-induced hemolytic anemia, can occur. Skin eruptions may include erythema, pruritus, urticaria, angioedema, erythema multiforme, and photosensitivity, and severe reactions, such as those seen in Stevens-Johnson syndrome and toxic epidermal necrolysis, may also occur. Pulmonary complications, including bronchospasm and airway obstruction, can occur. Delayed hypersensitivity reactions may be manifested as a contact dermatitis from drugs applied topically.

Diagnosis is best determined by a careful and thorough history. Treatment is supportive, with oral or parenteral antihistamines, glucocorticoids, and b-adrenergic agents, as discussed above. Immediate drug withdrawal is important; however, reactions can continue or recur after a period of abstinence. Referral to an allergy specialist may be indicated. [13]

31 NEUROGENIC SHOCK

Brian Euerle
Thomas M. Scalea

Neurogenic shock, characterized by hypotension and bradycardia, occurs after an acute spinal cord injury that disrupts sympathetic outflow, leaving unopposed vagal tone.[1] The term neurogenic shock must be carefully differentiated from another that has a very different meaning—namely, *spinal shock*. Spinal shock refers to the temporary loss of spinal reflex activity that occurs below a total or near total spinal cord injury. [2] These terms are not interchangeable. This chapter focuses on neurogenic shock.

The vast majority of patients who sustain a spinal cord injury are initially evaluated in an emergency department (ED). Although the definitive care of these patients is provided by a variety of specialists, the emergency physician usually performs the initial evaluation, resuscitation, stabilization, and transfer. The patient's prognosis and eventual outcome depend on initial ED care. Early recognition of the potential injury, along with early spinal immobilization, will help prevent any possible worsening of an injury. For high-dose methylprednisolone therapy to be effective, it should be given within 8 h of injury. [3] The search for associated injuries must be done early, often by the emergency physician.

EPIDEMIOLOGY

Acute spinal cord injury is usually due to blunt trauma; penetrating trauma causes only 10 to 15 percent of cases. [1,4] Focusing only on penetrating injuries, the majority are caused by gunshot wounds, with a small minority due to stab wounds.[1] Of the blunt trauma causes, automobile accidents are the most frequent, followed by falls and sports.[4,5 and 6] The cervical region is the most commonly injured, followed by the thoracolumbar junction, the thoracic region, and the lumbar segments. [6] The area of the spinal cord injured has important implications for the incidence and severity of neurogenic shock. Approximately 10,000 people sustain spinal cord injury in the United States each year.[6] Because of the long-term care involved with many of these patients, the economic costs are staggering.

PATHOPHYSIOLOGY

The spinal column is composed of 33 bony vertebrae with interspersed cartilaginous intervertebral disks. The typical vertebra consists of an anterior vertebral body and a posterior vertebral arch. These elements form the borders of the vertebral foramen, which contains and protects the spinal cord. The superior and inferior articular processes arising from most vertebrae allow the spine to be a strong yet flexible structure. The pedicles and laminae form the sides of the vertebral arch and are notched to allow for the passage of nerves and blood vessels.

The spinal cord is a cylindrical structure arising at the base of the brain and passing through the skull at the foramen magnum. It is surrounded and protected by three layers of meninges as well as cerebrospinal fluid. Thirty-one pairs of spinal nerves exit the spinal column via the intervertebral foramen. The spinal nerves are formed by the junction of the anterior and posterior nerve roots as they exit from the spinal cord.

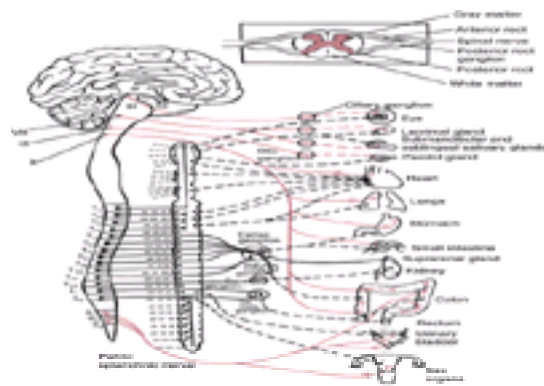
The spinal cord consists of both white and gray matter. In general, the white matter is the outer covering of the cord. It contains the nerve fibers running up and down the spinal cord in tracts. The gray matter is made up of nerve cells and is formed in the shape of an H when viewed on cross section (Fig. 31-1).


FIG. 31-1. Section of the spinal cord, showing the white and gray matter, spinal roots, and spinal nerve (Adapted with permission from Snell RS: *Clinical Anatomy for Medical Students.* Philadelphia, Lippincott-Raven, 1973, p. 828.), as well as the efferent portion of the autonomic nervous system. (Used with permission from Snell RS: *Clinical Neuroanatomy for Medical Students.* 4th ed. Philadelphia, Lippincott-Raven, 1997, p. 463.)

The autonomic nervous system, which maintains the internal balance of the body's many systems, has two main divisions: the sympathetic and parasympathetic. The sympathetic nervous system activates the "fight or flight" response, increasing the heart rate and blood pressure and constricting arterioles of the skin and intestines in order to redistribute blood flow, preferentially to the brain, heart, and skeletal muscle. The parasympathetic nervous system has the opposite effect, slowing the heart rate, decreasing blood pressure, and increasing the peristaltic activity of the gastrointestinal tract.

The anatomy of the autonomic nervous system is quite complex (Fig. 31-1). The outflow portion of the sympathetic system starts with neuron cell bodies located in the lateral gray horns of the first thoracic to the second lumbar segments. In some cases they may extend to the third lumbar segment. These cells are controlled by the hypothalamus via descending tracts of the reticular formation. The axons from the sympathetic nerve cells in the lateral gray horns leave the spinal cord in the anterior nerve roots and connect to the ganglia of the paraspinal sympathetic trunk. The sympathetic trunk is located along each side of the spinal column and extends along the entire length of the vertebral column. Axons arising from neurons in the sympathetic ganglia then travel throughout the body. The sympathetic fibers that innervate the heart arise primarily from the second to fourth thoracic segments.

The anatomy of the parasympathetic system is very different. The majority of the parasympathetic system is carried along the cranial nerves, although there is a portion that involves the second to fourth sacral segments of the spinal cord. The parasympathetic axons synapse with the cranial nerves in peripheral ganglia close to or within the target organ. The parasympathetic axons from the sacral segments form the pelvic splanchnic nerves. The portion of the parasympathetic system that innervates the heart originates in the dorsal nucleus of the vagus nerve and travels to the heart via the vagus nerves.

In evaluating patients with spinal cord injuries, the concepts of primary and secondary cord injury are important. When the spinal cord is initially injured, the pathologic picture may be relatively benign, showing some scattered hemorrhages and edema. [7] Several weeks later, the appearance is much worse, with large cavities surrounded by gliosis and fibrosis. [7]

These primary or initial changes are caused by the traumatic event, which can cause compression, laceration, or stretching of the cord. [8] Over several days to weeks, the initial injury evolves to what is termed *secondary cord injury*. Spinal cord ischemia has been suggested as the principal etiology of secondary changes, although other mechanisms may exist.[3,8] Ischemia of the spinal cord can be caused by a variety of events. The blood supply to the spinal cord is, in general, not very

substantial, and can be easily disrupted by either local trauma to the small anterior and posterior spinal arteries or injury and thrombosis to a large regional vessel, such as the great radicular artery of Adamkiewicz. General systemic hypotension and shock, if severe enough, can cause a low-flow state such that blood flow to the cord is compromised, even with an intact arterial supply.

The clinical relevance of secondary injury is that a patient's presentation can change in the period following the traumatic event. An incomplete lesion can evolve to a complete injury, or the level of injury can become higher because of the cord changes that occur during secondary cord injury.

CLINICAL FEATURES

The initial cardiovascular response after spinal cord injury may include hypertension, widened pulse pressure, and tachycardia. [1] This acute response has been shown experimentally to last from 2 to 3 min.[9] In animal experiments, the hypotension that is characteristic of neurogenic shock generally begins within 5 min of the acute spinal cord injury.[9]

Patients with neurogenic shock are hypotensive and usually have warm, dry skin. [10] Bradycardia is characteristic but not universal. The patient may lose the ability to redirect blood from the periphery to the core because of the loss of sympathetic tone. [10] This can result in excessive loss of heat from the skin, with subsequent hypothermia.[10]

These symptoms of neurogenic shock can be expected to last from 1 to 3 weeks.[10] In some cases, significant rehabilitation using elastic stockings, an abdominal binder, and a tilt table may be required to prevent an orthostatic drop in blood pressure when the patient is placed upright. [11]

The anatomic level of the spinal cord injury influences the likelihood and severity of neurogenic shock. Any injury above T1 should be capable of disrupting the spinal tracts that control the entire sympathetic system. Any injury from T1 to L3 has the potential to partially disrupt the sympathetic outflow; intuitively, the higher the injury in this zone, the more likely or more severe the resulting neurogenic shock. [1] In one of the few studies to quantify this relationship, Zipnick and colleagues described this relationship in five patients with true neurogenic shock resulting from penetrating injuries: two in the cervical region, one in the lumbar region, and one each in the upper and lower thoracic regions.[1]

The question of an incomplete versus a complete spinal cord lesion causing neurogenic shock has also been considered. In a large study of 408 patients with cervical cord/column injuries, Soderstrom and Ducker reported a near equal incidence of neurogenic shock in patients with incomplete versus complete lesions. [12] The explanation for this is not entirely clear. Guha and Tator, working with an acute spinal cord injury model in rats, have suggested that the decline in cardiac output following acute cord injury is not due to decreased sympathetic tone alone but may also be caused by direct myocardial injury, similar to that seen after head injury or subarachnoid hemorrhage.[9]

An interesting difference has been found with regard to incidence of neurogenic shock between patients with blunt versus penetrating spinal cord injuries. [1] In a study of patients with blunt cervical spine/cord injury, neurogenic shock alone was believed to be responsible in 69 percent of all patients in shock. [5] In Zipnick's study of patients with penetrating spinal injury at various anatomic levels, neurogenic shock was thought to be responsible in only 22 percent of patients in shock. [1] The reason for the difference is unclear but probably related to the fact that the two groups were not equivalent: blunt trauma patients had only cervical injuries, while the penetrating injury patients had injuries at all levels of the spinal cord. Also, part of the difference may stem from the fact that patients with penetrating trauma are more likely to have associated injuries.

TREATMENT

Evaluation and treatment of patients with spinal injury and neurogenic shock starts with the "ABCDEs" of trauma assessment: the "A" is not only for airway but also includes cervical spine protection, and the "D" represents disability, or neurologic evaluation [13] (Table 31-1). Cervical spine protection and neurologic evaluation are not discussed further here except to say that they form the cornerstone of all further management of patients with neurogenic shock.

ABCDE:
    Airway with cervical spine protection
    Breathing
    Circulation
    Disability (neurologic evaluation)
    Exposure

Fluid resuscitation with crystalloid—consider pulmonary artery catheter to avoid over hydration.

Administer methylprednisolone 30 mg/kg over 15 min in the first hour; then 5.4 mg/kg/hr × 23 hours.

Carefully search for and treat any possible causes of hypotension and blood loss.

Consider vasopressor support with dopamine or dobutamine.

Transfer patient, after resuscitation, to regional spine or trauma center.

TABLE 31-1   Treatment of Neurogenic Shock

It is impossible to separate the initial evaluation and management of the patient with neurogenic shock from that of the general trauma patient. In essence, the diagnosis of neurogenic shock should be one of exclusion. Certain clues—such as bradycardia and warm, dry skin—may be evident, but hypotension in the trauma patient can never be presumed to be due to neurogenic shock until all other possible sources of hypotension have been eliminated. [1] Again, a difference has been noted between blunt and penetrating spinal injuries, but a large percentage of these patients will have significant concomitant injuries, causing blood loss, which will explain their hypotension.[1,5] It is only after these other injuries have been excluded that neurogenic shock can be said to be present.

Once the ABCDEs have been attended to and all other possible sources of hypotension have been investigated and treated, the treatment will focus on the hypotension and bradycardia of neurogenic shock.

Hypotension is treated by rapid infusion of crystalloid; this is usually effective in treating neurogenic shock. [14] During neurogenic shock, blood pools in the distal circulation because of the loss of sympathetic innervation. Infusion of intravenous crystalloid will correct this relative hypovolemia. Adequate fluid resuscitation should be undertaken with the aim of keeping the mean arterial blood pressure above 70 mmHg.[14] This level of blood pressure is a bit arbitrary and has been arrived at by clinical experience. It is thought that this level of pressure provides adequate perfusion and minimizes the effects of secondary cord injury.

The use of fluids in neurogenic shock must, however, be judicious. There is a danger of excessive fluid replacement, with resultant heart failure and pulmonary edema.[15] The placement of a pulmonary artery catheter and its resultant pressure measurements can be of tremendous benefit and help prevent excess fluid administration.[16] If intravenous fluids are not adequate to maintain organ perfusion, the use of positive inotropic pressor agents such as dopamine or dobutamine may be beneficial. [10] These agents will improve cardiac output and raise perfusion pressure. [16] The doses required are variable and should be titrated to the patient's hemodynamic response.

Bradycardia, when present, usually occurs within the first few hours or days of spinal cord injury [9] because of a predominance of vagal tone to the heart. In severe cases and when the patient's hemodynamics warrant, atropine can be used for treatment. In some patients who may present with heart block or asystole, a pacemaker may be required.[9]

One topic that deserves discussion is the physiologic significance of the hypotension associated with neurogenic shock. For most patients treated in the ED, an adequate blood pressure is important to ensure perfusion and normal functioning of end organs. This can be especially important in the patient with a spinal cord

injury, in whom optimal perfusion and oxygenation of the spinal cord may maximize nervous system recovery.[15] On the other hand, the authors' clinical experience has shown that moderate hypotension may be tolerated by some of these patients without any evident sequelae. In these patients, more harm than good may be done by trying to normalize the blood pressure, as evidenced by the pulmonary edema that can result from overvigorous fluid resuscitation. Perhaps, in these patients, careful monitoring and the tincture of time, allowing the sympathetic nervous system to recover its function, might be the best course of action. This group of patients might more accurately be labeled as having "neurogenic hypotension" rather than "neurogenic shock." This is because these patients, though hypotensive, have no problems with peripheral perfusion. They maintain clear mentation and adequate urine output, and do not develop the typical laboratory abnormalities of patients that are in shock.

DISPOSITION

Any patient with neurogenic shock has suffered a severe traumatic injury and obviously will be admitted to the hospital. In general, the patient with a spinal cord injury is best cared for at a trauma or spine center. Most areas have a regional spine care center, centralizing the extensive resources needed for the care of these patients and standardizing patient care.

While in the ED, the patient with a spinal cord injury and neurogenic shock can benefit from early consultation and involvement of the appropriate specialty services, namely neurosurgery, trauma surgery, and orthopedics. Early consultation and the consideration of transfer is most important for the patient with continuing or worsening hypotension, an evolving deficit, or a progressing level of injury.

32 ACUTE PAIN MANAGEMENT, ANALGESIA, AND ANXIOLYSIS IN THE ADULT PATIENT

Erica Liebelt
Nadine Levick

In both the United States and the United Kingdom, in excess of 60 percent of all emergency department (ED) patients present with conditions associated with pain. However, inadequate analgesia continues to be documented in the ED setting. Acute pain management consists of pain relief and anxiolysis with preservation of airway reflexes and consciousness. The Agency for Health Care Policy and Research (AHCPR) guidelines for acute pain management [1] are a useful guide but should be supplemented with more detailed and current information. [2]

The experience of pain is determined by many factors, including medical condition, developmental level, emotional and cognitive state, personal concerns, meaning of pain, family issues and attitudes, culture, and environment. Fear and anxiety accentuate physical pain. Effective pain management should address psychological and physical aspects by using both nonpharmacologic and pharmacologic modalities.

The utility of oral medications in the ED is limited because emergent operative or investigational procedures often mandate NPO status, and gastrointestinal absorption may be poor because of the patient's underlying condition. Repeated intramuscular doses of narcotic analgesia no longer represent an approach of choice except in patients where vascular access must be preserved (sickle cell patients). A multifaceted approach combining titrated intravenous medications, regional and topical medications, adequate anxiolysis, and incorporation of nonpharmacologic techniques to enhance patient care and comfort is preferred.

PATHOPHYSIOLOGY

Pain involves release of potent mediators of inflammation, and is modulated by neurocognitive factors resulting in an unpleasant sensory and emotional experience. The peripheral pain system (e.g., nociceptors, C fibers, A-d fibers, free nerve endings) registers the original noxious stimulus and conducts it to the central nervous system (CNS). The primary afferent peripheral nociceptors have poorly differentiated nerve fiber terminals and slow conduction velocities (ranging from C fibers at 2.5 ms^{-1} to A-d fibers at 2.5 to 20.0 ms^{-1}) and are normally activated by stimuli of strong to noxious intensity. They release several neurotransmitters. Glutamate, an excitatory amino acid (EAA) released from these nociceptors, elicits fast synaptic responses in second-order neurons that are mediated by at least two EAA receptor subtypes. Some primary afferent nerve fibers also express and synthesize neuropeptides (substance P, neurokinin A, and calcitonin gene–related peptide) that are coreleased with glutamate within the spinal cord. [3] The dorsal horn of the spinal cord (e.g., dorsal root ganglion, inhibitory interneurons, ascending pain tracts) integrates and modulates pain and other sensory stimuli. Supraspinal centers (e.g., hypothalamic centers, thalamic nuclei, the limbic and reticular activating systems) integrate and process pain information, allowing detection and perception of pain. Cognitive interpretation, localization, and identification of pain and triggering of emotional and physiologic reactions also occur at this site. Parietal pain pathways are more complex and differ in structure from visceral pain pathways, which may explain the poor localization of visceral pain as opposed to parietal pain.

Assessment and Reassessment of Pain

Pain assessment in the ED involves determining its location, quality, and severity. Since pain is dynamic and changes with time, its severity requires assessment and reassessment, ideally involving the use of validated objective and subjective pain assessment instruments.

The awake, cooperative, competent patient can describe and locate pain and be assessed easily and reliably. [1] Patients who have difficulty communicating are at risk of inadequate pain management. Patients who are cognitively impaired, psychotic, or severely emotionally disturbed as well as children, the elderly, patients who do not speak the language of their health care team, and patients whose level of education or cultural background differs significantly from that of their health care team are at particular risk. [4] These scenarios require a more objective than subjective approach. Involvement of family members is often valuable.

For comprehensive assessment of pediatric pain, age-appropriate, developmentally specific techniques are essential, and assessment is enhanced by the involvement of the parents or caregiver. (See Chap. 130.)

The elderly often report pain very differently from younger patients because of physiologic as well as psychological and cultural changes associated with aging. The high prevalence of visual, hearing, motor, and cognitive impairments among the elderly can be barriers to effective pain assessment, affecting the reliability of traditional pain assessment instruments.

Ethnicity has bearing on different cultural concepts of pain and on the characteristics of culturally appropriate pain-related behaviors. There is also interplay between the ethnicity of patient and physician. Most pain instruments are to some extent language-dependent. In practical consideration of language difficulties and cross-cultural measurement, visual analogue scales have been preferred. Confounding issues are the interplay of socioeconomic status and also the degree of accommodation to the dominant culture. [5]

Gender-related differences in reporting of pain intensity are equivocal, but women are more likely to express pain and to actively seek treatment. Physicians have a tendency to underestimate and undertreat pain in female patients. [6]

Approaches to Pain Assessment

NON-SELF-REPORT MEASUREMENT Respiratory and cardiovascular changes as well as changes in patient expression and movement can all occur due to pain. However, factors other than pain can cause or inhibit the same changes, making interpretation difficult. Physiologic parameters may be more useful to confirm a

clinical impression than as a primary assessment tool. The more developed non-self-report tools are used in the pediatric setting. (See Chap. 130.)

SELF-REPORT MEASUREMENT   Self-report measurement scales include numerical or adjective ratings and visual analogue scales. These tools may also be used simply by asking the patient for a verbal response. Small changes in pain severity may not have clinical importance. For example, with a 100-mm visual analogue scale, a change in severity of less than 13 mm has statistical but minimal clinical significance.

Pain Assessment Tools

Self-report tools are the mainstay of pain assessment. These tools should be reliable, valid, and easy for the patient and health care provider to use in the ED environment. The ideal tool should be applicable to any individual regardless of psychological, emotional, cultural, cognitive, or developmental status.

The adjective rating scale (ARS) is a simple, descriptive pain-intensity scale presented graphically or verbally as a linear list of pain descriptors (Fig. 32-1). A 10-cm baseline is recommended.[1]

No	Mild	Moderate	Severe	Very	Worst
pain	pain	pain	pain	severe	possible
				pain	pain
FIG. 32-1. Adjective rating scale.

A numerical rating scale (NRS) can be presented as a verbal or graphic scale to describe pain intensity (Fig. 32-2). The patient is asked to self-report pain on a scale of zero to ten (0 = no pain, 10 = worst possible pain) and mark it off graphically, self-report verbally, or—where language or speech is difficult—indicate the numerical value with upheld fingers. While not as precise as the visual analogue scale (VAS), (see below), the NRS requires no visual or manual skill and is easy to use. [1]

0   1   2   3   4   5   6   7   8   9   10

No	Moderate	Worst
pain	pain	possible pain
FIG. 32-2. Numeric rating scale.

The VAS is a 10-cm linear scale marked at one end with a term like *no pain* and at the other with *worst imaginable pain* (Fig. 32-3). The patient places a mark on the line at the point that best represents the pain. The VAS scale is scored by measuring the distance of the patient's mark from either end. The VAS has been validated,[7] but debate continues over the clinical relevance of statistically significant differences in VAS scores. [8] A disadvantage of the VAS is that it requires visual, manual, and some conceptual skill.

MODALITIES OF PAIN MANAGEMENT

Effective management of acute pain includes nonpharmacologic cognitive-behavioral and physical techniques combined with the pharmacologic agents—administered systemically, regionally, locally or sometimes via novel delivery systems.

Pharmacologic Modalities

The pharmacologic management of acute pain includes systemic agents such as opioid and nonopioid analgesics and adjunct medications (anxiolytics and antiemetics) in addition to the nonsystemic local and regional agents (Table 32-1). Agents such as nonsteroidal anti-inflammatory drugs (NSAIDs) should be considered for mild pain, and systemic opioids and/or NSAIDs should be considered for moderate to severe pain. Local or regional neural blockade is a useful technique to minimize the use of narcotic agents (Table 32-2).

TABLE 32-1   Pharmacologic Agents for Analgesia and Anxiolysis

TABLE 32-2   Comparison of Pharmacologic Agents

Analgesics are the drugs most often associated with adverse drug events, with similar rates for overmedication as for undermedication despite the likely reporting bias for overmedication. Sedatives are the next most likely category of medication to cause adverse reactions. [9]

NONOPIOID AGENTS   *Acetaminophen* (*paracetamol* in some countries) is an effective analgesic, adequate for mild to moderate pain. Its efficacy is significantly enhanced when it is combined with codeine. Acetaminophen does not affect platelet aggregation, nor is it anti-inflammatory. Acetaminophen may be hepatotoxic above 140 mg/kg per day in the setting of normal hepatorenal function.

NSAIDs are a class of drugs including aspirin, naproxen, indomethacin, ibuprofen, and ketorolac (standard doses are shown in Table 32-3). In therapeutic doses these agents decrease levels of inflammatory mediators generated at the site of tissue injury. They do not cause sedation or respiratory depression or interfere with bowel or bladder function. [10] Even when insufficient alone, NSAIDs have significant opioid dose-sparing effects. There are oral, rectal, intravenous, and topical preparations. The NSAID ketorolac is approved by the U.S. Food and Drug Administration for parenteral use. Topical NSAIDs, effective in acute musculoskeletal injuries, are associated with the lowest side-effect profile. [11] They are available in Australia and the United Kingdom but currently not in the United States. Adverse effects of NSAIDs include platelet dysfunction, impaired coagulation, and gastrointestinal irritation and bleeding; hence they should be used with care in patients with thrombocytopenia or coagulopathies and in those at risk for bleeding or gastric ulceration. Acute renal failure has been reported and may be precipitated in patients who are volume depleted or have lost more than 10 percent of their blood volume, have preexisting renal or cardiac disease, or are taking loop diuretics. Ibuprofen is safer than ketorolac in this respect. [12]

TABLE 32-3   Nonopioid Analgesics

OPIOID AGENTS   Opioid analgesics are the cornerstone of pharmacologic management of moderate to severe acute pain (standard doses are shown in Table 32-4). Proper use of opioids involves selecting a particular drug, and considering (1) route of administration, (2) suitable initial dose, (3) frequency of administration titrated against analgesic response, (4) optimal use of nonopioid analgesics and adjunct agents, (5) incidence and severity of side effects, and (6) whether the analgesic will be continued in an inpatient or ambulatory setting. Patients vary greatly in their responses to opioid analgesics; these variations are related to age, body mass, and previous or chronic exposure to opioids. Relative potency estimates provide a rational basis for selecting the appropriate starting dose to initiate analgesic therapy, changing the route of administration (e.g., from parenteral to oral), or switching to another opioid (Table 32-5). An oral opioid such as a codeine-acetaminophen combination, or a stronger compound such as oxycodone with acetaminophen is useful for ED pain patients able to take oral medications.

TABLE 32-4   Opioid Analgesics

Opioid	Equipotent IV Dose, mg/kg	Equipotent PO Dose, mg/kg	Parenteral/Oral Ratio
Morphine	0.1	0.3–0.5	20–33%
Meperidine	1.0	1.5–2.0	50–60%
Fentanyl	0.001	0.01–0.015 (transmucosally*)	25–50% (of transmucosal dose)
Alfentanil	0.05	—	—
Hydromorphone	0.015	0.02–0.1	20–70%
Codeine	1.2	2.0	66%
Oxycodone	—	0.1	—

*Less than 25–50% of a transmucosal dose is absorbed systemically.

TABLE 32-5 Equianalgesic Opioid Doses

The opioids include the phenanthrene derivatives (e.g., morphine, codeine, and hydromorphone), the phenylpiperidine derivatives (e.g., meperidine and fentanyl), and the diphenylheptane derivative (methadone). When they are used in equianalgesic doses, there is no compelling evidence to recommend one opioid over another. Accumulation of the toxic metabolite of meperidine (normeperidine) has been shown to cause CNS toxicity in patients with compromised renal function or those taking monoamine oxidase inhibitors (MAOIs).[13] Morphine, in contrast to meperidine, has an active rather than a toxic metabolite. Adverse effects of opioids include nausea, vomiting, constipation, pruritus, urinary retention, and respiratory depression.

Codeine, hydromorphone (Dilaudid), oxycodone, morphine, and meperidine can be administered orally (Table 32-4), hydromorphone and codeine being readily absorbed from the gastrointestinal tract. Fentanyl is now available as a raspberry-flavored fentanyl-impregnated lozenge preparation (Oralet).

Codeine can be given both orally and intramuscularly; intravenous administration is not recommended due to a higher side-effect profile via this route. Codeine is a very useful agent in the ED for adjunct oral pain therapy with acetaminophen for discharge analgesia. At therapeutic doses, the analgesic effect reaches a peak within 2 h and persists between 4 and 6 h. The plasma concentration does not correlate with brain concentration or relief of pain. Codeine crosses the blood-brain barrier and is found in fetal tissue and breast milk, but it is not bound to plasma proteins. The plasma half-life is about 2.9 h. The elimination of codeine is primarily via the kidneys, and about 90 percent of an oral dose is excreted by the kidneys within 24 h of dosing. Patients who report allergy to codeine or morphine (phenanthrine) can usually be offered meperidine or fentanyl (phenylpiperidine) unless they describe allergies to both classes of agents.

Opioids are frequently combined with an anxiolytic as an adjunct (hydroxyzine or benzodiazepines), which may provide pain relief at a lower opiate dose than using an opiate alone. However, hydroxyzine can only be given intramuscularly. Use of antiemetics (such as metoclopramide, prochlorperazine, or promethazine) is useful to control the side effects of nausea and vomiting. When a benzodiazepine or promethazine is given with an opioid, the sedative effects will be additive.

Concerns have been raised about delayed-release transdermal formulations, because of delayed onset and prolonged duration of action. Transdermal fentanyl preparations are used in the chronic pain and oncology setting. Generally, transdermal fentanyl should be avoided for acute pain management.

Side effects (e.g., confusion, respiratory depression, hypotension, urinary retention, or pruritus) associated with opioids are greater with intravenous, transmucosal, and epidural administration than oral administration and require frequent assessment and monitoring. Opioids should generally be withheld whenever there is respiratory depression (usually fewer than 10 breaths per minute).

OTHER AGENTS   Ketamine and nitrous oxide are two agents that have been used widely for brief analgesic therapy; these agents also have sedative properties.

Ketamine, a phenylcyclidine derivative, produces analgesia and dissociative anesthesia and has the advantage of causing minimal respiratory depression. The ability of ketamine to produce amnesia makes it a good agent for brief minor procedures and for wound dressing. Adverse effects include increased intracranial pressure (ICP) and intraocular pressure, hypersalivation, and reemergence phenomena (disagreeable dreams or hallucinations upon awakening). It should be avoided in patients with closed head injuries or other conditions associated with increased intracranial pressure. It is a useful agent in the pediatric ED (see   chapter 130).

Nitrous oxide is a fast-onset, short-acting analgesic and sedative inhalational agent useful for wound dressing, and brief minor procedures. The primary adverse effects are nausea and vomiting. Barriers to ED use of nitrous oxide include the need for patient cooperation and an effective scavenging system. Adverse effects are nausea and vomiting. In addition, it cannot be used in patients with altered mental status, head injury, suspected pneumothorax, or perforated abdominal viscus. Severe pulmonary disease may also alter the respiratory elimination of nitrous oxide.

Choosing a Route to Administer a Pharmacologic Agent

Systemic pain medications can be given orally, rectally, intravenously, intramuscularly, transmucosally, transdermally, by inhalation, or by epidural administration (Table 32-6). Intravenous opioids are suitable for bolus administration or continuous infusion and are preferred to intermittent intramuscular injections. Patient controlled intravenous analgesic systems do have a role in the ED for the stabilized patient who is to be admitted. Repeated intramuscular injections can themselves cause pain and trauma and may deter patients from requesting pain medication. Oral administration is convenient and inexpensive and is appropriate once the patient can tolerate oral intake; it is a mainstay of pain management in the ambulatory ED population. Nonsystemic agents can be delivered transdermally or transmucosally or by infiltrative local and regional injection, or intravenously for specific regional blocks. Alternative delivery techniques such as iontophoresis and single-dose jet injectors, which are now available for topical local anesthetic drug delivery, warrant consideration and further investigation.

TABLE 32-6 Comparison of Delivery Routes for Systemic Pharmacologic Agents

Analgesic Dosage, Precautions, and Comorbidity

The key principle for safe and effective use of opioids is to titrate the dose against the desired effect—pain relief—and minimize unwanted effects. Opioids in larger doses than necessary to control pain, or when given to patients who are not in pain, can result in respiratory depression and hypotension. Relative potency estimates provide a rational basis for selecting the appropriate dose (see Table 32-5). In the setting of comorbid conditions that include underlying neurologic deficits, altered mental status, hemodynamic instability, respiratory dysfunction, or multisystem trauma, systemic narcotics should be used cautiously.

Patients at the extremes of age are at risk for both inadequate analgesia and pharmacotherapy complications. For the comprehensive management of pediatric pain, age-appropriate assessment techniques and medication dosages and developmentally specific nonpharmacologic adjuncts are essential (see   chapter 130). Elderly

patients may have more than one source of pain and comorbidity and are at increased risk for drug-drug as well as drug-disease interactions. The elderly, especially opioid-naive patients, are more sensitive to the analgesic effects of opioid drugs as they experience a higher peak and longer duration of pain relief. Moreover, they are more sensitive to sedation and respiratory depression and cognitive and neuropsychiatric dysfunction. Some patients may have concerns about physiologic or psychological dependence and should be informed that this is extremely unlikely after short-term use for acute pain. [1,14,15]

As most analgesics are metabolized by the liver or kidney, caution is essential when using opioids in patients with altered hepatic or renal function. Renal excretion is a major route of elimination for such pharmacologically active opioid metabolites as norpropoxyphene, normeperidine, morphine-6-glucuronide, and dihydrocodeine. Mild renal failure can impede excretion of the metabolites of many opioids, resulting in clinically significant narcosis and respiratory depression.

Patients with respiratory insufficiency and those with chronic obstructive pulmonary disease, cystic fibrosis, and neuromuscular disorders affecting respiratory effort (e.g., muscular dystrophy, myasthenia gravis) are particularly vulnerable to the respiratory depressant effects of opioids and nitrous oxide. Appropriate monitoring of respiratory rate and effort and adequacy of gas exchange is necessary.

Opioids may have adverse synergistic sedative effects in patients with psychiatric illnesses taking anxiolytics or other psychoactive drugs. The use of MAOIs with meperidine has been associated with severe adverse reactions, including death through mechanisms that mimic malignant hyperthermia. The tricyclic antidepressants clomipramine and amitriptyline may increase morphine levels.

Patients in shock, as well as those with trauma and burns, and hemodynamic or respiratory instability mandate judicious use of narcotics. Cautious titration, in consideration of cardiovascular and respiratory stability, of an intravenous short-acting opioid analgesic such as fentanyl [16] and maximal use of regional analgesia are recommended.[1] The intramuscular route has poor and variable absorption and bioavailability in this setting and should be avoided. Additionally, in the trauma patient there is potential for masking occult trauma with excessive use of systemic narcotics. Use of analgesic therapy also must allow for continuous monitoring of neurologic status after a head injury and neurovascular status after limb injury. In the setting of closed head injury or multiple injuries, maximal use of regional and nonpharmacologic modalities minimizes the use of systemic analgesics. While of value in the patient with minor trauma, the use of NSAIDs in the major trauma patient remains controversial. The risk of excessive bleeding from platelet dysfunction, gastric stress ulcers, and potential for acute renal failure in the volume-depleted patient minimize their utility for this patient group.

Nonpharmacologic Modalities (Cognitive-Behavioral and Physical Therapies for Analgesia and Anxiolysis)

Traditionally, nonpharmacologic techniques of pain management in the ED are limited to application of heat or cold, and immobilization and elevation of injured extremities. Other techniques may prove to have a role in the ED and post-ED setting. Among these are cognitive-behavioral techniques, which are effective in reducing pain and anxiety, may control mild pain when used alone, and also enhance patient satisfaction. These techniques include reassurance, explanation, relaxation, music, psychoprophylaxis, biofeedback, guided imagery, hypnosis, and distraction. They are a useful adjunct to pharmacologic management of moderate to severe pain.[1] Successful application of these therapies requires a cognitively intact patient and skilled personnel, but many of the techniques require only a few minutes to teach the patient.

Physical nonpharmacologic agents are becoming increasingly relevant to ED pain management. In addition to the traditional techniques noted above, the less commonly used physical modalities such as transcutaneous electrical nerve stimulation (TENS) and acupuncture, particularly the newer electroacupressure techniques,[17] may have some potential role in the ED environment in the future. Although specific technical skills and equipment are required, there is no need for intravenous access, and there is no systemic effect or depression of respirations or mental status.

Specific Situations

There are a number of situations where the ideal ED analgesic management approach is complex or somewhat controversial. Acute abdominal pain and migraine are two such situations.

ABDOMINAL PAIN   Unfortunately, withholding of analgesics in the setting of abdominal pain remains widespread practice that is not evidence based. [18] Early administration of intravenous opiate has been shown to be a safe[19] and effective analgesic in patients with acute abdominal pain in the ED and does not have adverse effects on the accuracy of the evaluation,[20] the diagnosis, and management.[18] Some studies have shown that narcotic administration not only does not mask the diagnosis but actually enhances diagnostic accuracy. [21]

MIGRAINE   The choice of the best analgesic agent for use in the ED to manage a migraine headache remains broad. There have been reported success rates as high as 95 percent for the phenothiazines, chlorpromazine (Thorazine) and prochlorperazine (Compazine). [22] Both drugs were associated with decreasing pain scores, but the effect of prochlorperazine was greater. Headache recurrence has been reported to be as high as 50 percent with 5-hydroxytryptamine agonist (Sumatriptan) or dihydroergotamine (DHE). Headache rate at 24 h was significantly higher for patients who left the ED with persisting headache compared to those who left with no pain. More aggressive ED treatment may result in higher successful treatment rates but may also be associated with more adverse effects from the therapy. Dopamine antagonist, antiemetics, metoclopramide, phenothiazines, haloperidol, Sumatriptan, DHE, NSAIDs, acetaminophen, codeine, and narcotics have all been studied. [23] The relative benefit of these agents or combinations of therapies remains unclear. Ketorolac, meperidine, and saline each produced significant pain reduction in a recent study.[24] Opioid use has lost favor due to poor performance in clinical trials as well as the potential to be associated with drug-seeking behavior. [25]

Management of pain related to other conditions is discussed in their respective chapters and is outlined in Table 32-7.

TABLE 32-7   Painful Conditions and Suggested Analgesic Management Approaches (a Conjunction to Definitive Care)

DISPOSITION

Inpatient or outpatient management determination of certain conditions may be affected by pain intensity alone. However, acute pain significant enough to warrant inpatient management is often associated with an underlying condition that is the primary reason for the admission. Safety of discharging patients home on narcotics with conditions necessitating acute pain management is dependent on two main precautions: a disease process that could be masked by analgesic medications and the likelihood of serious complications with the use of these medications in an unmonitored environment. Knowledge of the underlying pathologic diagnosis and an awareness of the home environment, support system, and the ability of the patient to manage home medications safely all impact on the determination for admission. Awareness of the duration of action of analgesic medications and the time of offset with respect to discharge planning and disposition is essential. Where the cause of the pain is determined and under control, long-acting medications minimize the frequency of analgesic medication. However, where there is less diagnostic clarity, these agents could be problematic in delaying symptom recognition by the patient until after discharge home. Longer acting pain medications are likely to result in longer ED stays, to monitor the patient's baseline pain and also to ensure the safety of discharge.

Written discharge instructions detailing specific medication procedures will help patients to take their medications correctly and also enhance patients' awareness of side effects. This information should include names of medications, dosages and frequencies, and adverse effects.

LOCAL ANESTHESIA

Local and regional anesthesia are essential tools in the ED for procedural- and trauma-related pain management, such as for wound repair, lumbar puncture, insertion of intravenous catheters, arterial lines, chest tubes, arthrocentesis, fracture pain, and fracture manipulation and reduction. Local anesthetic (LA) techniques provide short-term pain relief by (1) infiltration or application of LA directly into the area to be anesthetized, (2) infiltration of local anesthetic into the environment of nerve fibers supplying the area, or (3) intravenous regional block. Knowledge of the dosages, actions, and toxicity of the LA medications is required for safe use of these agents. In addition, specific skills and anatomic knowledge for regional anesthesia techniques are necessary for the effectiveness of these procedures.

Local Anesthetic Agents

LAs are all synthetic drugs derived from cocaine. The chemical structure includes a hydrophillic and hydrophobic region and a linkage (amide or ester) region. LAs are weak bases supplied as a salt (usually HCl), with an acidic pH to increase stability, solubility, and shelf life. The most commonly used pharmacologic agents for local infiltrative as well as regional anesthesia are the amide agents, lidocaine and bupivacaine. Lidocaine has a shorter duration of action compared to bupivicaine but has a lower toxicity profile. Tetracaine, an ester LA, is frequently used in topical anesthetic preparations. Esters are metabolized via hydrolysis by cholinesterase enzymes in plasma. Amide LAs are metabolized by hepatic microsomal enzymes. The metabolism rates of amide LAs (prilocaine > lidocaine > bupivacaine) are slower overall than those of ester LAs, creating the potential for sustained plasma levels and cumulative effects of amide LAs. Maximum doses, volumes, and duration of action of various anesthetics are shown in Table 32-8.

TABLE 32-8   Local Anesthetic Dosages for Infiltration

The mechanism of action of LAs is to decrease the rate and degree of depolarization and repolarization, decrease conduction velocity, and prolong the refractory period of the neural action potential. LAs bind to receptor sites on the voltage-gated sodium channels (a four-subunit transmembrane protein) in the neuronal membrane and impair or block sodium influx, thereby blocking or slowing nerve conduction. Potency is related to lipid solubility and pK_a; the higher the lipid solubility and the lower the pK_a, the more un-ionized drug present at tissue pH. The un-ionized form traverses lipid layers to the axoplasm. However, the drug must return to the cationic state to bind to the channel receptors. Buffering, by the addition of sodium bicarbonate (NaHCO$_3$), increases the amount of uncharged drug available and decreases pain of infiltration. Duration of action is related to protein binding: the longer the LA binds to the sodium channel, the longer the duration of the blockade.

Addition of epinephrine (usually 1:200,000 or 5 μg/mL) provides a longer duration of anesthesia, provides wound hemostasis, and slows systemic absorption, thereby decreasing the potential for toxicity and allowing a greater volume of agent to be used for extensive laceration repair. Epinephrine may actually increase the pain of infiltration because it lowers the overall pH of the solution. *Epinephrine should never be used in an end-arterial field,* e.g., digits, pinna, nose, penis. Inadvertent intraarterial injection of LA with epinephrine or infiltration into an end-arteriole region can cause prolonged vasospasm and ischemia. This may be reversed with local or intravascular injection of 1.5 to 5 mg phentolamine. Phentolamine, 2 mg, has been used successfully as a "digital block" for digital ischemia. Use of 10 mg has been reported for local infiltration in the extremities. The side effect of phentolamine, hypotension, is less likely in this setting.

Toxicity

Toxicity is determined by the total dose and mode of LA delivered, modulated by factors influencing systemic uptake. The relative absorption of LA is site dependent. The absorption, from highest to lowest, is: intercostal/intratracheal > epidural/caudal > brachial plexus > mucosal > distal peripheral nerve > subcutaneous. Caution should be exercised with intercostal blocks: the recommended LA dose for intercostal blocks is one-tenth of maximum for peripheral blocks. Serious adverse reactions including systemic toxic reactions are more frequently encountered with the use of amide rather than ester LAs, due in part to the slower amide metabolism. However, patients with atypical plasma cholinesterase may be prone to systemic toxicity from ester LAs. The systemic toxicity of LAs is enhanced by hypercarbia, hypoxemia, and acidosis. Systemic toxicity is usually the result of rapid inadvertent intravenous injection or delivery of an excessive total dose of LA.

Serious toxicity primarily involves the CNS and cardiovascular system. CNS toxicity results from a combination of central excitatory and depressant activity of the LA, ranging from perioral tingling and numbness to confusion, seizure, and coma (see Table 32-9). Cardiovascular toxicity relates to the Na+ channel blockade and results in myocardial depression and dysrhythmias. Bupivacaine, due in part to its prolonged binding to the receptor site and slow metabolism, is particularly cardiotoxic and for this reason contraindicated for intravenous regional anesthesia. Methemoglobinemia has also been reported from excessive dosage.

TABLE 32-9   Toxicity of Local Anesthetics

True allergic reactions to local anesthetics are rare. They are usually due to the metabolite para-aminobenzoic acid (PABA) in the case of ester anesthetics and the preservative methylparaben (MPB), structurally similar to PABA, in the case of amide anesthetics. Esters are more commonly associated with allergic reactions than amides. If a true allergy is suspected based on history or documentation, the optimal approach is to use a preservative-free agent from the other class.

Diphenhydramine (0.5 to 1.0 percent) is an alternative anesthetic choice in patients allergic to the amides and/or ester-type anesthetics. Although it is effective in reducing local infiltrative pain, it has been demonstrated to be more painful than lidocaine and can cause tissue irritation and even skin necrosis. Thus, its role for

local anesthesia is extremely specific and limited to those patients who have true allergies to ester or amide anesthetics, which are quite rare.

Management of systemic LA toxicity should follow standard advanced life-support protocols (ensure a patent airway, 100 percent oxygen, ventilatory and circulatory support), and there should be immediate discontinuation of administration of LA and prompt treatment of the CNS and cardiovascular complications. Correcting hypoxia, hypercarbia, and metabolic acidosis is paramount as all of these conditions enhance the toxicity of LAs. Incremental doses of intravenous benzodiazepines are usually effective to control seizures.

Specific Agents

Lidocaine is an amide anesthetic available in 0.5 percent, 1.0 percent, and 2 percent concentrations and is the most commonly used anesthetic in the ED because of its excellent efficacy and low toxicity profile. Decreased metabolism occurs with hepatic failure and decreased hepatic blood flow (e.g., congestive cardiac failure) and in these circumstances can lead to high plasma levels. Its onset of action is within 2 to 5 min and its duration of action is 1 to 2 h. Lidocaine can be combined with epinephrine and bicarbonate.

Bupivacaine (0.25 percent) is an amide anesthetic and is highly protein bound. It has a longer duration of action than lidocaine, 4 to 6 h, and is more cardiotoxic. Bupivacaine is preferred for prolonged procedures (such as ingrown toenail removal), when longer postprocedural analgesia is desired, and for non-IV regional blocks. Bupivacaine is contraindicated for IV regional blocks due to its cardiac toxicity, from which fatalities have been reported. Similar caution regarding conditions affecting hepatic metabolism should be followed as for lidocaine. The onset of action of bupivacaine is similar to that of lidocaine, but some studies suggest its injection is more painful.

Prilocaine, an amide LA with a lower cardiac toxicity profile than lidocaine or bupivacaine, has similar anesthetic potency, milligram for milligram. After intravenous injection, its CNS toxicity is less than lidocaine due to a lower blood level because of differences in its distribution and peripheral uptake. It is also broken down by amidases in the liver more rapidly than lidocaine, resulting in a shorter duration of toxic effects. Prilocaine and tetracaine are the active agents in EMLA cream (eutectic mixture of local anesthetics) for topical use on intact skin. Prilocaine may lead to methemoglobinemia after a large intravenous bolus (or total dose > 600 mg). Due to its lower toxicity, it is commonly used in Australia for intravenous regional arm blocks.

Procaine is an ester LA and can be used for patients who are allergic to the amide anesthetics (e.g., lidocaine). It has a rapid onset but short duration of action. *Tetracaine* is an ester LA and is more lipid soluble and longer acting than other LAs in its class. It is commonly used for topical LA preparations.

Additives and Adjuncts to Minimize Pain of Infiltration

Many variables influence the degree of pain experienced with local anesthetic infiltration. Slow infiltration of the anesthetic (30 s per mL) with a 27- or 30-gauge needle will decrease the pain compared to rapid injection with a larger needle, probably because of less rapid distension of local tissue. Numerous clinical studies have demonstrated attenuation of pain on infiltration with buffered lidocaine. It is prepared by mixing 9 mL of 1 percent lidocaine (with or without epinephrine) with 1 mL of 8.4 percent (1 meq/mL) sodium bicarbonate solution. Bicarbonate can cause precipitation of bupivacaine and should not be used with this anesthetic unless it can be used immediately. It is prepared by mixing 29 mL bupivacaine (0.25 percent) with 1 mL (1 meq/mL) NaHCO$_3$ solution.

The exact mechanisms by which buffering of lidocaine reduces pain is not clear. Buffering to a higher pH may reduce direct tissue irritation by reducing the acidity of the agent. Additionally, buffering increases the concentration of lidocaine in the uncharged form, which theoretically may allow more rapid tissue dispersion resulting in more rapid sensory nerve blockade. Because buffered lidocaine undergoes biodegradation at room temperature, its shelf life is limited. One study suggests 7 days, while another suggests that efficacy is maintained up to 30 days. Each ED must compare the cost and utilization of premixed solution with single dose preparation.

Studies evaluating the efficacy of warm lidocaine (anywhere from 37 to 42°C) to decrease injection pain have yielded equivocal results. It is postulated that heating the anesthetic causes faster diffusion into tissues and reduces or avoids stimulation of cold receptors, increasing the rate of onset of neuronal block. Lidocaine can be warmed either in dry heat (blanket warmers) or in temperature-regulated water baths at 37°C. From a practical standpoint, anesthetics should at least be administered at room temperature. Unlike buffered lidocaine, heated lidocaine undergoes no chemical denaturation, placing no limitations on shelf life.

Local Anesthetic Infiltration

The most common usage of LA in the ED is local infiltration for wound repair and invasive painful procedures. It is a rapid-onset technique. Infiltration can be into the wound margins or as a field block in a "diamond-shaped wheal" of LA surrounding the wound. Lidocaine is the drug of choice for local anesthetic infiltration for brief procedures. Bupivacaine is preferable for longer procedures due to its longer duration of action, but with due caution regarding the increased toxicity. Epinephrine can be added to enhance safety and efficacy, and bicarbonate to minimize pain of infiltration. The maximal dosages commonly cited (see Table 32-8) apply to infiltration of local anesthetic, in contrast to the lower maximal dosages for most regional procedures.

TOPICAL ANESTHETICS

Topical anesthetics such as tetracaine (0.5 percent), adrenaline (0.05 percent, 1:2000), and cocaine (4 percent to 11.8 percent) (TAC); lidocaine (4 percent), epinephrine (0.1 percent, 1:1000), and tetracaine (0.5 percent) (LET); and EMLA can be used for a number of different painful procedures and may eliminate or decrease the need for painful infiltrative injection. Compared to infiltrative anesthesia, TAC and LET provide good hemostasis, do not distort wound edges, and can be applied painlessly. Until recently, TAC was the most frequently used topical anesthetic in the United States. Concerns over the safety of TAC stem from the reported cases of seizures, respiratory arrest, and even death in children from the inadvertent systemic absorption of cocaine from its improper application. TAC is a controlled substance, making it less readily available and creating the potential for abuse. In addition, TAC has been estimated to cost from 10 to 17 times more than LET, depending on the concentration of cocaine. LET has been found to be just as effective as TAC in providing local anesthesia for laceration repair. For these reasons, LET is a safer, more practical, and more cost-effective choice.

LET should be made available in single-dose individual vials with a maximum volume of 5 mL. Several drops of the solution can be dripped into the wound with a syringe. Alternatively, a gel can be made by adding methylcellulose powder to each vial, allowing the LET to be "painted" in the wound with a sterile, cotton-tipped swab, with less chance for dripping the solution into mucous membranes. The remainder of the solution/gel should be placed on a cotton ball or sterile gauze roughly the size of the wound and either taped to the wound or held by the patient or caregiver wearing a glove. It should be left in place at least 20 min for the maximum anesthetic effect. LET should be avoided on mucous membranes, the pinna of the ear, the nose, penis, and fingers and toes. The gel form may be used cautiously near the eyes, nose, or mouth.

Lidocaine may be used as a topical anesthetic for a variety of painful conditions and procedures. It is marketed in solution, jelly, and ointment forms in concetrations from 2 percent to 10 percent. Viscous lidocaine solutions (2 percent) can be used for temporary relief of inflamed or irritated mucous membranes of the mouth and pharynx (viral stomatitis). A sterile preparation of the viscous solution can be used for insertion of Foley catheters and gastrostomy tubes. Strict instructions to the patient and caregivers about sparing use of the viscous oral solution must be given. Only a limited amount (about 2 ml) of the solution should be applied. Topical benzocaine anesthetic solutions such as Auralgan (antipyrene/benzocaine) may be effective in temporarily alleviating pain due to acute otitis media or external otitis media.

EMLA is an emulsion in which the oil phase is a eutectic (melting point below room temperature) mixture of lidocaine and prilocaine in a ratio of 1:1 by weight (lidocaine 2.5 percent and prilocaine 2.5 percent). Each gram of cream contains 25 mg lidocaine and 25 mg prilocaine, carboxypolymethylene (thickening agent), sodium hydroxide to adjust to a pH of 9, and purified water to 1 gram. EMLA is for use on intact skin. It contains no preservative, is not sterile, and is not recommended for anesthesia of open wounds, although this is being further investigated. Onset, depth, and duration of dermal analgesia depend primarily on the duration of the application. EMLA cream should be applied under an occlusive dressing. There are also new EMLA prepackaged transdermal adhesive disks available. Satisfactory analgesia is achieved after 1 h, peaks at 2 h, and persists for 1 h after removal; both delivery systems have similar pharmacokinetics. The indications are to provide topical anesthesia for venipuncture, arterial puncture, vascular cannulation, drug reservoir or port access, lumbar puncture, sites for needle insertion for regional blocks, and superficial minor skin procedures. However, the time required for adequate anesthesia limits its use for emergent procedures in the ED. Higher effectiveness observed in children over 7 years and adults suggests the importance of emotional and psychological support of younger children undergoing procedures.

Absorption is more rapid on diseased, facial, or Caucasian skin, when compared with nondiseased intact skin, the extremities, or African American skin. Although the incidence of systemic adverse reactions is very low, caution should be exercised, particularly with application to large areas or for longer than 2 h (Table 32-10). Local reactions of blanching or erythema are common. In infants <3 mos there is a theoretical risk of methemoglobinemia because of the low levels of methemoglobin reductase at this age. Toxicity as for lidocaine and prilocaine may be encountered, but is unlikely when EMLA is used as recommended; it is not contraindicated in labor and delivery.[26,27]

Do not use in infants <1 month (or infants <12 months at risk of methemo-globinemia)

Limit the area and duration of application with children <20 kg

Avoid ingestion (potential for toxicity), ensure the dressing is well secured

Not for ophthalmic use

Not recommended for use on open wounds

Caution with nursing mother, milk:plasma ratio for lidocaine is 0.4 and is not determined for prilocaine

Caution in patients on class I antiarrhythmics (as for injectable local anesthetics)

TABLE 32-10   EMLA Contraindications and Precautions

Refrigerant Anesthetic Sprays

Refrigerant anesthetic sprays such as Ethyl Chloride (chloroethane) and Fluori-Methane (dichlorodifluoromethane, trichloromonofluoromethane) offer another effective and convenient alternative for topical anesthesia. Ethyl Chloride has been used as a local anesthetic for over 100 years. Vaporization of the liquid spray on the skin lowers its temperature to –20°C, thereby temporarily freezing it. Anesthesia is almost immediate, providing a distinct advantage in a busy outpatient clinic or ED over EMLA cream.

Refrigerant anesthetic sprays have been used to reduce pain associated with minor surgical procedures on the skin, abscess incision, deep intramuscular injections (immunizations), lumbar punctures, venous cannulation, bone marrow aspiration, digital blocks, and port access in children. In addition, these vapocoolants have been used to reduce pain associated with athletic injuries, muscle pain, and myofascial pain. This needle-less form of anesthesia offers a clear psychological advantage to a child's perception and anxiety about pain, compared to a needle injection.

Ethyl Chloride can be applied by inverting the bottle and directing a stream of spray about 30 cm from the skin until the area turns white, while protecting the adjacent skin with petrolatum. Alternatively, apply the spray to a sterile cotton ball for 10 s and then apply it to the skin for 10 s. The liquid maintains its sterility and the cost is minimal. Disadvantages includes its short duration of only 30 seconds to 1 minute, superficial level of anesthesia only, possible pain on thawing, possible lowered resistance to infection, and delayed skin healing. Prolonged spraying causes chemical "frostbite" and skin ulceration. These sprays cannot be used on the mucosa. Inhalation should be avoided because it can produce opioid and general anesthetic effects. Ethyl Chloride is flammable and must be used in a well-ventilated room, never in the presence of open flames or electric cautery.

Novel Topical Techniques and Agents

JET INJECTOR   Compressed air high-pressure jet injectors are available to deliver LA agents both in liquid and powder form through the epidermis in a needle-less fashion. This is a delivery method suitable for most skin types and has been used extensively by blood banks to minimize pain during blood donation. There is concern about potential cross infection due to "splash back" when these devices are used on multiple patients without sterilization occurring between each use. However, single dose systems are now available.

IONTOPHORESIS   Iontophoresis is a recently developed, single-use delivery system to enhance the speed and depth of delivery of topical LA agents. It also is a needle-less system. However, its effect is variable depending on skin type, thickness, and degree of skin moisture. This system requires specific equipment, is more expensive than the routine topical preparations, and can only be used on intact skin. The anesthetic effect is not immediate and may take up to 15 minutes. The patient may experience a burning sensation under the adhesive electrical pad used for this delivery system.

OTHER PHARMACOLOGIC AGENTS   Topical preparations of NSAIDs are being introduced. These preparations are analgesics, not anesthetics. Topical NSAIDs have relatively lower efficacy than oral NSAIDs but also have lower systemic side effects. Another topical agent currently used for chronic pain management that may also have a role in local acute pain management is capsaicin cream, which blocks substance P. There are a number of allopathic preparations available without prescription for topical analgesia, such as aloe and tea-tree oil. Scientific evidence supporting the effectiveness of these preparations is limited. Tea tree oil is toxic if ingested.

REGIONAL PROCEDURES

Regional procedures include peripheral nerve blocks, hematoma blocks, intravenous arm blocks (Biers block), neural plexus blocks, and epidural anesthesia. Although the latter two techniques may be performed in the ED, they usually require anesthesiology participation and oversight in most institutions. The scope of ED practice encompasses the remaining regional blocks. These procedures can shorten ED patient stays, minimize narcotic requirements, and decrease the need for general anesthesia and admissions. The safety and effectiveness of LAs for regional blocks depend on proper dosage, correct technique, adequate precautions, and readiness for emergencies. Regional procedures with LA should be employed only by clinicians who are well versed in diagnosis and management of LA dose-related toxicity and other acute emergencies that might result from inadvertent systemic absorption of the LA or intraarterial injection of an epinephrine-containing LA solution. The setting should be such that resuscitative measures can be initiated immediately if necessary. For major regional blocks (Biers block, brachial plexus blocks) IV access must be established. LA should be administered in the lowest dosage that results in an effective block. Epinephrine is often added to enhance the duration, quality, efficacy, reliability, and safety of a block. Epinephrine is contraindicated in nerve blocks in end-arterial areas. There have been reports of cardiac arrest and death with the use of bupivacaine for intravenous regional anesthesia, and thus its use is contraindicated.

Nerve Blocks

Peripheral nerve blocks are advantageous in the ED environment, particularly for procedures on the digits or penis. They require less total LA medication, and the site of drug delivery is often less painful than for local infiltration. It is important to document neurovascular status prior to application of the block, to prevent masking a primary traumatic neurovascular injury. The onset of anesthesia is more delayed than by direct infiltration and may be up to 15 min. The duration depends on the agent used and the amount of drug injected. Complications of nerve blocks include nerve injury. During a block, severe pain suggests that contact has been made with the nerve. In this circumstance, the needle must be withdrawn and repositioned before anesthetic is injected. Intravascular injection can result in limb and systemic toxicity. LA dose exceeding the maximum may result in systemic toxicity (primarily cardiac and CNS), as discussed above. In order to minimize the likelihood of intravascular injection, the plunger on the needle syringe apparatus should be drawn back in all nerve block procedures prior to infiltration. If blood is withdrawn, the procedure is halted. The suggested dosages for regional blocks are shown in Table 32-11.

Nerve Blocks	WITH EPINEPHRINE 1% LIDOCAINE OR 0.25% BUPIVACAINE	
	Volume, mL	Total Dose, mg
Femoral	10–25	100–250
Intercostal	2–10	20–100
Pudendal	3	30
	WITHOUT EPINEPHRINE 1% LIDOCAINE OR 0.25% BUPIVACAINE	
	Volume, mL	Total Dose, mg
Digital	1–3	10–40
Web space	2–5	20–50
Penile	10	100

TABLE 32-11 Suggested Dosages for Regional Blocks for Adults (and Children >40 kg)

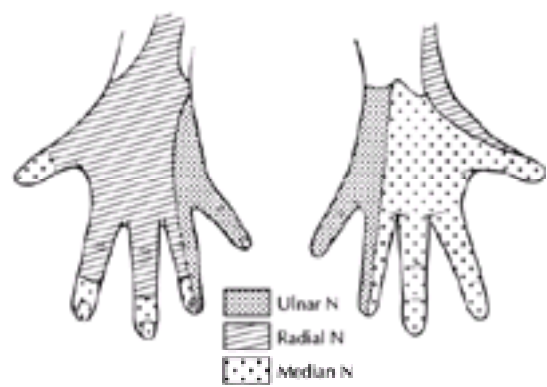
HAND BLOCKS/ANATOMY **Median Nerve** The median nerve provides sensation to the lateral two-thirds of the palm of the hand, palmar surfaces of the lateral three and one-half digits and their finger tips. The palmar branches of the median digital nerves extend dorsally over the digit to supply the dorsum of the thumb, the index, the middle finger and lateral half of the ring finger distal to the interphalangeal joint and including the nail and the nail bed. The median nerve enters the hand through the carpal tunnel, deep to the flexor retinaculum, between the tendons of the flexor digitorum superficialis and the tendon of the flexor carpi radialis. The median nerve sends cutaneous sensory fibers to the entire palmar surface and sides of the thumb, index finger, middle and lateral half of the ring finger, and the dorsum of these digits distal to their proximal interphalangeal joints (Fig. 32-4).


FIG. 32-4. The cutaneous distribution of anesthesia with block of major nerves of the wrist.

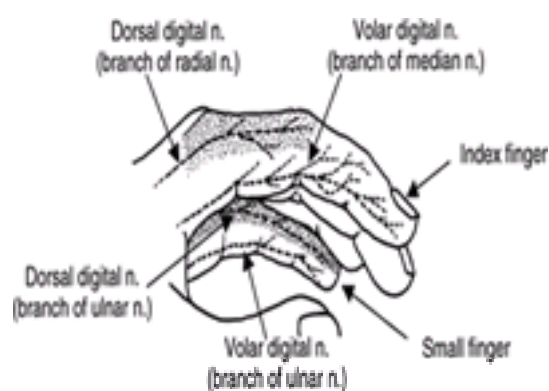
Ulnar Nerve The ulnar nerve can be blocked at the elbow or the wrist to provide anesthesia to the medial aspect of the hand and the small finger, including its nail and nail bed. Just proximal to the wrist, the ulnar nerve gives off a palmar cutaneous branch, which passes superficially to the flexor retinaculum and palmar aponeurosis to supply the skin of the ulnar side of the palm (see Fig. 32-4). It also gives off a dorsal cutaneous branch that supplies the ulnar half of the dorsum of the hand, the small finger, and the ulnar half of the ring finger. The ulnar nerve ends by dividing into a superficial and a deep branch. The superficial branch supplies cutaneous fibers to the anterior surfaces of the small finger and the ulnar half of the ring finger. In the small finger, the dorsal digital nerve extends to the tip of the digit. In the median nerve distribution, the volar nerve supplies the dorsum of the digit distal to the proximal interphalangeal joint (Fig. 32-5).


FIG. 32-5. The dorsal digital nerve extends to the tip of the digit in the small finger. In areas of the median nerve distribution (i.e., the ring finger), the volar nerve supplies the dorsum of the digit distal to the interphalangeal joint.

Radial Nerve The radial nerve provides sensation to the lateral two-thirds of the dorsum of the hand, the proximal aspect of the dorsum of the thumb and index finger and lateral aspect of the dorsum of the middle finger, excluding the nails and nailbeds of these digits. The superficial branch of the radial nerve is the direct continuation of the radial nerve along the anterolateral side of the forearm and is entirely sensory. It pierces the deep fascia near the dorsum of the wrist to supply skin and fascia over the lateral two thirds of the dorsum of the hand, the dorsum of the thumb, and proximal parts of the lateral one and one-half fingers (see Fig. 32-4).

HAND BLOCKS/TECHNIQUE For lacerations of the hand, regional blocks at the wrist are performed at the level of proximal volar skin crease (Fig. 32-6). The median nerve is anesthetized by inserting a 27-gauge needle perpendicular to the skin between the tendons of the palmaris longus and flexor carpi radialis muscles at the midpoint of the distal volar crease. A regional block of the ulnar nerve is accomplished by passing the needle between the ulnar artery and the flexor carpi ulnaris. Once inserted, the needle is moved fanwise transversely until paresthesia is elicited. When paresthesia occurs, the needle is held in place and 5 to 10 mL of 1 percent lidocaine with epinephrine (1:100,000) is injected slowly.
FIG. 32-6. Regional blocks of the ulnar and median nerves.

The superficial rami of the radial nerve can be blocked by raising the subcutaneous ring with 5 to 10 mL of 1 percent lidocaine with epinephrine (1:100,000) beginning at the level of the tendon of the extensor carpi radialis and extending around the radial border of the wrist dorsal to the styloid process (Fig. 32-7).
FIG. 32-7. Regional block of several rami of the radial nerve.

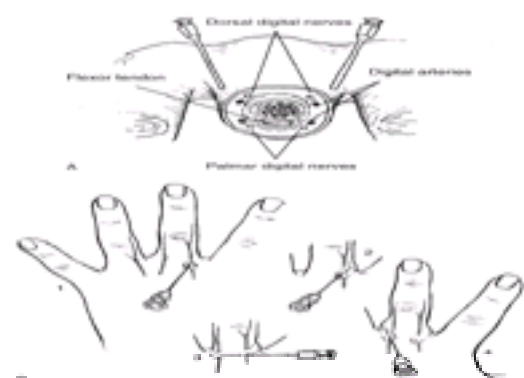
FINGER BLOCKS   **Digital Nerve Block**   The digital nerve block provides excellent anesthesia for fingers and toes and has a more rapid onset although it is as painful a block as the metacarpal block. It is commonly used for laceration repair, incision and drainage of paronychia, finger or toenail removal or repair. Preparation with EMLA or Ethyl Chloride can minimize the pain of injection for these blocks. Epinephrine is contraindicated for this block. Contraindications to performing this block are any compromise to the digits' blood supply. Complications are few, however, large volumes of anesthetic can result in a 'compartment' syndrome. Each digit is supplied by a palmar (volar) and dorsal digital nerve on each side of the digit, superficial to the digital arteries (Fig. 32-8A).


FIG. 32-8. Digital nerve block. **A.** Cross section. (From Yaster M et al: *Pediatric Pain Management and Sedation Handbook.* St. Louis, Mosby, 1997, p 183. Used by permission.) **B.** Positions for needle (see text).

TECHNIQUE   A 27- or 30-gauge needle is inserted through the skin into one side of the extensor tendon of the affected finger just proximal to the web (Fig. 32-8B,1). After aspirating, approximately 1 mL of 1 percent lidocaine or 0.25% bupivacaine is injected superficially into the subcutaneous tissue lying on the dorsal surface of the extensor tendon to block the dorsal digital nerve. The needle is then advanced toward the palm until its tip is palpable beneath the volar skin at the base of the finger, just distal to the web (Fig. 32-8B). After aspirating, another 1 mL of the anesthetic solution is injected to block the volar digital nerve.

Before removing the needle, it is redirected across the extensor tendon to the opposite side of the finger and approximately 1 mL of the anesthetic solution is injected into the tissue overlying the other dorsal digital nerve (Fig. 32-8C). Five minutes later, the needle is reintroduced in the anesthetized skin on the opposite side of the finger and the same technique is repeated (Fig. 32-8D). The total volume of the anesthetic agent should not exceed 4 mL. Epinephrine must *not* be used as an adjunct to lidocaine because it may result in irreversible ischemic injury to the finger.

Metacarpal Block   Metacarpal blocks can be used to anesthetize either the index, long, ring, or small finger although digital blocks are preferred. The block is performed on each side of the affected finger by inserting a 27-gauge needle at a 90° angle to the dorsum of hand approximately 1 cm proximal to the metacarpophalangeal joint midway between each metacarpal bone. The needle is then advanced at a 90° angle to the skin until its tip is at the level of the lateral volar surface of the metacarpal head or until resistance of the palmar aponeurosis is detected. After aspirating, 3 mL of 1 percent lidocaine is injected slowly.

ANKLE BLOCKS/ANATOMY   These regional nerve blocks are used for anesthesia of surgical procedures of the foot. There are 5 nerves which supply sensation to the foot. Most foot blocks involve a block of at least two nerves. It is unusual in the ED setting to have need to block the whole foot. The sole of the foot is a commonly injured area. Regional nerve blocks are the preferred LA technique. Local infiltration directly into the sole is extremely painful and difficult to perform effectively and is not recommended. Buffered lidocaine 1%, or bupivacaine 0.25% are the LA agents of choice. Epinephrine is contraindicated, and these blocks should not be used in patients with peripheral vascular disease, or traumatic circulatory compromise.

The peripheral nerves involved in blocks of the foot are all branches of the sciatic nerve, except for the saphenous nerve (a branch of the femoral nerve) (Fig. 32-9). The sensory innervation of the plantar surface of the foot is primarily the two main branches of the tibial nerve (posterior tibial and sural nerves) which lie posteriorly, and a small contribution from the saphenous nerve medially over the arch. The sensory innervation of the dorsum of the foot is predominantly from the two main branches of the common peroneal nerve (the superficial and deep peroneal nerves), with contribution from the sural nerve laterally and the saphenous nerve medially.

FIG. 32-9. Sensory innervation of the foot and ankle.

The saphenous nerve is the only branch of the femoral nerve below the knee. It becomes subcutaneous at the medial side of the knee joint and then follows the

saphenous vein to a site anterior to the medial malleolus. It provides sensory innervation to the skin over the medial malleolus extending to the skin over the medial side of the foot to the base of the great toe.

The superficial peroneal nerve becomes the dorsal digital nerves. It descends toward the ankle in the lateral compartment, entering the ankle just lateral to the extensor digitorum longus, and provides the cutaneous supply to the dorsum of the foot and all five toes, except for the adjacent sides of the first and second toes (deep peroneal nerve) and lateral side of the fifth toe (sural nerve) (see Fig. 32-9). It is most commonly located lateral to the extensor digitorum longus at the level of the lateral malleolus superficially. It also supplies the peroneus longus and brevis. The sensory supply of the deep peroneal nerve is limited to the 1 cm area of web space between the first and second toes. Thus, blocks of the deep peroneal nerve are not reasonable or practical to perform.

SOLE OF FOOT BLOCK (SURAL NERVE, POSTERIOR TIBIAL NERVE AND SAPHENOUS NERVE)   The three nerves which supply the sole of the foot are the posterior tibial nerve via its medial and lateral plantar branches (medial and lateral sole) and medial calcaneal branch (the heel), the sural nerve (posterolateral sole) and the saphenous nerve (small area, medially over the arch) (Fig. 32-9).

The posterior tibial nerve is located along the medial aspect of the ankle, lying between the medial malleolus and the Achilles tendon, just posterior and slightly deeper than the posterior tibial artery (Fig. 32-10) and gives off the three terminal branches, medial calcaneal branch, and medial and lateral plantar nerves. The sural nerve travels with the short saphenous vein (Fig. 32-10), posterior and inferior to the lateral malleolus, it terminates as the dorsal lateral cutaneous nerve. The saphenous nerve follows the great saphenous vein to the medial malleolus.
FIG. 32-10. Posterior view of the left foot demonstrating the sites for tibial and sural nerve blocks.

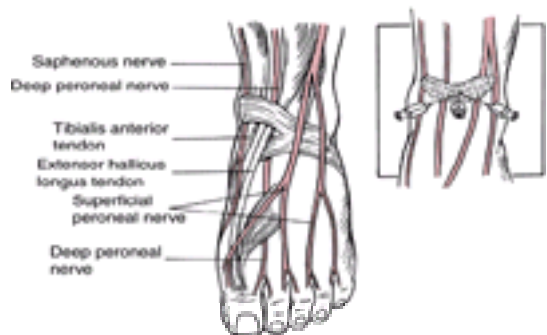
Technique   This block is best performed with the patient in the prone position. The posterior tibial nerve is blocked as it passes posterior to the medial malleolus, the tibial artery is palpated just posterior to the medial malleolus (Fig. 32-10). Buffered lidocaine 1% (or bupivacaine 0.25%) is injected with a 30-gauge needle lateral to the tibial artery and just anterior to the medial border of the Achilles tendon, at the level of the upper border of the medial malleolus. A syringe with a 25-gauge needle is then introduced at 90° to the skin, just lateral and posterior to the tibial artery (Fig. 32-10). Once paresthesia is elicited and after careful aspiration to ensure no inadvertent intravascular access, 3 to 5 mLs of LA is injected. If no paresthesia is encountered, then 5 to 7 mLs of LA should be injected as the needle is withdrawn. Onset of anesthesia should occur within about 5 to 10 minutes if paresthesia has been elicited and in about 30 minutes if it is not elicited. The sural nerve is blocked between the lateral malleolus and the Achilles tendon (Fig. 32-10). It is superficial, lying just anterior to the short saphenous vein. Buffered lidocaine 1% (or bupivacaine 0.25%) is injected with a 30-gauge needle just lateral to the Achilles tendon 1 cm above the lateral malleolus. A 25-gauge needle is then introduced into this area and 3 to 5 mLs of LA is injected subcutaneously as the needle is withdrawn. The saphenous nerve lies superficially between the medial malleolus and the anterior tibial tendon (Fig. 32-11) and is blocked anteriorly by infiltration of 3 to 5 mLs of LA between these landmarks as the needle is withdrawn.


FIG. 32-11. Deep peroneal, saphenous, and superficial peroneal nerve blocks.

DORSUM OF FOOT BLOCK   Regional block of the dorsum of the foot has fewer ED applications than blocks for the sole of the foot, as direct infiltration of the dorsum is more easily performed. The sensory innervation of the dorsum of the foot is primarily supplied by the superficial peroneal nerve, with contribution from the deep peroneal nerve over the first web space, the sural nerve laterally extending to the lateral malleolus, and the saphenous nerve medially over the arch and the medial malleolus (Fig. 32-11).

TECHNIQUE   This block is best performed with the patient in the supine position. With a 30-gauge needle a small wheal of LA is raised just above the level of the talocrural joint in the midline anteriorly, between the extensor digitorum longus and the extensor hallucis longus. The superficial peroneal nerve is then blocked by infiltration of 5 mLs of buffered lidocaine 1% (or bupivacaine 0.25%) in a large wheal extending from this point just superior to the talocrural joint at the anterior border of the tibia to the lateral malleolus (Fig. 32-11). The deep peroneal nerve can be blocked by infiltrating 5 mLs of buffered lidocaine 1% (or bupivacaine 0.25%) between the tendons of the tibialis anterior and the extensor hallucis longus also just above the talocrural joint. However, the area supplied by the deep peroneal nerve is so small a digital block or local infiltration would achieve the same effect. Saphenous and sural nerves are described above.

TOE BLOCKS   Digital nerve blocks of the toe are used for laceration repair and minor surgical procedures of the toe. Epinephrine must not be used as an adjunct to lidocaine because it may result in irreversible ischemic injury. A 27- or 30-gauge needle should be introduced through the skin on the dorsal aspect of the base of the midpoint of the involved toe (Fig. 32-12). The needle should be angled around the bone until it induces blanching of the skin on the plantar surface. As the needle is withdrawn, approximately 1.5 mL of 1% lidocaine is injected. Before the needle is withdrawn completely from the skin, it should be redirected to the opposite side of the injured toe to inject the local anesthetic agent in a similar manner. The total volume of the injected local anesthetic agent should not exceed 3 mL.
FIG. 32-12. (*Top*) Regional block of great toe. (*Bottom*) Regional block of other toes.

For the hallux (great toe), a modified collar (ring) block is used (see Fig. 32-12). The 27-gauge needle is inserted through the skin on the dorsolateral aspect of the base of the toe until it blanches the plantar skin. As the needle is withdrawn, 1.5 mL of 1% lidocaine is injected into the tissues. Before the needle is removed completely from the skin, the needle is passed under the skin on the dorsal aspect of the toe and 1.5 mL of 1% lidocaine is injected as the needle is withdrawn from the skin. The needle is then introduced through the anesthetized skin on the dorsomedial aspect of the toe and advanced until it produces blanching of the plantar skin, at which time the needle is withdrawn and 1.5 mL of 1% lidocaine is injected. Usually, approximately 4.5 mL of 1% lidocaine is needed to anesthetize the hallux.

FACIAL AND ORAL BLOCKS   Facial blocks are ideal anesthesia techniques for commonly injured areas such as the forehead, chin, lips, nose, tongue and ear, where local infiltration is often either not possible, extremely painful or results in tissue distortion or potential tissue necrosis. These blocks, as for foot blocks, often require blockade of more than one nerve to provide for adequate regional anesthesia. For all intraoral routes of infiltration, a small amount of 2% viscous lidocaine should be applied to the mucosa prior to injection. For percutaneous routes of infiltration, topical EMLA cream or refrigerant sprays should be applied prior to injection.

Forehead (Trigeminal Nerve, Ophthalmic Branch, Frontal and Supratrochlear Nerves)   The sensory innervation of the forehead (anterior aspect from eyebrows extending posteriorly to the lambdoid suture) is supplied by the lateral and medial branches of the frontal (or supraorbital) nerve and the supratrochlear nerve, branches of the ophthalmic branch of the trigeminal nerve (Fig. 32-13). Regional nerve block can be easily achieved by infiltration of 3 to 6 mLs of lidocaine 1% (or bupivacaine 0.25%) with a 27-gauge needle into the skin immediately above the full length of the eyebrow.
FIG. 32-13. Regional blocks of (1) the lateral branch of the frontal nerve, (2) the medial branch of the frontal nerve, and (3) the supratrochlear nerve. Infiltration anesthesia is an alternative approach to anesthetizing lacerations of the forehead.

Lower Lip, Chin (Trigeminal Nerve, Mandibular Branch, Inferior Alveolar and Mental Nerve)   Direct infiltration to the lip is very painful and causes tissue distortion which can interfere with the quality of the repair of lacerations. The skin of the chin and lower lip are supplied by the mental nerve (branch of the inferior alveolar nerve). A block of the inferior alveolar nerve as it enters the mandibular foramen, medial and just below the anterior border of the ramus of the mandible is performed by the intraoral route (Fig. 32-14). Regional block of the mental nerve can be performed by an intraoral (Fig. 32-15) or extraoral route. The mental foramen is located at the mucosal reflection of the lower lip and the lower gum, just posterior to the first premolar tooth.

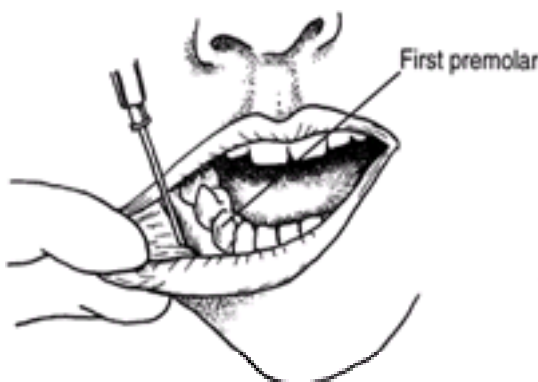
FIG. 32-14. Regional intraoral block of the lingual and inferior alveolar nerves.


FIG. 32-15. Regional intraoral block of the mental nerve.

TECHNIQUE   The landmarks for the inferior alveolar nerve block are the inferior aspect of the vertical ridge of the anterior border of the ramus of the mandible (oblique line), and the oral mucosa 1 cm above the occlusal surface of the third molar tooth. After the mucosal injection site is anesthetized, the oblique line is

identified by palpation. A 27-guage needle is inserted just medial to this ridge and 1 cm above the third molar tooth, and slowly advanced along the medial side of the ramus of the mandible to a depth of 2 cm, keeping the syringe in parallel position with the body of the mandible and the occlusal surfaces of the teeth of the lower jaw. While the needle remains in proximity to the medial aspect of the ramus of the mandible, 2 to 4 mLs of lidocaine 1% (with or without epinephrine) is infiltrated after the syringe is rotated over to the premolar region of the opposite side of the mandible, maintaining the same horizontal plane.

For the oral approach to the mental nerve the lip is retracted with the thumb and index finger (see Fig. 32-15). A 27-gauge needle is inserted at the mucosal junction of the lower lip and gum near the mental foramen. 2 ml of lidocaine 1% with epinephrine (1:100,000) is infiltrated taking care that the needle is not introduced into the mental foramen to avoid neural injury. Similarly for the extraoral approach, identification of landmarks, and percutaneous infiltration of 2 mL of LA close to the mental foramen.

Tongue (Trigeminal Nerve, Mandibular Branch, Lingual Nerve)   Direct infiltration into the sensate and moving of the tongue is very painful and poorly effective, and a regional block is preferred. The lingual nerve provides sensory innervation to the anterior two-thirds of the tongue, the floor of the mouth and gums. It lies in close proximity to the inferior alveolar nerve at the entrance to the mandibular foramen. The lingual nerve can be blocked by the intraoral route similarly to the inferior alveolar nerve (Fig. 32-14).

TECHNIQUE   From an intraoral approach the vertical ridge of anterior border of the ramus of the mandible is identified by palpation with the index finger (Fig. 32-15). After the mucosal injection site is anesthetized topically, the procedure for an inferior alveolar nerve block (same as above) is followed. Infiltration of the LA as the needle is withdrawn will anesthetize the lingual nerve. Alternatively the lingual nerve can be anesthetized by injecting 2 to 3 mLs of LA into the lateral floor of the mouth adjacent to the premolar teeth.

Cheek, Lower Eyelid, Upper Lip and Lateral Aspect of Nose (Trigeminal Nerve, Maxillary Branch, Infraorbital Nerve)   The infraorbital nerve supplies sensory innervation to the cheek, lower eyelid, upper lip and lateral aspect of the side of the nose. A regional block of the infraorbital nerve can be performed by an intraoral approach (Fig. 32-16) or extraoral transcutaneous approach. The duration of action is more prolonged with the intraoral approach.

FIG. 32-16. Intraoral approach to regional nerve block of the infraorbital nerve.

TECHNIQUE   To identify the infraorbital foramen, the midpoint of the lower margin of the orbit is palpated, approximately 1 cm inferior to this point the infraorbital nerve exits the infraorbital foramen. For the intraoral approach, a palpating finger is positioned over the infraorbital foramen (Fig. 32-16). The cheek is retracted cephalad with the thumb and index finger and a 27-gauge needle with syringe, held in the other hand directed through the mucosa at the reflection of the upper gum opposite and parallel to the long axis of the upper premolar tooth. The needle is then advanced until it is palpated near the infraorbital foramen, approximately a depth of 2.5 cm. Use caution not to introduce the needle directly into the infraorbital foramen to avoid neural injury and subsequent numbness of the cheek, also use caution not to direct the needle too far superiorly or posteriorly to avoid inadverntently entering the orbit. Aspirate to ensure facial artery and vein are avoided. Instil 2 to 3 mLs of lidocaine 1% (or bupivacaine 0.25%) adjacent to the foramen. The extraoral approach uses the same landmarks for identification of the infraorbital foramen, but with a percutaneous approach. Epinephrine is best avoided due to the proximity of the facial artery.

Nose (Trigeminal Nerve, Ophthalmic Branch, Infratrochlear and External Nasal Nerves; Maxillary Branch, Infraorbital Nerve, Posterior Nasal and Nasopalatine Nerves)   The sensory supply of the nose is supplied by both the ophthalmic and maxillary branches of the trigeminal nerve. It is important to note that block of the infraorbital nerve alone will not provide adequate anesthesia of the nose. The mucosal surface of the nose can be anesthetized by topical application of LA spray or gel. The ophthalmic branch of the trigeminal nerve (infratrochlear and external nasal nerves) provides sensation to the majority of the external nose in the midline. These nerves can be blocked by percutaneous infiltration of LA at the sites of their emergence from bony foraminae. The remaining aspects of the nose are supplied by the maxillary branch of the trigeminal nerve, the infraorbital nerve for the lateral aspect (see above for intraoral and extraoral block technique) and the posterior nasal and nasopalatine nerves for the septum and inferior midline. The posterior nasal and nasopalatine nerves are best approached intraorally in the midline from the mucosal surface of the reflection of the upper lip.

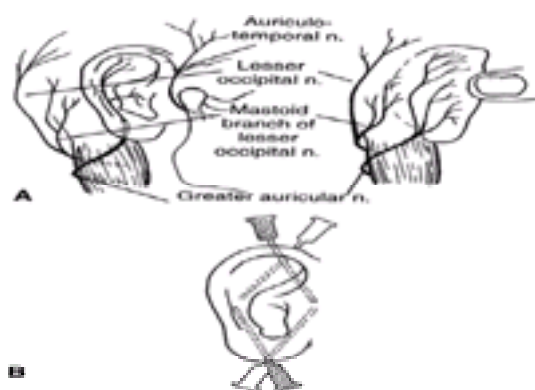
Ear (Trigeminal Nerve, Mandibular Branch, Auriculotemporal Nerve; Cervical Plexus C2 and C3; Greater Auricular Nerve and Mastoid Branch of Lesser Occipital Nerve)   The sensory innervation to the external ear is supplied anteriorly by the auriculotemporal nerve (mandibular branch of the trigeminal nerve), and posteriorly by the greater auricular nerve and the mastoid branch of the lesser occipital nerve (branches of the cervical plexus). Direct infiltration of the pinna should be avoided due to the risk of tissue necrosis. Regional block of the ear is achieved by infiltration of lidocaine 1% (or bupivacaine 0.25%) via a 27- or 30-gauge needle at the base of the ear from an inferior and superior direction both anteriorly and posteriorly (Fig. 32-17 A and Fig. 32-17B)


FIG. 32-17. A. Sensory nerve supply of the auricle. **B.** Technique of regional anesthesia of the auricle.

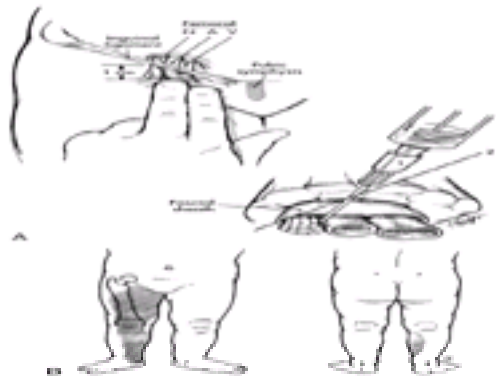
FEMORAL NERVE BLOCK   Femoral nerve block is an effective technique for relieving pain of a femoral shaft fracture and is useful in the multitrauma patient when minimizing narcotics is important. The femoral nerve is lateral to the femoral artery at the inguinal ligament and innervates the anterior thigh, the periosteum of the femur, and the knee joint (Fig. 32-18).


FIG. 32-18. A. Regional block of the femoral nerve. (Adapted from Nichols DG et al: *Golden Hour: The Handbook of Advanced Pediatric Life Support,* 2d ed. St. Louis, Mosby Yearbook, 1996, p 335. Used by permission.) **B.** Sensory innervation of the skin and femur by the femoral nerve is depicted in the shaded area. (From Yaster M et al: *Pediatric Pain Management and Sedation Handbook.* St. Louis, Mosby, 1997, p 176. Used by permission.)

Technique Bupivacaine, 0.5 mL/kg (maximum 1 mL/kg, or 25 mL) of a 0.25 percent solution, is suggested as the preferred LA agent because of its longer duration of action. The usual adult dose is 10 to 20 mL. A sterile field is prepared over and surrounding the femoral triangle. The femoral artery is located midway between the anterior superior iliac crest and the pubic tubercle. The femoral artery is compressed 1 to 2 cm below the inguinal ligament with the nondominant hand. A weal of local anesthetic is raised in the skin and subcutaneous tissues lateral to the artery; the needle is then introduced 60° to the skin lateral and parallel to the femoral artery. A double loss of resistance or "pop" is felt as the needle traverses the fascia overlying the femoral nerve. Onset of anesthesia is 10 to 20 min, and the duration is 3 to 8 h.

INTERCOSTAL BLOCK   Intercostal block is valuable for the management of pain after chest trauma (typically rib fracture) or discomfort from a chest tube. It is a simple block; however, caution should be exercised due to the rapid and high systemic absorption of local anesthetic at this site. Contraindications are local soft tissue disease and contralateral pneumothorax. Complications include pneumothorax and systemic toxicity. The intercostal nerves run anteriorly within the neurovascular bundle along the inferior portion of the rib. Addition of epinephrine enhances the safety of this block. The dosage range for an adult is 3 to 5 mL per segment (child, 1 to 3 mL) 1% lidocaine or 0.25% bupivacaine. To perform this procedure, the landmarks are the palpable intercostal spaces and the midaxillary line. The intercostal space is identified by palpation. On the upper margin of this space the inferior border of the upper rib is palpated. At the mid or posterior axillary line the needle is inserted and advanced at a 90° angle until the rib is reached. The needle is withdrawn slightly and redirected caudally to the inferior aspect of this upper rib (Fig. 32-19).

Hematoma Blocks

Hematoma blocks are a simple, quick, and effective mode of regional anesthesia for isolated closed fracture reduction. Although hematoma blocks are safe the anesthesia that they provide is not as efficacious as the intravenous regional Bier block (see below). The hematoma block is a useful alternative when the Bier block is contraindicated.[28]

Technique Superficial anesthesia is obtained with local infiltration or other technique such as EMLA applied to the skin over the fracture site. An analgesic dose of narcotic can also be given if deemed appropriate. The fracture site is identified and using sterile technique, the hematoma is aspirated using a 10-mL syringe and 20- to 22-gauge needle. Lidocaine 1% without epinephrine is infiltrated (3 to 10 mL, maximum of 0.5 mL/kg) into the fracture cavity and around the periosteum. The block is effective within 5 to 10 min, with several hours duration.

Intravenous Regional Block (Bier Block)

A Bier block is a reliable regional anesthetic procedure involving intravenous administration of local anesthetic distal to an inflated pneumatic tourniquet. It is useful for fracture reductions, large laceration repairs, and foreign body removal. Duration of regional anesthesia is 30 to 60 min. In addition to routine monitoring and resuscitation equipment, the procedure requires a double-cuff tourniquet with a constant pressure gas source (Table 32-12). A standard blood pressure cuff is not acceptable and can result in catastrophic systemic leakage of local anesthetic. Contraindications are listed in   Table 32-13. The need for patients to have nothing by mouth for 4 h prior to the procedure may limit the usefulness of the technique. Use of this technique has also been applied to the lower limb in children, but it is less frequently used for the lower limb with larger children or adults.

Equipment
Double pneumatic cuff with constant-pressure gas source
ECG and BP monitoring
Oxygen
IV access ×2 (24 gauge in the injured limb)
Resuscitation equipment
Medication
Lidocaine 0.5%, 3 mg/kg (1.5 mg/kg minidose)
*Prilocaine 0.5%, 3 mg/kg
Availability of diazepam and resuscitation meds.

*Only in Australia and the United Kingdom.

TABLE 32-12   Equipment and Medications for Bier Block

Peripheral vascular disease
Raynaud's syndrome
Sickle cell disease
Cardiac conduction abnormalities
Hypertension, BP > 200 mmHg systolic
Cellulitis/infected extremity
Uncooperative patients
Young children (<5 years)
Local anesthetic allergy

TABLE 32-13   Contraindications to Bier Block

Technique   Lidocaine (0.6 mL/kg of 0.5 percent solution) without epinephrine is used. In Australia and the United Kingdom, prilocaine (0.6 mL/kg of 0.5 percent solution) is used. Increased efficacy has been shown with the addition of 60 mg of intravenous ketorolac or fentanyl (1 μg/kg) to the lidocaine. Bupivacaine is absolutely contraindicated due to cardiac toxicity. A "minidose" of 1 to 1.5 mg/kg 0.5 percent lidocaine without epinephrine has been used effectively in children. [29]

The patient should have nothing by mouth for at least 4 h. Vital signs and limb neurologic status and perfusion should be recorded and monitored. Intravenous access should be established in both upper limbs, distal to the fracture site on the affected limb. Standard resuscitation equipment and medications should be available. A small dose of narcotic may allay apprehension and the pain of the cuff, which usually occurs after 15 to 30 min.

The injured extremity is elevated and an Esmarch bandage may be applied (distal to proximal) to exsanguinate the limb. Protective padding is then applied to the upper arm to minimize cuff discomfort. Pneumatic double cuffs are then positioned over the padding on the upper arm. The proximal cuff is inflated to 50 to 100 mmHg above systolic pressure. A venous tourniquet may be positioned just proximal to the fracture site to contain the intravenous local anesthetic to this site. The lidocaine (or 0.5 percent prilocaine) is injected slowly over 2 min into the intravenous cannula in the affected limb. Mottling of the affected limb should occur within 2 to 5 min, followed by anesthesia and paresis of the limb. After 10 min, the distal cuff should be inflated (the area under this cuff should now be anesthetized); once the distal cuff is securely inflated, the proximal cuff can be deflated to minimize cuff pain. The distal cuff should not be de-inflated until at least 20 min has elapsed from the time of LA injection for tissue binding of the LA agent to occur, and thus to minimize the potential for toxicity. Loss of tourniquet pressure prior to this time will result in a systemic bolus of local anesthetic and potential systemic cardiac and CNS toxicity.

33 SYSTEMIC ANALGESIA AND SEDATION FOR PAINFUL PROCEDURES

David D. Nicolaou

Pain is either the chief complaint or is implicit in the chief complaint of many patients who seek care in the emergency department (ED). The recognition of its significance is sufficiently widespread that it has been included in the list of symptoms comprising the "prudent layperson" statutory definition of a medical emergency. The treatment of pain is therefore the essence of emergency medicine practice.

The provision of analgesia by physicians has historically been inadequate, and this has been shown to be true in the ED. A study of 198 patients admitted with acutely painful conditions found that only 89 (44 percent) received analgesics in the ED. Of these, 69 percent waited more than 1 h and 42 percent waited more than 2 h for opioid analgesia.[1] Similar findings have been demonstrated in other ED studies of pain treatment, both in the United States and abroad.[2,3] "Oligoanalgesia," the term coined by Wilson and Pendleton to describe the inadequate use of opioids to treat pain, unfortunately is often still present in EDs. Patients likely to receive inadequate analgesia include those over 70 years of age[4] and members of certain ethnic groups.[5] There is conflicting evidence, though, as to whether age is a factor.[6]

The reasons for inadequate analgesia are numerous. Minimal attention to pain management in medical school and residency, concern about narcotic diversion, abuse or addiction, and a limited understanding of analgesic pharmacology have all been hypothesized to contribute to "oligoanalgesia" in the ED. Physical evidence of distress, such as facial expressions and pulse rate, correlates poorly with the patient's perception of pain.[7]

DEFINITIONS

Pain is a noxious sensation transmitted by specialized nervous structures to the brain, where its perception is modified by cognition and emotion.[7] Analgesic and anesthetic techniques may modulate pain at the level of the peripheral nerves, spinal cord, thalamus, or cortex.

Analgesia is "relief of perception of pain without intentional production of a sedated state. Altered mental status may be a secondary effect of medications administered for this purpose."[8] Agents for pain relief interrupt axonal action potential propagation (i.e., "local anesthetics"), modulate the inflammatory cascade (e.g., ibuprofen), or modulate central nervous system (CNS) responses to pain (e.g., enkephalins and opioids).[7,9]

Anxiolysis is the reduction of apprehension without alterations in the level of consciousness.[8] A kind approach to the patient, a realistic and unhurried explanation of what may be expected, distracting conversation, and music have anxiolytic properties.

Neurolepsis is quiescence, indifference to surroundings, and reduced motor activity. Agents used for this purpose include haloperidol and droperidol.

Dissociation is characterized by amnesia, analgesia, sedation, and maintenance of muscle tone. Ketamine is the only commonly used dissociative agent.

Sedation is controlled reduction of environmental awareness.[8] It is not so much a specific level of consciousness as it is a continuum, incorporating anxiolysis or light sedation at one extreme and general anesthesia at the other. The agent or agents chosen, the rate of delivery, the pharmacokinetics of CNS uptake and redistribution, the kinetics of metabolic and elimination pathways, and the degree of patient stimulation may result in varying degrees of sedation over time. The level of sedation is dynamic within a given patient and must be continually assessed to detect changes in its depth. *Light* or *conscious sedation* (CS) produces minimal depression in the level of consciousness and enables the patient to maintain a patent airway and respond appropriately to stimulation or commands.[8] *Deep sedation* produces marked depression of consciousness or unconsciousness and frequently results in loss of independent airway maintenance, protective reflexes, adequate respirations, and satisfactory hemodynamics.[8]

General anesthesia is the presence of "sensory, mental, reflex, and motor blockade and concurrent loss of all protective reflexes."[10]

PRINCIPLES OF CONSCIOUS SEDATION

The indications for CS include the treatment of severe pain, attenuation of the pain and anxiety associated with procedures, rapid tranquilization, and the need to perform a diagnostic procedure (Table 33-1). No single regimen fits all patients and their clinical problems, so doses and agents should be individualized. The physician must integrate the nature of the planned procedure with an assessment of the patient's wishes and physical status, the physician's skills, the patient's intended disposition, the available resources, and a sound knowledge of the pharmacology of the available drugs to formulate a management plan.

Abscess incision and drainage
Wound debridement
Tube thoracostomy
Laceration repair
Fracture manipulation
Joint reduction
Cardioversion
Diagnostic interview
Diagnostic study
Rapid tranquilization

TABLE 33-1   Selected Indications for Systemic Analgesia and Sedation

The agents used for CS often have a relatively narrow therapeutic index. *They should therefore be given in small incremental intravenous doses, allowing adequate time for the development and assessment of peak effect.* If the desired effect seems unusually difficult or easy to achieve, no additional medication should be administered and the patient should be carefully monitored until the cause is determined (Table 33-2). Monitoring of patients and medication administration should be performed by a second provider who understands the pharmacology of the agents used, possesses sound advanced airway-management skills, and will not be

distracted by other tasks during the period when the patients' ability to independently maintain their airway is in doubt.

TABLE 33-2   Differential Diagnoses of Unexpected Drug Effects by Phase of Drug Disposition

[Table 33-3](#) lists equipment for CS. A dedicated area for CS should ideally be established, with well-labeled supplies and equipment always in a consistent location. It can easily be stocked with drugs and labels, resuscitation and monitoring equipment, and equipment for common procedures. Drug dosages and documentation tools may be kept in a single location, improving risk management and quality-improvement efforts.

Adequate staff for monitoring and documentation*

Note: Not all equipment is required for all patients, procedures, and regimens. Suggested minimum equipment is marked with an asterisk.

TABLE 33-3   Equipment for Intravenous Analgesia and Sedation

The use of pulse oximetry during CS is important. By 1990, more than 80 deaths had been reported following the use of midazolam, commonly in conjunction with an opioid, for sedation.[11] Coadministration of midazolam (0.05 mg/kg) and fentanyl (2.0 μg/kg) to 12 healthy volunteers produced hypoxemia (Sa o_2 <90 percent for longer than 10 s) in 11 and apnea in 6.[11] A study of pulse oximetry and nasal end-tidal CO_2 values in 27 ED patients who were sedated with benzodiazepines and/or opiates for a painful procedure noted that one patient developed clinically significant apnea and eight developed clinically silent hypoxemia. [12] The American Medical Association's (AMA) Council on Scientific Affairs subsequently called for the development of standards by specialty societies for the use of pulse oximetry during conscious sedation.[13] Several authors have noted that when oxygen supplementation is given, extreme ventilatory insufficiency may develop in the absence of hypoxemia. The clinical significance of hypoxemia during sedation is still uncertain, but abnormal pulse oximetry certainly counsels providers to evaluate the patient carefully.

ASSESSMENT OF PATIENTS

A patient's general physical status can be conveniently described by using the American Society of Anesthesiologists' (ASA) classification ([Table 33-4](#)). Any medications or intoxicants should be solicited and their effects considered when selecting medications. The patient's airway should be systematically evaluated by the provider who will be responsible for its management during CS (see [Chap. 15](#), "Tracheal Intubation and Mechanical Ventilation"). Depending on clinical circumstances, a patient with an anticipated difficult airway or an ASA classification of 3 or 4 may require consultation with an anesthesiologist. Patients with underlying neurologic diseases such as cerebral palsy, myasthenia gravis, or mental retardation may be much more sensitive to sedatives and consultation is suggested in such cases.

Class	Description	Examples
I	Normal, healthy patient	—
II	Mild systemic disease	Asthma, controlled diabetes
III	Moderate systemic disease	Stable angina, diabetes with hyperglycemia, moderate chronic obstructive pulmonary disease
IV	Severe systemic disease	Unstable angina, diabetic ketoacidosis
V	Moribund	—
+E	Modifier added to any classification indicating "emergency" status	All emergency department patients

TABLE 33-4   American Society of Anesthesiologists Physical Status Classification

CS requires careful assessment of its risks and benefits based on the clinical scenario and the agents to be used. Patients should be fully informed of the risks of the procedure and the alternatives available. The patient's expectations should be carefully explored and should be corrected when they are not reasonable. Clarify that CS is not general anesthesia and that no surety of complete amnesia and analgesia can be offered. Written informed consent documents may be required at certain hospitals, but are not a substitute for the physician's note documenting patient discussion.

PHARMACOLOGY

Analgesics

Opioids are the most common analgesics used in CS. Classes of opioid analgesics include opium (morphine and codeine) and phenylpiperidine (meperidine, fentanyl, sufentanil, and alfentanil) derivatives. The analgesic activity of a drug is traditionally referenced to morphine ([Table 33-5](#)). Following systemic administration, morphine analgesia is mediated through supraspinal μ_1 receptors (possibly by activating descending inhibitory pathways to the dorsal horn cells, and possibly by activating more rostral mechanisms in the brainstem). Spinal cord analgesia is mediated by μ_2 receptors. All opioids have analgesic, sedative, and antitussive effects; they do not reliably produce amnesia when given in doses commonly used for CS. Opioids may also produce muscle rigidity, pruritis, nausea, vomiting, and

constipation, and impair ventilation. Respiratory depression is potentiated in the presence of other CNS depressants.

TABLE 33-5   Dose Equivalents and Pharmacokinetics of Analgesics

Agents in common use for ED CS include morphine, fentanyl, and meperidine.

Meperidine may be a poor choice for ED analgesia in general. It causes more histamine release than either morphine or fentanyl. Its primary metabolite, normeperidine, is bioactive and toxic. Normeperidine causes CNS excitation, including tremors, myoclonus, and seizures, effects that are not antagonized by naloxone. Because normeperidine is excreted by the kidneys, it accumulates in renal insufficiency and with repeated doses. [14] Meperidine may also cause a fatal reaction when coadministered with monoamine oxidase inhibitors. This reaction may be excitatory (agitation, rigidity, hyperpyrexia, seizures, and coma) or depressive (respiratory depression, hypotension, and coma). For these reasons, meperidine is considered a second-line agent in the treatment of pain when opioid analgesics are considered.

MORPHINE   Morphine is a naturally occurring opioid that is approximately 35 percent protein bound, 77 percent ionized at pH 7.4, and poorly lipid soluble. It therefore is slow to penetrate the blood-brain barrier and, after small bolus injections, 10 to 30 min are required before its peak effects are seen. Doses of 0.2 mg/kg result in peak effects in less than 1 h that may last for 4 to 6 h. It releases histamine and therefore may produce hypotension, especially in preload-dependent patients. Its analgesic effects, and its respiratory depression, have been shown to be potentiated by coadministration of hydroxyzine in postoperative patients; [15] the significance of this finding for ED CS is uncertain, especially since hydroxyzine is not recommended for intravenous (IV) use. Morphine undergoes hepatic glucuronidation to morphine-3-glucuronide and morphine-6-glucuronide; the latter is four times as potent as morphine and has a duration of action approximately double that of its parent. The daughter compounds are renally excreted and accumulate in renal insufficiency.

FENTANYL   Fentanyl is a synthetic phenylpiperidine derivative that is approximately 80 to 85 percent protein bound and 92 percent ionized at pH 7.4. However, it is highly lipid soluble, resulting in rapid CNS uptake and an effect onset half-time of 6.4 min. Fentanyl is also distributed into adipose tissue, though, creating a "reservoir" of fentanyl. The size of this reservoir is dose dependent, with higher doses resulting in a progressively increasing duration of effect as the drug is released from tissue stores and then eliminated. Furthermore, distribution from plasma may not result in drug levels below those associated with clinical effects and respiratory depression. Thus, the use of relatively high doses of fentanyl (i.e., in the range of 10 µg/kg) results in greatly prolonged clinical effects and elimination half-times. Fentanyl is metabolized in the liver to inactive compounds.

Fentanyl has been shown to have a low complication rate when used for CS in the ED. Chudnofsky and colleagues noted six cases of respiratory depression (largely in patients who were intoxicated or had received other drugs) and three cases of hypotension among 841 ED patients receiving fentanyl. [16] Respiratory depression occurs at significantly lower fentanyl doses when another respiratory depressant, such as alcohol or midazolam, is present. Chest wall rigidity may occur in a dose-dependent fashion following fentanyl administration; approximately half of healthy volunteers develop chest wall rigidity in response to 15 µg/kg, a dose not usually used in CS in the ED. Rigidity and apnea, however, may occur with even small doses of fentanyl, resulting in respiratory insufficiency. The rigidity is not reliably antagonized by naloxone and may require neuromuscular blockade and intubation to enable adequate ventilation. Fentanyl does not release histamine, which mediates most of the peripheral vascular effects of narcotics, so it rarely produces hypotension. [17]

Anxiolytics

The prototypical anxiolytics in common use for CS in the ED are the benzodiazepines, which potentiate the inhibitory activity of g-aminobutyric acid (GABA) in the CNS by binding to benzodiazepine-specific receptors on the GABA$_A$-benzodiazepine receptor complex, which induces a conformational change that potentiates GABA-mediated chloride influx. This activity results in sedation, amnesia, anxiolysis, and anticonvulsant effects, as well as respiratory depression. The benzodiazepine most commonly used for CS in the ED is midazolam, which produces earlier sedation, more frequent amnesia, less pain on injection, and improved 90-min alertness and readiness for discharge when compared with diazepam. [18]

Midazolam has a number of characteristics favorable for use in ED CS. Its diazepine ring opens at pH values of less than 4, in which form it is quite water soluble. At physiologic pH, the ring closes, rendering midazolam highly lipid soluble, with associated rapid CNS uptake producing peak effects within a few minutes of IV administration. Midazolam's relatively high volume of distribution compared with other benzodiazepines derives from its lipophilicity. This characteristic is greatly amplified in obese patients, resulting in an increase in plasma half-life from 2.7 to 8.4 h. Midazolam is cleared by hepatic hydroxylation to 1-hydroxymidazolam (which is pharmacologically active) and to 4-hydroxymidazolam and 1,4-dihydroxymidazolam, which are conjugated and excreted in the urine.

The combination of midazolam with alcohol or opioids greatly increases sedative and respiratory-depressant effects, and increases the risk of cardiovascular depression. Midazolam should be used cautiously in such cases, with careful monitoring of respiratory and hemodynamic status.

The dose of midazolam should be individualized. Midazolam should be given in small incremental doses until the desired effect is achieved. Aliquots of 0.25 to 0.5 mg given every 3 to 5 min in healthy adults, or 0.1 to 0.25 mg every 5 to 10 min in the intoxicated or elderly patient, is a reasonable starting point. Chronic alcohol users who do not have cirrhosis may require relatively high doses of midazolam to achieve the clinical effects desired.

Anesthetics

PROPOFOL   Propofol (2,6-diisopropylphenol) is a lipid-soluble anesthetic agent that is supplied in an emulsion of soybean oil and purified egg phosphatide, which most egg-allergic patients should tolerate, since it contains no protein. The emulsion is responsible for frequent burning on injection and contains no preservatives, resulting in the risk of bacterial growth in improperly handled solutions. When given by infusion, the onset of sedation is rapid (5 to 10 min), and it resolves rapidly (5 to 10 min) upon discontinuation of the infusion. [19] Amnesia, however, is not reliably produced in doses used for sedation. The drug possesses antiemetic properties. Propofol produces significant cardiovascular depression, with dose-related declines in systolic blood pressure of up to 25 to 40 percent when given in induction doses. This effect is more pronounced in those with hemodynamic compromise and in the elderly.

The use of propofol for ED CS is controversial, and its use outside the operating room by nonanesthesia personnel may be restricted by hospital policy. However, Swanson and colleagues employed a regimen of 2 µg/kg fentanyl and a propofol infusion at a loading rate of 0.21 (mg/kg)/min, followed by a maintenance rate of 3 to 6 (mg/kg)/h in 20 ED patients who required CS. This provided rapid onset of sedation (mean, 6.6 min) and rapid recovery (mean, 6.1 min), with high patient and physician satisfaction scores. Three patients had pain on injection, one had pain and brief hypotension, and two had brief episodes of apnea; 75 percent had amnesia for the procedure at 24 h. [19]

Propofol is a promising agent for CS in the ED because it rapidly produces sedation that quickly abates when the infusion is discontinued. In doses usually used for CS, however, both analgesic and amnestic agents may be required, which may result in hypoventilation and potentiate the already significant hemodynamic effects of

propofol. Further study is required before the routine use of propofol in the ED can be recommended.

KETAMINE Ketamine is a phencyclidine derivative that has analgesic and anesthetic properties. Ketamine anesthesia is often called "dissociative," reflecting electroencephalographically demonstrable discontinuity of the corticothalamic and limbic systems. The patient's eyes often remain open, with spontaneous horizontal and vertical nystagmus. Muscle tone may be increased, and corneal reflexes and spontaneous swallowing are preserved; occasional purposeful movements unrelated to the environment occur. Emergence reactions, characterized by disturbing dreams and vivid, sometimes frightening hallucinations, occur in 5 to 30 percent of patients. Patients at greatest risk for emergence reactions are over 16, female, normally dream, have personality disorders, or receive droperidol or atropine. These phenomena may be attenuated with benzodiazepines given before or at the completion of the procedure.

Ketamine is highly lipid soluble and has a pKa of 7.5, accounting for the rapid (within 1 min) onset of hypnosis following IV injection. Peak brain and plasma concentrations develop within 1 min; rapid redistribution to peripheral tissues results in a mean hypnosis time of 6 min (1.0 mg/kg) to 10 min (2.0 mg/kg). Ketamine is metabolized by the hepatic P-450 system to several active metabolites, the chief among which is norketamine. Norketamine appears within 2 min of a bolus injection and is one-tenth to one-third less potent than the parent drug, but does not appear to penetrate the CNS in quantities sufficient to produce hypnosis. Subsequent metabolites are conjugated and renally excreted, but, because they are much less active, the dose appears not to require adjustment in patients with renal insufficiency. Drugs which induce the P-450 system increase the metabolism of ketamine, whereas inhibitors prolong the duration of effect.

The hemodynamic response to ketamine is complex. It is a direct myocardial depressant and vasodilator, but these effects are typically overshadowed by stimulation of significant CNS sympathetic outflow, resulting in tachycardia and vasoconstriction. (The author's experience is that fentanyl, 1 to 2 µg/kg given 3 to 5 min prior to the procedure, attenuates this effect but increases the frequency of hypoxemia, especially when ketamine is given rapidly.) However, profoundly hypovolemic patients or those with little sympathetic reserve (e.g., cocaine users) may develop hypotension, particularly at rapid rates of injection.

The pulmonary effects of ketamine make it an appealing agent. Although it produces bronchodilation and bronchorrhea, it rarely causes significant respiratory depression unless given by rapid injection (over less than 60 s) or coadministered with other agents. Patients usually retain protective airway reflexes, but this is not a certainty, and careful monitoring is necessary when ketamine is used.

Before giving ketamine, it is important to consider the drug's likely nontherapeutic effects. If a hyperdynamic state or bronchorrhea may not be well tolerated, then appropriate premedication (opioids or glycopyrrolate) should be given or another agent chosen. A specific discussion of the emergence phenomenon with the patient, family, and friends will reduce the impact of this occasionally dramatic event.

The dose of ketamine commonly used for analgesia is 0.5 to 1.0 mg/kg over 60 s. Anesthesia is produced by doses of 1 to 2 mg/kg. When anesthetic doses are administered, midazolam should be given during the emergence phase to attenuate emergence phenomena.

Adjunctive Agents

Antiemetic agents are useful in the treatment of nausea and vomiting accompanying opioid therapy. Their value as "potentiators" of opioids is not clear, and they should not be routinely employed for this purpose.

Antidotal agents

NALOXONE Naloxone, which is a competitive antagonist of opioids at µ receptors, is indicated for reversal of unwanted respiratory depression following opioid administration. Patients who are opioid dependent may develop withdrawal following the administration of naloxone. Naloxone may not reverse chest wall rigidity caused by fentanyl. It should be given in small increments (0.1 to 0.2 mg every 1 to 2 min) until the desired effect is achieved. Because patients who receive long-acting opioids or who clear opioids slowly may redevelop respiratory depression after clearing all or part of an effective dose of naloxone, continual patient reassessment is required after naloxone administration.

FLUMAZENIL Flumazenil, which is a competitive antagonist of benzodiazepines, is given in IV aliquots of 0.1 to 0.2 mg every 1 to 2 min until the desired effect is achieved. It has a half-life of 45 to 104 min, rendering resedation a possibility if the effects of a long-acting benzodiazepine are reversed with flumazenil. It should be used with caution in benzodiazepine-dependent patients. Flumazenil was shown in a study of 133 ED patients to reverse midazolam-induced sedation safely and effectively. However, the time from completion of the procedure to discharge from the ED was no shorter in the group treated with flumazenil than in the control group.[26] Flumazenil is indicated for reversal of respiratory depression caused by benzodiazepine during CS, but its routine use to "awaken" patients cannot be recommended.

DISCHARGE

Discharge criteria for CS are outlined in Table 33-6. These guidelines may require modification based on patient age, clinical circumstances, the agents used, and the patient's social situation. Patients must not be permitted to drive or operate heavy machinery for at least 24 h after CS. The agents used for CS often produce anterograde amnesia, which may be present even when consciousness appears otherwise normal. It is therefore vital to evaluate the patient's ability to retain information prior to discharge.

Vital signs stable for at least a half hour
No evidence of respiratory distress
Minimal or no nausea, vomiting, or dizziness
Alert, oriented, and able to retain information
Able to take fluids and medications by mouth
Ambulation consistent with preprocedure status
Receives, comprehends, and retains discharge instructions
Responsible person present to accompany patient

TABLE 33-6   Discharge Criteria for Patients Receiving Conscious Sedation

Discharge planning is an important component of CS and should be part of the preprocedure evaluation process. A patient who is likely to require prolonged postprocedure monitoring or treatment should be considered for hospital admission. If a companion is required for discharge, he or she should be identified prior to beginning CS.

POLICY ISSUES

Clinical Standards and Documentation

The increasingly widespread use of IV sedation and analgesia outside the operating room has garnered the attention of various organizations. The clinician's decisions regarding CS are increasingly subject to regulations and standards, and these in turn are evolving in parallel with local and national CS experience. The development of guidelines concerning ED CS has been hampered by the lack of high-quality clinical evidence, such as clinical trials, supporting particular practices. As a result, few evidence-based standards exist.

The Joint Commission on Accreditation of Healthcare Organizations (JCAHO) standard specifies that a uniform standard of care must be provided throughout an

accredited institution. This means that situations in which protective airway reflexes are typically expected to be lost might be held to the standard of care provided in the operating room.[21] The American College of Emergency Physicians[22] and the American Society of Anesthesiologists[23] have also begun to promulgate guidelines. Each ED should develop standards for CS, and then strive to provide and document care consistent with that standard.

Costs

The true costs and benefits of CS are presently difficult to judge. The current costs of individual drugs are presented in Table 33-7. The costs of a properly equipped CS room, staff to monitor patients, drugs, and risk management have not been rigorously studied. The impact of CS on the length of stay, patient satisfaction, and referral patterns is difficult to assess. Although outcome and cost issues are not yet well defined, CS is nonetheless fundamental to the effective and humane performance of painful procedures in the ED.

Drug	Formulation	Cost
Morphine sulfate	10 mg/mL	$0.60
Fentanyl	100 μg/2 mL	$2.06
Midazolam	5 mg/mL	$10.90
Ketamine	500 mg/5 mL	$19.44
Propofol	200 mg/20 mL	$14.48
Naloxone	0.4 mg/1 mL	$5.25
Flumazenil	0.5 mg/5 mL	$36.88

Note: *Cost to pharmacist per unit of use (1 vial) based on case prices.

34 MANAGEMENT OF PATIENTS WITH CHRONIC PAIN

David M. Cline

Chronic pain is defined as a painful condition that lasts longer than 3 months. [1] Chronic pain can also be defined as pain that persists beyond the reasonable time for an injury to heal or a month beyond the usual course of an acute disease. There are four basic types of chronic pain: (1) pain persisting beyond the normal healing time for a disease or injury, (2) pain related to a chronic degenerative disease or persistent neurologic condition, (3) cancer-related pain, (4) pain that emerges or persists without an identifiable cause. Chronic pain differs from acute pain in its function. Acute pain is an essential biologic signal to warn the individual to stop a potentially injurious activity or to prompt one to seek medical care. Chronic pain serves no obvious biologic function. Chronic pain patients presenting to the emergency department (ED) have not been well studied, despite their apparent numbers.

Complete eradication of pain is not a reasonable end point in most cases. Rather, the goal of therapy is pain reduction and return to functional status. Chronic pain syndromes discussed in this chapter include myofascial headaches, "transformed" migraine headaches, fibromyalgia, myofascial chest pain, back pain, complex regional pain types I and II, postherpetic neuralgia, and phantom limb pain. Drug-seeking patients are also covered.

EPIDEMIOLOGY

Chronic pain affects about a third of the population at least once during a patient's lifetime, at a cost of—80 to 90 billion dollars in health care payments and lawsuit settlements annually. Chronic pain is also common in those who do not seek medical attention. Despite similar subjective pain, those who seek medical attention are less physically active, experience more social alienation and more psychologic distress than those who do not seek medical attention.

The causes of chronic pain are more complex than the causes of acute pain. Chronic pain may be caused by (1) a chronic pathologic process in the musculoskeletal or vascular system, (2) a chronic pathologic process in one of the organ systems, (3) a prolonged dysfunction in the peripheral or central nervous system, or (4) a psychological or environmental disorder. In contrast, acute pain may be influenced by, but is not primarily caused by, a psychological or continuous environmental disorder. A detailed listing of all the epidemiologic factors of the various chronic pain syndromes is beyond the scope of this chapter. However, in general, patients who attribute their pain to a specific traumatic event experience more emotional distress, more life interference, and more severe pain than those with other causes. [2]

PATHOPHYSIOLOGY

The pathophysiology of chronic pain can be divided into three basic types. Nociceptive pain is associated with ongoing tissue damage. Neuropathic pain is associated with nervous system dysfunction in the absence of ongoing tissue damage. Finally, psychogenic pain has no identifiable cause. [3] Many chronic pain states begin with an episode of nociceptive pain and then continue with neuropathic or psychogenic pain. For example, an acute injury with fracture involves nociceptive pain, but an associated nerve injury may lead to neuropathic pain. Chronic disability may lead to psychogenic pain. Nociceptive pain results from the stimulation of nociceptors in tissues or organs by noxious mechanical, thermal, or chemical stimuli. Chemical mediators of inflammation such as bradykinins and prostaglandins are essential elements in the pathophysiology of nociceptive pain. Examples of chronic nociceptive pain include cancer pain and pain due to chronic pancreatitis. Patients with nociceptive pain usually respond well to centrally acting analgesics. Neuropathic pain is caused by disease of the central or peripheral nervous system. Examples of neuropathic pain include complex regional pain type II (causalgia), postherpetic neuralgia, and phantom limb pain. Neuropathic pain responds poorly to common analgesics, including narcotics. Psychogenic pain is a diagnosis of exclusion and can be difficult to establish in the ED. Patients with psychogenic pain believe their pain is physical and tend to strongly reject the concept that it is psychological.

CLINICAL FEATURES

To better define the psychology of chronic pain, psychiatrists have divided patients' characteristics into two groups. [4] The first group has normal psychologic function at baseline. However, continued pain and its effects, such as inability to work or altered body image, result in psychological dysfunction. The second group has primary psychopathology that predates the onset of chronic pain. Hypochondriacal, hysterical, pain-prone, and depressive personalities are included in this group. The "seven D's" (Table 34-1) summarize the clinical features of these groups. [5]

Characteristic	Features
Drugs	Misuse of narcotics or other medications
Doctors	Tendency to "doctor shop" and play one physician against another
Dysfunction	Bodily impairment related to the physical and emotional factors
Disability	Inability to work or hold a job
Dependance	Loss of self-reliance and helplessness
Dramatization	Exaggeration, acting out by verbalization or by body language
Depression	Despair and negative attitudes

TABLE 34-1 Psychological Characteristics of Chronic Pain Patients

The following set of historical inquiries may prove helpful in the ED. The patients should be asked to describe the nature of the current pain, initiating and exacerbating or relieving factors. Other useful information includes determination of the chronic nature of their pain, quantification of similar episodes, and sources and modes of treatment, including medications and dosages for physician-prescribed, over-the-counter, or alternative medications. Outcomes of previous therapeutic efforts and the effect of the condition on the patient's functional status are also important. Addiction to drugs or alcohol or experience with detoxification programs should also be noted. Finally, a review of systems should be done to rule out any other conditions.

Substance abuse is a frequent problem in chronic pain patients. Patients referred to chronic pain clinics meet *Diagnostic and Statistical Manual of Mental Disorders,* third revised edition (DSM III-R) criteria for active substance abuse disorders in 12 to 24 percent of cases, while 9 percent meet criteria for remission diagnosis. [6,7] Drug detoxification is often the first step of the therapeutic plan for new patients referred to a pain clinic.

Objective findings of acute pain include tachycardia, hypertension, diaphoresis, and muscle spasms on stimulation. Objective evidence of chronic pain includes muscle atrophy in the distribution of pain due to disuse, skin temperature changes due to the effects of the sympathetic nervous system after disuse or secondary to nerve injury, and trigger points, which are focal points of muscle tenderness and tension. However, these findings do not have to be present for the pain to be factual.

Signs and symptoms of chronic pain syndromes are summarized in Table 34-2.

TABLE 34-2   Signs and Symptoms of Chronic Pain Syndromes

MYOFASCIAL HEADACHES AND TRANSFORMED MIGRAINE   Myofascial headache is a variant of tension headache and is characterized by the presence of trigger points on the scalp; constant, squeezing pain; and occasionally shooting pain. Nausea, vomiting, neck pain, and neck tenderness may be present. It is important to differentiate this disorder from common tension headache because myofascial headache may benefit from referral for injection of trigger points. "Transformed migraine" is a syndrome in which classic migraine headaches change over time and develop into a chronic pain syndrome. One cause of this change is frequent treatment with narcotics.[8] In this regard, patients who initially have "vascular symptoms" eventually have predominantly muscular symptoms: nonthrobbing, squeezing, bandlike pain associated with muscle tenderness and tension. Nausea and vomiting or failure of oral antimigraine medications often prompts an ED visit.

FIBROMYALGIA AND CHRONIC MYOFASCIAL CHEST PAIN   Fibromyalgia is classified by the American College of Rheumatology as the presence of 11 of 18 specific tender points, nonrestorative sleep, muscle stiffness, and generalized aching pain, with symptoms present longer than 3 months.[9] Chronic myofascial chest pain is classically a dull, constant pain associated with trigger points on the chest wall. Symptoms may mimic ischemic myocardial-type chest pain but usually is not provoked by exercise (unless the movement involves the use of chest or arm muscles) and is not completely relieved by rest.

BACK PAIN   Risk factors for chronic back pain following an acute episode include male gender, advanced age, evidence of nonorganic disease, leg pain, prolonged initial episode, and significant disability at onset.[10] Chronic back pain symptoms and causes can be divided into myofascial or muscular, articular, and neurogenic types. Myofascial back pain is characterized by constant dull and occasional shooting pain that does not follow a classic nerve distribution. Pain may or may not be exacerbated by movement. Usually trigger points can be found at the site of greatest pain, and muscle atrophy is not found. Range of motion of the involved muscle is reduced, but there is no actual muscle weakness. Previous recommendations for bed rest in the treatment of back pain have proven counterproductive.[11] Exercise programs have been found to be helpful in chronic low back pain.[12] Articular back pain is characterized by constant or sharp pain that is exacerbated by movement and associated with local muscle spasm. Myofascial and articular back pain may be indistinguishable from each other except by advanced imaging techniques beyond the usual scope of practice in the ED. Neurogenic back pain is classically characterized by constant or intermittent pain that is burning, shooting, or aching. The pain is usually more severe in the leg than in the back and follows a dermatome. Muscle atrophy as well as reflex changes can be seen over time.

COMPLEX REGIONAL PAIN   Complex regional pain type I, also known as reflex sympathetic dystrophy, and complex regional pain type II, also known as causalgia, may be seen in the ED 2 weeks or more after an acute injury.[13] These disorders cannot be differentiated from one another on the basis of signs and symptoms. Type I occurs because of prolonged immobilization or disuse, and type II occurs because of a peripheral nerve injury. These disorders should be suspected when a patient presents with classic symptoms: allodynia (pain provoked with gentle touch of the skin), and a persistent burning or shooting pain. Associated signs early in the course of the disease include edema, warmth, and localized sweating. Therefore, it may be difficult to distinguish this disorder from an underlying wound infection or osteomyelitis. Later signs include periods of edema and warmth that alternate with cold, pale, cyanotic skin and eventually atrophic changes. Complex regional pain is an important diagnosis to make, since early steroid treatment may prevent ongoing symptoms.

POSTHERPETIC NEURALGIA   The classic pain of postherpetic neuralgia may follow the course of an acute episode of herpes zoster. Pain is characterized by allodynia (defined above) and shooting, lancinating (tearing or sharply cutting) pain. Often, patients have hyperesthesia in the involved dermatome. Occasionally there are pigmentation changes in the distribution of the involved dermatome, but this is not unique to postherpetic neuralgia.

PHANTOM LIMB PAIN   Phantom limb pain is quite variable in presentation but is more frequent in patients who had pain in the extremity before amputation. Pain may be aching, cramping, burning, tearing, or squeezing. Failure to respond to any treatment, including narcotics, is common.

DIAGNOSIS

The most important task of the emergency physician is to distinguish chronic pain from an exacerbation that heralds a life- or limb-threatening condition. A complete history and physical examination should either confirm the chronic condition or point to the need for further evaluation when unexpected signs or symptoms are elicited. An electrocardiogram (ECG) may be needed in some cases of chronic myofascial chest pain to help differentiate it from acute ischemic chest pain. Because chronic pain patients may be frequent visitors to the ED, the entire staff may prejudge their complaint as chronic or factitious. Physicians should insist that routine procedures be followed, including a full triage assessment and a complete set of vital signs.

Rarely is a provisional diagnosis of a chronic pain condition made for the first time in the ED. The exception is a form of post–nerve-injury pain, complex regional pain. The sharp pain from acute injuries, including fractures, rarely continues beyond 2 weeks' duration. Pain in an injured body part beyond this period should alert the clinician to the possibility of nerve injury, and proper treatment, discussed below, should be instituted.

Definitive diagnostic testing of chronic pain conditions is difficult, requires expert opinion, and often expensive procedures such as magnetic resonance imaging (MRI), computed tomography (CT), and thermography. Therefore, referral back to the primary source of care and eventual specialist referral are warranted to confirm the diagnosis.

TREATMENT

Emergency physicians must avoid labeling patients with pain as either drug seekers or legitimate patients deserving narcotics for pain relief. With these labels, emergency physicians may exacerbate the problem and promote the learned pain response, where patients believe that they must come to the ED for pain relief. Chronic pain patients often request narcotics, although the lure of going to the ED can be just as strong without receiving narcotics. Any drug that alters sensorium can exacerbate the learned pain response. The external rewards of visiting the ED for medication or evaluation are many: attention and comforting from family and nursing staff, status as a special patient who must go the ED for pain control, avoiding responsibilities at work and at home, potential money if litigation is involved, and potential income if a disability claim is pending.

Treatment with opiates frequently contributes to the psychopathologic aspects of the disease. Chronic pain and disability lead to distress and increased stress in the life of the patient. The potentiated psychological stress heightens physiologic arousal, which increases pain sensations. Elevated pain sensations exacerbate the patient's disability. Opiate use only temporarily relieves the pain sensations, but the side effects frequently increase the disability associated with chronic pain, therefore exacerbating the psychological stress and the syndrome. Furthermore, a new problem is created as the patient becomes preoccupied with seeking pain

relief from opiates. Another essential consideration is that many types of chronic pain are poorly controlled by opiates, and yet the side effects remain. It is interesting to note that the presence of objective evidence of pain does little to influence a physician's administration of narcotics. Physicians' opiate-prescribing habits are most commonly prompted by observed pain behaviors, such as facial grimacing, audible expressions of distress, or patients' avoidance of activity regardless of the physical findings.[15]

With the exception of cancer-related pain, the use of opioids in the treatment of chronic pain is controversial. Many pain specialists feel that they should not be used. There are two essential points that affect the use of opioids in the ED on which there is agreement: (1) opioids should only be used in chronic pain if they enhance function at home and at work, and (2) a single practitioner should be the sole prescriber of narcotics or should be aware of their administration by others. Finally, a previous narcotic addiction is a relative contraindication to the use of opioids in chronic pain. In contrast to the concerns listed above, narcotics are both recommended and effective treatment for cancer pain. Long-acting narcotics such as methadone or transdermal fentanyl may be more effective than the short-acting agents.

The management of chronic pain conditions is listed in Table 34-3. The medications listed under "Primary ED Treatment" are familiar to emergency physicians. While NSAIDs are most helpful in conditions where there is ongoing tissue injury, such as chronic inflammatory arthritis or cancer-related nerve or bone damage, they are also helpful in many cases of chronic pain where no evidence of tissue damage or inflammation is evident. Nonsteroidal anti-inflammatory drugs have been shown to be more helpful in acute than in chronic pain.[16] However, the need for long-standing treatment of chronic pain conditions may limit the safety of the NSAIDs. Standard dosing procedures may be followed except in the elderly (see following section).

Disorder	Primary ED Treatment	Secondary Treatment*	Possible Referral Outcome

*If started in the ED, consultation and/or follow-up with pain specialist or personal physician recommended.
Abbreviations: NSAIDs, nonsteroidal anti-inflammatory drugs; RSD, reflex sympathetic dystrophy; TENS, transcutaneous electrical nerve stimulation.

TABLE 34-3   Management of Chronic Pain Syndromes

Antidepressants and, most commonly, the tricyclic antidepressant drugs, are the most frequently used drugs for the management of chronic pain. Often, effective pain control can be achieved at doses lower than typically required for relief of depression.[3] Tricyclic antidepressants appear to enhance endogenous pain inhibitory mechanisms.[17] When antidepressants are prescribed in the ED, a follow-up plan should be in place. Discussion with a pain specialist is often beneficial. The most common drug and dose is amitriptyline 10 to 25 mg, 2 h prior to bedtime.

Anticonvulsants are used for several pain disorders, especially neuropathic pain. Anticonvulsants prevent bursts of action potentials, which may prevent the severe lancinating pain of certain neuropathic syndromes. Carbamazepine (start 100 to 200 mg bid), valproic acid (start 15 mg/kg/d divided bid), and clonazepam (start 0.5 mg tid) are the most frequently used.

Muscle relaxants, such as cyclobenzaprine 10 mg every 8 h, have been useful for chronic pain patients. Their sedating effects may limit their success.

Tramadol is an atypical centrally active analgesic. It has less respiratory depression, less tolerance, and less abuse potential than do opiates. Tramadol has been used with success in patients with fibromyalgia, migraine headaches, low back pain, and neuropathic pain. The dose of tramadol is 50 to 100 mg every 4 to 6 h by mouth.

Chronic Pain in the Elderly

Elderly patients frequently complain of chronic pain. Unfortunately, many of the commonly used medications for pain have higher complication rates in the elderly. In particular, the nonsteroidal anti-inflammatory drugs (NSAIDs) are associated with higher rates of gastrointestinal bleeding and renal disease in the elderly. Opioids also may cause debilitating sedation and/or constipation in the elderly; however, opioids may have less debilitating side effects than NSAIDs. Doses of many agents should be reduced when treating the elderly, to avoid side effects, and it is essential that a follow-up plan be in place at the time of discharge. There is a perception that the elderly are undermedicated for pain control. While this may be true, the elderly do not seem to be undermedicated more than other age groups.[14]

DISPOSITION

Referral to an appropriate specialist is one of the most productive means of aiding in the care of chronic pain patients who present to the ED. Chronic pain clinics have been successful at changing the lives of patients by eliminating opioid use, decreasing medication use by two-thirds, and pain levels by one-third, and increasing work hours twofold.[15] Patients' compliance with pain clinics may improve if the benefits are explained. The Canadian health system has initiated a chronic pain registry.[19] Patients are referred to the registry if they have had ten or more pain-related visits to the ED in a 12-month period or by the discretion of an emergency physician. An independent third-party consultation with a chronic pain specialist is provided. The success of the system is being assessed.

Admission to the hospital is rarely indicated for chronic pain patients. However, occasionally patients may be admitted for pain control, possibly using self-controlled analgesic administration.

MANAGEMENT OF PATIENTS WITH DRUG-SEEKING BEHAVIOR

There are few controlled studies on "drug-seeking behavior." Although it is known that approximately 10 percent of patients seeking treatment for drug addiction identify a prescription drug as the principal drug of abuse,[20] there is no statistical documentation of the problem in the ED. The spectrum of drug-seeking patients includes those who have chronic pain and have been advised to avoid taking narcotics, the drug addict who is trying to supplement his or her habit, and the "hustler" who is obtaining prescription drugs to sell on the street. Patients may move from chronic pain patient to addict to hustler as their social and financial support deteriorates.

Epidemiology

It is impossible to separate prescription drug abuse from other forms of substance abuse. Narcotics, stimulants, depressants, and unexpected drugs of abuse, such as antibiotics (used to treat patients with suspected intravenous drug abuse infections) and b blockers (used to limit debilitating subjective anxiety), are examples of abused agents. The magnitude of this problem has been cited as being huge, but the accuracy of the statistics has been called into question.[21] Physicians have been well implicated in this process. The "four D's" have been used by the American Medical Association to describe physicians who contribute to prescription drug abuse: (1) the disabled (impaired) doctor; (2) the dishonest ("script") doctor, who illegally sells drugs; (3) the duped doctor, who unwittingly prescribes drugs of abuse to drug-seeking patients; and (4) the dated doctor, whose obsolete prescribing practices may lend themselves to drug dependency or abuse.[22] Drug-seeking patients are very persistent and successful. A study conducted in Portland found that drug-seeking patients presented to the ED 12.6 times per year, visited 4.1 different hospitals, and used 2.2 different aliases. Patients who were refused narcotics at one facility were successful in obtaining narcotics at another facility 93 percent of the time and were later successful at obtaining narcotics from the same facility 71 percent of the time.[23]

Clinical Features

Because of the spectrum of drug-seeking patients, the history given may be factual or fraudulent. Drug seekers may be demanding, intimidating, or flattering. In one ED study, the most common complaints of patients who were drug seeking were (in decreasing order): back pain, headache, extremity pain, and dental pain.[23] Patients may complain of panic disorder or drug withdrawal symptoms and request benzodiazepines. Additional fraudulent techniques are listed in Table 34-4. In some cases, observations of vital signs and physical examination findings will help the physician identify factitious illness, but even experienced clinicians are frequently misled.[23]

TABLE 34-4 Common Fraudulent Techniques Used by Drug Seekers and Their Management

Patients should be examined for signs of intravenous drug addiction, including needle marks and healed or active superficial cutaneous abscesses, and the heart should be examined for evidence of a new murmur and other signs of endocarditis. Patients attempting to simulate nephrolithiasis can falsify hematuria by biting their buccal mucosa and spitting into the urine sample or by pricking their finger and dipping it into the urine sample. Patients who are suspected of factitious hematuria should be examined for these findings. Patients with factitious acute injury may massage old deformities to create the appearance of erythema and swelling, but this will dissipate over time if the clinician stops the patient from holding the extremity. Patients may self-mutilate, usually with the dominant hand, and seek narcotics. Patients may have evidence of chronic pain or, most commonly, have completely normal physical examination findings. Finally, it is widespread anecdotal experience that such patients will relate "allergy" to alternative pharmacotherapy, insisting that only one or two specific narcotics are effective.

Diagnosis

The diagnosis of drug-seeking behavior may not be possible in the ED. The medical record can provide a wealth of information regarding the patient, including documentation proving the patient is supplying false information. Often the diagnosis is suspected in the ED but cannot be confirmed. In such cases, a notation should be made in the chart listing the physician's concerns, but physicians should be careful when using diagnoses such as "drug-seeking behavior" without solid evidence. A listing or card file at the nurses' desk of "drug seekers" violates patient-physician confidentiality unless it is part of the patient's permanent medical record and subject to the same controls restricting access. Drug-seeking behaviors can be divided into two groups: "predictive" and "less predictive" of drug-seeking behavior (Table 34-5). The behaviors listed under "predictive" are illegal in many states and form a solid basis to refuse narcotics to the patient. However, the possibility still exists that the patient could have pain and should be evaluated for a medical or surgical illness and possibly treated with a nonnarcotic drug.

Behaviors Predictive of Drug-Seeking Behavior*

Sells prescription drugs
Forges/abuses prescriptions
Factitious illness, requests narcotics
Uses aliases to receive narcotics
Admits to illicit drug addiction
Conceals multiple physicians prescribing narcotics
Conceals multiple ED visits receiving narcotics

Less Predictive of Drug-Seeking Behavior

Admits to multiple doctors prescribing narcotics
Admits to multiple prescriptions for narcotics
Abusive when refused
Multiple drug allergies
Uses excessive flattery
From out of town
Asks for drugs by name

*Behaviors in this category are unlawful in many states.

TABLE 34-5 Characteristics of Drug-Seeking Behavior

Specific Issues: Legal Implications

The Drug Enforcement Agency licenses physicians (along with state agencies) to administer or dispense controlled substances. However, it is state law that determines most prescribing regulations. All physicians should be aware of state laws regulating controlled substances prescribed in their practice setting. For example, some states mandate reporting the use of schedule II agents, and some states limit monthly dosing. Prescribing narcotics to a known drug addict could result in restriction of the physician's medical license in some states. However, if a patient refuses to acknowledge his or her addiction, the physician cannot be held accountable unless medical records at the facility where the patient presents document the addiction. In all states it is illegal for patients to forge or alter prescriptions. In some states it is illegal for patients to use aliases or factitious illness to obtain narcotics. Further, in some states, concealing previous or recent prescriptions for narcotics when requesting narcotics from a new practitioner is illegal. Physicians should ask patients about previous addiction and recent treatment with narcotics.

Treatment and Disposition

The treatment of drug-seeking behavior is to refuse the controlled substance, consider the need for alternative medication or treatment, and consider referral for drug counseling. Unfortunately, successful management has been documented only by anecdote and case report.[24]

The patient who complains of multiple drug allergies can be difficult. Occasionally the medical record will show previous administration of the drug in question (usually a narcotic substitute) with no adverse reaction other than no pain relief. When confronted with a physician's discovery of their fraudulent behavior, many drug-seeking patients become verbally abusive, and hospital security may be required to escort the patient out of the department. Alternatives to narcotics can be offered, and patients should understand that refusal to prescribe narcotics is not a refusal of care.

When drug-seeking behavior is confirmed or suspected in ED, it should be documented in the chart with careful attention to the facts. When physicians are notified by a pharmacist of forged or altered prescriptions, law enforcement authorities should be called, and physicians should cooperate with the legal investigation. The prosecution of many fraudulent behaviors, such as using aliases to obtain narcotics, requires the involvement of the state bureau of investigation or a similar agency of the state. Physicians may inquire about the legal proceedings with either the hospital attorney or the police. Finally, the primary care provider or pain specialist can be contacted to establish a contract with the patient. Such contracts may include specific directions for ED treatment and usually stipulate that prescriptions will only be given by the primary care provider. Such contracts ease the burden for emergency physicians and set realistic expectations for the patient.

35 EVALUATION OF WOUNDS

Louis J. Kroot

Acute traumatic wounds are routinely evaluated in emergency departments. The most common include isolated lacerations, abrasions, and avulsions, along with those wounds associated with multiple trauma. This chapter discusses the basic principles of acute wound assessment.

EPIDEMIOLOGY

Approximately 12 million traumatic wounds are treated annually in US emergency departments, accounting for more than 10 percent of all visits. [1] The two groups most frequently treated are males, aged 15 to 44, and women over age 75. The most frequently involved body locations are the face, scalp, fingers, and hands. [2,3,4 and 5] Approximately half of traumatic lacerations seen in the emergency department are sustained from blunt objects. Children have different wound epidemiologic characteristics: wounds are more likely to be located on the head, linear, shorter, less contaminated, and more often caused by blunt trauma, compared with wounds of adults.[6]

PATHOPHYSIOLOGY

Acute traumatic wounds are caused either by shear, compressive, or tensile forces, which vertically separate the epithelium and dermis. [7] Shear forces are produced by sharp objects that cut through the skin. The amount of energy required to cut through the skin with a sharp object is relatively low and directed to a very small area. Thus, little energy is deposited into the surrounding tissue and there is minimal cell damage. Typically, the resultant wound has straight edges, little contamination, and heals with a good result. Compressive and tensile forces are produced when a blunt object impacts the skin at right and oblique angles, respectively. In contrast to shear forces, the amount of energy deposited from compressive and tensile injuries is larger, with significant amounts applied to the area around the wound causing disruption of the microvasculature. The amount of force required to produce a cutaneous laceration is in the range of 2.5 J/cm ^{2}. The devitalized tissue creates an anaerobic environment, which impairs the ability of leukocytes to function and supports bacterial proliferation. Experimentally, wound infections have been produced in compressive injuries with inoculums of about 100,000 organisms per gram of tissue compared with the requirement for about 10,000,000 organisms per gram in shear injuries. Compressive wounds tend to be stellate or complex, with ragged or shredded edges. Tensile wounds tend to be triangular or produce a flap. In cross section, tensile wounds tend to be "skived," that is, cut oblique through the skin with a thin edge on one side and a thick edge on the other.

The body responds to the injury by initiating a series of restorative stages to recover tissue continuity and strength. In general, tensile strength of the wounded area recovers approximately 50 percent by 40 days and nearly 100 percent by 150 days after injury. These stages of wound healing are described as hemostasis, inflammation, epithelialization, angiogenesis, fibroplasia, contraction, and scar maturation. All these stages are stimulated by various tissue growth factors (Table 35-1).

Platelet derived
 Transforming growth factors (TGF's): TGF-α and TGF-β
  Stimulate fibroblasts and epithelial and vascular endothelial cells
  Promote epithelialization and neovascularization
 Platelet-derived growth factor (PDGF)
  Stimulates fibroblasts and smooth muscle cells to migrate toward the
   wound
  Facilitates formation of procollagen and collagen fibrils
Macrophage derived
 Acidic fibroblast growth factor (aFGF)
 Basic fibroblast growth factor (bFGF)
 Macrophage-derived growth factor (MDGF)
 Interleukin 1 (IL-1)
  Stimulates procollagen production to form collagen fibrils
  Smooth muscle cells help collagen fibrils contract and increase tensile
   strength
Epithelial cell derived
 Epidermal cell-derived growth factor (EDF)
  Stimulates epithelial cells mitosis and accelerates healing

TABLE 35-1   Tissue Growth Factors and Their Effects

Hemostasis is initiated at the time of injury. Tissue and vascular smooth muscle contraction compresses small bleeding vessels. Activation of platelets and the coagulation cascade produce a fibrin clot within the lumens of the severed vessels and within the exposed wound.

Inflammation is stimulated by chemotactic factors released by activated platelets and the complement cascade, which initially attract neutrophils followed by macrophages. Neutrophils and macrophages phagocytose dead tissue, foreign material, and bacteria, providing physiologic debridement and preventing infection. Neutrophils perform this function for the first 72 h after injury, and macrophages perform this task for up to 30 days after a traumatic wound.

Epithelializatior reaches a peak about 24 h after the injury as the inflammatory response stimulates cell division in the stratum germinativum. Epithelial cells migrate across a closed traumatic wound during the first 24 to 48 h, making the wound impervious to water. Eschar and surface debris impede this process.

Angiogenesis is vital to wound repair. New vessel growth is detectable at 72 h and reaches its peak at 7 to 10 days, accounting for the often-marked erythema seen at this time. As the wound matures, vascularity decreases nearly back to baseline at 30 days.

Fibroplasia, with collagen synthesis, reaches a peak by 7 days and essentially replaces the inflammatory mass in the wound by 3 weeks. At the same time as increasing collagen synthesis, hydrolysis and breakdown of old and damaged collagen are also taking place. The period between 7 and 10 days is the vulnerable time when the balance between collagen synthesis and breakdown is most tenuous and unwanted wound separation occurs.

Wound contraction and scar remodeling occur over the next several months. Contraction significantly modifies the cosmetic appearance of treated wounds. An important principle of wound repair is to take this expected contraction into account and repair lacerations with everted edges. Remodeling is such a powerful process that, at the time of suture removal, it is impossible to predict the ultimate appearance of wounds. [8]

During wound healing, excess fibroblastic activity can create excess tissue, developing either a hypertrophic scar or a keloid. Hypertrophic scars are excess collagen confined to the original boundaries of the wound and are more common in areas of increased tissue tension. Keloids have excess scar tissue from the wound extending beyond the original borders. Keloids are most often seen in African Americans but can occur in any dark-pigmented skin area.

PRIORITIES

Unless airway and breathing are compromised or there is active bleeding from the wound edge, acute traumatic wounds are evaluated and treated after other life- or limb-threatening conditions have been evaluated and managed. To maximize patient safety and comfort, it is generally best to evaluate patients supine on a stretcher. Hemostasis may be required and is best done by local pressure. Sometimes, wound repair must be delayed to address other issues. In this case, fresh wounds

should be covered by saline-moistened gauze to prevent drying. Most wounds can be assessed without analgesia and anesthesia, provided the physician proceeds slowly and carefully. Encircling clothing, rings, and jewelry should be removed as soon as possible to reduce the potential for damaging edema and contamination.

Wound repair has been traditionally divided into three categories. *Primary closure* (healing by primary intention) is performed with sutures, staples, or adhesives at the time of initial evaluation. *Secondary closure* (healing by secondary intention) is where the wound is allowed to granulate and fill in with eventual epithelialization with only cleaning and minimal debridement. *Tertiary closure* (delayed primary closure) is where the wound is initially cleaned, debrided, and observed for a period of time (typically 4 or 5 days) before closure.

MEDICAL HISTORY

The existence of the wound is often so obvious that the importance of a proper medical history is sometimes forgotten [9] (Table 35-2). The patient's symptoms should be noted, including pain, swelling, paresthesias, and loss of function. It is important to elicit information about the specific mechanism of injury that will either influence treatment or affect outcome. Blunt-force wounds with compressive or tensile forces are more prone to infection. Wounds sustained from contaminated objects or occurring in contaminated environments have increased risk of infection. The most common foreign body in wounds is soil, and the particular composition greatly affects the risk of infection. Clay-containing soils and soils with large amounts of organic material (e.g., swamps) have a high potential for wound infection, whereas sand and black dirt from the highway surface have a low potential. Some body locations have a higher concentration of normal flora and are more prone to infection. For example, most of the surface area of the human body has only a few thousand bacteria per square centimeter, but the perineum, axilla, toe webs, fingernail edges, and intertriginous areas can have over a 1 million/cm^2. Animal bite wounds are prone to infection with organisms different than those, which produce infection in nonbite wounds.

TABLE 35-2 Medical History

A patient should be asked whether the wound was sustained from an intentional act (e.g., assault or self-inflected) or unintentional event. Most states have regulations that require the reporting of intentional injuries, and self-inflicted injuries are grounds for involuntary holding and psychiatric evaluation. Occupational injuries are reportable to the appropriate agency.

The time of the injury and delay in seeking care will influence the decision for primary closure. In experimental models, a delay of more than 3 to 5 h allows the bacterial population to increase to greater than 1 million bacteria per gram of tissue and significantly increases the chances of infection. Treatment performed by a patient before seeking care, or lack thereof, may influence wound appearance. The possibility of a retained foreign body should be assessed by asking about the wounding object and any sensation of an object still in the wound. The presence of a foreign body dramatically increases the potential for infection; experimentally, infection can be initiated with as little as 100 bacteria per gram of tissue.

The impact of the wound on the patient's daily function will vary according to handedness and occupation. Tetanus immunization status should be assessed for every traumatic wound. Allergies will influence treatment with analgesics, anesthetics, antibiotics, and dressings. Patients with a latex allergy must be examined with latex-free gloves.[10] Current medications, including those purchased without prescription, should be noted. Patients who are taking warfarin or aspirin may not be able to spontaneously stop bleeding. Lastly, chronic medical conditions that may influence the incidence of wound infection or be associated with poor outcome should be noted. Patients with severe peripheral vascular diseases may not have an adequate blood supply to an injured part of the body for proper healing. Old age can affect healing through debility of a patient's physiology.

PHYSICAL EXAMINATION

Wound examination is greatly facilitated by a calm and cooperative patient, appropriate positioning, adequate lighting, and, sometimes, magnification. [11] Sterile technique would seem to be important, but studies using clean, but nonsterile, gloves found no increase in the incidence of wound infections. However, it is important to practice universal precautions and protect the patient and physician from cross infection.

Several factors should be noted and documented during wound examination (Table 35-3). Areas with excellent vascular supply and a low incidence of infection include the scalp, face, neck, and trunk. Lacerations on the extremities are at increased risk for infection, and those on the feet and hands are at greatest risk. Lacerations on the hands can damage tendons, nerves, and joints important for normal function. Lacerations over joints may penetrate into the joint capsule and are at risk for hypertrophic scar formation. Any laceration over the metacarpophalangeal joint is suspicious for a clenched-fist injury. Lacerations in the perineum have a high likelihood for contamination.

TABLE 35-3 Physical Examination

Wound characteristics are important to note. Large wounds, both in length and width (gaping), are at increased risk of infection. Likewise, wounds with flaps, stellate shape, complex arrangement, avulsed tissue, jagged edges, or deep penetration are at increased risk of infection.

The skin has static and dynamic forces that normally create tension within the tissue and vary depending on anatomic site. Lacerations heal with the best results when the long axis of a laceration is in the direction of the maximal skin tension. When static skin tension is perpendicular to the wound edges, tissue retracts and the wound edges gap. Although Langer more than a century ago published his text on the orientation of these forces on the human body, it is now realized that the majority of his findings were incorrect and have almost no application in the care of acute traumatic wounds. The degree of skin tension depends more on the length

and configuration of the wound: there is less tension on a jagged wound compared with a straight wound because of the increased length of the laceration in a jagged wound. Therefore, the meticulous repair of a jagged wound, rather than converting it into a straight wound, results in a more cosmetically satisfactory outcome.

Neurologic function should be assessed by evaluating distal sensory and motor function. Absent distal pulses and capillary refill indicate a vascular injury, but their presence does not exclude one. Tendon function should be performed for each one in isolation, where possible. The underlying and adjacent structures should be carefully inspected. The wound should be inspected to its full extent and depth for visible contamination and foreign bodies.

Although most traumatic wounds can be treated by an emergency physician, a prudent physician knows when to call for a consultant (Table 35-4).

Wounds involving the tarsal plate of the eyelid or lacrimal duct
Wounds involving an open fracture or joint space
Wounds associated with multiple trauma that need surgical admission
Wounds of the face that require extensive plastic reconstruction
Wounds associated with amputation
Wounds associated with loss of function
Wounds that involve tendons, nerves, or vessels
Wounds that involve a significant loss of epidermis

TABLE 35-4   Wounds That Usually Require Consultation

ANCILLARY STUDIES

In general, there is very little need for ancillary tests in most patients with traumatic wounds, with the exception of possible imaging studies to detect and locate retained foreign bodies. Foreign bodies are suggested by either the mechanism of injury, persistent foreign-body sensation reported by the patient, or palpation of a hard object by the examining physician. Fortunately, pieces of metal, glass, gravel, teeth, and bone larger than 1 mm are readily visible on plain radiographs when taken using the soft tissue technique and with multiple views to avoid overlapping bone (see Chap. 42, "Soft Tissue Foreign Bodies"). Unfortunately, some foreign bodies (plastic, wood, and other organic material) are radiolucent and not visible on plain radiographs. For these objects, computed tomography is the best imaging modality for detection and localization. Ultrasound, though attractive, does not have the required sensitivity to exclude a retained foreign body under clinical circumstances.

36 WOUND PREPARATION

Susan Stone
Wallace A. Carter

Wound preparation is a vital step in emergency department wound care for restoring the integrity and function of the injured tissue while minimizing the risk of infection and maximizing the cosmetic result. While the vast majority of wounds treated in emergency departments heal with a good outcome, careful preparation is particularly important when underlying medical conditions or wound factors may alter wound healing and increase the chance of infection (Table 36-1). Many traditional methods of wound preparation have surprisingly little scientific validation. [1,2] This chapter reviews the basic principles of wound preparation, using available experimental models and prospective clinical studies, where available, to justify these techniques.

Immunosuppression
  Diabetes
  Chemotherapeutic agents
  Steroids
  Chronic renal failure
  Hematologic malignancies
  Congenital immunodeficiencies
Tissue ischemia
  Peripheral vascular disease
  Anemia
  Vasculitis
Poor wound repair
  Elderly
  Malnourished
  Connective tissue disorder
Wound factors
  Crush injury
  Tissue loss
  Contamination
  Foreign bodies
  Location

TABLE 36-1   Risk Factors for Poor Wound Repair Outcome

ANESTHESIA

In general, pain control should be provided before extensive wound preparation. Not only more humane, anesthesia and analgesia will enable better preparation and treatment if patients are relaxed and able to cooperate without undue anxiety and pain. Prior to the administration of local or regional anesthetic, the sensory, motor, and vascular examination should be performed.

HEMOSTASIS

Control of bleeding is necessary for both hemodynamic stability and for proper evaluation of a wound. Bleeding most often occurs from the subdermal plexus and superficial veins. Direct pressure with saline-soaked sponges or gauze is usually effective in stopping this type of bleeding.

Bleeding from an exposed lacerated vessel is best controlled by direct pressure with a gloved fingertip directly onto the vessel. Once bleeding is halted, persistent control can be achieved by clamping the involved vessel, isolating a short length, and ligating with absorbable synthetic suture (typically 5-0). This approach is most useful for rapidly bleeding minor vessels in the extremities, but major arteries of an extremity should not be ligated. Extreme caution must be exercised in the face because of the proximity of important facial structures. Scalp lacerations can bleed extensively from the wound edges due to the highly vascular subcutaneous layer. This bleeding can be controlled by the use of specially designed clips applied along the wound edges. For bleeding wounds where the involved vessel is not visible, a figure-of eight or horizontal mattress suture applied adjacent to the wound edge near the site of bleeding will sometimes achieve control. However, this technique may obstruct significant blood flow and leave nonviable tissue in the wound.

Chemical means of hemostasis include epinephrine, Gelfoam, Oxycel, Actifoam, and cyanoacrylates. Topical epinephrine is not very effective. More commonly, epinephrine is mixed with local anesthetics in concentrations of 1:100,000 or 1:200,000 and injected into the wound area. This will induce local vasoconstriction that will allow a longer duration of anesthesia and a larger total dose due to the depot effect of the vasoconstriction. Epinephrine should never be used in end organs such as fingers, toes, and tip of nose, ears, and penis. Although there is a theoretical risk of increased infection with the addition of epinephrine to local anesthetics, observational studies on emergency department wound repair have not found a significant increase in the incidence of wound infection after suturing. Gelfoam, made from denatured gelatin, has no intrinsic homeostatic properties and works by the pressure it exerts as it becomes a fluid-filled sponge. Oxycel, a cellulose derivative, and Actifoam, a collagen sponge, react with blood, forming an artificial clot. These products are not particularly effective for actively bleeding wounds, as the blood can wash them out. Cyanoacrylates form a gluelike substance, bringing wound edges together when applied to the skin surface. Cyanoacrylates should never be applied into the depth of a wound.

Bipolar electrocautery can achieve hemostasis from blood vessels smaller than 2 mm in diameter but, if improperly or too extensively applied, results in tissue necrosis. Electrocautery units are not routinely available in many emergency departments. Battery-powered hand-held cautery units are more readily available but do not generate sufficient heat to produce coagulation in vessels larger than capillaries.

Extremity wounds that are refractory to direct pressure, ligation, or cautery may require a tourniquet. Although helpful in stopping exsanguination, tourniquets may compress and damage underlying blood vessels and nerves, reducing tissue viability. The simplest tourniquet to use in an emergency department is a blood pressure cuff placed proximal to the wound and inflated above the patient's systolic pressure. Elevating the extremity to reduce venous blood volume prior to cuff inflation is useful. If an extremity tourniquet is needed to control bleeding, the patient is best explored and repaired in the operating room and a surgeon should be immediately consulted.

FOREIGN-BODY REMOVAL

Obvious foreign debris should be carefully removed from the wound, with care to avoid injury to the physician from sharp edges or points. Retained foreign bodies can cause wound infections. Some diagnostic clues to the presence of a foreign body may include point tenderness or increased pain on range of motion, in conjunction with clinical suspicion. Visual wound inspection, down to the full depth and along the full course of the wound, is the most important method of detecting foreign bodies. Imaging modalities—plain radiology, ultrasound, computed tomography (CT), and magnetic resonance imaging—have a role in selected patients (see Chap. 42, "Soft Tissue Foreign Bodies"). In general, glass, metal, and gravel fragments larger than 1 mm should be readily visible on plain radiographs taken with soft tissue technique and with multiple views to avoiding overlapping bone. Painted plastic and wood may be radiopaque and visible on plain radiographs. However, unpainted plastic or wood and other organic material is radiolucent and not routinely visible on plain radiographs. If these potential foreign bodies are suggested by the history and not detected during wound exploration, CT is the imaging modality most successful in detecting and locating such objects. Ultrasound, an attractive modality because of the lack of radiation exposure and the ability to image and assist during foreign-body removal, lacks sufficient sensitivity for soft tissue foreign-body detection and cannot be recommended as the sole imaging modality.

HAIR REMOVAL

Because it can act as a foreign body, increasing the risk of wound infection, hair should be removed as completely as possible with clipping 1 to 2 mm above the skin with scissors.[1,2] Shaving the area with a razor damages the hair follicle, allowing bacterial invasion, and is associated with a tenfold increase in infection rates when compared with clipping. An alternative method to clipping is to use ointment or saline to clear hair away from wound edges. Hair should never be taken from the eyebrows, because of the potential failure of that hair to regenerate. Likewise, hair may provide good landmarks for alignment of wound edges during suturing, and removal at the skin-hair interface (eyebrows or scalp) should be avoided when possible.

IRRIGATION

Effective high-pressure irrigation decreases bacterial count and helps to remove foreign bodies, thereby reducing the risk of wound infection. [1,2] Because of the discomfort involved, local anesthetic should be given prior to irrigation. Irrigation pressures of 5 to 8 psi are recommended, which is easily achieved using a 19-gauge needle with either a 35-mL or 65-mL syringe.[3] Sufficient pressures will not be generated using a bulb syringe or fluid directly from the intravenous fluid bags. Although the exact volume of irrigant required is not known, some authors have found 60 mL/cm of wound length as a useful guideline. [2] The other approach is to use 1 L of saline as a standard volume, although a large prospective observational study found little correlation between the incidence of infection and the volume of irrigation, provided at least 200 mL was used.[4]

Wound soaking is not effective in cleansing contaminated wounds and may actually increase wound bacterial counts. [5] Scrubbing traumatic wounds with a sponge is also ineffective and inflicts trauma and impairs resistance to infection.

Saline, the least expensive irrigant, also has the lowest toxicity. There is no added benefit to the addition of an antiseptic (such as povidone-iodine or hydrogen peroxide) to the irrigant.[6] These agents are actually toxic to open wounds and impair resistance. Povidone-iodine, hydrogen peroxide, chlorhexidine, and detergents all cause tissue and fibroblast toxicity. Therefore, although these agents are bactericidal, they are not beneficial in wound care.

Universal Precautions should be observed while participating in wound care. Irrigation is often a time when contaminated fluid can be splashed onto the health care workers. Barrier protection should be used. Irrigation wet shields attached to the irrigation system may prevent some of the splashing associated with irrigation but are still not a substitute for Universal Precautions.

Recently, the need for routine irrigation of traumatic wounds has been questioned, particularly for simple nonbite, noncontaminated wounds in highly vascular areas, such as the scalp and face.[7,8] Although irrigation produced a slight trend toward a better outcome (less wound infection and optimal cosmetic appearance), the results were not statistically significant. [7] However, this was a nonrandomized observational study and therefore routine irrigation is still recommended at this time.

DEBRIDEMENT

The next step in wound preparation is debridement of nonviable tissue. [1,2] Devitalized tissue may increase the risk of infection and delay healing by acting as a culture medium and inhibiting leukocyte phagocytosis. Debridement not only removes foreign matter, bacteria, and devitalized tissue, but also creates a sharp wound edge that is easier to repair. After debridement is completed, wounds should be reirrigated.

The most effective type of debridement is excision, because it converts a contaminated wound into a clean surgical wound. A standard surgical blade and scissors are used. Tissue that has a narrow base or lacks capillary refill will require excision. Heavily contaminated wounds require more extensive debridement, whereas adequate debridement of soft tissue, which includes specialized tissue such as tendons and nerves, may require consultation.

The goal of debridement is to reestablish a margin of normal tissue at wound edges. The easiest technique for excisional debridement is to mark an elliptical area around the sides of the wound and then, using a no. 15 surgical blade, cut only through epidermis. Skin lines should be respected, and extensive excision should be avoided.

Wounds with an extensive amount of nonviable tissue are more problematic. They may require a large amount of tissue removal (e.g., crush injuries) and will need more delayed wound closure or grafting. In general, a surgeon should be consulted to manage these wounds.

Debridement has become such a standard in wound care, it is difficult to conceive of a situation where this technique should not be applied. However, a recent study of low-velocity civilian gunshot wounds to the extremities found that conservative wound care had the same incidence of wound infection as routine wound debridement.[9]

ANTIBIOTICS

Infections occur in approximately 3 to 5 percent of traumatic wounds repaired in emergency departments, although this rate varies widely according to mechanism, location, and patient factors.[1,7,8,10,11 and 12] Delays of over 3 h in seeking care, wound location, extremes of age, crush injuries, puncture or avulsion wounds, retained foreign bodies, and contamination with saliva, feces, and soil are all risk factors for infection. Delays of over 3 h in seeking care allow bacterial proliferation to increase exponentially. Less vascular areas, moist areas (axilla and perineum), and exposed areas (feet and hands) also tend to be at higher risk for infection. Crush or puncture wounds are more prone to infection due to the tensile and compressive forces generated that increase the potential for devitalized tissue. Additionally, wounds contaminated with saliva or feces are at risk. Soil may increase infection by direct interference with leukocyte function.

To reduce the incidence of wound infections, antibiotics have been commonly used for years, although there is no clear evidence that antibiotic prophylaxis prevents wound infections in most patients whose wounds are closed in the ED. [1,2] Antibiotic prophylaxis has been studied and well accepted in some surgical procedures. The principles learned from these studies are that effectiveness requires the achievement of antimicrobial blood levels prior to or rapidly after wound contamination, and there is no benefit for continuing antibiotics past 24 h in most cases. [13,14 and 15] The common practice of giving a patient a prescription for an oral cephalosporin for 7 days upon discharge, which the patient may not fill for hours, clearly fails to meet these principles. If used, antibiotic prophylaxis for traumatic wounds in an emergency department should be (1) started rapidly, ideally within 1 h and before significant tissue manipulation; (2) performed with agents that are effective against predicted pathogens; and (3) administered by routes that rapidly achieve desired blood levels. For most circumstances, this will require intravenous broad-spectrum or combination antibiotic regimens. Oral administration, though theoretically less effective, may also work if done in the emergency department before manipulation and by using an agent with appropriate spectrum and rapid oral absorption.

The most important step in prevention of a wound infection is adequate irrigation and debridement.

Current literature does not support the routine use of antibiotics for most wounds encountered in emergency departments. [12] However, in wounds contaminated by debris or feces, or caused by punctures or bites, in wounds with tissue destruction or in avascular areas, and in neglected wounds, sufficient bacteria may be present to cause infection, and antibiotics are often administered. If antibiotics are chosen, and since most wound infections are due to staphylococci or streptococci, a penicillinase-resistant penicillin (e.g., dicloxacillin) or a first-generation cephalosporin (e.g., cephalexin) provides reasonable coverage. For dog, cat, and human bites, penicillin should be added to cover both *Pasteurella* and *Eikenella,* respectively. Alternatively, amoxicillin-clavulanate alone can be used for therapy in bite wounds but is a more expensive alternative. There is no proven benefit, though, for antibiotic prophylaxis of low-risk dog-bite wounds. [11,16] Full-thickness oral lacerations also warrant antibiotics and should be treated with penicillin. [17] Wounds contaminated by freshwater, and plantar puncture wounds through athletic shoes, should include *Pseudomonas* coverage, preferably with a fluoroquinolone.

The duration for antibiotic prophylaxis is unknown; most physicians use 5 to 7 days. Patients with established wound infections usually require longer treatment. A wound warranting antibiotics can be reevaluated at 24 to 48 h, or patients should be given clear instructions to return at the earliest sign of infection. Contaminated wounds, or those with undetected foreign bodies, may still develop infection despite antibiotic prophylaxis.

TETANUS PROPHYLAXIS

Tetanus is a devastating disease with significant morbidity and mortality rates, and all patients must be asked about their immunization status, even those with clean, "minor" wounds. Of the 124 cases of tetanus reported in the United States during 1995 through 1997, a total of 93 were related to acute injury. [18] Importantly, the most common injury type that preceded tetanus infection was a puncture wound in 46 cases (49 percent). Since the incubation period is from 7 to 21 days, it is acceptable to give the adsorbed tetanus toxoid days after injury. The concept of "tetanus-prone wounds" is still cited, although the incidence of tetanus occurring in minor wounds makes this distinction suspect. Tetanus-prone wounds are considered to be those that are older than 6 h; stellate or avulsion; over 1 cm deep; due to a missile, crush, or frostbite; or have visible contamination with dirt or saliva.

Guidelines for tetanus prophylaxis in wound management have been developed by several public and professional organizations. Most clinicians refer to the recommendations developed by the Centers for Disease Control (CDC) Advisory Committee on Immunization Practice (ACIP) [19] (Table 36-2). Tetanus immune globulin (TIG) will provide passive protection for several weeks and can be given days after an injury, particularly in patients presenting with high-risk wounds and not up to date on vaccination. TIG and toxoid should be given at separate sites. Due to the large number of inadequately immunized adults, a liberal policy should be used with regard to prophylaxis. Immunization and immune globulin administration are safe during pregnancy.

Wound Type	Incomplete Immunization (Unknown or <3 Doses)	<5 Years from Last Immunization	5–10 Years from Last Immunization	>10 Years from Last Immunization
Clean/minor	Begin immunization with tetanus toxoid	None	None	Tetanus toxoid
All other wounds	Tetanus immune globulin 250 units and Tetanus toxoid	None	Tetanus toxoid	Tetanus toxoid

Tetanus toxoid
  <7 years old: Diphtheria tetanus (DT) toxoid 0.5 mL
  >7 years old: Tetanus-diphtheria (Td) toxoid 0.5 mL

TABLE 36-2   Guidelines for Tetanus Prophylaxis

WOUND COVERAGE

Wounds should be covered after irrigation and cleaning. Allowing a wound to stay open during time in the emergency department increases the risk of continued contamination and interferes with healing. After discharge, coverage with a topical antibiotic reduces the incidence of wound infection. [20] Wounds closed with tissue adhesives should not have topical ointments applied as they may remove the adhesive.

37 METHODS FOR WOUND CLOSURE

Julia Martin
Rob Herfel

The ideal wound closure is one that will repair tissue, recover function, reduce the risk of infection, and restore appearance. In order to obtain a cosmetic closure, it is important to understand the principles of wound healing, have a knowledge of the different techniques, and practice these approaches to become efficient. This chapter addresses the general concepts of closure techniques useful in the emergency department (ED).

After wound preparation, the physical integrity and function of the injured tissue must be restored. Most wounds seen in the ED require some form of closure, and the method chosen depends on the type of wound. There are three categories of wound closure: primary, delayed primary, and secondary.

Primary wound closure is the closing of the wound near the time of injury. Primary closure without tissue loss is almost always possible with clean wounds seen within 4 h after injury. The incidence of bacterial contamination and the risk of infection increase with injuries more than 4 h old. However, with clean wounds in highly vascular areas (scalp, face, and neck), the incidence of infection is so low that primary closure may be possible even up to 24 h after injury. [1] Primary closure of wounds in areas with poor blood supply (e.g., distal extremities) and cxontamination (e.g., debris) can generally be attempted if they are seen within 4 to 8 h and should be avoided if they present after 12 h from the time of the injury. Wounds with associated tissue loss usually require grafts or flaps to close the defect; these procedures are usually performed by specialists, often in the operating room.

Delayed primary closure is the approach of cleaning the wound, leaving the wound open under a moist dressing for approximately 4 to 5 days, and then suturing the wound if there is no evidence of infection. Heavily contaminated wounds, wounds resulting from high-energy missile injuries, or large wounds due to animal bites are ideal for delayed primary closure. Wounds contaminated by pus, vaginal discharge, feces, or saliva as well as those where treatment is delayed longer than 12 h should also be considered for open wound management. The first step in delayed primary closure is through cleaning and removal of debris and devitalized tissue. Prophylactic antibiotics should be started in the ED. The wound is packed open with moist, sterile, fine-meshed gauze and then covered by a dry sterile dressing. The wound should not be disturbed for the first 4 to 5 days after injury unless the patient develops an unexplained fever; unnecessary inspection during this period increases the risk of contamination and subsequent infection. On the fourth or fifth day, the wound can be undressed and inspected. In the absence of infection (no purulence or erythema beyond the edges of the wound) and devitalized tissue, the wound edges can be approximated with minimal risk of infection. [2]

Closure by secondary intention is allowing the wound to heal without mechanical closure. Over a period of time the tissue slowly granulates, forming a slightly larger scar than that would be seen with primary wound closure yet less of a scar than would be seen if a sutured wound became infected.

Once it is decided to close the wound, a closure technique must be selected that allows the most accurate and secure approximation of the skin edges. Suturing is the oldest and most commonly used method. However, alternative techniques—including skin staples, skin-closure tapes, and tissue adhesives—can be used in selected patients. The short-term goal of any closure method is to hold tissue in apposition until the tensile strength of the wound is sufficient to withstand stress. The long-term goal of wound closure is to accurately reapproximate wound edges with the most esthetically pleasing results.

CLOSURE METHODS

Sutures

The placement of sutures is the oldest and most common method of wound closure. An ideal suture material would have the following characteristics:

1. A low friction coefficient, so it will not stick to tissue as it is drawn through and not bind to itself as knots are being tied.
2. High pliability, so the suture will not deform tissue when it attempts to straighten itself after being tied.
3. Knot security, so that the ties will not unravel. Sutures with a low friction coefficient will slip more easily and the knots will spontaneously unravel, as opposed to materials with a high friction coefficient.
4. Tensile strength to hold the wound closed.
5. Low tissue reaction to reduce inflammation and the risk of infection.

No suture material possesses all these characteristics; different suture materials are chosen as acceptable compromises for specific types of wounds (Table 37-1). Sutures are generally divided into two general classes based on their rate of degradation:

1. Sutures that undergo rapid degradation in tissues, losing essentially all their tensile strength within 60 days, are considered "absorbable" sutures.
2. Sutures that maintain their tensile strength for longer than 60 days are "nonabsorbable" sutures.

TABLE 37-1   Sutures Commonly Used for ED Wound Repair

This terminology is somewhat misleading, because most absorbable sutures lose half their tensile strength within 4 weeks and some nonabsorbable sutures (e.g., silk and nylon) lose some tensile strength during this 60-day interval. Silk loses approximately half of its tensile strength in 1 year and has no strength at the end of 2 years. Nylon preserves its strength the longest, losing only about 25 percent of its original strength over 2 years.

Sutures are sized according to their diameter. The smallest in general use is designated 6-0 and is used for percutaneous closure on the face and other cosmetically important areas. Suture sizes 5-0 and 4-0 are progressively larger and used on the trunk and extremities. Very thick skin, like that on the scalp and sole of the foot, may require percutaneous closure with size 3-0 sutures.

NONABSORBABLE SUTURES   Nonabsorbable sutures can be of either natural or synthetic origin. Natural nonabsorbable sutures include fibers (silk) and metal (stainless steel). Natural materials like silk are easy to handle but incite moderate tissue reaction. Synthetic nonabsorbable fibers include polyamides (nylon), polyesters (Dacron, Dupont), polypropylene, and polybutester. Synthetic suture materials are useful for wound closure because they cause the least tissue reaction. Sutures may be classified according to their physical configuration. Sutures made of one filament are called *monofilament sutures* (nylon, polypropylene, polybutester, and stainless steel). Knot security with monofilaments is low; therefore at least two square knots (four throws) are required to achieve an adequate hold with 4-0 suture.[3] Sutures composed of multiple fibers braided together are called *multifilament sutures* (silk, nylon, polyester, and stainless steel). Multifilament sutures have greater pliability and increased knot security; they are less likely to unravel than monofilament sutures.[4] The disadvantage of multifilament sutures is that bacteria can migrate down the gaps between the individual filaments into the wound, increasing the likelihood of infection. Nylon and stainless steel are available as both monofilament and multifilament sutures.

ABSORBABLE SUTURES   Absorbable sutures are made from either collagen or synthetic polymers. Collagen sutures are derived either from the submucosa of ovine or bovine small intestine (gut suture) or from reconstituted collagen manufactured from bovine tendon collagen (collagen suture). This collagenous tissue is treated in an aldehyde solution, which cross-links and strengthens the suture, making it more resistant to enzymatic degradation. Suture materials treated in this way are called *plain gut* or *plain collagen*. If the suture is additionally treated in chromium trioxide, it becomes *chromic gut* or *chromic collagen*, which is more highly cross-linked and more resistant to absorption than plain gut or collagen. The shortcomings of collagen and gut sutures include variable strength, unpredictable absorption, and marked inflammation during absorption by proteolytic enzymatic digestion. Gut sutures should be avoided in areas close to surface. Other disadvantages of gut sutures are less tensile and knot strength, a higher infection rate, and more dehiscence than with synthetic sutures. Gut sutures are primarily used to close oral mucosal lacerations, as these wounds heal rapidly and do not require prolonged suture support. Chromium-treated sutures are absorbed less rapidly than plain gut but more rapidly than synthetic sutures. Because of its coating, chromic gut causes less inflammation than plain gut. Chromic gut can also be used in the oral mucosa and for closure of scalp lacerations in children; these sutures typically fall out in 1 to 2 weeks with little or no complication and no need for a return visit for suture removal.

Synthetic substitutes commonly used instead of gut sutures are produced from polyglycolic acid (Dexon, Sherwood Davis & Geck) or polyglactin 910 (Vicryl, Ethicon, Inc.). These braided sutures lose half their strength in tissues approximately 2 weeks after implantation, with absorption essentially complete by 2 months. Two other synthetic absorbable monofilament sutures, polyglyconate (Maxon, Sherwood Davis & Geck) and polydioxanone (PDSII, Ethicon, Inc.), retain their tensile strength longer. The chemical degradation of all these synthetic absorbable sutures is by hydrolysis of their ester bonds and opposed to the proteolytic inflammatory reaction required to degrade gut sutures. Absorbable suture materials are useful when working just below skin surface and in special circumstances when later suture removal is awkward (in children and inaccessible sites). Synthetic braided polymers are less reactive and more resistant to infection from contaminating bacteria than plain or chromic catgut. Polyglycolic acid has excellent knot security and will hold tight with a single square knot (two throws). The main drawback is that its high friction coefficient makes it "bind and snag" when wet. Major uses of polyglycolic acid are for single deep (dermal) closures or superficial fascial closure as well as ligature of small bleeding vessels. Dexon Plus (Sherwood Davis & Geck) is coated with polaxamer 188, which reduces friction and drag through tissues; it is easier to handle but more throws (four to six) are required to prevent knot slippage than with plain polyglycolic acid. Polyglactin 910 (Vicryl, Ethicon, Inc.) mentioned above, is used for deep closures. It has less knot security, similar dry tensile strength, and longer in vivo strength as compared with polyglycolic acid.

INFECTION   All sutures compromise local tissue defenses and increase the potential for infection for the following reasons:

1. The trauma of inserting a needle is sufficient to incite an inflammatory response.
2. Sutures that are tied too tightly impair blood flow and cause tissue necrosis of the wound edges.
3. Sutures that penetrate the intact skin provide an avenue for wound contamination through the perisutural cuff (Fig. 37-1).
FIG. 37-1. A. Epithelial cells migrate along the suture track, forming a perisutural cuff. **B.** If percutaneous sutures are not removed before 8 days, needle puncture scars develop.

4. The quantity of suture and the chemical reactivity of the material increase the susceptibility to infection.

Sutures made of natural fiber potentate infection more than other nonabsorbable sutures and should be avoided in contaminated wounds. The incidence of infection from monofilament sutures is less than that from multifilament sutures made of comparable materials. Therefore synthetic monofilament sutures should be used for wounds at risk for infection.

NEEDLES   The ideal surgical needle should guide the suture through the tissue and provide for meticulous approximation of the wound edges with the least damage.[5] All surgical needles are produced from stainless steel alloys, which have excellent resistance to corrosion. High nickel maraging adds resistance to bending and breakage compared with plain stainless steel surgical needles. Every surgical needle has three basic components: swage, body, and point.

The swage is the point of attachment of the suture to the needle. The swaging process provides a smooth junction between the needle and suture as opposed to the rough junction of a thread being attached to the needle by insertion through an eye. Almost all sutures used today have laser-drilled swages down the center of the needle for about 2 mm for the attachment of sutures. Channel needles have a channel cut into one side of the needle for about 6-mm for attachment of the suture. The needle is attached to the suture by uniformly compressing the walls of the swage against the suture. In most uses, this attachment strength is so great that separation of the needle from the suture is most easily accomplished by cutting the suture. A swage requiring lower uniform forces to detach its suture, sometimes called *pop-off* or *control release*, is also available. The control release was originally developed for abdominal wound closure, bolus dressings for skin grafts, and hysterectomies in which large numbers of interrupted sutures are used; eliminating the need to cut the suture considerably reduces the length of the operation. For ED wound closure, where a single length of suture is used for multiple loops, the control-release attachment is rarely used.

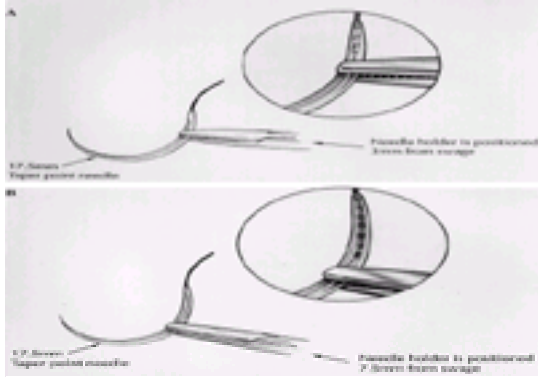
Both laser-drilled and channel swaged needles are more susceptible to bending and breakage by the needle-holder jaws when grasped over the swage than the body of the needle. To prevent this, the needle should be grasped with the needle holder on the body of the needle, not over the swage. Conversely, suturing is easier when as much of the needle as possible is available for passage through the tissue in one stroke, therefore the needle holder should be close to the swage end but not over it. Since laser-drilled swages are shorter than channel swages, the needle can be grasped with more available for passage through the tissue (Fig. 37-2).


FIG. 37-2. A. The laser-drilled swage is only 1.5 mm long and the needle holder can grip close to the end of the needle, leaving more length available for passage through tissue on the initial movement. **B.** The channel swage is 6 mm long and the needle holder must grip further along the needle, leaving less needle available for passage through tissue on the initial movement.

The body of the needle is the portion that is grasped by the needle holder. The security with which needle-holder jaws grasp the needle is influenced primarily by the presence of teeth in the needle-holder jaws and the ratchet setting of the needle-holder handle and less so by the cross-sectional shape of the needle body.

The overall biomechanical performance of the surgical needle and holder combination is determined by (1) needle sharpness, (2) needle resistance to bending, (3) needle ductility, and (4) needle-holder clamping moment. Sharpness measures the force needed to pass a needle through a membrane that simulates the density of human tissue, and needle resistance to bending is measured by recording the force required to bend the needle 90°. But the more critical measurement to the emergency physician is the force required to deform the needle irreversibly—the yield moment. Ductility is a measure of the needle's resistance to complete breakage. The needle-holder clamping moment is a measure of the force exerted by the needle-holder jaws on a curved surgical needle.

The body of a suture needle can be defined according to (1) the cross-sectional shape and (2) the geometric configuration. The cross-sectional shape will determine the resistance of the needle to bending as well as the security with which the needle-holder jaws grasp the needle. The cross-sectional shapes in common use are round, triangular, trapezoidal, rectangular with rounded sides, and side-flattened. Rectangular cross sections are created by flattening the inner and outer surfaces of the circular wire during the manufacturing process. Needle holders are able to hold the body more securely when it has flat surfaces parallel to the grasping face of the jaws. With rectangular and trapezoidal shapes, the needle-holding security against twisting and rotation is greater than with any other cross-sectional configuration. Unfortunately, flattening the inner surface reduces resistance to bending, partially reducing the benefit of enhanced needle holding security. For suturing of tough tissues, side-flattened needle bodies are preferred because they exhibit greater resistance to bending than any other cross-sectional shape.

The geometry of the suture needle can be described by its radius, curvature, diameter, length, and chord length. The radius of the needle is the distance from the center of the circle to the body of the needle if the curvature of the needle is continued to make a full circle. The curvature at the needle is measured in degrees of the subtended arc and may vary from 90° ($\frac{1}{4}$) to 225° ($\frac{5}{8}$) (Fig. 37-3). Needles with a curvature of 135° are ideal to approximate divided edges of thin planar structures that are readily accessible (e.g., skin), requiring a limited arc of wrist rotation to pass the needle. It is difficult to use the 135° needle in deeper tissues (e.g., muscle, fascia) because the limited arc of the wrist rotation involved in passing this needle is usually not sufficient to expose the needle point, which will remain buried in the tissue. The 180° needle is ideally suited for use in deeper tissues because a limited arc of wrist rotation will successfully pass the entire needle through the tissue, allowing adequate exposure of the needle point for easy retrieval of the needle. Curved needles are ideally suited for closure of thin layers, such as epidermis and fascia. The compound curved needle is most often used to alter the 135° needle; the straight point readily facilitates initial entrance through the tissue and controls the depth, while the tight curvature beyond the point permits accurate exiting at a selected level. This design offers a mechanical advantage over the standard needle with one radius of curvature. The compound needle is useful for closure of the dermis.
FIG. 37-3. Geometry of length of needle.

Needle diameter is the width of the original circular wire utilized in the manufacturing process for the production of the needle. Cord length is the linear distance measured from the central point of the needle swage to the point of the needle. Needle length is the length of the needle measured at the center of the wire's cross section.

The point of the needle extends from the tip of the needle to the maximum cross section of the body. A variety of needle-point configurations have been designed to penetrate specific types of tissue.

The simplest configuration is the taperpoint, where the needle tapers to a sharp tip (Fig. 37-4). The taperpoint spreads the tissue without cutting and is used for soft tissue that does not resist needle penetration, such as vessels, fascia, and muscle. The taperpoint makes the smallest hole in tissue and does not cut small incisions at the periphery of the hole.
FIG. 37-4. Taperpoint surgical needle. **Top left**. Front view of point. The geometry of this needle tapers to a point and has no cutting edges. **Side view**. The point of this needle has a narrow taperpoint geometry. **Bottom right**. The body of the needle has a side-flattened cross-sectional configuration.

For suturing cutaneous wounds in the ED, needles with cutting edges are useful to penetrate the relatively tough skin. Cutting-edge needles have at least two opposing edges that are designed to separate tough tissue. Usually, a third cutting edge is added, and the position of this third cutting edge categorizes the needle as either a conventional cutting-edge needle or a reverse cutting-edge needle.

A conventional cutting-edge needle has the third edge located on the inner or concave surface, which produces two effects during suturing: (1) cutting action directed toward the center of the wound and (2) pressure that directs the needle point toward the skin as it passes through tissue (surface-seeking) (Fig. 37-5). The central cutting action has a tendency to divide tissues that ultimately will be encircled by the suture. As the needle passes through the skin, it produces a triangular defect, the apex of which is directed toward the incision. If it is positioned in this apex, the suture may cut through when tied.
FIG. 37-5. Conventional cutting edge surgical needle. **Top left.** Front view of point. The point of the needle has three cutting edges, with its apical cutting edge on the inside, concave surface of the needle. **Side view.** Its apical cutting edge is positioned on the inside, concave surface of the needle. **Bottom right.** The body of the needle has a side-flattened cross-sectional configuration.

In contrast, the reverse cutting-edge needle has the third cutting edge located on the outer, convex curvature of the needle (Fig. 37-6). This configuration has the flat surface of the needle closest to the edges of the incision or wound and directs the point of the needle toward the depth of the wound (depth-seeking). The skin hole left by the reverse cutting-edge needle leaves a flattened wall of tissue for the suture to be tied against, which should resist suture cut-through.
FIG. 37-6. Reverse cutting edge surgical needle. **Top left.** Front view of point. The point of the needle has three cutting edges, with its apical cutting edge on the outer, convex surface of the needle. **Side view.** Its apical cutting edge is located on the outer, convex side of the needle. **Bottom right.** The body of the needle has a side-flattened cross-sectional configuration.

Sharpness of cutting needles can be enhanced by narrowing the point configuration, reducing the angles of the cutting edges, and coating the point with silicone. For conventional and reverse cutting-edge needles, the shape of the needle point is triangular, with two lateral cutting edges and a cutting edge at the apex. The bevel-edge needle has opposing concave surfaces rather than the straight planar surfaces encountered in the standard cutting-edge needles (Fig. 37-7). The angles of the cutting edges at the apex and sides of the bevel cutting edges are 45° and 52.5°, respectively, rather than the 60° for the standard cutting-edge needles, which enhances the sharpness. Coating the cutting-edge surfaces with silicone increases their initial sharpness in tissues and maintains the sharpness after repeated passage (durability).
FIG. 37-7. Bevel conventional cutting edge surgical needle. **Top left.** Front view of point. The opposing sides of the point of the needle have a concave geometry that reduces the angle of its cutting edges. **Side view.** The sides of the point of this bevel conventional cutting edge needle are beveled to reduce the angle of its cutting edges. **Bottom right.** The body of the needle has a side-flattened cross-sectional configuration.

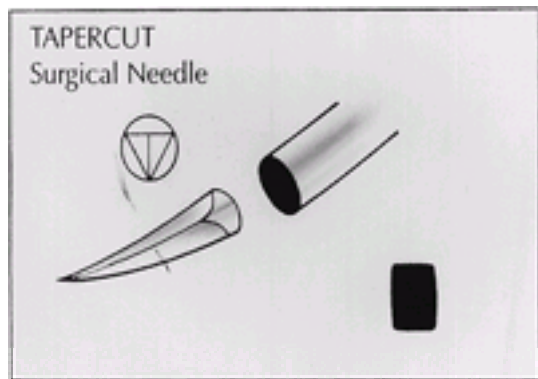
Tapercut needles combine the unique features of taperpoint and cutting-edge needles (Fig. 37-8). The cutting edges of the tapercut needle extend only a very short distance from the needle tip and blend into a round taper body. This needle provides smooth passage through oral mucous membrane, yet its round shaft without cutting edges will not cut through the deeper tissues.


FIG. 37-8. Tapercut surgical needle. **Top left.** Front view of point. This tapercut needle has a short reverse cutting edge that blends into a taperpoint geometry. **Side view.** The reverse cutting edges are confined to a small portion of the tip of this needle. **Bottom right.** The body of the needle has a side-flattened cross-sectional configuration.

Surgical sutures currently in use have a needle-to-suture diameter ratio of approximately 2:1; the hole left by the needle will not be completely filled by the suture and the unfilled space at each suture hole may invite infection to pass through. To resolve this problem, two new sutures attached to taperpoint needles have been developed. A polytetrafluoroethylene monofilament suture can be produced with a porous microstructure that is approximately 50 percent air by volume. This porous nature allows it to be swaged to a needle that closely approximates its suture diameter; a needle-to-suture ratio of 1:1. Alternatively a monofilament polypropylene suture can be made with a tapered end that is significantly smaller than that of the remainder of the suture, and swaged to a needle with a needle-to-suture diameter ratio approaching 1:1.

Staples

Skin closure by metal staples is quick (at least four times faster than closure with sutures) and economical (slightly less total cost than suturing). [6,7 and 8] An additional advantage of staples is their low level of tissue reactivity; wounds with staple closure exhibit resistance to infection superior even to that of the least reactive suture. [9] These advantages of skin staples must be weighed against one notable drawback—the skin staple does not provide the same meticulous coaptation of lacerations with irregular skin edges that can be achieved with sutures. For staples to achieve accurate closure, the skin edges must be aligned before the staples are placed. Because accurate prepositioning of the wound edges is very difficult in many lacerations, staple implantation will often result in malapposition of wound edges, which is an invitation to the development of scar deformity. Consequently, skin staples are usually reserved for lacerations in anatomic sites where the healing scar is not readily apparent (e.g., scalp).

The basic shape of an applied cutaneous staple is an incomplete rectangle; the top bridges the laceration off the skin surface and the points are directed 90° inward off the side legs (Fig. 37-9). As staples are placed, the stapling device pushes the points toward each other; they impinge the skin and evert the wound edges. When placing staples, the wound edges should be held together with tissue forceps. The stapling device should be placed gently (not firmly or with pressure) against the skin surface before the trigger is slowly (not rapidly) squeezed. A properly placed staple should have its top side off the skin surface.
FIG. 37-9. A cutaneous staple properly placed will evert the skin edges and not be in contact with the skin surface.

A variety of stapling devices that implant stainless steel staples are commercially available for use in the ED. There are several features of a stapling device to be considered in choosing a particular product:

1. The stapler should be designed so that it does not obstruct the physician's view of the wound edge.
2. The stapler should have a mechanism that holds the staple securely during its formation.
3. The stapler should have an ejection spring that automatically releases the staple.
4. The handling characteristics of the stapler should be such that the physician can easily implant a large number of staples without becoming fatigued.

Other features to be considered in choosing stapling devices include size (smaller ones are better for lacerations in tight areas) and quantity of staples (more are required when closing large lacerations).

Staples were originally developed to close surgical incisions, and there was initially a reluctance to use them for traumatic lacerations. [6] Clinical studies have found that for the scalp, neck, trunk, and extremities, staples produce a cosmetic result that is identical to that from sutures. [6,7 and 8] Staple removal requires a special instrument that deforms the top and spreads open the points. Staple removal is slightly more painful than suture removal.

Skin-Closure Tapes

Skin-closure tapes are used as an alternative to sutures and staples for wound closure and for additional support after suture and staple removal. [9] Tapes do not require anesthesia and the patient does not need to return for their removal. Skin-closure tapes work best on flat, dry, nonmobile surfaces where the wound edges fit together without tension. Conversely, oily or wet surfaces, movable areas, or wounds that stay open with tension are not appropriate for surgical tape closure. Taped wounds are more resistant to infection than sutured wounds; therefore tapes are useful for wounds at increased risk of infection. Tapes can be used for skin flaps, where sutures may compromise perfusion, and for lacerations with thin, friable skin that will not hold sutures.

The ease with which wounds can be closed by tape varies according to the anatomic and biomechanical properties of the wound site. Linear cutaneous wounds subjected to minimal static and dynamic tensions are easily approximated by tape. The relatively lax skin of the face and abdomen makes it amenable to wound closure by tapes. Contrary to expectation, tape closure without sutures is more easily accomplished in obese patients, and the thick cut edges of adipose tissue tend to evert the skin. The taut skin of the extremities, which is subjected to frequent dynamic joint movements, requires dermal sutures before taping. The copious secretions from the skin of the axillae, palms, and soles discourage tape adherence.

A variety of skin-closure tapes are commercially available, with differing biomechanical characteristics. The ideal tape should primarily possess excellent adhesion and strength; porosity, flexibility, and elasticity are less important. In the United States, tapes sold for ED use come in widths of $\frac{1}{4}$ and $\frac{1}{2}$ in., in varying lengths, in sterile, single-use packages. The $\frac{1}{4}$-in. width is appropriate for wounds less than 3 to 4 cm in length; longer wounds should use the $\frac{1}{2}$-in. width. The individual tapes

are applied to nonadherent backing that can be bent at a scored perforation to free up one end of the tape without deforming it. The tapes should be removed from the backing by grasping the free end with forceps.

Adherence of tapes is enhanced by the use of benzoin or mastic to the skin surface 2 to 3 cm beyond the wound edges. These agents are best applied with applicator sticks or applicator-tipped single-use vials. Care should be taken not to allow any benzoin or mastic to enter the wound. The agent should be allowed to dry and become tacky before the tape is applied.

Tapes should be long enough to stretch 2 to 3 cm on either side of the wound. Using forceps, the tape is attached to the skin on one side, then pulled across the wound to coadapt the wound edges and applied to the opposite side. Coadaption of the wound edges can be facilitated by using a finger to push the wound together as the tape is being pulled across. Longitudinal alignment of the wound edges is facilitated when taping starts in the middle and progresses toward each end. Individual tapes are applied with some space between them but not so much that the wound edges gap open between the individual tapes (Fig. 37-10).
FIG. 37-10. Skin-closure tapes should be applied perpendicular to the wound edges and spaced so that the edges do not gape.

When skin-closure tapes are properly employed to close linear wounds subjected to weak tensions, cosmetic results are excellent. Additionally, the discomfort of anesthetic infiltration, the need for suture removal, and the development of suture puncture scars is avoided. Wounds closed with tape cannot get wet or be washed. Dressing over a taped wound is problematic; on the one hand, the dressing may protect the tape ends from becoming lifted, but, on the other, a dressing may promote the collection of moisture and premature tape separation. Tapes should stay in place about as long as an equivalent suture and will spontaneously detach as the underlying epithelium exfoliates.

Tissue Adhesives

Cyanoacrylate tissue adhesives have been available in Canada and Europe for years, and one product, 2-octylcyanoacrylate, is now available in the United States (Dermabond, Ethicon, Inc.).[10] Cyanoacrylate adhesives polymerize rapidly when applied to tissues through an exothermic reaction catalyzed by a small amount of moisture. These adhesives close wounds by forming an adhesive layer on top of intact epithelium, which holds the edges together. Cyanoacrylate adhesives cause an intense inflammatory reaction within subcutaneous tissues and should never be applied within wounds. Adhesives cannot be used near the eye, on mucous membranes or mucosal surfaces, on infected areas, on wounds that are wet or exposed to body fluids, or in areas with dense hair (e.g., scalp). When used on appropriately selected wounds, tissue adhesives can be applied in less than half the time required for sutures and without the need for anesthesia or return for removal.[11,12 and 13]

Adhesives are most useful when they are used on wounds that close spontaneously, have clean or sharp edges, and are located on clean, nonmobile areas. Wounds where the edges are separated more than 5 mm by the underlying skin tension are unlikely to stay closed with tissue adhesives alone. In this case, subcutaneous sutures can be inserted to relieve this tension and approximate the edges. Also, lacerations longer than 5 cm are prone to shear forces and unlikely to remain closed with tissue adhesives alone.

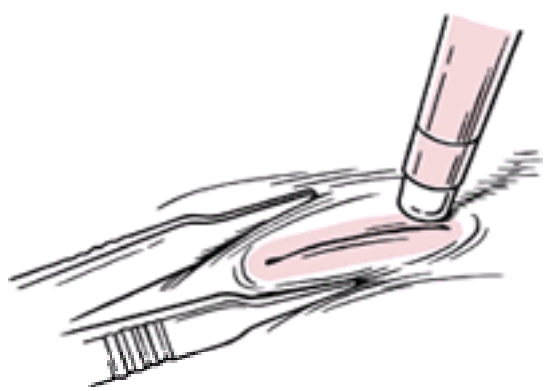
Two-octylcyanoacrylate is commercially available in a single-use vial with an applicator tip. A violet colorant is added to make it visible during application. Wounds should be cleaned and bleeding controlled before the tissue adhesive is applied, but absolute dryness is not required. The wound should be held together and the edges slightly everted with tissue forceps. Adhesive is applied by lightly wiping the applicator tip over the area (at least 5 mm beyond the skin edges) in the direction of the long axis of the wound (Fig. 37-11). Three to four thin layers should be applied successively; droplets or a single thick layer is to be avoided. The wound edges should be held together for about 60 s after the last adhesive application to ensure that the adhesive has time to set fully. Some articles have described the application of tissue adhesives as "spots" along the laceration or as intermittent "stripes" applied perpendicular to the laceration. These techniques might be less useful, since cyanoacrylates are only slightly more viscous than water and subcutaneous penetration is possible from dabs applied to the skin or from unintentional opening of the edges by wiping the applicator tip across the wound. Adhesive applied to unwanted areas can be removed by using petroleum jelly or acetone. Once applied, cyanoacrylates should not be covered with ointment, bandage, or dressing.


FIG. 37-11. Tissue adhesives are applied in several light coats over the wound, carefully avoiding entry of the adhesive into the wound.

Patients should be instructed not to use ointments, apply bandages, or pick at edges of the adhesive. After 24 h, the area can be gently washed with plain water but should not be scrubbed, soaked, or exposed to moisture for any length of time. The adhesive will spontaneously slough off in 5 to 10 days. Should a wound open, the patient should immediately return for closure.

As compared with suturing, wounds closed with tissue adhesives initially have less tensile strength; after 7 days, however this difference disappears. [10] The manufacturer of 2-octylcyanoacrylate notes that the incidence of wound infection with this product is 3.6 percent and the incidence of dehiscence requiring retreatment is 2.2 percent; neither was statistically different by comparison with equivalent wounds closed with sutures. An animal model has found that 2-octylcyanoacrylate can be used to close contaminated wounds with a lower infection rate, although this use has not been validated in humans. [14] The ultimate cosmetic appearance of wounds closed with tissue adhesives is identical to that of closure with sutures. [13,15]

SUTURING TECHNIQUES

General Principles

Suturing continues to be the most common method for laceration repair in the ED and percutaneous sutures that pass through both the epidermal and dermal layers are the type most frequently used. Dermal, or subcuticular, sutures reapproximate the divided edges of the dermis without penetrating the epidermis. Occasionally, dermal and percutaneous sutures are used together in a layered closure. As noted above, dermal sutures can be used with either surgical tapes or tissue adhesives for epidermal closure. Sutures can be applied in a continuous manner ("running," with knots at each end of a long closure) or as interrupted sutures (each loop being individually tied).

Monofilament nylon or polypropylene sutures are most commonly used for skin closure because these materials have acceptable mechanical properties and low tissue reaction. Polybutester sutures have unique performance characteristics that may be advantageous for the closure of wounds that might expand from edema and then contract as the swelling resolves. Polybutester can elongate in response to low forces and has elasticity, enabling it to return to its original length once the load is removed. Sutures with less extensibility under low forces—like nylon, polypropylene, polyester, or silk—will frequently lacerate or necrose encircled tissue in edematous wounds, thereby increasing the susceptibility to infection.

Percutaneous sutures are recommended for closure of stellate lacerations resulting from crush injuries. In these wounds, meticulous closure with percutaneous sutures approximates the skin edges more exactly than does tape. Closing these wounds is often like putting together a jigsaw puzzle, and tapes have little practical value. The more accurate approximation of skin edges by skillfully applied sutures leads to a more pleasing cosmetic result. Damage to the local tissue defenses is related to the quantity of the suture within the wound (diameter and length); therefore, the suture with the narrowest diameter and sufficient strength to resist disruption of the closure should be used.

Straight, shallow lacerations can be closed with percutaneous sutures only, sewing from one end toward the other and aligning edges with each individual suture bite. Deep, irregular wounds with uneven, unaligned, or gaping edges are more difficult to suture. Certain principles have been identified by years of clinical experience:

1. The uneven edges can be aligned by first approximating the midportion of the wound with the initial suture. Subsequent sutures are placed in the middle of each half, and so on, until the wound edges are aligned and closed.
2. Wounds where the edges cannot be brought together without excessive tension should have dermal sutures placed to close the gap partially and reduce the force on the epidermal closure.
3. Adipose tissue beneath the skin should not be sutured; obliteration of this potential dead space between the cut edge of adipose tissue by even the least reactive suture increases the incidence of infection.
4. When wounds of different thickness are to be reunited, the needle should be passed through one side of the wound and then drawn out before reentry through the other side. This maneuver ensures that the needle is inserted at comparable levels on each side of the wound. Unless appropriate adjustment of the bite is made on the thinner side, uneven coaptation of the skin will occur, resulting in a step-off scar.

Dermal sutures can be used alone or as adjuncts to percutaneous sutures in wounds subjected to strong skin tensions, to serve as an added precaution against disruption of the wound. Some physicians prefer a synthetic absorbable suture for dermal closure, while others favor a synthetic nonabsorbable suture. The nonabsorbable suture is applied in a continuous manner with the ends brought out the skin and secured at both ends of the wound. This suture can then be removed before the eighth day after wound closure to prevent the development of needle puncture scars. When dermal closure alone is used, it is advisable to close the skin with surgical tapes or tissue adhesive for more accurate approximation of the epidermis.

In clean wounds (e.g., elective surgical incisions), subcutaneous sutures do not significantly increase the incidence of wound infection. However, in traumatic wounds, particularly with contamination, dermal sutures potentate wound infection. [16] Once an infection develops, the collecting purulent exudate spreads preferentially between the divided edges of fat rather than penetrating the closed dermis. By the time the infection becomes clinically apparent, it has usually involved the entire extent of the wound. One value of dermal closure is thought to be that by reducing tension across the wound, scar width will be lessened. However, despite the immediate, esthetically pleasing appearance of dermal skin closure, it does not improve the ultimate cosmetic appearance of the healing wound; scar width after dermal skin closure is comparable to the scar width of wounds healing in the absence of dermal sutures. Another effective method of reducing tension during closure is to undermine the skin edges. However, this benefit must be weighed against the potential damage to the skin blood supply, which may compromise the host's defenses and invite infection. Consequently, undermining of the wound edges of lacerations should be done in carefully selected situations in the ED.

Suturing Instruments

The surgical needle holder used in suturing lacerations should have several features. [5] First, it should hold the needle securely to direct it through the tissue. Second, it should release the needle easily to allow the suture to be tied. And third, it should have a design that can readily grasp the suture end to be used for the instrument tie.

The appropriate needle holder should hold the needle firmly without crushing it. The jaws of the needle holder may be flat or scored ("teeth"). Teeth may limit twisting and rotation of the needle, allowing it to be directed through tissue more accurately. However, teeth may damage needles and monofilament synthetic sutures, reducing their breaking strength. Smooth-face needle-holder jaws with rounded edges do not cause structural damage to either monofilament suture or needles. However, their smooth jaw surfaces provide limited resistance to twisting or rotation of the needle. Needle-holder jaw faces can be textured with tungsten carbide particles to create a fine granular surface, making them an attractive alternative to either smooth jaws or those with teeth. The textured face provides more needle-holding security than smooth jaws but significantly less than jaws with teeth. The needle-holder jaw should grasp only the needle body; clamping the needle point damages the cutting edge and dulls the needle. The suture needle should be aligned perpendicularly to the long axis of the needle holder and grasped between the jaws about 2 mm from the their tips. As noted above, the needle should be grasped 1.5 mm beyond the depth of the channel or swage hole, a site that provides optimal resistance to bending.

The finger holes of the needle holder are used for directing the needle and latching and unlatching the jaws. The needle holder can be grasped by either the thenar grip or the thumb-ring finger grip; each has its advantages. Both grips, however, do not place the index or middle finger through the ringlet holes; instead, the index finger is placed along the side of the needle-holder arms and the middle finger is pressed against the outside curve of the bottom ringlet for more control as the suture is placed. When placing a suture, the hypothenar side of the hand holding the needle holder can be placed against the patient's skin in order to brace the hand against sudden movement. This is particularly useful when placing a suture in a child or a moving patient.

With the thenar grip, the thenar eminence and skin overlying the first metacarpophalangeal joint are pressed against one ringlet, while the long, ring, and small fingers encircle the other ringlet. This position aligns the needle holder in the same direction as the longitudinal axis of the wrist and forearm, allowing the hand and needle holder to be positioned comfortably into recessed cavities (e.g., the oral cavity). In addition, the needle can be released and regrasped by the needle holder without changing positions. The needle can be redirected in preparation for the next stitch by spinning the needle holder clockwise in the palm. The disadvantage of this grip is the lack of precision when releasing the needle; when the thenar eminence applies pressure to the ringlet, it disengages the ratchet mechanism uncontrollably, causing inadvertent movement of the needle.

In the thumb-ring finger grip, the tip of the thumb is positioned in one ringlet, while the tip of the ring finger is placed in the other ringlet. The greatest advantage of this grip is its controlled disengagement of the ratchet mechanism, permitting precise manipulation of the needle. This advantage must be weighed against the relatively larger size of the physician's hand and needle holder; the palm is separated from the needle holder, making it more difficult to position the needle holder in recessed cavities (e.g., the mouth).

To align skin edges, a skin hook is preferred over forceps with teeth; hooks do not crush tissue, as do forceps. When forceps are used, they should pick up and elevate the skin as opposed to grasping the epidermis between the teeth. Conversely, the dermis can be grasped with the forceps, again, avoiding grasping the epidermis.

Because the ratchet mechanism of most needle holders is designed for right-handed individuals, most physicians prefer to hold the needle holder with the right hand, allowing them to hold skin hook or tissue forceps with the left hand. Before passing the needle through tissue, lay the free end of the suture away from the wound. The curved suture needle is passed through the tissue by starting with the hand prone and then twisting the wrist to a supine alignment, driving the needle through in one motion. For small lacerations being closed with only percutaneous sutures, this one motion can drive the needle from one side, across the wound, and out the other

side without the need to release the needle. For larger lacerations, those with gaps, or those where approximating the layers is important, the needle is released after the point comes out in the wound, regrasped, and repositioned for placement through the other side.

Percutaneous sutures should be placed to achieve eversion of the edges. To accomplish this, the needle should enter the skin at a 90° angle. The curving motion of the needle and wrist movement then drives the needle first downward and then across the wound. The needle point should also exit the opposite side at 90°. It is desirable for the depth of the suture to be wider than the width (from entry to exit). Sutures placed in this manner (similar to the shape of an Erlenmeyer flask) will encompass a portion of tissue that will evert when the knot is tied (Fig. 37-12). Percutaneous sutures should also match opposing layers; the exit at one side of the wound should be at the same level as the entrance on the opposite side.
FIG. 37-12. A single interrupted percutaneous suture with everted edges.

An adequate number of sutures should be placed so that the wound edges are closed without gaping. The general rule that the space between individual sutures should be roughly equal to the length of each bite (distance from needle entry point to the wound edge) can really be used only in straight wounds with sharp edges (e.g., surgical incisions). Experience and practice are the most useful guides to placement and spacing of percutaneous sutures in traumatic wounds.

Bleeding should be controlled before wound closure. Most bleeding stops after gentle compression with gauze sponges applied to the wound surface, using aseptic technique. Persistent bleeding should be controlled as noted in Chap. 36.

Knot Construction

Sutures are secured by tying the free ends into a series of square knots, often beginning with the surgeon's knot, where the initial double throw offers better knot security with less slipping of the suture material as the wound is pulled together during tying. The initial double throw is followed by subsequent single throws to create the series of square knots. The square knot is used because it is the strongest knot that can be tied while still keeping the knot small. Knot tying can be accomplished by either instrument or hand tying technique. The instrument tie is useful for both deep and superficial closures. Because the needle holder does not have to be moved on and off the hand, the instrument tie is also faster than hand tying for placing a series of percutaneous sutures during wound closure.

Formation of each throw is accomplished in three steps. The first step is the formation of a suture loop. In the second step, the free suture end is passed through the suture loop to create a throw. The final step is to advance the throw to the wound surface as tension is applied to the suture ends in opposite directions. The initial throw should approximate the wound edges as it is advanced down to the wound surface. Once this throw contacts the wound, the physician will have a preview of the ultimate apposition of the wound edges. Additional throws are placed in succession, reversing the direction of the suture ends as tension is applied. The knot should be constructed by carefully snuggling each throw tightly against the preceding one. The rate of applying tension to each throw should be relatively slow. Ideally, the knotted suture should reapproximate the wound edges without strangulating the tissue encircled by the suture loop.

With the instrument tie, knots can be tied rapidly in the following steps:

1. The suture is placed through the tissue leaving a short free end, usually 2 cm.
2. The initial throw is started by looping the portion of suture attached to the needle around the instrument in a counterclockwise manner.
3. A complete loop is then formed around the tip of the needle holder with the long end directed away from the wound (Fig. 37-13).
FIG. 37-13. Formation of the first suture loop. The fixed suture end held by the left hand is wrapped counter-clockwise over and around the needle holder jaws to form the first suture loop. (If the suture is wrapped twice around the needle holder jaws, the first, double-wrap throw of the surgeon's knot square will be formed. A double-wrap, first throw displays a greater resistance to slippage than a single-wrap throw, accounting for its frequent use in instrument ties in wounds subjected to strong, static skin tensions.)

4. The needle holder then grasps the free end of the suture and pulls it through the suture loop while the left hand slides the loop off the needle holder down and around the free end of the suture.
5. Tension is applied to both the fixed and free ends in opposite directions to form half of the square knot.
6. The second throw is created by passing the suture around the needle holder tip in a clockwise direction, opposite that of the first throw.
7. The loop created again has the long end directed away from the wound.
8. The free end is grasped and pulled through the suture loop.
9. The suture loop is slipped off the needle holder to form the second half of the square knot, this time with tension applied in a direction opposite the first throw.
10. Additional square knots are placed down over the first knot. For monofilament and multifilament nylon sutures of 2-0 to 4-0 size, two square knots (four throws) placed snugly against each other are adequate for knot security. Finer sutures, 5-0 and 6-0, should have three square knots (six throws).

The direction of the suture loops will determine the type of knot created. When successive throws are in opposite directions, a square-type is created. In contrast, a granny-type knot will result when the suture loops are in the same direction for two successive throws.

The major disadvantage of an instrument tie is that it is difficult to apply continuous tension to the suture ends and maintain wound edge coaptation during the process of tying. Consequently, widening of the suture loop and separation of wound edges due to slippage is frequently encountered in wounds subjected to strong tensions. Instrument ties are ideally suited for closing a wound that is subjected to weak tensions. Instrument ties can be accomplished more rapidly and accurately than hand ties while conserving considerably more suture; the parsimonious physician can complete 10 interrupted suture loops from one length of suture measuring 18 in. (46 cm), a feat that would be impossible if the knots were tied by hand. Instrument ties are invaluable in special situations where hand ties are impractical or impossible,

such as body recesses or cavities (e.g., the mouth); there, instruments can form knots where hands could never gain access.

Failure of the knotted suture loop may be the result of either knot slippage or breakage, suture cutting through tissue, or mechanical crushing of the suture by surgical instruments. All knots slip to some degree, regardless of the type of suture material, and the cut ends of the knot must provide the additional material to compensate. If the amount of knot slippage exceeds the length of the cut ends, the throws of the knot become untied. In general, leaving the free ends approximately 3 mm in length will accommodate most knot slippage. To facilitate removal in some locations (e.g., scalp or eyebrow), it may be useful to leave longer suture ends so that they can be easily located and grasped with forceps. Dermal sutures are, however, an exception to this rule. Because the ends of dermal suture knots may protrude through the wound, it is best to cut the dermal suture ends close to the knot. It must be emphasized that knot security is enhanced by additional throws and not by longer ends.

Suture Patterns

Simple interrupted sutures represent the most versatile suture technique and are good for realigning irregular wound edges and stellate lacerations with more meticulous approximation of the wound edges (Fig. 37-14). An advantage of interrupted sutures is that only the involved sutures need to be removed in the case of wound infections. Wound integrity is greater and the risk of premature separation (dehiscence) is less because the wound is held together with multiple individual suture loops.
FIG. 37-14. Stellate laceration closed with interrupted sutures.

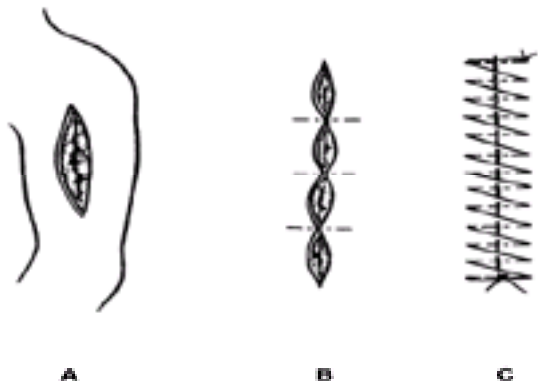
Continuous running sutures are quick, easy, and may save time in the ED because only two knots need to be tied at each end of the laceration as opposed to individual knots for each interrupted suture loop (Fig. 37-15). Continuous sutures are best when repairing linear wounds. However, a break in suture may ruin the entire repair and may cause permanent marks if placed too tightly. This type of suture is often used where hemostasis is important, such as the vagina and scalp, where locking the running suture aids in hemostasis (Fig. 37-16). Another advantage of the continuous suture is that it accommodates to the developing edema of the wound edges during healing. In contrast, the dimensions of the interrupted suture remain unchanged, constricting the edematous tissue within each suture loop. For either interrupted or continuous percutaneous suture closure, a monofilament synthetic nonabsorbable suture is used.


FIG. 37-15. A. Linear laceration of the arm subjected to strong skin tensions, with marked retraction of wound edges. **B.** Three interrupted dermal sutures markedly reduce the retraction of the skin edges. **C.** Continuous percutaneous suture.
FIG. 37-16. Running locked suture.

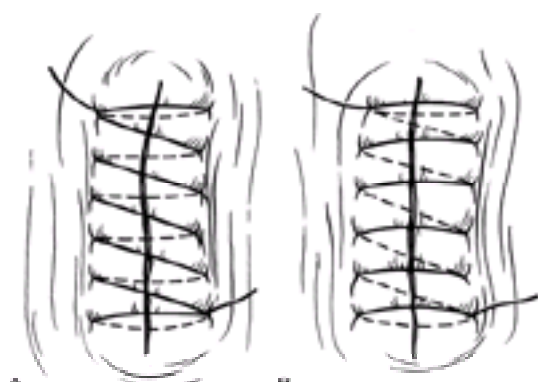
Continuous suture closure of a laceration can be accomplished by two different patterns. In the first pattern, the needle pathway is at a 90° angle to the wound edges and results in a visible suture that crosses the wound edges at a 45° angle (Fig. 37-17A). In the other pattern, the needle pathway is at a 45° angle to the wound edges, so that the visible suture is at a 90° angle to the wound edges (Fig. 37-17 B). In either case, the physician starts the continuous suture closure at the corner of the wound that is farthest away, and suturing progresses toward the physician, rather than away.


FIG. 37-17. A. Running suture crossing wound at 45°. **B.** Running suture crossing wound at 90°.

Dermal (subcuticular) sutures, either interrupted or continuous, may be necessary prior to skin closure to reduce tension and gaping. Interrupted dermal sutures are started by entering the skin near the base and exiting just beneath the dermal-epidermal junction. Entry into and exit from the opposite side is at corresponding levels. Tying the ends with an instrument tie "buries" the knot in the wound depth; starting the suture at the dermal-epidermal junction would leave the knot close to surface (Fig. 37-18). The compound curved needle is ideal for this type of suture because the suture loop is smaller than that achieved with a simple curved needle.
FIG. 37-18. Dermal suture. **A.** Entry is at base of wound on one side and exit at the dermal-epidermal junction. **B.** Entry on the opposite side is at the dermal-epidermal junction with exit at the base. **C.** The tied loop has the knot buried in the wound away from the skin surface.

Continuous dermal (or subcuticular) sutures are useful in wounds subjected to strong skin tensions, patients prone to keloid formation, children frightened by suture removal, and those individuals who are unable to contact a health professional for suture removal. Absorbable synthetic braided or monofilament sutures (4-0 and 5-0 size) are ideally suited for continuous dermal sutures because they do not have to be removed. In contrast, nonabsorbable continuous dermal sutures have to exit percutaneously from the ends of the wound as well as surfacing every 3 cm through the skin, to facilitate removal. Continuous dermal sutures are begun as an interrupted dermal suture with its knot buried in the subcutaneous tissue (Fig. 37-19). After the physician cuts the free end close to the knot, the suture attached to the needle is used for the continuous closure. The next stitch is passed horizontally along the length of the wound through the superficial dermis (Fig. 37-19). After the dermis is exited, the position of the next bite is identified by pulling the suture across at right angles to the wound. Accurate positioning is assured by slight backtracking of each bite. During passage of the needle, the skin is stabilized by one arm of the toothed forceps. As the horizontal bites are taken, gentle constant traction on the fixed suture brings the wound edges together. At a point one bite from the end of the wound, a smaller horizontal bite is passed toward the end of the wound. The suture from this corner stitch is withheld, forming a loop that will be used in constructing the knot. After passing the suture horizontally through a small bite of dermis in the opposite wound edge, the fixed suture end and the long loop of the free suture are used to construct the terminal square knots. The skin edges can be approximated with either percutaneous sutures, skin staples, skin-closure tapes, or tissue adhesives.
FIG. 37-19. Continuous subcuticular suture.

Continuous dermal sutures can be used by themselves when percutaneous sutures might cause cosmetic problems. They are ideal for linear facial lacerations, where sutures placed completely below the surface of the skin minimize scaring. One disadvantage is that complete suture removal may be required if local infection demands wound reopening. Wound integrity is dependent on only one piece of suture as opposed to multiple loops if interrupted sutures were used. For the best cosmetic results, a compound-curved, reverse cutting-edge precision-point needle is recommended.

Vertical mattress sutures allow for precise edge to edge alignment and are especially good to match thick to thin skin (Fig. 37-20). This suture enhances skin edge eversion and avoids the tendency for inversion common with deep nonlinear lacerations. When placing the sutures, care must be taken not to make them too tight, which might strangulate the tissues. The resulting scar may be inferior to that from some of the other suturing techniques; therefore this approach should be used for areas that are not cosmetically important. For conventional vertical mattress sutures, the first bite is a large one starting approximately 1 to 1.5 cm away from the wound edge and crossing through the wound to an equal distance on the opposite side. The needle is then reversed and a very small, shallow bite (1 to 2 mm) at the epidermal/dermal edge is placed in order to closely approximate the epidermal layer. The ends are tied with the knot falling on one side of the wound. The vertical mattress suture is useful in areas of lax skin (elbow, dorsum of hand), where the wound edges tend to fall or fold into the wound and eversion of the skin is harder to obtain. The vertical mattress suture can also act as a deep as well as superficial suture—an "all in one" suture; avoiding the need for a layered closure. The modified vertical mattress suture places the small bite first and then uses elevation on the suture ends to raise the wound edges, to make placing the larger and deeper second bite easier. This modification allows faster placement of individual stitches. [17]
FIG. 37-20. Vertical mattress suture.

Horizontal mattress sutures are faster and better at eversion than vertical mattress (Fig. 37-21). The repair may look poor early on, but with good eversion, the scar will have a better cosmetic effect in 2 to 3 months. This suturing technique may be faster because it covers more linear distance. It is especially useful in areas of increased tension such as fascia, joints, and callused skin. Individual sutures must be tied loosely to avoid tissue strangulation. The first throw is similar to a simple interrupted suture but instead of tying the suture a second bite is taken approximately 5 mm adjacent to the first exit on the same side and directed back to the initial side. This second bite exits approximately 5 mm from the initial entry point. The knot is tied leaving an everted edge.

FIG. 37-21. Horizontal mattress suture.

Horizontal half buried sutures are good for repairing flaps and triangular wounds (Fig. 37-22). It minimizes tissue tension so it doesn't strangulate the interposed tissue. Similar to vertical mattress sutures, horizontal half buried sutures are also useful to approximate thick to thin edges. To accomplish this, it is important to bury the suture in the thicker edge and tie the suture on the thinner side to allow eversion and reapproximation of the skin edges.

FIG. 37-22. Horizontal half-buried suture.

Purse-string suture is very useful at reapproximating multiple flap tips and corner wounds back together (Fig. 37-23). This technique is used in these areas in order to preserve the blood supply and minimize tissue destruction at the tips of the skin edges.
FIG. 37-23. Purse-string suture.

The dog-ear maneuver is a technique used to handle excess tissue at one end of the wound (Fig. 37-24). Basically the wound is extended from the apex toward the long side in the form of a hockey stick. Then the triangular piece of excess skin is removed and the skin edges are sewn together. Undermining may be necessary to help remove the excess tissue and suture the edges closed.
FIG. 37-24. Dog-ear maneuver. **A.** Incision is carried off one end of the wound at 45° toward the side with excess tissue. **B.** The excess tissue is pulled over the incision and cut away. **C.** The sutured laceration now has a "hockey stick" angulation.

PROBLEM WOUNDS

Several factors should be considered in choosing the best approach for wound closure. For example, deep wounds produce potential spaces, which, when the overlying skin is closed, can be susceptible to infection. Closure of deep space is controversial, as absorbable sutures placed to close this potential space increase

the risk of infection due to the presence of the suture foreign body. Parallel lacerations may have compromised perfusion to the "island" of skin between the lacerations that could be further impaired by percutaneous sutures. To minimize damage to subcutaneous blood vessels and reduce skin tension on the intervening strips of skin, horizontal mattress sutures or closure with skin-closure tapes or tissue adhesives alone should be considered (Fig. 37-25).

FIG. 37-25. Parallel lacerations can be closed with horizontal mattress sutures.

Elderly Skin

With aging, there is a decrease in the cellular growth rate and a degeneration of collagen and elastic fibers, resulting in a loss of both dermal and subcutaneous tissues and a thinning of the epidermis. Consequently, the skin loses its elasticity and appears transparent, wrinkled, thin, dry, fragile, and lacking in tensile strength. Normally, the epidermis attaches firmly to the dermis by projecting extensions of epidermis into the dermis in a tongue-in-groove fashion (rete pegs). With aging, this dermal-epidermal junction flattens owing to loss of capillaries, collagen fibers, and glycoproteins. There is also an increase in the fragility of the capillaries in the basement membrane zone, making the skin prone to subcutaneous hemorrhage or senile purpura. Because of all of these changes, aging skin tears with minor friction or shearing forces. These tears become an invitation to bacterial invasion and subsequent infection.

In the elderly, skin tears usually present as epidermal flaps. If the flap remains attached to its pedicle, it should be replaced on the dermis and approximated to adjacent tissue by skin-closure tapes or tissue adhesives (not sutures or skin staples). When the epidermal flap becomes separated from the skin, healing of the wound will be considerably delayed. With complete loss of the epidermal flap and exposure of 500 mm^2 or more of the dermis, coverage with a split-thickness skin graft may be necessary.

U-Shaped Flaps and Jagged Lacerations

A U-shaped skin flap is often caused by compressive forces on skin overlying bone. The flap usually has abraded skin and extends deep with attached subcutaneous tissues. The edges of the flap are usually irregular and fit together with adjacent wound edges, like a jigsaw puzzle. The survival of a rectangular-shaped flap is dependent on the blood supply from vessels that enter the flap at its base. Survival of a flap is more dependent on its length and not the width of the base; wide and narrow-based flaps survive equally if they are of the same length. Other factors that favor survival include the following: (1) the presence of direct cutaneous arteries or veins coursing the longitudinal axis of the flap (axial-pattern flap); (2) location of the flap in the head or neck, where the vascularity is excellent; (3) younger patients and those without diabetes mellitus or arteriosclerosis; (4) location above the knee and not in areas of scar or previous exposure to radiation, which, especially in the elderly, have diminished vascularity; and (5) absence of excessive tension, kinking, pressure, hematoma, or infection, which may interfere with circulation.

The most reliable way to determine tissue viability in a flap is reexamination 24 h after injury, at which time the viability is well demarcated and can be clearly ascertained. For fresh skin wounds, active bleeding from the distal and dermal margins indicates viability. U-, C-, or V-shaped flaps usually heal with a trapdoor or pincushion effect that results in an elevated bulging of the tissues. Various theories to explain this phenomenon are lymphatic and venous obstruction, hypertrophy of the scar, excessive fatty and redundant tissues, beveled wound edges, and contracture of the scar. Because the traumatic wound is susceptible to the development of infection, it is best to reapproximate the edges of a vascularized flap with the least reactive synthetic monofilament suture using interrupted percutaneous sutures. Approximation of the irregular wound edges is like putting together a jigsaw puzzle (Fig. 37-26). The wound edges of these lacerations often have a beveled edge rather than a perpendicular configuration (Fig. 37-27). It can be argued that this beveled edge may have a favorable influence on healing by providing a large interface between the divided edges, thereby enhancing repair. Consequently, repair of the beveled edges is advocated rather than revising the edges to create perpendicular edges. Suturing beveled edges may be time-consuming because the needle must be passed separately through one edge before it is passed through the other to ensure that the suture passes through the same depth on each side of the wound to align equivalent layers. This time-consuming maneuver is worthwhile because it prevents malapposition of the wound edges and an unattractive scar deformity.
FIG. 37-26. A. V-shaped laceration with irregular wound edges. **B.** An interrupted percutaneous suture approximates the midportion of the wound. **C.** Two additional percutaneous sutures are used to approximate the lateral sides of the wound. **D.** Additional percutaneous sutures are positioned between the previously placed percutaneous sutures. **E.** The interrupted percutaneous sutures allow the wound to be reconstructed like a jigsaw puzzle.
FIG. 37-27. Closure of beveled edges requires careful approximation of the wound edges. This is facilitated by removing the needle from the needle holder after passage through one side, regrasping the needle, and passing it through the opposite side.

When a portion of the flap is devascularized, this segment should be excised. The excised flap should then be defatted, converting the flap into a skin graft that is applied to the defect and secured by a tie-over bolus dressing. After the skin graft heals without infection, the patient should be referred to a plastic surgeon for follow-up evaluation. Six months after wound closure, the plastic surgeon can correct the trapdoor deformity by performing Z- and W-plasties accompanied by peripheral undermining of the wound. For small trapdoor deformities, simple excision of the deformity resulting in a lenticular defect that can be primarily closed is an excellent alternative.

Corners

Irregular lacerations often have corners or sharp angles; from a simple corner to V-shaped, Y-shaped, or stellate lacerations. Corners have less blood supply than edges, and closure should be done carefully to prevent further impairment of perfusion and minimize tension. The horizontal half buried suture is designed to accomplish both purposes (Fig. 37-22).

Lacerations Subjected to Strong Skin Tensions

Lacerations subjected to strong skin tensions are prone to wound dehiscence and healing with wide, hypertrophic scars. These lacerations can be identified by retraction of their wound edges more than 5 mm and the alignment of the long axis of the wound with the wrinkle lines or transverse axis of the joint. Undermining the wound edges is one method to reduce tension, but this technique can diminish the blood supply to the wound, thereby damaging wound defenses and inviting the development of infection. Attempting to reduce tension by closure of adipose tissue is to be avoided because it enhances infection without strengthening the wound.

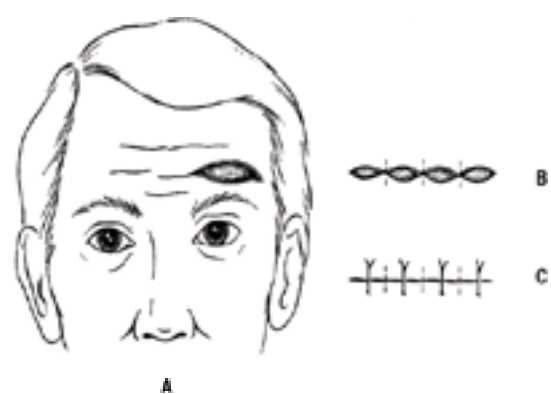
Dermal skin closure is recommended in these wounds to maintain their strength and prevent the development of wound dehiscence after removal of the skin sutures or the exfoliation of skin-closure tapes or tissue adhesives. Because dermal sutures allow early removal of the percutaneous suture, needle puncture scars and tracts do not develop, but there is no reduction in scar width. Dermal repair should be accomplished with the least number of interrupted sutures and with buried knots using braided synthetic absorbable sutures. The suture ends are cut flush with the knot. Interrupted percutaneous synthetic monofilament sutures positioned between the dermal sutures are then used to close the skin edges (Fig. 37-28). Alternatively, if the skin edges are close together after dermal suturing, the epidermis can be closed with skin-closure tapes or tissue adhesives.


FIG. 37-28. A. Linear laceration of left forehead subjected to strong static skin tensions. **B.** Three interrupted dermal skin sutures bring the retracted wound edges together. **C.** Four interrupted percutaneous sutures positioned between the dermal sutures provide meticulous approximation of the wound edges.

Wound undermining reduces wound tension by releasing the dermis and superficial fascia from their deeper attachments, allowing the wound edges to be brought together with less force. Undermining is potentially useful in the scalp, forehead, and lower legs, particularly in the tibia area, where the skin is under a great deal of natural tension. Caution must be taken because this procedure can spread bacteria into deeper tissues as well as creating a deeper and larger dead space. Undermining is performed by using scissors placed underneath the dermis and gently spreading them to bluntly dissect in a parallel fashion, releasing the dermis from deeper attachments. Cutting is kept to a minimum to minimize bleeding.

Crushed Tissue

As a general rule, crushed tissue should be excised. Crushed tissue leads to additional edema, fibroplasia, and more scarring. The extent of crushed tissue may not be easily visible. One way to demonstrate the extent of crushed tissue is to use hydrogen peroxide, which will produce a white patch wherever the wound edges were crushed. However, full excision of all crushed tissue may create more problems in the long run, particularly if excision will leave defects that cannot be covered with available skin. During the repair of traumatic lacerations in the ED, excision should be limited and completely avoided on the nose, vermilion-cutaneous junction, or eyelid. Wounds in these areas should be closed while preserving as much tissue as possible. The most important principle in repairing crushed tissue is to do most of the work at the subcutaneous level and use very few percutaneous sutures. Another principle is to position the pieces so that they heal in proper relation to each other so that scar revision, if necessary, will be easier. With all crush injuries, the patient should be warned about the possibility of a residual scar but also informed that plastic surgery revision is an option.

TIPS FOR A PLASTIC CLOSURE

There are several general principles to cosmetic closure. All wounds heal with some scarring, the goal is to use techniques that make the scar as small and invisible as possible. Scars become visible when they cast a shadow, have a rough surface, are wide, or develop permanent secondary color change.

Scars most often cast a shadow when they become concave from wound contraction during healing. Wound-edge eversion during the initial repair will therefore gradually flatten with healing and have a final appearance that is cosmetically acceptable. Wounds that are not everted will contract into linear depressions that will become noticeable cosmetic defects because of the tendency to cast shadows under incident light.

In closing a laceration, it is important to match each layer of a wound edge to its counterpart. The epithelium-to-epithelium interface should match perfectly to create a hairline smooth scar. Care must be taken to avoid having one wound edge rolled inward, so that the cut edge of the epithelium on one side is opposed against the dermis on the other side. The skin edges may look matched up but actually are not. The rolled-in edge occludes the capillaries, promoting wound infection. The dermal side will not heal to the rolled epidermal side, causing wound dehiscence when the sutures are removed. Everting the edges helps prevent skin rolling. Likewise, overeverting the edges causes problems; the exposed dermal surfaces promote granulation tissue and a rough scar.

The relationship between the wound tension and the distance between sutures is also important for a cosmetic repair. The more tension on the wound, the closer the sutures need to be to each other to minimize the tension on the wound edge. Further spaced sutures have more tension that is distributed to each loop leading to cut-over marks, stitch marks, and stitch holes. Another technique to reduce tension on the wound is to close the wound in layers. However, deep stitches can cause an inflammatory response, leading to increased scarring as well as an increased risk of infection. Sutures placed through the epidermis can cause stitch-mark scars. Therefore, the minimum number of sutures necessary to accomplish closure should be placed just far enough from each other that no gap appears between the wound edges. The knots should be placed away from the wound edges to prevent an inflammatory response.

To prevent the development of needle-puncture scars, percutaneous sutures must be removed as soon as possible and the wound edges reinforced with skin-closure tape to prevent wound dehiscence.

Topical agents (antibiotics, vitamin E, and aloe vera) have been found to reduce the incidence of wound infection, accelerate healing, and increase wound tensile strength after suturing. Dressings are usually necessary for only the first 12 to 24 h, after which gentle periodic cleaning with mild soap and water can commence. The area should be gently patted dry and re-dressed with a sterile dressing. Wounds closed with skin-closure tapes or tissue adhesives should not be covered with a

dressing or washed. Pressure dressings are useful in minimizing intercellular fluid collection and limiting the dead space, both useful in achieving cosmetic closure. Abraded wound areas may develop an exudate that dries on the surface, forming a scab during the first 24 h. This dry scab resists epidermal cell migration and interferes with wound healing. If abraded areas are covered with a dressing to maintain moisture during the first 24 h, epidermal cell migration is encouraged and healing promoted. If sutures are placed in and around abraded areas, small amounts of water-soluble ointment may be beneficial in preventing scab formation. Gently cleaning the wound with half-strength hydrogen peroxide every 6 h until the wound edge is free of blood prevents scarring due to clot formation around the wound edge.

Exposure of abraded skin and healed lacerations to sunlight during the first 6 months after injury may cause permanent hyperpigmentation. Hyperpigmentation can be prevented by protecting the injured skin area from sunlight with a sun-blocking agent with sun protection factor of 15 to 30 for 6 to 12 months.

38 LACERATIONS TO THE FACE AND SCALP

Wendy C. Coates

EPIDEMIOLOGY

Each year, more than 12 million wounds are treated in emergency departments (EDs) across the United States.[1] The most cosmetically devastating are those that appear on the face; therefore careful evaluation and meticulous repair technique are important for excellent results. The emergency physician can repair the majority of facial lacerations; however, because of the cosmetic impact of these wounds, consultation with specialists is encouraged when the technical aspects of closure exceed the physician's ability. In addition, the patient may insist on a specialist to repair such wounds as are readily visible. Wounds to the face that involve areas of tissue avulsion may best be repaired primarily in the operating room so that flaps or grafts can be applied. When the emergency physician initially evaluates the wound, it should be cleaned and properly irrigated even if a delayed repair by a specialist is anticipated.

In today's society, a growing number of victims of domestic violence are being identified in the ED. Anyone with facial trauma should be questioned about the possibility of domestic violence; if this is strongly suspected, appropriate authorities should be notified. Prompt identification and intervention are critical in preventing future injury.[2,3]

PATHOPHYSIOLOGY

Facial and scalp wounds are most often caused by a combination of sharp and blunt mechanisms. For example, a victim of a motor vehicle accident may bluntly strike the windshield and be cut by the glass as it shatters. People involved in interpersonal trauma or falls may have a similar pattern of injury. Lacerations caused by sharp objects are likely to have more discrete edges but may be deeper and involve underlying structures such as the muscles of facial expression, nerves, and/or arteries. Wounds caused by blunt forces burst the skin open, damage cells, and produce tissue edema, which slows down the wound-healing process. As a result, it takes an average of ten times fewer bacteria to cause an infection as in a blunt wound as opposed to a sharp wound. Blunt forces are more likely to cause diffuse underlying damage, such as fractures of the facial bones or skull. The presence of foreign bodies such as soil, glass, or wood fragments further complicates the potential for good healing.[1,4,5 and 6]

SCALP AND FOREHEAD

Anatomy

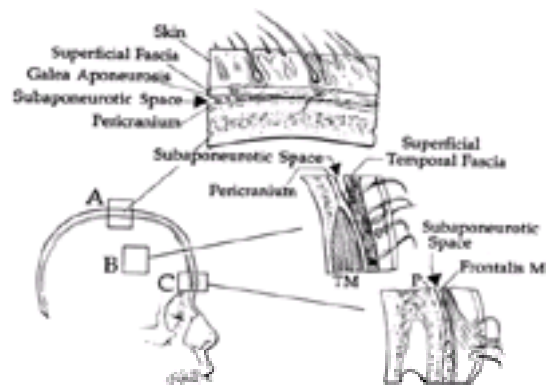
The scalp and forehead have similar structure (Fig. 38-1). The skin is thick, and over the scalp has abundant hair follicles and sebaceous glands. There is a rich network of blood vessels: the arterial supply to each side of the scalp involves three branches off the external carotid artery (occipital, superficial temporal, and posterior auricular arteries) and two branches from the internal carotid artery (supraorbital and supratrochlear arteries).[7] Since the dermal tissue is so fibrous, vessel retraction is limited following injury, and significant hemorrhage can result. The potential space between the periosteum and the galea aponeurosis allows for easy movement of the scalp over the cranium. However, hematoma and infection can collect and spread within this space to involve the entire forehead and scalp. This high degree of mobility sometimes leads to a scalping injury, in which a large segment of the scalp is torn off in one piece.


FIG. 38-1. The layers of the **A.** scalp, **B.** forehead, **C.** and eyebrow.

Evaluation

For many patients with scalp and forehead lacerations, the wound may be a minor part of the overall injury; prior to definitive wound care, airway, breathing, circulation, hemorrhage control, and spinal and neurologic injury should be addressed. In some cases, it may be necessary to control scalp hemorrhage urgently by applying direct pressure or clamping the involved vessel(s) at the wound edges (e.g., using Raney clips).

Routine lacerations should be inspected and gently palpated to their depth, noting whether the galea is lacerated or if there is an underlying depressed skull fracture. Palpable depressions in the outer table of the skull should be evaluated further by computed tomography. The orientation of forehead lacerations has important cosmetic implications. In general, wounds that fall along the lines of skin tension have better cosmetic results. Skin tension lines are always perpendicular to the underlying muscles. As an obvious example, the horizontal lines seen on the forehead when the brow is raised are perpendicular to the frontalis muscle underneath (Fig. 38-2). Forehead lacerations that extend to other structures, such as the eyebrow, nose, or ear must be evaluated and managed with the cosmetic result of these structures in mind.
FIG. 38-2. Skin tension lines are perpendicular to underlying muscles.

Wound Preparation

Routine wound care should be undertaken. Sedation may be required to ensure that the patient is safe and relaxed during the procedure. [8] Anesthesia can be provided by topical, local, or regional infiltration. A supraorbital block can be used to anesthetize one side of the forehead and anterior third of the scalp. The advantage of a regional block in the face is that the volume of locally instilled anesthetic does not distort the wound. [9] Local anesthetics containing epinephrine are often used in these highly vascular wounds to help control hemorrhage from small vessels. While many clinicians describe this effect, there are few data to support the belief that epinephrine reduces bleeding during wound repair. Conversely, the theoretical adverse effects of added epinephrine (increased risk of infection, ischemia of portions of the wound with poor circulation, and cardiovascular effects of epinephrine) are rarely an issue with facial and scalp lacerations. Thus, the use of a local anesthetic with or without epinephrine is a matter of personal preference. Topical agents such as TAC (tetracaine-adrenaline-cocaine) or LET (lidocaine-epinephrine-tetracaine) may be useful in this area. [10,11] LET has several practical advantages and is recommended over TAC.

All traumatic wounds are commonly irrigated to reduce contamination and lessen the risk of wound infection. However, in nonbite, noncontaminated facial and scalp wounds presenting within 6 h, routine irrigation does not alter the rate of infection or subsequent cosmetic appearance after suture repair. [12] Regardless of irrigation, the overall incidence of wound infection in sutured scalp and facial wounds is about 1 percent.

Repair of Scalp Lacerations

It is not necessary to shave the scalp prior to closure; shaving actually increases the likelihood of a wound infection and produces a less desirable cosmetic result in the short term. In most cases, the hair can be brushed aside. One can also apply an ointment such as bacitracin zinc or petrolatum to mat down the hair adjacent to the laceration. Hair braiding has been described as an alternate closure technique. [13] Large galeal defects should be repaired if possible to prevent a wide, depressed appearance of the final scar and to minimize the development of a subgaleal hematoma. Buried 4-0 nonabsorbable monofilament nylon [e.g., Surgilene (Sherwood Davis & Geck)], or polypropylene [e.g., Prolene (Ethicon, Inc.)] interrupted or horizontal mattress sutures may be used (Table 38-1). In large wounds, the muscle layer may be approximated with 4-0 absorbable monofilament [e.g., Monocryl (Ethicon, Inc.)] or multifilament [e.g., Dexon (Sherwood Davis & Geck) or Vicryl (Ethicon, Inc.)] in a simple interrupted fashion. This also serves to reduce the apparent width and depth of the final scar. Conversely, the skin and muscle layers can be closed with a single suture layer through both structures. The skin can be closed with surgical staples or by simple interrupted nylon or rapidly absorbable braided [e.g., Vicryl rapide (Ethicon, Inc.)] sutures.[14] It is helpful to leave the tails long and use sutures of a color different than the hair to facilitate removal. Tissue adhesive is not recommended for the scalp. A pressure dressing should be considered for the first 24 h on a deep laceration to prevent the formation of a hematoma. Patients who have sustained a significant scalping injury should be sent to the operating room for definitive repair.

Area	Suture	Size	Anesthetic	Removal
Scalp and face				
Galea	Nylon	4-0	Local or supraorbital	Not removed
Muscle	Monofilament or braided absorbable	4-0	Local or supraorbital	Not removed
Skin	Staples	Standard	Local or supraorbital	10–14 days
	Nylon	4-0		
	Rapidly absorbing	4-0		
Forehead	Coated or plain nylon	6-0	Local or supraorbital	5 days
	Tissue adhesive	May need deep layer		
Face	Coated or plain nylon	6-0	Local, infraorbital, or mandibular	5 days
	Tissue adhesive	May need deep layer		
Eyelid	Coated or plain nylon	6-0 or 7-0	Supra- or infraorbital	5 days
Nose				
Cartilage	Braided absorbable	5-0	Intranasal pack (no epinephrine)	Do not remove
Skin	Coated or plain nylon	6-0	Intranasal pack (no epinephrine)	3–5 days
Ears				
Cartilage	Coated nylon	6-0	Auricular block (no epinephrine)	Do not remove
Skin	Coated nylon	6-0	Auricular block (no epinephrine)	5 days
Lips				
Mucosa	Rapidly absorbing	5-0	Local, infraorbital, or mandibular	Do not remove
Muscle	Monofilament or braided absorbable	4-0 or 5-0	Local, infraorbital, or mandibular	Do not remove
Skin	Plain or coated nylon	6-0	Local, infraorbital, or mandibular	3–5 days

TABLE 38-1 Suturing Guidelines for the Face and Scalp

Repair of Forehead Lacerations

The deep layers may be approximated in a similar fashion to the scalp. In this area, unrepaired muscle layers are more likely to produce noticeable scars, especially when the facial muscles of expression are involved. The superficial layers may be closed with 6-0 nonabsorbable interrupted suture (nylon, coated nylon, or polypropylene) or tissue adhesive. For deep wound under tension, a buried 5-0 intradermal, absorbable monofilament (e.g., Monocryl) or multifilament (e.g., Dexon or Vicryl) can be used. The epidermal layer can be closed with 6-0 nonabsorbable nylon in a simple, interrupted fashion; with wound closure strips [e.g., Steri-strips (3M Company) or Dermaseal (Personna Medical)] over tincture of benzoin; or with tissue adhesive. [15,16] These alternate methods of closure are especially attractive if the patient is at risk to develop keloids or hypertrophic scars (e.g., people with darkly pigmented skin). Care should be taken in the forehead to approximate the skin tension lines and hairline precisely (Fig. 38-3).

FIG. 38-3. Key stitches in the forehead.

Repair of Eyebrow Lacerations

The eyebrow marks the lowest portion of the forehead. The eyebrows should never be clipped or shaved because their delicate contour and form are valuable landmarks for the meticulous reapproximation of the wound edges. Furthermore, it is unlikely that they will grow back in exactly the same fashion as they had been prior to the injury. If debridement in any hairy area must take place, the scalpel should cut in an angle parallel to the hair follicles to minimize the area of subsequent alopecia.

Disposition

Patients whose overall medical condition does not warrant surgery or admission to the hospital can be discharged safely with routine wound-care instructions. If their injury resulted from a major blunt impact, a companion should be instructed to bring the patient back for altered level of consciousness, nausea or vomiting, or persistent bleeding or headache. Removal of scalp sutures or staples should take place in 10 to 14 days, while nonabsorbable sutures in the face should be removed in 3 to 5 days.

EYELIDS

Anatomy

The eyelid is a thin tissue that covers the globe and is composed of five layers: skin, subcutaneous tissue, orbicularis oculi muscle, tarsal plate, and conjunctiva. The muscular layer controls lid closure and forms both the medial and lateral canthus; fibers of the orbicularis oculi wrap around the lacrimal system. Nerve supply to the eyelid arises from the temporal and zygomatic branches of the facial nerve. The tarsal plate forms the main body of the lower half of the lid and consists of elastic tissue in a dense matrix of connective tissue. Embedded in the tarsal plate are the meibomian glands, which open into the white line just in front of the conjunctival edge of the lid margin. In the lid margin, the eyelashes are arranged in three irregular rows with their follicles extending obliquely into the tarsal plate.

The lacrimal system begins at the upper and lower puncta as they form the canaliculi. The nasolacrimal duct extends 3 to 5 mm above the level of the medial canthus. It is responsible for tear drainage.[7]

Evaluation

The structures surrounding the eye and eyelids are very delicate; they are cosmetically and functionally important. Depending on the mechanism of injury, a high degree of suspicion for injury to these structures must be maintained. The emergency physician should have a low threshold for referring lacerations in this area to an ophthalmologist or oculoplastic specialist for definitive treatment.

The eyelids are very thin and do not offer any protection from penetrating injuries to the globe. A complete exam of the eye's structure and function and a search for the presence of foreign bodies must be completed before local wound care can be attempted. Once the integrity of the globe and muscular structures is verified, the lid should be examined for involvement of the canthi, the lacrimal system, or penetration through the tarsal plate or lid margin. The following wounds should be referred to an ophthalmologist or oculoplastic specialist: (1) those involving the inner surface of the lid, (2) those involving the lid margins, (3) those involving the lacrimal duct, (4) those associated with ptosis, and (5) those that extend into the tarsal plate. Poor approximation of the lid margins leads to a notched appearance (ectropion). Failure to recognize and properly repair the lacrimal system can result in chronic tearing (epiphora) or dacrocystitis. In general, wounds that are superficial and especially those parallel to the lid margins may be carefully repaired by the emergency physician (Fig. 38-4).[17]
FIG. 38-4. Eyelid anatomy. **A.** External landmark. **B.** Simple closure of a superficial laceration of the upper lid.

Treatment and Disposition

Gentle irrigation to prevent lid edema should be performed after anesthesia. Caustic substances should be avoided. Closure with 6-0 or 7-0 nonabsorbable simple interrupted nylon suture (e.g., Ethilon, Dermalon) or polypropylene (e.g., Surgilene, Prolene) is preferred. Extreme care should be taken to avoid deep penetration of the needle into the globe as it is passed through the skin. Small bites only through the skin layer should be taken. Tissue adhesive is contraindicated near the eye. In the event of inadvertent contact with the eye, copious irrigation and/or application of a petrolatum ointment is indicated. Routine evaluation and treatment of the subsequent corneal abrasion should be followed. Sutures should be removed in 3 to 5 days. A thin layer of antibiotic ointment may be applied in place of a dressing.

NOSE

Anatomy

Being a protuberant structure, the nose is especially vulnerable to blunt trauma. It is composed of cartilaginous and osseous structures that support the overlying skin and musculature and the underlying mucosa. It is separated into halves by the septum. The tip of the nose is formed by two C-shaped alar cartilages that are covered directly by skin. The interior of the nose is covered by specialized skin with mucus-producing cells and thick, long hairs near the end, while the proximal portion of the

nasal lining is made up of ciliated pseudostratified columnar epithelial cells. [7]

Evaluation

The most important assessment of nasal lacerations is to determine their depth and the involvement of the deeper tissue layers. Exposed cartilage or penetration through all tissue layers increases the risk of infection. When there is septal trauma, the presence of a hematoma underneath the cartilage and its protective mucoperichondrial layer may eventually lead to permanent thickening of the septum, causing partial airway obstruction of the nasal passage. Alternatively, the pressure exerted by a large, untreated septal hematoma may cause necrosis and subsequent erosion of the septum, enabling communication between the nasal passageways. Besides the annoyance to the patient, it may lead to a cosmetic saddle-nose deformity. If the mechanism of injury included a blunt force delivered to the nose, the presence of cerebrospinal fluid rhinorrhea should be sought to diagnose a possible injury to the cribriform plate.

Treatment and Disposition

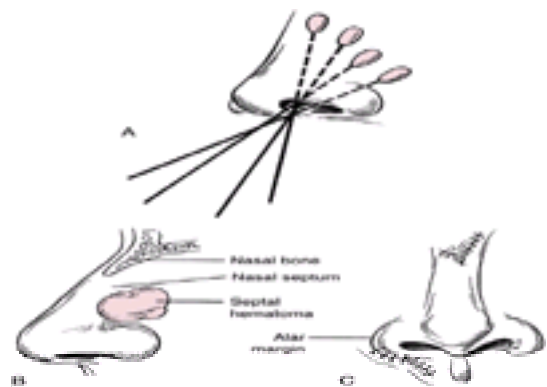
Local anesthesia of the nose may be attempted but is difficult because of the tightly adhering skin. Injection of epinephrine-containing anesthetics should be avoided on the nose. Regional anesthetic injection is difficult, but topical application of lidocaine mixed with epinephrine may provide sufficient anesthesia. Insertion of multiple cotton-tipped swabs or plain nasal packing gauze soaked in the mixture is usually sufficient (Fig. 38-5). After several minutes and prior to repair, the swabs or gauze should be removed.


FIG. 38-5. The nose. **A.** Nasal anesthetic technique using cotton-tipped applicators. **B.** Septal hematoma and lateral anatomy. **C.** Frontal view showing closure of skin edges.

Superficial lacerations to the skin layer may be closed with 6-0 nonabsorbable monofilament simple interrupted sutures, which may be removed in 3 to 5 days. Lacerations in which the cartilage is exposed should be closed promptly. Small pieces of cartilage that may be present should be preserved under the skin to provide the optimal cosmetic result. Future revision by a plastic surgeon will be easier if there is abundant tissue available for reconstruction.

If the laceration extends through all tissue layers, closure should begin with a 5-0 monofilament synthetic suture that aligns the skin surrounding the entrance to the nasal canals at the alar rim (Fig. 38-5). Initially, the ends can be left untied and long to facilitate the closure of the deeper structures. *Gentle* traction on this suture provides alignment of the mucosa and cartilage layers. The mucosal layer is closed with a 5-0 rapidly absorbable interrupted suture (e.g., Vicryl rapide) and the area is reirrigated gently from the outside. The cartilage may rarely need to be approximated with a minimal number of 5-0 absorbable sutures. In sharply demarcated linear lacerations, closure of the overlying skin is usually sufficient. Finally, the initial stitch at the alar margin should be reevaluated for precise alignment and tied; then the remainder of the skin should be sutured with 6-0 monofilament nonabsorbable material. Removal of the external sutures may take place in 3 to 5 days.

Septal hematomas should be drained. For a small, unilateral hematoma, the clot can often be aspirated through an 18-gauge needle. Larger hematomas require a horizontal incision at the base (Fig. 38-5). Following the procedure, nasal packing prevents the reaccumulation of blood. A brief course of prophylactic antibiotics is recommended to prevent infection of the cartilage. The packing may be removed in 2 to 3 days. Bilateral hematomas should probably be drained in the operating room.

LIPS

Anatomy

The external surfaces of the lips have three distinct regions: the skin, the vermilion, and the oral mucosa. The cosmetically important junction of the skin and the red portion of the lip is called the *vermilion border*. The orbicularis oris muscle surrounds the mouth. Its integrity is responsible for retaining the saliva inside the mouth, producing the bilabial sounds of speech, and providing important facial expressions. The infraorbital nerve supplies the upper lip and the mental nerve supplies the lower lip. Both are branches of the trigeminal nerve and can easily be blocked by regional anesthetic techniques. The lips are richly supplied by the labial arteries. [7]

Evaluation

External as well as intraoral examination must take place to appreciate the complete injury, and lacerations should be fully explored. Missing, impacted, or fractured teeth; involvement of the parotid (Stensen's) duct; or exposed bone of the maxilla or mandible should be noted. Lacerations that cross the vermilion border are of the utmost cosmetic importance.

Treatment and Disposition

Isolated intraoral mucosal lacerations may not need to be sutured. Through-and-through lacerations that do not include the vermilion border can be closed in layers. The mucosal layer is closed with a 5-0 rapidly absorbable suture (e.g., plain gut, Vicryl rapide). Gentle re-irrigation from the outside is recommended to prevent wound infection from intraoral organisms. Next, the orbicularis oris muscle is approximated with 5-0 absorbable suture material (e.g., Vicryl, Dexon, Monocryl) with a simple interrupted or horizontal mattress technique. Finally, the skin is sutured with 6-0 nonabsorbable monofilament material in a simple interrupted fashion. The sutures should be removed in 5 days. Alternatively, the skin can be approximated with tissue adhesive. The use of tissue adhesive on mucosal surfaces is contraindicated.

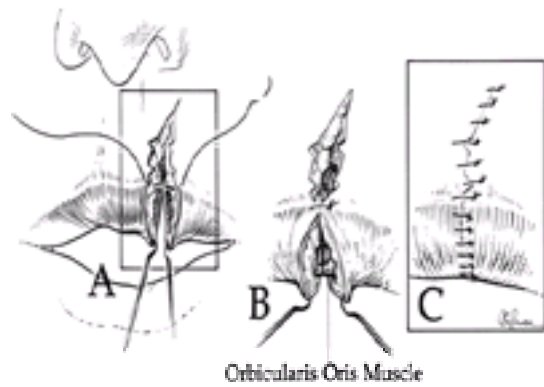
Wounds that cross the vermilion border should be repaired by placing the first stitch to approximate the edges of the vermilion border precisely (Fig. 38-6). Even 1 mm of step-off will be cosmetically unpleasing. Following this first stitch, the repair can proceed as previously described. In some cases, it is helpful to place this crucial suture and leave it untied until the remainder of the skin is sutured. Gentle traction on the ends can help approximate underlying tissue to provide optimal cosmesis. Care should be taken to avoid pulling the suture through the skin in this cosmetically delicate area.


FIG. 38-6. Irregular-edged vertical laceration of the upper lip. **A.** Traction is applied to the lips and closure of the wound is begun first at the vermilion-skin junction. **B.** The orbicularis oris muscle is then repaired with interrupted, absorbable 4-0 synthetic sutures. **C.** The irregular edges of the skin are then approximated.

If an underlying fracture of the maxilla or mandible is suspected, radiographic evaluation is required. Patients with open fractures should receive prophylactic antibiotics that provide coverage against oral flora, and a maxillofacial specialist should be consulted.

EARS

Anatomy

The external ear begins with the external auditory canal and extends to the fibrocartilaginous framework and finally the earlobe. The blood supply arises from the superficial temporal and posterior auricular arteries. The majority of the sensory innervation is from the anterior and posterior branches of the greater auricular nerve. The posterior wall of the external auditory canal is supplied by the auricular branches of the vagus nerve, so lacerations that involve this area must be anesthetized separately.[7]

Evaluation

It is crucial to identify lacerations caused by blunt forces to the ear, as a ruptured tympanic membrane or the formation of a subchondral hematoma can have devastating consequences. Hematomas must be identified and treated even in the absence of a laceration. The presence of cerebrospinal fluid otorrhea may signal a basilar skull fracture. Lacerations caused by blunt or shear forces may involve the cartilage.

Treatment and Disposition

Routine wound preparation is appropriate for ear lacerations. For patient comfort, a cotton plug can be inserted into the ear canal during irrigation. If a wound extends deep into the canal, the integrity of the tympanic membrane should be verified. Regional anesthesia by auricular block is ideal. Epinephrine should be avoided in lacerations involving the ear. Impeccable hemostasis prior to repair is required to prevent the formation of a hematoma.

Superficial lacerations to the skin can be closed with 6-0 monofilament interrupted sutures (Fig. 38-7). Any exposed cartilage should be covered to prevent subsequent infection. If an injury produces several crushed pieces of cartilage under the skin, they should not be removed; remaining cartilage will be beneficial if reconstructive surgery is necessary. Debridement of skin is not advisable, since there is very little excess skin available to cover the existing cartilage. In most through-and-through lacerations of the auricle, the skin can be approximated and the underlying cartilage will be supported adequately. In a large, gaping wound, one or two 6-0 nonabsorbable coated nylon stitches can be used to approximate the edges of cartilage. The knots should be tied so they will not cause an obvious deformity through the skin. If the overlying skin is avulsed, referral to a plastic surgeon for repair using a flap is recommended. Following repair of the simple ear laceration, a small piece of nonadherent gauze may be applied over the laceration only and a pressure dressing applied. Gauze squares are placed behind the ear to apply pressure and the head is wrapped circumferentially with gauze [e.g., Kerlix (Kendall Healthcare Products, Inc.)]. The dressing may be tied into place by cutting the last portion of the gauze longitudinally (Fig. 38-8). Sutures should be removed in 5 days. Complete avulsion of the ear must be urgently referred to a plastic surgeon.
FIG. 38-7. A. Laceration through auricle. **B.** One or two interrupted, 6-0 coated nylon sutures will approximate divided edges of cartilage. **C.** Interrupted nonabsorbable 6-0 synthetic sutures approximate the skin edges.

FIG. 38-8. Pressure dressing for ear lacerations. **A.** Gauze placed behind auricle. **B.** Bandage wrapped around head with two ends cut for tying. **C.** Ends tied.

If an auricular hematoma is suspected, consultation with a plastic surgeon or otolaryngologist is recommended. Proper treatment requires the complete and permanent evacuation of the hematoma and definitive control of the bleeding that caused it. Neglecting to treat an auricular hematoma may produce a "cauliflower" ear type of cosmetic defect of the cartilage.

THE CHEEKS AND FACE

Lacerations that involve the surface of the face may be repaired carefully using standard wound-care techniques. In general, facial lacerations are closed with 6-0 monofilament nylon simple interrupted sutures that are removed in 5 days. Tissue adhesive may be used in superficial wounds after proper irrigation. If there is significant tension, an underlying layer of 4-0 absorbable suture closure is indicated. Attention to underlying anatomic structures including the facial nerve and parotid gland is necessary[7] (Fig. 38-9). If these structures are involved, operative repair is indicated.
FIG. 38-9. Anatomic structures of the cheek. The course of the parotid duct is deep to a line drawn from the tragus of the ear to the midportion of the upper lip. Branches of the facial nerve: temporal (T), zygomatic (Z), bucial (B), mental (M), and cervical (C).

39 FINGERTIP AND NAIL INJURIES

Robert S. Chang
Wallace A. Carter

Fingertip injuries are those that occur distal to the insertion of the flexor and extensor tendons at the level of the lunula. This is among the most frequently injured parts of the hand and such injuries may involve the skin, pulp tissue, distal phalanx, and perionychium, made up of the nail, nail bed, and surrounding structures (Fig. 39-1). Injuries may be classified as closed crush, simple lacerations, open crush with partial amputation, and complete amputation. [1] The approach to treatment depends on the number versus other factors, including the specific digit involved (thumb or index finger); patient's age, sex, handedness, and occupation; as well as the size and angle of the wound, presence or absence of exposed bone, mechanism of injury, concurrent medical problems, and anticipated future use of the hand. The goals are to maintain length and cosmetic appearance, have the fingertip approach normal sensation and function, and have as short and uncomplicated a healing period as possible. This chapter is organized to separate distal fingertip injuries with and without bone exposure from those directly involving the perionychium.
FIG. 39-1. Anatomy of the perionychium.[From Zook, EG: The perionychium, in Green, DP (ed): *Operative Hand Surgery*, 2d ed. New York: Churchill Livingstone, 1988, p 1332, with permission.]

MANAGEMENT—GENERAL PRINCIPLES

History and Examination

The majority of fingertip injuries are isolated injuries and can be managed in the emergency department (ED). Complex or extensive injuries calling for skin grafting or technically demanding skills will require consultation with a specialist, as will those associated with other bodily injuries. Before evaluating the injury, an adequate history must be taken. Specific considerations must be taken into account if the digit involved is the thumb or index finger. In the thumb, it is crucial to establish a functional, sensate tip with preservation of as much length as possible. The second most important digit to consider is the index finger, where the goal is to preserve pinch. [2] The mechanism of injury (crush versus clean cut), age, hand dominance, occupation, and future hand use will influence the method of repair. Where the function of the fingers is vital to the patient's occupation (e.g., that of a concert pianist), early consultation with a hand or plastic surgeon is necessary.

In all cases, however, one is dealing with contaminated wounds in the hand; therefore examination and care of the involved digit must begin with meticulous attention to wound care. In addition to active tetanus toxoid immunization, a severely contaminated wound—one that has been in contact with soil, feces, or organic material—may require passive immunization using tetanus immune globulin (TIG) at the time of presentation. Further examination of the involved digit includes assessment of the extent of damage to the soft tissue, the nail, and nail bed; the level and angle of amputation; the presence or absence of exposed bone; and vascular status (e.g., capillary refill). A sterile needle applied along either side of the involved digit can easily test for sensation. Similarly, the ability to flex and extend at the distal interphalangeal (DIP) joint suggests that the integrity of the flexor and extensor tendons is at least partially intact.

Radiographic evaluation with anteroposterior (AP), lateral, and oblique views of the involved finger is necessary to assess for bone injuries and retained radiopaque foreign bodies.

Anesthesia and Irrigation

Adequate anesthesia is then administered to further delineate the extent of injury as well as allow for copious saline irrigation and débridement of necrotic tissue, as needed. There are several different types of nerve blocks that can be used, such as the digital, metacarpal, carpal, and axillary blocks. The choice of which to use is based on various factors, such as the number of digits involved, the size and location of the wound, as well as the personal preference of the physician. In the ED, the digital nerve block is a simple yet usually effective means of achieving digital anesthesia.

Following adequate anesthesia, the wound should be irrigated to remove foreign debris, reduce bacterial contamination, and lessen the risk of wound infection. Animal studies suggest that irrigation under pressure with adequate total volume lowers the infection rate in contaminated wounds; however, the required pressure and amount of irrigant is subject to debate. Irrigation through an 18- to 20-gauge needle attached to a 30- to 60-mL syringe generates a peak pressure of about 30 psi; this is usually adequate to dislodge foreign material from wounds. As to the irrigation amount, many clinicians have adopted the rule of thumb of 60 mL/cm of wound length. However, the total amount must be adjusted according to the condition and location of the wound. Unless there is extraordinary contamination, irrigation of fingertip wounds can usually be accomplished with a total amount of 250 to 500 mL of normal saline.

Adequate Visualization

A bloodless field provides the optimal setting for the performance of a digital repair. Several types of tourniquets have been described in the literature, including the pneumatic tourniquet placed around the upper arm, the digital tourniquet using a 1-in. Penrose drain, and a surgical glove. In the last of these techniques, the patient wears a glove that has a cut fingertip corresponding to the injured digit. As the glove is rolled from distal to proximal, a tight band acting as a tourniquet is created around the base of the digit. [3] The disadvantage of this technique is that different glove sizes, the varying thickness of the glove material, and the varying number of rolls produced may generate a wide range of pressures, making this technique less desirable in the ED setting. In the ED, a simple yet safe means of achieving

hemostasis is with the digital Penrose tourniquet. With a 1-in. Penrose drain, the finger is carefully wrapped from distal to proximal, thereby exsanguinating the digit. The drain is then carefully removed from distal to proximal and placed around the base of the finger, secured with a hemostat, to serve as a "tourniquet." Excessively high pressures, which can cause neurovascular damage, may be avoided by limiting the stretch of the drain to no more than 50 percent of the original length. [4]

A magnification loupe can be extremely useful in the surgical repair of an injured finger. However, not many EDs are equipped with this tool. If a repair cannot be achieved without a loupe, the hand or plastic surgery specialist must be consulted.

Wound Dressing and Postrepair Care

Once the fingertip injury is repaired, it should be dressed in nonadherent gauze, such as Adaptic (Johnson & Johnson Medical, Inc.) or an antibiotic-impregnated petrolatum gauze, such as Xeroform (Kendall Healthcare Products) and wrapped with sterile gauze dressings. If possible, it is desirable to observe capillary refill after the dressing has been placed. The fingertip should always be wrapped loosely to allow for adequate circulation. A metal or plastic-cap splint should be incorporated into the last layer of dressing for protection and avoidance of painful stimulation. The hand should be kept elevated. These injuries tend to be very painful, so adequate analgesia with oxycodone or hydrocodone should be offered to all patients. A follow-up wound check by the hand or plastic surgeon is recommended after 2 days. Sutures are usually removed 2 weeks after the injury. Exercises to prevent joint stiffness are begun 10 to 14 days following soft-tissue injuries and after 3 weeks if a distal phalangeal fracture is involved. [5]

Broad-spectrum antibiotics are not routinely recommended. They may be considered in wounds that are contaminated, for injuries that are more than 12 h old, in the presence of exposed bone, or in patients with concurrent medical problems that may affect wound healing (i.e., those with diabetes, renal, or peripheral vascular disease).[5] Antibiotics should be chosen to cover suspected contaminants and pathogens: *Staphylococcus aureus*, streptococci, gram-negative bacilli, and/or anaerobes, depending on the circumstances. Antibiotics should be given early and by a route to achieve high blood and tissue levels, often intravenously.

Indications for admission to the hospital include injuries that require repair in the operating room, those that require a course of intravenous antibiotics, as well as social issues such as homelessness or the patient's inability to follow basic aftercare instructions.

SPECIAL CONSIDERATIONS

In a child, identifying a fracture with plain radiographs may be difficult owing to an open epiphysis. It is often necessary to obtain radiographs of the uninvolved hand for comparison. If a surgical procedure is indicated and the child is unable to tolerate the procedure after a digital nerve block alone, conscious sedation may be required. Medications commonly used for conscious sedation include the sedatives/anxiolytics, such as benzodiazepines and barbiturates; pain relief is achieved using opioids such as fentanyl and morphine. In children, a commonly used agent is ketamine, a nonopiate phencyclidine derivative that produces both analgesia and sedation. Before performing conscious sedation, specific attention should be paid to allergies (including those to latex), current medications, and last oral intake of solids and liquids.

Keeping dressings intact on children poses a problem because of their continuous activity, rendering a routine hand dressing and protective finger splint ineffective. If the dressing is deemed essential to wound healing, the child should be placed in a long arm cast. [6] Consultation with the hand or plastic surgeon is recommended for proper follow-up and neurovascular evaluation.

SPECIFIC TREATMENT STRATEGIES

Digital Tip Injuries with Skin and Pulp Tissue Loss Only

Distal fingertip amputations that are 1 cm^2 or less in size without exposed bone can usually be treated conservatively in the ED with serial dressing changes alone. This is a desirable option, because healing occurs by secondary intention and results in very little scarring. Follow-up is arranged in 2 days for wound check and the patient is made aware that wound care is vital to the success of this technique. The patient is instructed to soak the injured fingertip in warm water to which an antibacterial soap has been added once a day for 10 min, followed by tap-water irrigation and application of a sterile nonadherent dressing. This procedure is performed daily for the first 10 to 15 days and every other day thereafter. On average, complete healing may take 4 to 8 weeks, and both the cosmetic appearance and sensibility of the fingertip are quite satisfactory with this technique. Conservative management is advocated in children less than 12 years of age, since they have greater regenerative potential than do adults. [6] Loss of volume, lack of pulp firmness, and increased sensibility (particularly to cold) have been reported in approximately 30 percent of patients.[7]

In cases where the severed skin tip is available, an alternative means of treatment is to use the amputated portion as a full-thickness skin graft. The amputated tissue is cleaned and debrided of nonviable tissue, the undersurface of the skin is then defatted with sharp scissors and sutured to the defect using nylon sutures. Sutures are left long and tied over a 2- by 2-cm gauze stent dressing to compress the graft firmly against the fingertip. Appropriate follow-up is made and unless obvious purulence ensues, the stented dressing is left undisturbed for 7 to 12 days.

A split- or full-thickness skin graft harvested from a distant site is another means of wound closure. This procedure may be indicated in situations where the severed skin tip is either not available or nonviable, significant pulp tissue loss is greater than 1 cm ^{2}, or the patient's desire to have full use of the hand precludes waiting the 4 to 8 weeks necessary for healing by secondary intention. In these cases, consultation with a specialist is appropriate. Most surgeons recommend using the hypothenar eminence of the injured hand as the donor site, since the skin from this region is the same type of glabrous skin as is present on the fingertips. [1] The graft is left in place for 7 to 12 days and allows for rapid wound closure and healing. Complications with skin grafts include decreased sensibility of the fingertip, scar tenderness both at donor and graft sites, cosmetically poor quality of coverage, and hyperpigmentation in patients with dark skin. [7]

Many authors agree that conservative management of fingertip injuries without bone exposure, as opposed to the above techniques, is superior in terms of cosmetic appearance, improved function, and sensibility of the involved digit. [1,6,8]

Digital Tip Injuries with Exposed Bone

If a significant loss of tissue to the fingertip causes exposure of the tuft of the distal phalanx, skin grafting will be unsuccessful since bone does not provide adequate vascularity to support the donor tissue. Several treatment options exist, always keeping in mind the important goals of preserving digit length, especially with regard to the thumb and index finger, as well as sensitivity and functionality of the fingertip. The size and geometry of the injury, the angle of tip amputation, and the availability of the amputated tip will determine the options available for wound closure.

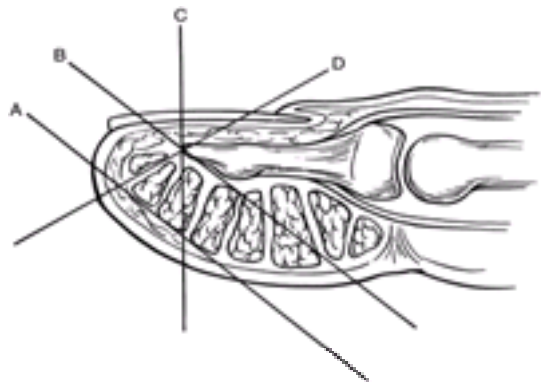
If the bony protuberance is less than 0.5 cm in length and the soft tissue defect is less than 1 cm ^{2}, the bone may be trimmed back using a rongeuer and the wound left to heal by secondary intention as previously described. A dorsal obliquely angulated wound (Fig. 39-2*D*) may be treated in the ED with bone shortening followed by primary closure of the wound using the adjacent volar tissue. An injury of this type has a favorable prognosis because the sensate volar skin is intact. Fat from the local tissue may need to be trimmed to allow wound closure without tension. The nail should be removed and attention paid to associated injuries to the nail bed and surrounding structures. Although results are comparable to those following conservative management, shortcomings include loss of length as well as tenderness of the fingertip and some degree of functional disability.


FIG. 39-2. Fingertip amputations. **A.** Volar angulation without bone exposure. **B.** Volar angulation with bone exposure. **C.** Transverse or perpendicular angulation with bone exposure. **D.** Dorsal angulation with bone exposure.[From Russell RC: Fingertip injuries, in McCarthy J (ed): *Plastic Surgery*. Philadelphia: Saunders, 1990, p 4479, with permission.]

Amputations that are angled either in a transverse or volar direction (Fig. 39-2*B* and Fig. 39-2*C*) have less favorable outcomes because they do not always have adequate soft tissue and skin coverage to allow for primary closure and preservation of length. Consultation with a plastic or hand surgeon is necessary, as these injuries often require the use of sophisticated local V-Y advancement or adjacent pedicle flaps to maintain length and provide tissue coverage, a technique beyond the scope of practice by most emergency physicians.

Incomplete digital tip amputations, defined by the retention of the neurovascular bundle as well as portions of the underlying bone, may be replaced as a composite graft. However, as reported in the literature, these are among the most difficult injuries to reconstruct and require consultation with a specialist. If adequate circulation is retained in the tip, the injury is treated with fracture reduction, internal pin fixation, and repair of the soft tissue injury. This procedure is optimally performed in the operating room.

In all patients with a complete amputation that occurs proximal to the lunula, consultation with the hand or plastic surgeon is recommended for possible replantation in the operating room. Conversely, in the adult patient, replantation of a complete amputation distal to the lunula is not usually advocated. This is because the procedure is technically demanding owing to the arborization of the neurovascular bundle at this location, and it carries a poor prognosis. However, consultation with the surgical specialist is clearly indicated in all patients with specific occupational concerns and when the injured digit is the thumb or index finger.

Although fingertip injuries are quite common in children, most require only conservative management because of the rapid healing process. Repairs should be done using absorbable sutures. Surgical procedures such as grafts and advancement flaps should be avoided where possible. A completely amputated composite tip may be reattached to serve solely as a biological dressing, and parents should be informed that the tip might necrose, dry up, and turn black as the underlying wound continues to heal. However, in children less than 6 years of age, replantation and revascularization of the composite tip may be a viable treatment option performed by the surgical specialist.

Injuries Involving the Perionychium

The nail, nail bed, and surrounding soft tissue make up the perionychium (see Fig. 39-1). The nail bed is made up of the germinal and sterile matrix. The germinal matrix begins 3 to 5 mm proximal and deep to the eponychium and extends distally to the lunula. From there, the sterile matrix (responsible for producing the majority of the nail) extends distally to the hyponychium. Injury to the perionychium is most commonly due to closure of the fingertip in a door and often occurs in the distal portion of the nail bed; it may occur as an isolated injury or in combination with any of the injuries previously discussed. Injuries can be described as simple nail bed laceration, stellate laceration, severe crush, and complete avulsion. The mechanism of injury is a force directed to the dorsum of the nail, causing it to bend or break and crushing the nail bed against the unyielding tuft of the distal phalanx. There is an associated distal tuft fracture in approximately 50 percent of nail bed injuries; thus all patients require the standard three radiographic views of the involved digit(s). Nail plate deformity affecting permanent nail growth is the most common complication resulting from lack of treatment. Therefore it is important to recognize when these injuries have occurred and to treat them appropriately.

Subungual Hematoma

These are injuries due to the disruption of the blood vessels of the nail bed. The area of the hematoma is directly proportional to the degree of vascular damage. If the hematoma covers less than 50 percent of the area beneath the nail, treatment can be accomplished with trephination of the nail plate to allow for adequate decompression and drainage of the hematoma. Various tools have been used effectively for this purpose, including a heated paper clip, electric nail drill, electrocautery, 18-gauge needle, and scalpel. The disadvantages with the heated paper clip include coagulation of the hematoma and introduction of carbon particles called "lampblack" into the nail bed, which may delay healing. [8] Use of a needle, scalpel, or nail drill can be painful and may necessitate local anesthesia. A hand-held electrocautery device permits rapid and painless trephination and is sterile and disposable. [8] However, not every ED will be equipped with such a tool, and emergency physicians will likely perform nail trephination using tools they are familiar with. Patients are discharged with local wound care instructions to soak the affected finger in warm water containing antibacterial soap two to three times a day for 7 days.

It is commonly recommended that for a subungual hematoma occupying more than 50 percent of the nail bed area, the nail be removed in order to evaluate the nail bed and repair any associated laceration. [2,5,8] However, there are two prospective studies which found that simple trephining produces a good to excellent outcome in about 85 percent of patients with subungual hematoma regardless of its size, the presence of fracture, or infection. [9,10] Therefore, simple trephination is an adequate treatment for most simple subungual hematomas, with nail removal recommended if there is associated nail avulsion or surrounding nail fold disruption.

Nail removal can be accomplished with adequate anesthesia, digit exsanguination, nail elevation using a small hemostat, elevation of the eponychium off the nail, and then removal by gentle longitudinal traction with a hemostat. Lacerations of the nail bed are carefully repaired using 7-0 absorbable sutures. Crush injuries often result in stellate lacerations, which may require extensive meticulous repair with a magnification loupe. The nail is gently cleaned with saline, taking care not to damage the germinal matrix; it is then trephinated and secured in its anatomic position. This is accomplished by placing a 5-0 nylon suture through the distal end of the nail plate and then passing it underneath and through the center of the eponychial fold. Once the nail plate is returned to its anatomic position, the suture is tied down over the nail. The replaced nail acts as a natural splint to the terminal phalanx, prevents formation of synechiae, and protects the sensitive nail bed. If the nail is not available, nonbiological stents made of Silastic (Dow Corning) or silicone may be used to elevate the eponychium and protect the nail bed. Similarly, a sterile piece of aluminum foil used to wrap suture materials may be fashioned into the dimension of the avulsed nail and inserted under the eponychium. The fingertip is then dressed in nonadherent gauze and placed in a volar splint to limit movement at the DIP joint. Patients are given postoperative wound care instructions (e.g., as to hand elevation) as well as neurovascular checks and given adequate pain relief. Unless obvious purulence is noted, the dressing is left undisturbed for 5 to 7 days after which the site is examined for new hematoma formation. The suture attached to the nail is removed after 3 weeks; the existing nail will be dislodged by the new ingrowing nail after 1 to 3 months.

If an associated distal phalanx fracture coexists with a nail bed laceration, it usually manifests as an avulsion of the nail out of the proximal eponychial fold. If this happens, the nail is removed, the fracture is stabilized by manual reduction, and the nail bed is repaired as previously described. The nail replaced in its anatomic position serves as a biological splint to maintain fracture reduction, owing to its proximity to the underlying bone. Unstable reductions require consultation with a plastic or hand surgeon for internal fixation using Kirschner wires to prevent deformity of the nail bed.

Nail Bed Avulsion Injuries

An avulsion or crush injury may tear the nail completely away from the digit or raise a flap of nail bed matrix. Often fragments of matrix tissue may be left on the underside of the avulsed nail; these should be preserved for use as free grafts and, when possible, attached to the nail bed using fine 7-0 absorbable sutures. When the nail or avulsed nail bed fragments are not available, or in the case of a large defect, a full-thickness nail bed graft can be harvested from the patient's toe and sutured into the nail bed of the affected finger. As these injuries are complex and their repair is technically challenging, consultation with a hand or plastic surgeon is

appropriate. In addition, avulsion injuries to the nail bed have the poorest prognosis of any fingertip injury.

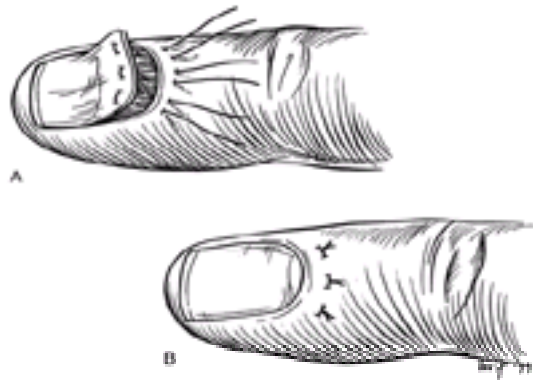
Avulsion injuries may also incompletely tear the proximal portion of the nail bed or the germinal matrix, normally located under the eponychium. When this happens, the germinal matrix may lie on top of the eponychium. Management entails replacement of the matrix into its anatomic position using a series of three horizontal mattress sutures (Fig. 39-3). One suture is placed through the center and one in each corner of the eponychial fold. The sutures are then passed through the proximal portion of the corresponding segment of avulsed germinal matrix and then back out through the nail fold, pulling the matrix back to its anatomic position. [8]


FIG. 39-3. Technique for repair of an avulsion of the germinal matrix using three horizontal mattress sutures.(From Chudnofsky CR, Sebastian S: Special wounds—Nail bed, plantar puncture, and cartilage. *Emerg Med Clinics North Am* 10:808, 1992, with permission.)

RING TOURNIQUET SYNDROME

A tight ring encircling the proximal phalanx may become entrapped because of distal swelling. Such swelling may be the result of trauma, infections, skin disorders, allergic reactions, or the tight ring alone. As the digit expands, venous outflow is restricted by the tight ring, producing more swelling. This vicious cycle may lead to nerve damage, ischemia, and digital gangrene.

The finger should be assessed for lacerations, sensory function (two-point discrimination), and perfusion (color and capillary refill). Digital artery pulsations can be detected with a Doppler flow meter, although this is usually not required. The presence of impaired sensation or diminished perfusion indicates significant constriction; rapid ring removal is then warranted. Rapid removal usually requires cutting the ring. If sensation and perfusion are intact, removal can be attempted with slower techniques that preserve the ring. The exception to ring preservation methods arises when there is an underlying phalangeal fracture; it is then prudent to cut the ring off.

In all methods, the hand should be elevated to encourage venous and lymphatic drainage, thus reducing swelling. Alternatively, the finger can be circumferentially wrapped with a 1/2- to 1-in. elastic band (e.g., Penrose drain), starting from the distal tip and winding the band tightly around the finger, progressing toward the proximal phalanx to reduce swelling. The wrap is left in place for several minutes before it is unwrapped and the ring is removed by one of the methods described below. Regional anesthesia is often required, particularly in patients who cannot tolerate the pain of circumferential compression. The metacarpal block is ideal because it produces less swelling of the finger than a digital block.

The simplest technique is lubrication. A variety of water-soluble lubricants can be applied to the digit and the ring removed with circular motion and traction.

The string technique uses a length of string wound circumferentially around the finger. When string is unwrapped, the ring is advanced toward and off the distal tip of the finger. Either string, umbilical tape, or 0-gauge silk sutures can be used. Synthetic monofilament sutures should not be used because they tend to cut the skin. The required length depends on the diameter of the string and the size of the finger; up to 100 in. of string may be required. The method starts by passing one end of the string under the ring and then wrapping the finger, starting next to the ring and winding clockwise, with each loop snug against the previous one, from proximal to distal. With each loop, the tissue underneath is compressed. When it is completely wrapped, the finger should be entirely covered by the string with no tissue showing between the loops (Fig. 39-4*A*). Wrapping and compression is a painful process and usually requires regional anesthesia. To remove the ring, the proximal end of the string is slowly unwrapped in a counterclockwise manner, advancing the ring toward the distal end as the string unwinds (Fig. 39-4*B*). The proximal interphalangeal region is the widest portion of the finger and is the most difficult site over which to maneuver the ring. Abrasions are commonly produced with the string method.
FIG. 39-4. String technique for ring removal. **A.** Completely wrapped. **B.** Unwrapping with ring advancing off with the string.

A variety of modifications to the string technique have been described. One involves wrapping from distal to proximal so as to reduce distal edema. Elastic band compression to reduce digital edema can be combined with a blood pressure cuff inflated above systolic pressure to prevent reaccumulation of edema once the elastic band is removed.[11] Another method uses a self-adherent compression bandage.[12]

The rubber band technique uses a 3- to 4-mm rubber band that is passed between the ring and skin; the two ends of the rubber band are then picked up by a clamp and used to place distal traction on the ring. The finger and ring are then lubricated. Traction is applied to the rubber band as it is moved circumferentially around the ring, slowly pulling it distal. [13]

Ring cutters are available in both manual and power models. The cutter has a small guard that fits underneath the ring and contains a channel allowing the circular blade to cut down through the ring without coming in contact with the skin. Sometimes, the swelling is so tight that the guard cannot slip under the ring. In these cases, reducing edema by using an elastic band, as noted above, may be successful. Alternatively, the circular ring may be deformed into an oval, creating a gap on the long axis of the ring. Rings should be cut in the thinnest and most accessible site. Thin and flexible rings may require only one cut; the ring is then removed by bending the two ends and pulling the ring open. Thick rings cannot easily be bent; such rings may need to be cut in two locations, opposite each other, separating the ring into two halves.

Very thick or tempered industrial objects (nuts or machine parts) may occasionally be placed on fingers and become stuck. Removal of these objects may require bolt cutters or motorized hand-held cutters. When these devices are used, the underlying skin should be protected from injury by a Silastic band or similar material. To prevent thermal burn from motorized cutters, water should be used for cooling during the cutting process.

After removal, sensation and perfusion should be reassessed. Tetanus prophylaxis may be required.

40 LACERATIONS OF THE EXTREMITIES AND JOINTS

Madonna Fernández
Wendy C. Coates

Greater than 12 million traumatic lacerations are treated every year in emergency departments (EDs) across the United States.[1] Extremities provide most of the interaction with the environment and are therefore particularly prone to injury.

Wounds may be caused by sharp or blunt mechanisms; each has different implications for evaluation and treatment (Table 40-1). Blunt-force wounds often have edges that are irregular and difficult to close; they are also more likely to contain an underlying fracture and are more susceptible to infection than wounds caused by sharp forces.[2] Contamination by soil, chemicals, and foreign bodies can adversely affect the outcome of any laceration, increasing the risks of infection and scarring and slowing the healing process. A more detailed discussion of hand and digit injuries can be found in Chapter 260.

	Sharp	Blunt
Edges	Straight	Irregular
Edema	Less	More
Underlying structures likely to be damaged	Tendons, nerves, vessels	Bones (fractures)
Susceptibility to infection	Less	More

TABLE 40-1   Sharp versus Blunt Trauma Wounds

CLINICAL AND DIAGNOSTIC FEATURES

History

The history required to evaluate lacerations to the extremities is the same as that required to evaluate lacerations elsewhere, with two important additions (Table 40-2). First, because of the mobility of the extremities, the position of the limb at the time of injury may influence the potential for damage to underlying tendons, nerves, blood vessels, and joints. Second, injuries to the dominant hand or limb are potentially more devastating than injuries to the nondominant limb.

When did the injury occur?
What object caused the injury?
Are there possible contaminants?
Is there a foreign body sensation?
Is there numbness or decreased sensation distal to the wound?
In what position was the extremity at the time of injury?
Which is the dominant hand?
What is the patient's occupation?
When was the patient's last tetanus immunization?
Was the injury self-inflicted?
Was the injury the result of an assault?

TABLE 40-2   Relevant History—Questions to Ask the Patient

Physical Examination

The diagnosis of an extremity laceration is straightforward, but damage to underlying structures must be excluded. Prior to administering anesthesia, the wound should be grossly inspected and the extremity assessed for injury to underlying tendons, nerves, and blood vessels. Pulses and capillary refill distal to the wound should be present and symmetrical when compared to the contralateral extremity. Distal peripheral nerve sensation should be tested separately for light touch (Fig. 40-1 and Fig. 40-2). Two-point discrimination at 5 mm should be assessed on both sides of each involved finger to evaluate individual digital nerves. Motor function may be assessed more easily after the wound is anesthetized, since the patient's effort will be less affected by pain. After administering a local or regional anesthetic, examine the wound for depth and size. The involved extremity or joint should be placed through its complete range of motion, both actively and passively. [3] Motor nerve function should be treated individually (Table 40-3). Particular attention to underlying structures in the position of injury is essential, since this is where damage is most likely to be seen. Each tendon function should be tested separately (Fig. 40-3 and Table 40-4). A partially lacerated tendon will still function, and the injury may be overlooked if visual inspection is not performed. Care should be taken to avoid excessive countertraction during physical examination because this could completely disrupt a partial tendon laceration.

Ancillary Studies

Soft tissue radiographs are required for all lacerations involving glass and any wound suspected of having a retained foreign body. Radiographs can detect glass fragments greater than 2 mm in diameter and gravel greater than 1 mm in diameter with greater than 95 percent sensitivity. [3] Wood, plastic, and most organic material is radiolucent. If a radiolucent foreign body is strongly suspected, computed tomography (CT) or magnetic resonance imaging (MRI) is recommended. [4] Although ultrasound has been advocated as a method to detect radiolucent foreign bodies, this technique has not been validated in prospective clinical studies. Plain radiographs of the involved extremity should be performed when an underlying fracture is suspected.

Lacerations over joints should be examined for joint capsule integrity. Unfortunately, prediction of joint penetration on physical examination alone is incorrect up to 43 percent of the time when compared with diagnosis by injecting the joint. [5] If joints are penetrated, management may change in up to 40 percent of these patients. If the depth of a wound suggests that the joint capsule could be violated, further evaluation is recommended. Plain radiographs may demonstrate air within the joint space, a

clear sign of joint penetration. One also may consider injecting the joint. The skin should be cleaned with antiseptic and the joint injected with sterile normal saline (NS) through one of the standard arthrocentesis approaches at a site separate from the laceration (Table 40-5). Fluid leaking from the wound indicates joint penetration. For smaller joints or lacerations, a few drops of sterile fluorescein can be added to the NS and the wound inspected under a Wood's lamp after injection.

Joint	Needle (gauge)	Volume of NS
Knee	18-20 G	60 mL
Elbow	18-20 G	20 mL
Ankle	20-22 G	20 mL
Wrist	20-22 G	5 mL
Digits	22-25 G	1-2 mL

TABLE 40-5   Recommended Volumes of NS and Needle Size for Joint Injection

SPECIFIC ISSUES THAT IMPACT EVALUATION AND TREATMENT

Several factors can have an impact on wound healing in the extremities and over joints. These include intrinsic patient characteristics and chronic diseases that may hinder the normal healing process, such as age, comorbidities, keloids, and suspected abuse or assault.

Extremes of age have clinical relevance to wound healing. Elderly patients tend to have thin skin and decreased subcutaneous fat, especially over the dorsum of the hand or the anterior shin, making wound edges more difficult to oppose. This also results in decreased tissue viability when under the tension of sutures. Elderly patients are more likely than others to have underlying systemic medical conditions that may contribute to delayed wound healing. In addition, they are less likely to be adequately immunized against tetanus. Only 28 percent of people over age 70 in the United States have detectable serum antibody to tetanus. [6]

Extremely young patients are also at high risk for poor wound healing. They may have difficulty limiting movement of the injured extremity, and they are more likely to contaminate their wounds. The general rule to follow is "the smaller the child, the larger the dressing."

Many comorbid medical conditions may adversely affect wound healing in the extremities. Patients with diabetes mellitus are more prone to wound infection as a result of peripheral vascular disease and hyperglycemia. Other medical conditions that can hamper wound healing include chronic renal insufficiency, end-stage liver disease, anemia, chronic corticosteroid use, obesity, and connective tissue diseases such as Ehlers-Danlos and Marfan syndromes and osteogenesis imperfecta.

Keloid formation can be a problem for many patients. It is more common in patients of African and Asian descent but can occur in patients of any ethnic origin. The most common sites are the ears, lower abdomen, sternum, and upper extremity. Previous keloid formation in a given patient should alert the physician to the risk of subsequent keloids.

Injuries over the midshafts of long bones should alert the emergency physician to the possibility of assault. The patient should be questioned as to the mechanism of injury and examined thoroughly for ecchymoses and lacerations in various stages of healing. It is the physician's duty to report suspected abuse to the local law enforcement agency in accordance with individual state laws.

TREATMENT

The Forearm and Wrist

Any patient with a laceration to the wrist or forearm must be questioned about suicide. If the laceration is the result of a suicide attempt or gesture, the patient should be placed in a secure environment with adequate supervision.

The function of all tendons and neurovascular structures, especially the abductor pollicis longus and extensor pollicis brevis functions, should be checked in lacerations of the radial aspect of the distal forearm. Most of these wounds can be closed with simple 4-0 nonabsorbable interrupted sutures (nylon or polypropylene). If the wound is gaping or under high tension, absorbable deep buried sutures or nonabsorbable horizontal mattress suture are recommended. The multiple parallel lacerations that are classic for a suicide attempt often preclude closure with simple interrupted sutures, and the horizontal mattress suture method, running through all lacerations with one suture is ideal (Fig. 40-4). The depth of this suture should be uniform throughout the entire stitch. This reduces wound tension, prevents ischemia, and approximates the edges with fewer sutures.
FIG. 40-4. Horizontal mattress sutures for multiple parallel lacerations.

The Palm

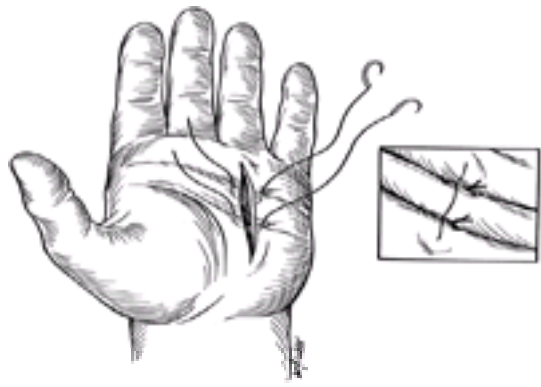
Anesthesia of the palm by local infiltration may be cumbersome, and a regional wrist block is often more effective. Lacerations of the palm should be examined carefully through range of motion to exclude flexor tendon or tendon sheath involvement (Table 40-4). Two-point discrimination should be carefully checked since the digital nerves are very superficial in the palm. Deeper lacerations between the metacarpophalangeal joints and distal wrist crease are judged to be in "no man's land," and specialty consultation for exploration often is needed. All flexor tendon lacerations require consultation by a hand surgeon, but primary repair of flexor tendon lacerations can be delayed. In this case, the emergency physician should close the skin, splint the extremity in the position of function, and have the patient evaluated by the hand surgeon within the next few days. The closure method of choice in the palm is horizontal mattress sutures with 5-0 nylon or polypropylene. This reduces the chance that the suture material will pull through the skin edges. Every attempt should be made to reapproximate palmar creases by placing a suture directly through the crease on either side of the laceration (Fig. 40-5). It is important to observe the placement of the needle with each pass to avoid catching underlying tendons or tendon sheaths.


FIG. 40-5. Approximating palmar creases.

The Dorsum of the Hand

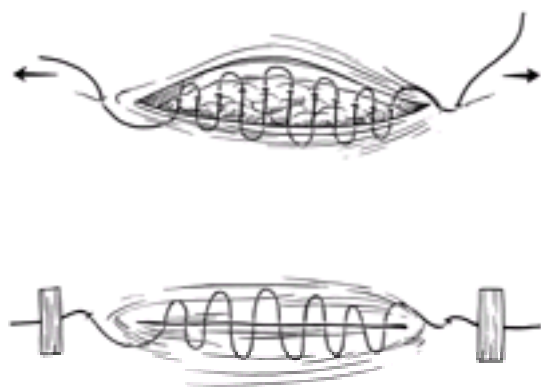
A radial nerve block is an excellent alternative to local infiltration for anesthesia on the dorsum of the hand. The skin on the dorsum of the hand is quite thin and can be difficult to approximate. Simple interrupted sutures using 5-0 nonabsorbable material are usually adequate. Since the dorsum of the hand is a cosmetically important area, alternatives include a dermal pull-through using 5-0 polypropylene or subcuticular sutures using 5-0 absorbable material (Fig. 40-6).


FIG. 40-6. Dermal pull through suture.

Lacerations over the metacarpophalangeal (MCP) joints suggest a potential clenched-fist injury (CFI) or "fight bite," a laceration sustained with a closed fist to the mouth of another person during a fight. Patients may be reluctant to admit to the mechanism but should be warned of the serious risk of infection. These wounds should be inspected carefully with the digits flexed, reproducing the position at the time of injury. Any visible laceration of the extensor tendon or the joint capsule overlying the MCP joint indicates possible joint penetration, and a hand surgeon should be consulted. Radiographs should be obtained to evaluate for underlying foreign bodies, fracture, and air in the MCP joint. Even if the evaluation finds no evidence of joint penetration or deeper injury, it is probably best to assume that all lacerations over the MCP joints sustained in fights are too contaminated for primary closure, and such wounds should be allowed to heal by secondary intention. The wound should be irrigated and dressed and the hand splinted. The patient should be placed on a 5-day course of an oral antibiotic to cover mouth flora. The patient should be reevaluated in 2 to 3 days, or sooner if signs of infection develop.

Extensor Tendon Lacerations

Wounds over the dorsum of the hand and fingers may involve extensor tendons. These lacerations must be examined through complete range of motion, paying particular attention to reconstructing the position of injury. Extensor tendon lacerations that are proximal to the MCP joint in some cases can be repaired by an emergency physician who is experienced and comfortable with the procedure.[7] Many methods are used for extensor tendon laceration repair. One simple and effective method is a figure-of-eight suture (Fig. 40-7). This method places the knot on the side of the tendon, making it less obvious under the skin after repair. Nonabsorbable 4-0 suture should be used. Consultation and follow-up with a hand surgeon are recommended. Extensor tendon lacerations over the distal interphalangeal joint result in mallet finger (Fig. 40-8A), and those over the proximal interphalangeal joint result in a boutonniere deformity (Fig. 40-8B). These are treated with splinting for 6 weeks when closed, but when they are open, they require surgical repair.[8] Tendon lacerations of the thumb should be repaired by a hand surgeon.
FIG. 40-7. Extensor tendon laceration repair with a figure-of-eight stitch.
FIG. 40-8. A. Mallet finger. **B.** Boutonniere deformity.

Lower Extremity Lacerations

Lacerations of the lower extremity are under greater tension than those of the upper extremity. Fascia may be loosely approximated with buried sutures of 4-0 absorbable material. Any lower extremity laceration under significant tension should be repaired with a multiple-layered closure first using buried deep 4-0 absorbable sutures followed by simple interrupted 4-0 nonabsorbable sutures. Simple interrupted sutures of 4-0 nonabsorbable suture material may be used for skin closure in lacerations under minimal tension, and horizontal mattress sutures are ideal for wounds under moderate tension in the lower extremity. Wounds proximal to the knee and in areas that are usually covered (i.e., where cosmesis is not an issue) can be closed with skin staples. In patients with diabetes or those with stasis changes, deep sutures should be avoided because they markedly increase the risk of wound infection. Skin staples or horizontal mattress sutures are an excellent alternative in these patients.

The Knee

Lacerations to the knee are under marked active tension. The wound should be examined through range of motion, checking for the integrity of all ligamentous structures (Fig. 40-9). If joint capsule involvement is suspected, approximately 60 ml NS should be injected in a sterile fashion at a site separate from the wound to assess for leakage. The common peroneal nerve is prone to injury as it runs over the head of the fibula laterally, and distal function should be assessed. Deep popliteal wounds can injure the popliteal artery and tibial nerve. Distal pulses and nerve function should be documented prior to anesthetic administration and closure. Popliteal artery injury requires emergent angiography and vascular surgery consultation because the leg has minimal collateral circulation distal to the knee. Skin can be closed with 4-0 nonabsorbable material, using simple interrupted or horizontal mattress sutures. Skin staples are an alternative in patients subject to poor wound healing. The knee should be splinted or placed in a knee immobilizer to decrease active tension and promote better wound healing.
FIG. 40-9. Ligaments of the knee.

Anterior Tibial Surface

Wounds over the anterior tibial surface are under considerable tension. Whenever possible, they should be approximated with a multiple-layered closure, first using buried deep 4-0 absorbable sutures followed by simple interrupted 4-0 nonabsorbable sutures. Horizontal mattress sutures using 4-0 nonabsorbable material are an alternative, especially in patients who are prone to wound infection.

The Ankle and Foot

Lacerations to the ankle and foot may involve the underlying tendons and neurovascular structures (Fig. 40-10). Sensory function should be assessed before anesthesia (see Fig. 40-2). After administering local or regional anesthesia, the ankle should be examined through complete range of motion, paying particular attention in the position of injury. The function of the extensor hallucis longus (EHL), tibialis anterior (TA), and Achilles tendons should be assessed (see Fig. 40-2). Partial tendon lacerations may be missed if the wound is not inspected visually through the range of motion, since some tendon function will remain unless the tendon is completely lacerated. The Achilles tendon is not the only tendon responsible for plantar flexion of the foot, and its individual function may be difficult to assess. The Achilles tendon can be palpated for defects; if it is completely lacerated, there should be a conspicuous absence of the tendon at the posterior ankle. The patient also can lie prone on the examination table with the foot dangling over the edge of the bed for the Thompson test (Fig. 40-11). The bellies of the gastrocnemius and soleus muscles are squeezed by the examiner. This should produce plantar flexion of the foot if the Achilles tendon is at least partially intact. Lacerations of the EHL, TA, and Achilles tendons require surgical consultation for repair because damage to these tendons can result in foot drop. The skin should be closed with simple interrupted or horizontal mattress sutures using 4-0 nonabsorbable material, and the ankle should be splinted.
FIG. 40-10. Anatomy of the ankle and foot.

FIG. 40-11. The Thompson test.

Lacerations to the sole of the foot should be inspected for a foreign body because they often result from stepping on a sharp object. Regional anesthesia is ideal for

the sole of the foot (see Fig. 40-2). Horizontal mattress sutures using 4-0 nonabsorbable material are recommended. The patient should be given crutches or a walking boot for comfort and to minimize trauma to the laceration while it heals.

DISPOSITION

Admission Criteria

The majority of patients with extremity lacerations can be discharged after repair. Indications for admission include associated injuries that would otherwise require admission, joint contamination requiring irrigation in the operating room, compartment syndrome, severe infection, or significant infection in an immunocompromised individual.

Consultation

Orthopedic consultation is required for joint capsule penetration, open fractures, nerve lacerations, lacerations of the EHL, TA, or Achilles tendon, and for suspected compartment syndrome. Hand surgery consultation must be obtained for all flexor tendon lacerations, as well as for extensor tendon lacerations distal to the MCP joint, and should be considered for extensor tendon lacerations proximal to the MCP joint. With peripheral nerve and tendon injuries, it is appropriate for the emergency physician to close the skin and have the patient followed in the consultant's office within the next few days. Injury to the large, named arteries requires vascular surgical consultation.

After-Care Instructions

Wounds should be kept clean and dry for 24 h after suturing. Thereafter, they may be cleaned with running water and covered with a clean, dry dressing. Discharged patients should return for suture or staple removal in 7 to 10 days for upper extremity lacerations, 10 to 14 days for lower extremity lacerations, and 14 days for lacerations over joints. This time can be extended a few days in patients over age 65 years because epithelialization and noncollagenous protein accumulation are delayed.[8] Routine antibiotic prophylaxis is not recommended.[1,9] Prophylactic antibiotics are recommended for joint penetration, bite wounds, and in delayed primary closure. For markedly contaminated wounds, which required extensive debridement and irrigation, it is appropriate to reexamine the patient in 48 h for signs of infection and then begin antibiotics if necessary. Patients should be instructed to return for severe pain, erythema, purulent discharge, fever greater than 38.6°C (101.5°F), ascending lymphangitis, paresthesias, or weakness. Acetaminophen or nonsteroidal anti-inflammatories are usually sufficient for pain control. Elevation of the injured extremity will decrease tissue edema and expedite healing.

41 FOOT LACERATIONS

Earl J. Reisdorff

EPIDEMIOLOGY

The human walks upright. Therefore, any injury to the foot jeopardizes the ability to function fully. Penetrating trauma involving the foot is sustained in a variety of novel manners from simple plantar puncture wounds to castastrophic lawnmower injuries. Urban children are at risk for sustaining foot lacerations while playing in water from fire hydrants.[1] These most commonly result from stepping on broken glass. Bicycle-spoke injuries result in complex lacerations with marked surrounding abrasions and even tissue loss.[2] Skin loss from bicycle-spoke injuries often occurs over the lateral malleolus and the base of the fifth metatarsal. Disastrous lawnmower injuries are usually sustained by push mowers, often when being pulled backwards.[3] Lawnmower-induced lacerations are heavily contaminated, averaging 3.1 organisms at the time of intraoperative culture. Lawnmower-induced foot lacerations are also sustained from debris flying out from the under carriage. Footwear does not usually prevent injury from mowers. High-pressure water-spray cleaning systems cause complex laceration-injection injuries. Due to the biomechanical importance of the foot and the enhanced risk of infection with wounds to the foot, lacerations must be treated properly to avoid complications.

PATHOPHYSIOLOGY

During standing and walking, the soles of the feet are in contact with the ground. This relatively small area of contact surface tells the body about its position, as well as detailed information about the terrain being traversed. The tough plantar epidermis and dermis are thick and able to withstand the numerous forces that a moving body produces. The primary "shock absorber" of the sole of the foot is a modified layer of fat. The blood and lymphatic vessels of the foot are under high hydrostatic pressure. As a consequence, edema easily results from injury and can retard healing. Except for the arch area, the epidermis and dermis of the soles are quite thick. Despite this, the foot is quite sensitive to two-point discrimination and pressure. The heel has an 18-mm-thick modified pad of fat separated into chambers by fibrous septae. There is an additional broad internal fibrous arch, called the inner cup ligament, aiding to maintain the shape of the heel. The skin of the sole readily hypertrophies and can become quite thickened, especially in people who walk barefooted.

The dorsal aspect of the foot provides little protection to underlying tendons, nerves, and blood vessels. The dorsum of the foot is particularly vulnerable to work-related injuries such as when heavy objects are dropped on the foot.

The pattern of pedal tendons roughly approximates that of the hand. One important location is just posterior to the lateral malleolus, where the peroneus longus tendon runs.

The structural design of the foot severely limits exploration of wounds to the plantar surface. The dense fibrous fatty tissue of the ball and heel makes exploration and visualization nearly impossible in the emergency department (ED), and the underlying structures are easily damaged. However, lacerations to the arch, although more uncommon, are more readily explored.

CLINICAL FEATURES

History

A limited, injury-specific history should determine when the trauma occurred. The mechanism of the injury helps determine the degree of injury, as well as the likelihood of injury to underlying tissue. High-energy injuries (e.g., a lawnmower injury) and crush injuries have a greater complication rate. The risk of a retained foreign-body and contamination risk should be determined. For example, was the laceration sustained by a farming accident (*Clostridium perfringens* contamination) or when wading in a freshwater stream (*Aeromonas hydrophila* infection)? High-pressure water systems used for cleaning surfaces cause severe laceration-injection injuries that are at risk for *Acinetobacter calcoaceticus* infection. Animal bites require consideration of infection by the rabies virus or bacterial pathogens such as *Pasteurella multocida* and *Capnocytophaga canimorsus* (formerly called DF-2 bacillus). The circumstances surrounding the injury are usually of limited concern unless dangerous activities are involved (e.g., knife-throwing contests among adolescents). Finally, the complaint of any new paresthesia, anesthesia, weakness, or the loss of function suggests a neurovascular or tendon injury, prompting a rigorous examination of the affected site.

The past medical history should include questions concerning tetanus immunization status and conditions that increase the risk for infection or delayed wound healing (diabetes mellitus, immunosuppression, valvular heart disease, and asplenia). The patient with diabetic neuropathy is at risk for recurrent trauma. Asplenic patients with a dog bite require prophylactic antibiotic treatment against *C. canimorsus.*[4]

Physical Examination

The physical examination determines the location, length, depth, and shape of the wound. Any wound on the weight-bearing surface is noted, because the wound care plan should consider avoiding weight bearing. As with all lacerations, the distal nerve function, motor function, and vascular integrity (pallor, capillary refill) should be checked. A foreign body is sought on general examination as well as during sterile inspection of the laceration just prior to wound closure. When possible, the wound is explored using a dry field. The loose thin skin over the dorsum of the foot allows for adequate visual, digital, and instrument exploration for tendon lacerations, as well as for foreign-body discovery. The dense tissue of the plantar surface of the foot severely limits wound visualization and exploration. The risk of creating new or further injury limits the exploration of wounds to the sole of the foot, especially at weight-bearing sites. The exception to this general policy is if a retained foreign body is suspected, such as an infected puncture wound presenting 48 h after the initial injury.

DIAGNOSIS

Laboratory studies are not indicated during the initial evaluation of an uncomplicated wound. If the wound becomes infected, a complete blood cell count may assist in determining the degree of cellulitis and the effectiveness of antibiotic therapy. Obviously, the most important parameter to monitor is the clinical appearance of the infection. Some clinicians also follow an erythrocyte sedimentation rate. Blood cultures and a wound culture are obtained if bacteremia is anticipated in immunocompromised patients. A wound culture of the laceration site immediately obtained in the ED for an open fracture or a grossly contaminated wound may be useful.

Radiographic imaging is required when an open fracture is suspected. The ideal form of radiographic imaging for foreign-body detection is debated. In cases of inert materials, standard plain-film radiographs and adequate wound exploration suffice. On the radiograph, the wound site is indicated with a radiodense marker. Though the retained material may be radiographically "invisible," there can be distortion of soft tissue shadows indicating the foreign body. When retained organic material is highly suspected, computed tomography is required. Retained foreign bodies can be visualized on ultrasound, although experience using this modality on the foot is limited.

TREATMENT

Wound Anesthesia

Certain areas of the foot, especially the plantar surface, are particularly sensitive to the infiltration of a local anesthetic. Lacerations involving the toes are anesthetized using standard digital blocks. Likewise, the lacerations to the dorsum of the foot are sufficiently prepared by local infiltration of lidocaine. Use of epinephrine-containing lidocaine is avoided in toe lacerations. Conscious sedation should be considered for plantar surface lacerations in children. For extensive lacerations, regional nerve blocks are used. Local infiltration of an anesthetic to supplement a regional block is frequently required. The two most commonly used foot nerve blocks are the sural nerve block and the posterior tibial nerve block. The posterolateral aspect of the sole is anesthetized using a sural nerve block, by depositing a generous bandlike deposit of lidocaine 1 cm posterior to the distal aspect of the lateral malleolus. The tibial nerve block numbs the anteromedial aspect of the sole. A posterior tibial nerve block is performed by infiltrating the area just next to the posterior tibial artery just posterior to the distal aspect of the medial malleolus. (See Chap. 279.)

Topical anesthetic preparations use lidocaine mixed with any combination of tetracaine, cocaine, and epinephrine. These preparations are poorly effective on the dense epidermis of the sole, especially at the contact areas. Adequate anesthesia with topical preparations can usually be achieved on a dorsal laceration. If topical preparations are used, the blood coagulum is first removed and the solution-soaked cotton pledget is placed firmly into the wound.

Wound Preparation and Repair

The repair of foot lacerations, and especially plantar surface lacerations, has been poorly studied. [5] Few clinical practices regarding foot lacerations have been scientifically evaluated. Due to the inherent risk of infection with foot lacerations, excellent wound irrigation with copious amounts of saline irrigation is essential. The ideal time to perform a thorough dry-field exploration to determine tendon integrity and to detect foreign bodies is when the wound is completely anesthetized.

Debridement removes devitalized tissue, reducing the risk of wound complication. Nonetheless, debridement should be limited on the plantar surface because the thick, dense, fibrous tissue is not pliable. On the sole, any defect resulting from debridement is, therefore, closed under tension across the laceration.

Lacerations associated with nail injuries require close attention. On the dorsum of the phalanx, the skin is attached directly to the periosteum with no intervening layer of subcutaneous tissue. Therefore, a laceration to the nailbed places the underlying bone at risk for bacterial contamination.

The timing of closure must be considered. The foot is a body area with a high concentration of bacteria. Therefore, the risk of foot infection increases significantly 4 to 6 h after the injury.[6] A delayed presentation should prompt consideration of a delayed primary closure. Most foot wounds should not be closed after 6 h. If heavily contaminated, the laceration should not be repaired using a primary closure technique, especially if it presents to the ED beyond 3 h from the time of injury. For delayed primary closure, the wound is packed with saline-soaked gauze and the patient is placed on an antistaphylococcal antibiotic. At 96 h after injury, the wound is closed by using interrupted nonabsorbable monofilament sutures.

PLANTAR LACERATIONS When repairing a laceration on the plantar surface, the patient is placed in a prone position. The foot should overhang the cart or be elevated by placing a pillow beneath the ankle. Heavy, large suture needles are required to penetrate the hypertrophied epidermis and dermis of the sole of the foot. Heavy nonabsorbable monofilament suture is used; absorbable suture material is typically avoided in the foot. The plantar surface is approximated without tension usually using 3-0 and sometimes 4-0 suture with a large curved cutting needle. On the plantar surface, simple interrupted sutures usually suffice. The advantage of interrupted sutures is that if the foot becomes infected, individual sutures can be selectively removed. If there is tissue loss or a site is under tension, a vertical mattress suture may be required. In the arch area, achieving tissue eversion can be difficult. Tapes and adhesives are avoided on the plantar surface. Likewise, staples provide an irregular surface for weight bearing.

DORSAL LACERATIONS Dorsal surface lacerations are repaired almost exclusively with nonabsorbable monofilament suture material. Most commonly, 4-0 is used; for small simple lacerations, 5-0 suture can be used. Though running sutures are avoided on the sole, they are acceptable on the dorsal surface. Under select circumstances, tapes and staples can be used.

INTERDIGITAL LACERATIONS Lacerations between the toes are difficult to repair. The interdigital space is confined with a deep-set web space. Having an assistant gently separate the toes enhances the exploration and repair of interdigital lacerations. The use of simple interrupted sutures often leads to skin inversion and risk of failure of the initial wound repair. The most effective closure technique, albeit somewhat more difficult, is to place horizontal or vertical mattress sutures. This is best accomplished with 5-0 monofilament nonabsorbable suture on a small cutting needle. In young children, monofilament absorbable suture can be used, thus avoiding suture removal. When a web space laceration involves the neurovascular bundle, the skin is usually closed without any subsequent consideration to repairing the neurovascular injury.

TENDON LACERATIONS Similar to hand lacerations, flexor tendons are more aggressively repaired than are extensor tendons. Extensor tendon lacerations are sometimes treated with skin closure and splinting. Moreover, extensor tendon lacerations involving the midfoot and forefoot can often go unrepaired without sacrificing any necessary foot function. Regarding tendon lacerations across the toes (excluding the great toe), both extensor and flexor tendon injuries can be ignored without significant functional sequelae. Occasionally, a hammer toe or claw toe deformity results from the failure to repair a tendon (usually flexor tendon) laceration. [7] Although 80 to 93 percent of surgeons recommend repair of the flexor hallucis longus, no long-term evaluation has determined that this is essential. [5] In fact, there is limited information that unrepaired flexor hallucis longus tendon lacerations do not result in a functional deficit, even among athletes. [8] Nonetheless, adhesion formation is a common complaint. Lacerations to the flexor tendons of the other toes are usually unrepaired.

RETAINED FOREIGN BODIES Retained (nonreactive) foreign bodies such as glass can pose a problem. Chronic pain, especially during walking, can occur if the material is not removed. In the absence of chronic discomfort, inert foreign bodies can remain in the foot. The material typically becomes encapsulated, as is sometimes seen with insulin needles retained in the foot of patients with diabetic neuropathy. Obviously, organic material must be aggressively sought. Deep foreign bodies in the foot can be extremely difficult to remove in the ED. Surgical consultation and removal under fluoroscopy can be required.

HAIR STRANGULATION Hair strangulation-amputation is an unusual type of toe injury that is seen during infancy. A long strand of hair becomes wrapped around a toe and can involve several loops of the hair strand, all of which must be removed. This can be an occult source of irritability for infants. Removal must be complete so that the neurovascular bundle is not transected. Moreover, complete removal eliminates any further circumferential laceration of the skin around the toe. A novel approach to removal involves the use of hair-dissolving compounds. This approach has not been studied sufficiently to recommend it. The most certain approach to salvage the compromised digit is to make a midline longitudinal incision along the extensor surface of the toe. The incision should be deep enough to split the fibers of the extensor ligament without transecting the fibers. The multiple strands of hair are then removed using fine forceps without teeth. Unfortunately, the toe often retains the initial appearance, making one uncertain whether all of the strands have been removed or cut.

DISPOSITION

A bulky dressing is applied to the plantar surface to cushion any plantar laceration. For large lacerations on the plantar surface, weight bearing is avoided for at least 5 days. However, infants will naturally step on the injured site. Crutches are too difficult to use in children younger than age 7 years. Therefore, younger children may need to be carried. Elevation of the extremity decreases swelling and infection risk. Sutures are removed in 10 to 14 days.

Antibiotic prophylaxis should be considered in foot lacerations. Infection occurs in 18 [9] to 34[1] percent of foot lacerations. In small lacerations to the dorsum of the foot, antibiotic prophylaxis is unnecessary. Animal bites require coverage against *Staphylococcus, Streptococcus,* and *Pasteurella.* Asplenic or immunocompromised patients who sustain a dog bite to the foot should receive coverage against *C. canimorsus.* Amoxicillin-clavulanate will cover all four organisms. A foot laceration caused from wading in freshwater streams should receive antibiotic prophylaxis for *Aeromonas hydrophila* (a gram-negative bacillus) with a fluoroquinolone. An *Aeromonas* infection should be suspected for rapidly developing infections involving foot lacerations. *Aeromonas* infections occur 8 to 48 h after inoculation and are rapidly progressive. There is a tendency for deeper structures to become involved: fascia, tendon, muscle, bone, or joint involvement occurs in 39 percent of cases. [10] Compartment syndrome, myonecrosis, and foot amputation can result. Effective antibiotic coverage against *Aeromonas* includes aminoglycosides, trimethoprim-sulfamethoxazole, and fluoroquinolones. Though fluoroquinolones are routinely used in the adult for *A. hydrophila*, their use is avoided in children. Open

fractures are most commonly infected by *S. aureus*, so patients should receive a first-generation cephalosporin and an aminoglycoside in the ED. For other lacerations, antistaphylococcal antibiotics are sufficient.

42 SOFT TISSUE FOREIGN BODIES

Richard L. Lammers

Soft tissue foreign bodies may be encountered when managing new wounds or evaluating complications of old wounds. [1] When evaluating fresh injuries, the physician is responsible for detecting foreign bodies and for deciding if removal is urgent, can be delayed, or is even necessary. Many foreign bodies should be removed in the emergency department (ED); for example, all foreign material within the cavities of fresh lacerations should be irrigated away, debrided, or extracted with instruments. The decision to remove foreign bodies embedded below the dermal layer of skin depends on the size, location, composition, accessibility, and anticipated mechanical and inflammatory effects of the object. Occasionally, patients with subcutaneous foreign bodies should be referred to appropriate physicians for delayed removal.

Many foreign bodies are detectable during clinical examination, but some will not be apparent to the sight or touch of the examining physician. Various imaging studies can be used to evaluate wounds when nothing is found during exploration but the probability of a concealed object remains high; some foreign bodies, however, may not be visible with any type of radiographic or sonographic study. Consequently, malpractice actions for missed foreign bodies will continue to plague emergency physicians.

PATHOPHYSIOLOGY

Transient inflammation is an integral part of normal wound healing. A small amount of foreign debris in a wound provokes an inflammatory response in an effort to eliminate or contain the invader. When large quantities of devitalized tissue, foreign debris, bacteria, or other irritants are present within a wound, this protective response intensifies. Excessive or prolonged inflammation may delay wound healing or destroy surrounding soft tissue and bone, producing periosteal reactions, osteolytic lesions, synovitis, and arthritis. If the body fails to dissolve or extrude foreign material, it will encapsulate it within a fibrous capsule. Many granulomas result from chronic inflammation caused by foreign bodies that inflammation could not eliminate. Once a retained foreign body is encapsulated, inflammation subsides. [1]

The type and intensity of an inflammatory reaction is determined primarily by the chemical composition and physical form of the foreign object. Material that is inert—such as glass, metal, or plastic—may not elicit any abnormal tissue response. Objects with smooth, nonporous surfaces produce less inflammation and fibrosis than those with rough surfaces. Most metals are inert, but those which oxidize will cause mild to moderate inflammation. Earrings with studs dipped in gold paint cause earlobe swelling and inflammation when the paint flakes off. Vegetative foreign bodies, such as wood, thorns, and spines, trigger the most severe inflammatory reactions. Sea urchin spines, other marine foreign bodies, and hair may cause chronic inflammation with granuloma formation.

In some cases, inflammation is caused by a local toxic reaction. For example, blackthorns contain an alkaloid that produces intense inflammation. The oils and resins in redwood and cedar splinters also cause considerable inflammation. Sea urchin spines and catfish spines contain venoms that cause severe burning pain at the puncture site and a variety of systemic symptoms.[2] A sudden, local inflammatory reaction from a rose thorn or cactus spine may be an allergic response to fungi on the plant. Some cacti cause a delayed hypersensitivity reaction. Systemic toxic and allergic reactions are unusual but serious complications of foreign bodies. Foreign bodies containing lead have the potential to produce systemic lead poisoning, particularly if they are in contact with pleural, peritoneal, cerebrospinal, or joint fluid. [3]

Infections are the most common complication of retained foreign bodies. Infection may result even when the foreign material itself is not contaminated. [4] Foreign bodies may incite a variety of soft tissue infections, including local wound infection, cellulitis, abscess formation, lymphangitis, tenosynovitis, bursitis, and osteomyelitis. These infections are characteristically resistant to therapy; antibiotics, anti-inflammatory drugs, and steroids may produce a partial regression of symptoms but seldom eradicate the infection. Some infections will resolve spontaneously once the foreign bodies are removed. Vegetative foreign bodies may cause fungal infections, particularly in immunosuppressed patients.

Foreign objects also can cause mechanical damage by compressing or lacerating anatomic structures or occluding vessels. Repeated movement of tissue containing a foreign object increases the fibrous reaction.

CLINICAL FEATURES

History

Every wound has the potential for concealing a foreign body, but only a small percentage of the lacerations and puncture wounds actually contain them. [1,5] Certain historical events are associated with a higher risk for a retained foreign body: the mechanism of injury, composition and shape of the wounding object, and the shape and location of the resulting wound. Objects that shatter, splinter, or break in the process of causing a wound often leave remnants behind. For example, a wound caused by glass that broke on the skin is more likely to contain shards than a wound caused by previously broken glass. Dental fractures following a blow to the mouth serve as a warning that fragments of teeth may be embedded in the lip or tongue of the patient or in the hand of the assailant. Thorns, spines, and sharp wooden branches are usually brittle and tend to penetrate deeply into puncture wounds before breaking. Wood splinters are notorious for fragmenting when they are pulled out of a puncture wound. Patients impaled by long, thin metallic objects such as hypodermic or sewing needles may remove them without realizing that a portion of the object broke off beneath the skin surface. Both remnants of a needle and impurities in street drugs can cause persistent pain or abscess formation at the site of intravenous drug use. Nails that penetrate socks and shoes may drive leather, rubber, or cloth into the plantar surface of a patient's foot. Blunt objects with a diameter greater than 4.5 mm may push a plug of skin deep into a wound, resulting in an epidermal inclusion cyst. If any object pulled from a wound does not appear intact, the wound should be explored for further contaminants.

Patients with retained foreign bodies may present to the ED after a wound heals, complaining of sharp pain with movement or with pressure over the site. Failure to heal a wound also may be evidence of a retained irritant. Chronic, delayed, and recurrent infections also can be associated with retained foreign bodies. New puncture wounds that become infected and infections that are resistant to antibiotic therapy suggest that a foreign body has been missed. Arthritis in a joint near an old puncture wound may be a thorn-induced synovitis. Delayed nerve, vessel, or tendon injuries also require further investigation.

Physical Examination

Physicians are occasionally surprised by foreign bodies that can be embedded in small or seemingly superficial wounds. [5] Several physical findings indicate the presence of a foreign body. A discoloration or visible mass under the epidermis makes the diagnosis obvious. Sometimes a mass cannot be seen but can be

palpated. Sharp, well-localized pain with palpation over a puncture wound is a useful sign. Patients who report the sensation of "something in the wound" should be taken seriously because their perceptions are often correct. If passive range of motion of a joint near a wound is limited, a foreign body may be responsible.

Old wounds with retained foreign bodies may have a persistent purulent drainage, a chronic draining sinus, or a chronic granulomatous reaction. A sterile abscess that complicates wound healing may be the result of a foreign body.

Some foreign bodies are discovered in wounds unexpectedly, but most are found during a deliberate and careful exploration of wounds considered to be at risk. Adequate lighting, good hemostasis, complete local anesthesia, and patient cooperation are essential. Every effort should be made to visually inspect all recesses of a wound. Wounds deeper than 5 mm and wounds whose depth cannot be visualized have a higher association with foreign bodies. [5] If punctures and other narrow wounds make direct visualization difficult and the physician is concerned about the possibility of a foreign body below the surface, the wound margins should be extended with a scalpel (Fig. 42-1). However, wounds that penetrate deeply into adipose tissue are difficult to explore and easily hide foreign material. Blind probing with a hemostat is a less effective but sometimes acceptable alternative to wound exploration when the wound is narrow and deep and extending the wound is not desirable. This method is used frequently to evaluate plantar puncture wounds caused by nails and to search for clear glass, which is difficult to see in a wound. A closed hemostat should be introduced into the wound and either used as a probe or spread open and then withdrawn. If an instrument strikes a metallic or glass foreign body, it will produce a grating sensation. The instrument should not be used to grasp blindly in hopes of clamping an unseen object. This technique is especially dangerous in hands, feet, or faces, where direct visualization is the preferred method of exploration.
FIG. 42-1. **A.** (Plate 1) This patient's leg was punctured by a wooden stake 2 days prior to presentation. Surrounding cellulitis and point tenderness lateral to the wound increased the probability of a retained foreign body. **B.** (Plate 2) The entrance to the wound was extended. **C.** (Plate 3) A 1.5-cm piece of wood was removed from a 3.5-cm-deep wound.

DIAGNOSIS

Soft tissue foreign bodies must be identified and located before treatment decisions can be made. Imaging studies should be ordered in most cases where a retained foreign body is suspected but not found during wound exploration or when thorough wound exploration is technically impossible. They are also useful after initial removal of multiple foreign bodies to determine if all the pieces were found.

A number of imaging modalities are available. The ability of any of these modalities to find a foreign body depends on the characteristics of the study as well as the object's size, shape, density, and orientation relative to the imaging beam. Materials that are the same density as surrounding soft tissue are difficult to see with any type of radiographic or sonographic technique.

Plain Radiography

It is fortunate that many foreign bodies are radiopaque; most foreign bodies that can be missed during the initial clinical evaluation can be seen on plain films. [6] Plain films are readily available but must be obtained with appropriate technique and inspected carefully to detect small and faint foreign bodies. Metal, mammalian bone, some types of fish bones, teeth, pencil graphite, certain plastics, glass, gravel, sand, and aluminum are visible on plain radiographs [1,7,8,9,10,11 and 12] (Table 42-1). Almost all glass is visible on radiographs if it is 2 mm or larger, and contrary to myth, glass does not have to contain lead to be visible on plain films. [1,5,7] A radiopaque fragment is more easily seen if it is positioned parallel to the central ray of the x-ray beam, which increases its apparent thickness.

TABLE 42-1   Experimental Studies on Foreign Body Imaging

Radiographs should be obtained with an underpenetrated "soft tissue technique," producing a lighter film that increases the contrast between the foreign body and surrounding tissue. [1] Plain films should be taken in multiple projections to separate the shadow of the foreign body from underlying bone and to help gauge the depth of the object in the tissue. Chronic inflammatory changes may create secondary bony changes such as osteolytic and osteoblastic lesions, pseudotumor formation, and periosteal reaction, revealing the object's location.

Many common or highly reactive materials such as wood, thorns, cactus spines, fish bones, most plastics, and other organic matter are not visible on plain films. [1] Sometimes there is indirect evidence of their presence; a radiolucent filling defect may occur when the object is less dense than surrounding tissue. Even radiopaque foreign bodies may be invisible on plain films if they are projected over bone or impacted in bone.

Computed Tomography (CT)

CT is capable of detecting more types of foreign materials than plain-film radiography because it is 100 times more sensitive in differentiating densities. [6,10] Subtle density differences can be distinguished with a narrow radiographic density window adjustment, particularly if a computer workstation is used to vary the gain and contrast settings. [10] Thorns, spines, wood toothpicks, and plastic foreign bodies have been identified with this method. CT may detect objects embedded in bone, and isodense objects may be outlined by surrounding air within the wound. Digital edge enhancement can further improve the visibility of these objects. [9] CT images can be created in multiple planes and can demonstrate the relationship of a foreign object to important anatomic structures. The principal disadvantages of CT are its cost and higher radiation dose. However, even CT may not demonstrate thorns, spines, and some types of wood. Wood may have a CT pattern that is similar to a gas bubble or bone fragment. [9] As wood absorbs fluid from tissue, it becomes isodense and difficult to distinguish from surrounding tissue.

Ultrasonography

Sonography has been described in clinical case reports to identify soft tissue foreign bodies such as wood, fish bones, sea urchin spines, and other vegetative materials.[13,14 and 15] However, this method has had a wide variation in sensitivity, specificity, and overall accuracy for the detection of soft tissue foreign bodies in experimental studies (see Table 42-1). Depending on the experimental model, the sensitivity for foreign body detection with ultrasound is 30 to 100 percent with a specificity of 70 to 90 percent.[15,16 and 17] In clinical practice, variation may be due to the size and sonographic nature of the foreign body, the presence of confounding objects (e.g., bone, blood, air, purulence, scars, old sutures) near or about the foreign body, and operator skill and experience. Areas with many echogenic structures such as calcifications, sesamoid bones, and tendons may hide foreign bodies within their acoustic shadows, so these areas must be scanned slowly to detect foreign bodies that are small or oriented perpendicular to the skin surface. Some areas of the body that are prone to foreign body penetration, such as the web spaces of the hands or toes, may not accommodate an ultrasound probe.

Once a foreign body is confirmed by plain films or CT studies, sonography can be used in place of fluoroscopy to guide an instrument to the object during retrieval.[18] The scanning beam should be oriented parallel to the long axis of a hemostat, which can be directed toward the long axis of the foreign body. Transverse and longitudinal scans provide views in multiple planes. A 7.5-MHz linear-array transducer can be used to find objects that are up to 3 cm deep.

The primary advantage of ultrasonography is that this imaging modality avoids radiation exposure. In addition, portable ultrasound machines are becoming increasingly available in EDs. The principal disadvantage of this modality is the variable sensitivity for foreign body detection for the reasons noted earlier.

Xeroradiography

Xeroradiographs enhance soft tissue images, improving images already visible on plain films. However, this modality fails to detect radiolucent foreign bodies and has been supplanted by other imaging techniques.[1,6,13]

Magnetic Resonance Imaging (MRI)

MRI can detect nonmetallic radiolucent foreign bodies and in limited comparison studies is more accurate than any other modality in identifying wood, plastic, spines, and thorns.[6] MRI should not be used with gravel or metal-containing foreign bodies because ferromagnetic streaks obscure visualization. MRI may prove more effective than CT in visualizing organic foreign bodies, but comparison studies are needed.

Selecting an Imaging Study

If a foreign body is suspected but not found during exploration of a wound, a plain film should be ordered first, since plain radiography will detect as many as 80 to 90 percent of all foreign bodies. It is prudent to order films if a patient believes there is a retained object. If the wound was caused by metal, glass, or gravel and no foreign body was found on plain films or wound exploration, the physician can end the search. For objects not routinely visible on plain radiography, CT scans are the modality of choice. Both plain films and CT scans are useful for identifying the composition, size, shape, and approximate location of an object in tissue. Ultrasound is not as reliable as CT in confirming the presence or absence of nonradiopaque foreign bodies. However, ultrasonography and fluoroscopy are effective methods for guiding an instrument toward a soft tissue foreign body.[18,19]

TREATMENT

General Principles

Once a soft tissue foreign body is discovered, the physician must weigh the risk of leaving the foreign body in place against the potential harm of attempting to remove it. Not all foreign bodies must be removed, and not all that require removal must be extracted in the ED. However, every effort should be made to identify their presence during the initial visit. General indications for foreign body removal include potential for later infection, toxicity, injury, and functional problems (Table 42-2). Usually, objects that are small, inert, deeply embedded, and causing no symptoms can be left in place. A common question concerns bullets that come to rest deep within a muscle belly; they are usually not removed because the procedure can cause more damage than leaving the foreign object in place. Projectiles may drag bits of clothing or skin into the wound, so the entrance wound deserves cleaning and debridement. Bullet migration and embolization are rare but possible complications. Bullets near vessels can enter the systemic circulation. Bullets that cause distal ischemia, thrombus formation, or wall erosion or that lie within the lumen of a blood vessel require immediate removal in the operating room.

Potential for inflammation or infection:
   Vegetative or chemically reactive material
   Heavy bacterial contamination (e.g., teeth, soil)
   Proximity to fractured bone
   Established infection
   Allergic reaction
Toxicity:
   Spines with venom
   Heavy metals
Functional and cosmetic problems:
   Impingement on nerves, vessels, or tendons
   Restriction of joint mobility
   Proximity to tendons
   Impairment of gait
   Persistent pain
   Cosmetic deformity (e.g., tattooing)
   Psychological distress
Potential for later injury:
   Intraarticular location
   Intravascular location
   Migration toward important structures

TABLE 42-2 Indications for Foreign Body Removal
