Kennelly proposed one of the most effective precautions against electrical injury in 1927 when he suggested keeping one hand in the pocket when visiting an electrical plant. [21] Household precautions include the education of parents about the hazards of unused sockets, including the use of plastic caps and two-step sockets, the hazards of extension cords, and restricting access to small metallic objects that can be inserted into the outlet. [22] A visit to the emergency department for a benign low-voltage injury in the toddler is a fertile time to provide safety education to parents.

Ground fault interrupters (GFIs) should be installed in circuits around water in the home (e.g., the bathroom or kitchen). These are fast-acting circuit breakers that electronically detect current leaks before they become a danger. A GFI will trip when it senses a 0.005-A difference in the current flowing into an appliance on the hot leg as compared with the current leaving the appliance on the neutral leg—thus assuring protection against a shock. Other measures that home handymen can take are to use double-insulated power tools, inspect cords and insulation on tools, and make sure that screw connections and contacts are tight and free from corrosion to prevent arcing.

197 LIGHTNING INJURIES

Kimberly N. Treat
Janet M. Williams
Ann S. Chinnis

Lightning injury is one of the most frequent injuries by natural phenomenon and, although accurate data is lacking, is likely to result in several hundred deaths per year in the United States.[1,2] Mortality rates associated with lightning have been estimated to range from 20 to 30 percent but are thought to be overestimated, because medical databases are biased toward collecting information on only the most severe and fatal cases and exclude the many less severe injuries that occur.[1] Nonfatal lightning injuries are more common, with estimates of several hundred to several thousand cases per year.[1,3,4] As many as 75 percent of survivors sustain significant morbidity and permanent sequelae.

A significant number of lightning injuries are associated with transportation.[5] The majority of transportation-related lightning injuries occur when victims are struck while standing near a vehicle. Aircraft are at risk for lightning strike that injures or kills the occupants. Between 1963 and 1985, the National Transportation Safety Board recorded 40 lightning-related aircraft accidents (10 commercial and 30 private aircraft), with 290 fatalities and 74 serious injuries.[6]

Sports are associated with increased risk of lightning injury. Among all outdoor activities, the largest number of injuries and fatalities have occurred during water sports.[7]

Even though lightning is electrical energy, lightning injuries differ substantially from high-voltage electrical injuries seen from human-generated sources: different injury patterns, different injury severity, and different emergency treatment.

PATHOPHYSIOLOGY

Unlike conventional electricity in which the alternating current tends to fix a victim to the current source by tetanic muscle contraction creating a longer contact time, lightning is direct current that imparts an instantaneous but extremely high-voltage discharge of electricity to the body. The pattern of injury seen with lightning differs from that of injury caused by both high-voltage and low-voltage alternating current (Table 197-1). Unlike conventional electricity, lightning current tends to flow over the body in a phenomenon called *flashover*, thus sparing injury to the deeper vital organs and explaining how victims are able to survive exposure to tremendous magnitudes of current. Less commonly, lightning current may enter victims and suddenly disrupt cardiac, respiratory, or neurologic function.

TABLE 197-1   Comparison of Lightning and Electrical Injuries

Injuries from lightning relate to its potential to impart electrical as well as mechanical, thermal, acoustic, and photic forces to victims. Lighting creates mechanical energy in two ways: through the direct force of the strike or as a result of the rapid expansion of the surrounding air, which may cause victims to fall or be struck by flying debris. Blunt injury has been reported in 32 percent of lightning victims.[8] Lightning may inflict thermal injury as moisture on the victim's skin is transformed into steam, reaching temperatures between 8000° and 30,000°C. An individual found dead with tattered clothing nearby might even be mistaken for a crime victim when, in reality, the rapidly expanding steam blew clothing and shoes off. Lightning can also heat metal objects such as jewelry, watches, and coins in pockets and cause burns through direct skin contact. Sound waves caused by the thunderclap may rupture tympanic membranes and lead to other acoustic injuries. Photic injury caused by the bright flash may cause retinal damage and cataracts.

The nature and severity of injury also vary according to the type of lightning strike. There are five basic types of lightning strikes. A   *direct strike* occurs when a victim is struck directly by a lightning discharge; this is the most serious form of lightning injury. The risk of a direct strike increases when individuals carry a metal object such as an umbrella or golf club or wear metal accessories such as hairpins, jewelry, hearing aids, or shoes with metal cleats. The   *side flash* occurs when a nearby object is struck and current then traverses through the air to strike a victim. A side flash may injure multiple victims simultaneously, such as a softball team in a huddle near a structure that is struck. A *contact strike* occurs when lightning strikes an object that an individual is touching and current is directly transferred to the person. A   *ground current* occurs when the lightning hits the ground and is transferred to a person standing near the strike site. The amount of current reaching a victim decreases as the radius between the victim and the strike point increases. A *stride potential* or *step voltage* occurs when lightning strikes the ground and encounters a potential difference between the legs of a person. The current enters the closer leg, traverses the lower body, and exits through the farther leg. This may result in *keraunoparalysis*, which is characterized by temporarily paretic, cold, insensate, and pulseless legs.

CLINICAL FEATURES

Although lightning injuries may involve all organ systems, injuries to the cardiovascular system and central nervous system (CNS) are usually the most devastating [9] (Table 197-2).

TABLE 197-2   Complications Associated with Lightning Strikes

Cardiovascular Injury

The immediate cause of death due to a lightning strike is usually direct current depolarization of the myocardium and sustained cardiac asystole. Although cardiac automaticity may spontaneously return, concomitant respiratory arrest due to medullary respiratory center paralysis may outlast cardiac arrest and ultimately lead to a hypoxic cardiac arrest. The duration of apnea, rather than the duration of asystole, appears to be a critical prognostic factor. Patients may suffer a variety of other cardiovascular effects, including direct myocardial damage, coronary artery spasm, cardiac contusion from blunt trauma, acute global cardiac dysfunction, atrial and ventricular dysrhythmias, pericardial effusion, and transient hypertension and tachycardia. The electrocardiogram (ECG) may show acute injury with ST-segment elevation and a prolonged QT interval. T-wave changes may be seen especially in the presence of cerebrovascular injuries. Although creatine kinase (CK) and CK-MB (isoenzyme) fraction elevations are common, myocardial infarction is not, occurring in only 7 percent of victims.

Neurologic Injury

The nervous system is particularly vulnerable to lightning injury, since resistance to current flow is lowest in nerve tissue. In addition to direct electrical trauma, CNS injuries may result from hypoxia secondary to cardiac arrest or to blunt trauma. [10] The most lethal CNS injuries involve heat-induced coagulation of the cortex (as current passes through the brain parenchyma), formation of epidural or subdural hematomas, paralysis of the medullary respiratory centers, and intraventricular hemorrhage. When lightning victims present with coma, the differential diagnosis may include prolonged hypoxia, acute cerebral edema, closed head injury, ischemia, and hemorrhage, as well as other less obvious etiologies such as hypoglycemia, drug toxicity, and hypothermia (Table 197-3). Autonomic dysfunction caused by the lightning strike may manifest as pupillary dilation, areflexia, anisocoria, or Horner's syndrome. These pupillary abnormalities are not related to CNS injury and have no relation to prognosis in comatose lightning-strike victims.

TABLE 197-3   Assessment and Treatment Essentials

Neurologic symptoms are typically classified either as immediate but transient or as delayed and usually progressive. However, some neurologic injuries can be severe, immediate, and permanent.[11] Immediate but transient symptoms include confusion and amnesia, loss of consciousness, temporary lower extremity paralysis, and temporary upper extremity paralysis.[10] Lower extremity paralysis (keraunoparalysis) is often a consequence of step-voltage injury and is usually associated with paleness, sensory loss, loss of pulses, and vasomotor changes. [12] These immediate but transient symptoms typically resolve within 24 h. Delayed and usually progressive disorders include seizures, spinal muscular atrophy, amyotrophic lateral sclerosis, parkinsonian syndromes, progressive cerebellar ataxia, myelopathy and neuropathy, paraplegia and quadriplegia, paresthesias, and chronic pain syndromes.

Respiratory Injury

Paralysis of the brainstem respiratory center may result in apnea, but this central apnea may be temporary and a patient may survive if ventilated until cardiac and respiratory activity return. Other respiratory injuries include immediate and delayed pulmonary edema, pulmonary contusion, adult respiratory distress syndrome, and pulmonary hemorrhage.

Peripheral Vascular Effects

Lightning that traverses the lower extremities during a stride potential pathway may cause vasomotor instability and the aforementioned phenomenon of keraunoparalysis. Paresis, blue, cold, and pulseless lower extremities characterize this transient form of paralysis. [12] Keraunoparalysis is thought to be caused by endogenous catecholamines and does not usually require surgical intervention. Some victims will develop permanent paralysis and paresthesias due to prolonged vasospasm. Initially, keraunoparalysis may be difficult to distinguish from acute spinal cord injury.

Dermatologic Injury

The six main dermatologic manifestations of lighting injury are feathering burns (Lichtenberg figures), flash burns, punctate burns, contact burns, erythema, and blistering, and linear streaking. The pathognomonic skin finding for lightning is the *Lichtenberg figure*, which results from electron showering over the skin surface, which is not a true burn.[13] Lichtenberg figures are superficial, appear in a fern pattern, and resolve within 24 h (Fig. 197-1). A comatose patient exhibiting Lichtenberg figures should be treated as a victim of lightning injury. *Flash burns* are similar to those found in welders, appear as mild erythema, and may involve the cornea. *Punctate burns* look similar to cigarette burns in that they are usually smaller than 1 cm and are full-thickness burns. *Contact burns* occur when metal worn close to the skin, such as coins, zippers, and belts, is heated by the lightning current. *Erythema* and *blistering* are usually transient, and superficial skin loss may occur. *Linear burns* may be seen in areas of sweat, such as the axilla or groin, and are full-thickness burns usually less than 5 cm wide. Less common burns found on lightning victims include those associated with ignition of clothing. Entrance and exit wounds, characteristic of nonlightning electrical injuries, are not commonly seen in lightning victims.

FIG. 197-1. Lichtenberg figures demonstrating the superficial ferning pattern.

Ocular Injury

Half of all lightning victims will have ocular injuries, including optic nerve atrophy, papilledema, retinal hemorrhage, retinal detachment, corneal abrasion, hyphema, uveitis, vitreous hemorrhage, and cataracts. Cataracts are the most common single injury and may develop immediately or as late as 2 years after a strike. Pupillary findings may include iridocyclitis, mydriasis, anisocoria, and Horner's syndrome. Dilated unresponsive pupils may be due to transient autonomic dysfunction and should not be used as a sign of brain death.

Otologic Injury

Otologic injuries range from transient hearing loss and vertigo to complete disruption of the auditory system. Tympanic membrane rupture is seen in more than 50 percent of lightning victims and may result from the explosive forces of the strike, basilar skull fracture, direct trauma to the ear canal, or direct lightning burn to the canal. Victims who were using a conventional corded telephone at the time of the lighting strike are at higher risk for these injuries. Long-term complications may include chronic otitis media and hearing loss.

Gastrointestinal Injury

Gastrointestinal complications include paralytic ileus, gastric dilatation, stress ulcers, and upper gastrointestinal bleeding. Blunt abdominal trauma may result in a ruptured viscus or solid organ injury.

Renal Injury

Permanent renal damage is rare but may occur from prolonged hypotension. Myoglobinuria occurs less commonly than in electrical burns and is seen in only 6 percent of lightning victims.[14] Routine forced diuresis and alkalinization of the urine is not recommended in lightning victims, due to the risk of volume overload and cerebral edema.

Musculoskeletal Injury

A variety of musculoskeletal injuries may result, including fractures and soft tissue injuries due to blunt forces, compartment syndromes, muscular rupture, and posterior shoulder dislocations, and cervical spine fractures from intense myotonic contractions.

Psychosocial Problems

Lightning victims may suffer from long-term cognitive dysfunction, depression, and anxiety. Posttraumatic stress disorder and storm phobias are known to develop. Children are more prone to anxiety, storm phobias, and recurrent nightmares.

Pregnancy

Although maternal outcomes are generally good, there is a 50 percent rate of fetal death in pregnant women struck by lightning, because amniotic fluid serves as a preferential path for the electrical current flow. Fetal monitoring should be performed on all pregnant women with lightning injuries.

DIAGNOSIS

All patients with lightning injury should have a 12-lead ECG performed to evaluate for arrhythmias and injury patterns (Table 197-3). Laboratory tests that should be conducted in most patients with moderate to severe injuries include determination of serum electrolytes, calcium, magnesium, blood urea nitrogen, creatinine, CK, CK-MB, arterial blood gas, and urine myoglobin levels; coagulation studies; a complete blood count; and urinalysis. A chest x-ray should be obtained to evaluate for aspiration, pulmonary edema, pulmonary contusion, rib fractures, and pneumothorax. Cervical spine films should be obtained in patients with suspected spinal injuries or trauma secondary to falls, and in obtunded patients in whom a history of trauma is uncertain. Computed tomography of the head should be performed in patients with an altered or deteriorating level of consciousness or evidence of a head injury. Additional studies may be indicated based on clinical findings.

The differential diagnosis of an unwitnessed victim of lightning strike is quite broad and includes trauma, metabolic disturbance, toxic exposure, and other causes of an altered mental status (Table 197-4). Lightning injuries can be suspected when the environmental setting is compatible and a victim displays physical findings unique to such injuries. For example, an unconscious rain-soaked patient with perforated tympanic membranes and Lichtenberg figures (fernlike skin markings) who is found in a field near a tractor is almost definitely a lightning victim.

Cerebrovascular accidents

Seizure disorders

Cerebral, spinal cord, or other neurologic trauma

Stokes-Adams attacks

Toxic ingestion or envenomation

Myocardial infarction

Cardiac dysrhythmias

Hypertensive crisis with intracranial hemorrhage

Physical assault

TABLE 197-4 Common Misdiagnoses of Lightning Injuries

TREATMENT

Prehospital Treatment

Emergency medical service personnel and bystander safety must be the first priority, since lightning can and does frequently strike twice in the same place. The standard airway, breathing, circulation, disability, and exposure protocols with advanced life support (ALS) protocols are required. Reverse triage (care for the apparently dead first) is appropriate in the case of multiple victims, because (a) most victims who are not in cardiopulmonary arrest survive without the need for ALS and (b) victims in cardiac arrest may survive if ventilated until cardiac and respiratory activity resumes. [15] Thus, concentrating limited ALS resources on apparently dead victims in a multicasualty lightning-strike event is appropriate. Due to the unusual neurologic manifestations of lightning injuries, patients with fixed and dilated pupils may survive and live a normal life. Patients who are blue, with mottled extremities, in whom it may be difficult to find a pulse or a blood pressure, may recover without sequelae. Aggressive fluid resuscitation is rarely required. Victims of a lightning strike should be transported in full spinal immobilization, due to the possibility of traumatic injuries.

Emergency Department Treatment

Standard ALS and trauma treatment principles should be followed. Intravenous access, supplemental oxygen, and continuous cardiac monitoring should be initiated immediately. Lightning victims in cardiac arrest have a better prognosis than do victims in arrest due to trauma or acute myocardial infarction. [16] For this reason, aggressive resuscitative efforts should be taken even after a prolonged anoxic period. Hypotension warrants a search for occult hemorrhage, such as intraabdominal or intrathoracic hemorrhage, and pelvic or long-bone fractures.

Once the primary survey is completed, a careful head-to-toe examination should be performed to identify occult injuries. The cutaneous examination may disclose burns and may help determine the path of the current and locate potential organ injuries. Care for a superficial lightning burn includes cleansing, debridement, application of a topical antimicrobial agent, and administration of tetanus prophylaxis, if indicated. Fasciotomy is rarely indicated, since circulatory disorders are frequently consequences of vasospasm and resolve spontaneously. A careful neurologic examination should be performed to detect motor and sensory deficits. Ophthalmologic (including slit-lamp examination) and otologic examinations should be done to rule out visual and hearing disturbances, as well as tympanic membrane rupture. Abdominal distention due to ileus should be treated with gastric decompression. An acute abdomen may be due to blunt injury and intraperitoneal injury.

DISPOSITION

The majority of patients with lightning strike injuries require admission to a center with appropriate capabilities for providing specialized, comprehensive care. Conditions associated with serious mortality and morbidity include cardiorespiratory arrest, cranial burns, leg burns, ECG changes and dysrhythmias, any CNS lesions or loss of consciousness, any neurologic injuries without rapid resolution, and myoglobinuria. [14] Consultation with trauma surgery, neurosurgery, cardiology, and neurology services may be indicated. All pregnant patients require admission for fetal monitoring and ultrasound fetal assessment.

Those with minor injuries who show improvement within the first several hours after a strike may benefit from admission for careful monitoring of neurologic and cardiovascular status, due to the potential for delayed sequelae. Patients who have no neurologic deficits and only minor abnormalities found on a thorough examination may be monitored in the emergency department and discharged with adequate follow-up. Consider neurologic; ear, nose, and throat; and ophthamologic referral for evaluation of potential long-term sequelae in all victims.

PREVENTION

The risk factors and recommendations for the prevention of lightning injuries are well described. [17] Lightning is more likely to occur on hot, humid days. Static on a local radio station may indicate high electrical activity in the atmosphere. In anticipation of a thunder and lightning storm, individuals should remain indoors or seek shelter in a vehicle. Individuals should avoid open doorways or open windows, stay clear of metallic objects (stoves, water pipes, sinks, and bathtubs), and not use plug-in electrical appliances such as radios, televisions, and telephones. Campers should avoid placing tents under tall trees, near bodies of water, or on the highest hill in an area. If caught outside during a storm, all metal objects (fishing rods, golf clubs, umbrellas, and jewelry) should be discarded. If no shelter is possible, individuals should head for dense woods or lie on the ground in a ditch. Groups of people should separate to avoid all becoming victims. All machinery work outside should be stopped; for example, tractors are often struck by lightning. Individuals should get out of water and off small boats. A lightning strike is imminent when an individual's hair stands on end (due to surrounding electrical charge). The individual should squat (much like the position of a baseball catcher) with hands on knees and feet close together to decrease strike potential.

198 CARBON MONOXIDE POISONING

Keith W. Van Meter

Carbon monoxide (CO) exposure and toxicity is a potentially lethal disorder with immediate and delayed side effects.

EPIDEMIOLOGY

In the United States and most industrialized countries, CO is the single toxin responsible for more mortality and morbidity than any other. [1,2] Industrial sources of CO include fossil fuel engine exhaust, gas- or coal-heater emissions, smoke from accidental fires, and fumes from cupolas of steel foundries, pulp paper mills, or formaldehyde-producing plants. Indoor burning of charcoal—particularly in some countries such as Korea, with a tradition of charcoal subfloor home heating—produces a disproportionate level of accidental CO intoxication. [3] Unintentional CO toxicity and deaths are more common in northern climates and during the winter months.[4]

Interestingly, industrial sources produce slightly less environmental CO per land area as compared with CO produced from the burning of tropical forests. [5] Little is known about the impact these low atmospheric levels have on health. It is known that regular cigarette smoking can produce carboxyhemoglobin (HbCO) levels of 5 to 10 percent, and this chronic CO exposure is implicated in the acceleration of atherosclerosis seen in smokers. Truck drivers sitting in the cabs of their vehicles in heavy traffic can reach similar levels of HbCO as tobacco smokers. Besides combustion, CO toxicity can develop when inhaled methylene chloride vapor in paint strippers or from leaking "bubble" electric Christmas tree lights is slowly metabolized to produce CO. [6]

PATHOPHYSIOLOGY

CO is an odorless, clear gas (in extremely high concentrations, it has a lavender odor), with a density of 0.97 that of air. In most instances, CO mixes evenly in turbulent air. A small amount of CO is endogenously produced from the metabolism of hemoglobin to bilirubin and HbCO levels rise in hemolytic anemia. CO may function as an endogenous central nervous system (CNS) neurotransmitter. [7]

CO forms a ligand with respiratory pigments and enzymes such as hemoglobin, myoglobin, cytochrome P-450, and cytochrome aa$_3$. In fact, cytochrome P-450 was named after the *peak* (p) absorption of light at 450 μm when the enzyme is 50% saturated with CO. Respiratory enzymes have varying binding affinities for CO compared to oxygen. For example, CO bonds with hemoglobin 210 to 280 times as tenaciously as oxygen, but CO has only one-ninth the affinity of oxygen for cytochrome aa$_3$.[8] When CO competes with oxygen for binding sites, it prevents utilization of oxygen by that enzyme or pigment. Thus, HbCO will carry less oxygen according to the number of binding sites occupied by CO.

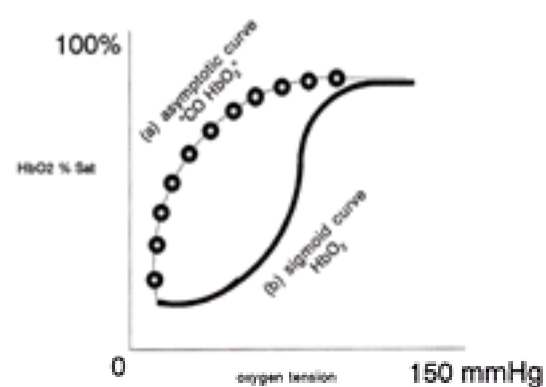
In addition, the binding of CO to hemoglobin also transforms the oxyhemoglobin dissociation curve from a sigmoid shape to an asymptotic shape, increasing the ability of HbCO to hold on to oxygen at the remaining heme moiety sites (Fig. 198-1). In CO toxicity, both the reduced oxygen carriage and the transformation of oxyhemoglobin dissociation curve impair tissue oxygen delivery. In effect, high HbCO imposes the equivalent of a sudden "chemical" anemia in the patient. The tolerance of the patient to this sudden chemical anemia may be worse than its hemorrhagic equivalent because of the toxic effects of CO on other respiratory pigments and enzymes. While tissue oxygen delivery is decreased, CO delivery still occurs by the dissolved CO in the circulating plasma. Experimental exchange transfusion in dogs of autologous red blood cells (RBCs) exposed extracorporeally to CO before transfusion, resulting in HbCO 60%, demonstrated no signs of CO toxicity. Thus, while impairment of O$_2$ delivery by reduction of O$_2$ carriage is a part of CO toxicity, it may be that delivery of CO contributes more to the toxic effects of CO. In fact, hemoglobin may provide a protective buffer, preferentially binding CO and preventing binding to other respiratory pigments and mitochondrial cytochromes.


FIG. 198-1. HbCO "shift to the left" by reshaping of the Hb O_2 dissociation curve [(a) hyperbaric oxygen (HbO_2) asymptotic and (b) HbO_2 sigmoid]. (Remember, decrements in temperature, H$^+$ concentration, CO$_2$ and DPG levels also "shift to the left" of the Hb O_2 dissociation curve in a similar fashion.)

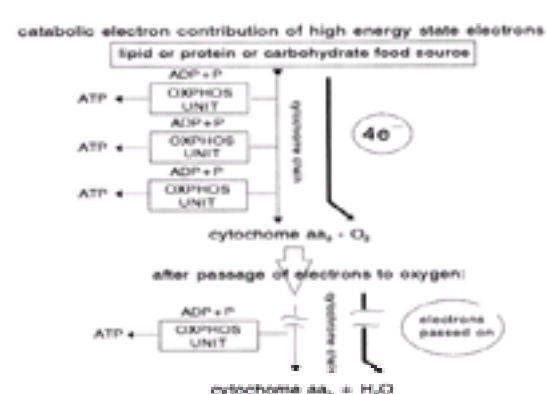
CO binding to mitochondrial cytochromes stops electrons—derived from aerobic metabolism of lipids, protein and carbohydrates—from flowing through the cytochrome chain. The cytochrome chain "encases" the fall in energy level of the electrons, allowing a four-electron reduction of nascent O$_2$ attached to cytochrome aa$_3$ at the end of the mitochondrial cytochrome chain. Thus, oxygen gets reduced to H$_2$O without formation of potentially destructive oxygen free radical intermediates, such as O^-, OH$^-$, and H$_2$O$_2$[8] (Fig. 198-2). As electrons pass down the cytochrome chain, energy is captured and stored by the generation of ATP in a process called *oxidative phosphorylation.* CO binding to cytochrome aa$_3$ prevents the attachment of O$_2$, preventing the reduction of O$_2$ to H$_2$O. The cessation of cytochrome oxidative phosphorylation causes CO to "wreck the machine," as Haldane so aptly described the role of CO toxicity in aerobic metabolism.


FIG. 198-2. Nascent oxygen can attach to cytochrome aa$_3$. Oxygen, with its electron-deficient shell, becomes an electron sink (electrophile). Oxygen attached to cytochrome aa$_3$ in this manner prevents the formation of intermediate destructive oxygen free radicals ($\overline{O}$, OH^-, and H_2O_2). Water is the end product instead.

CO binds strongly to intracellular pigments, such as myoglobin. In muscle with high oxygen utilization, such as the heart, the binding of CO to myoglobin markedly reduces the availability of oxygen for aerobic metabolism. CO poisoning of myocardial myoglobin reduces myocardial contractility, diminishes cardiac output, and further decreases tissue oxygen delivery.

CO toxicity, by imposing ischemic damage, causes white blood cells to become adherent to endothelial surfaces of tissue microvasculature on reperfusion of ischemic tissue.[9] Immediately after reperfusion of ischemic CO-poisoned tissue, products from these adherent white cells accelerate cell membrane lipid peroxidation, a process termed *reperfusion injury*.[10]

CLINICAL FEATURES

High-oxygen-extracting organs like the brain and the heart easily become dysfunctional from CO intoxication. Neurologic symptoms and signs include fatigue, malaise or flulike symptoms, nausea, difficulty in thinking, emotional lability, dizziness, paresthesias, weakness, vomiting, lethargy, somnolence, stroke, coma, seizure, or respiratory arrest. Cardiovascular symptoms and signs include chest pain from myocardial ischemia, palpitations from dysrhythmias, mildly to severely mottled skin from diminished circulation, poor capillary refill, hypotension, or cardiac arrest. In a pattern of secondary injury from ischemia imposed by CO poisoning, the following clinical injury syndromes may occur[11]:

1. Rhabdomyolysis
2. Noncardiogenic pulmonary edema (NCPE)
3. Multiorgan failure (MOF)
4. Disseminated intravascular coagulation
5. Dermal blistering or increased dermal susceptibility to dermal pressure wounding
6. "Interval CO syndrome" of leukoencephalopathy of the centrum ovale (cerebral subcortical white matter) along with ischemic damage to basal ganglia and hippocampus
7. Acute tubular necrosis

It has been observed that the symptoms and signs of CO toxicity are exacerbated by circumstances that increase neurologic and myocardial oxygen demand. It is common that patients will describe the onset of symptoms while at rest and a marked increase after physical exertion. One example would be a patient who develops toxicity from using an internal combustion engine in a closed space. Starting to feel ill, the patient walks or runs outside to fresh air, only to collapse as his or her brain and heart are not able to utilize oxygen to meet the increased metabolic demands. It has also been observed that CO intoxication is more severe in patients who have increased oxygen demands from the comorbidity of trauma, concurrent drug ingestion, burns, myocardial ischemia, cerebrovascular disease, and smoke inhalation. [12]

DIAGNOSIS

Signs and symptoms of CO injury correlate reasonably well with on-the-scene co-oximetry determination of HbCO. However, by the time the patient gets to the ED after breathing air and with prehospital oxygen administration, the positive predictive value (PPV) of HbCO levels falls considerably. A very careful history, coupled with a careful screening neurologic examination that includes a CO neuropsychometric screening battery (CONSB), is a sensitive but not specific assay for CO intoxication. The CONSB has a good PPV for discerning neurologic dysfunction or injury from CO intoxication. [13,14] The CONSB should be done with the patient breathing room air to be most sensitive.

Patients with CO exposure and only mild symptoms (no loss of consciousness, no cardiopulmonary symptoms, awake and cooperative) require minimal ancillary testing: a measure of HbCO and possibly an electrocardiogram (ECG) to detect silent myocardial ischemia. Patients with moderate to severe exposures should have additional studies done to assess the extent of ischemic injury.

1. Co-oximetry determination of HbCO measures actual levels. Pulse oximetry confuses HbCO for oxyhemoglobin and gives spuriously high values for percent of oxygen saturation.[15]
2. The extent of metabolic acidosis—as measured by the serum pH, serum bicarbonate level, or serum lactate level—is a measure of the ischemic damage. CO, by blocking the cytochrome chain, reduces pyruvate utilization by the Krebs cycle, and the excess pyruvate is metabolized to lactate (Fig. 198-3). The arterial blood gases (ABG), serum electrolytes, and serum lactate are used to detect metabolic acidosis.
FIG. 198-3. In mitochondria, the cytochrome aa$_3$ CO ligand brings to a halt the orderly flow of electrons from food sources to oxygen. As a result, pyruvate stops its entry into the Krebs cycle and redirects its metabolic route to formation of lactate.

3. A complete blood count (CBC) will help in evaluating hemoglobin level to estimate arterial oxygen content (Ca $_{O_2}$).
4. The ECG is indicated if the patient has chest pain, palpitations, or dysrhythmia on the monitoring lead. The ECG should also be used in older patients who may have silent myocardial ischemia.
5. The extent of myocardial injury can be measured by serum CK isoenzyme (CK-MB) and troponin levels.
6. The extent of skeletal muscle injury (e.g., rhabdomyolysis) can be measured by serum CK, serum myoglobin, and urine myoglobin.
7. For patients short of breath, with abnormal ausculatory findings, or with multiple trauma, the chest radiograph is indicated.
8. Urine toxicologic screens can be useful when concurrent drug ingestion is suspected.
9. Computed tomography (CT) and magnetic resonance imaging (MRI) of the brain are modestly sensitive but nonspecific in documenting CNS ischemic injury 6 h after CO exposure.[16] Diffusion-weighted MRI brain scanning is being investigated for its utility in defining brain injury from CO intoxication.
10. Single-photon-emission computed tomography (SPECT) with radiolabeled hexamethylpropylene amine oxime (HMPAO–technetium 99m) is immediately sensitive but not specific for acute ischemic CNS injury in CO poisoning. [17] The brain HMPAO/SPECT scan has the advantage that the radionuclide may be initially injected as the patient arrives in the emergency department without interrupting the resuscitation effort. The patient can be scanned later after stabilization, with a lasting "snapshot" of pre-resuscitation brain metabolism and perfusion. The bulk of HMPAO is taken up by the brain on first pass as it crosses the blood-brain barrier. Accordingly, the HMPAO "locks" into CNS tissue without much redistribution during the successive half-lives of the HMPAO radionuclide. The positron emission tomography (PET) brain scan may be helpful in illustrating CNS ischemic injury, but the scanner is rarely available and hard to have on-line for critically injured patients.

SPECIFIC ISSUES

CO intoxication is especially harsh on the very old and very young. It does not differentiate as to gender. Pregnant patients with CO intoxication have no greater risk, but the fetus is at greater risk than the mother for ischemic injury due the greater affinity of fetal hemoglobin than adult hemoglobin for CO. [18]

CO intoxication is more severe in patients with the comorbidity of multiple trauma, thermal or chemical burns, smoke inhalation, cerebral ischemia, or myocardial ischemia. CO intoxication coupled with drug intoxicants increases the risk of failure at self-evacuation from a toxic atmosphere. Further, concurrent inhalation of inert gas (natural gas), carbon dioxide, or chemical asphyxiants (NO, H_2S, HCN) can augment ischemic insult in a CO patient.

Missed diagnosis of CO intoxication is a potential malpractice liability for the emergency physician. The return of a patient to a yet unidentified toxic environment must be prevented. In particular, the failure to understand that serious CO intoxication with residual ischemic injury may exist in a patient even with low HbCO levels has led to malpractice judgments against the emergency physician. In addition, the failure to identify, in a CO-injured patient, nonresponse to normobaric oxygen treatment and hence the failure to access hyperbaric oxygen treatment has resulted in large awards to the patient.

TREATMENT

The ABCs (airway, breathing, and circulation) of resuscitation apply to the seriously ill or injured victim with presumed CO intoxication. Normobaric oxygen (NBO) therapy should be administered as soon as possible with 100% oxygen by mask [nonrebreathing mask with reservoir (NRMR)]. Patients who require ventilatory assistance should have bag-valve-mask (BVM) ventilation with 100% oxygen until spontaneous ventilation recovery or endotracheal intubation can be performed in the field or the ED.

Once the patient reaches the ED, decisions about further treatment are guided by the clinical evaluation (Table 198-1). Patients with only mild symptoms (nausea, headache, weakness, or flulike malaise) should receive 100% NBO for a period of about 4 h, with periodic reassessment. The ability of oxygen treatment to eliminate CO from the body has often been estimated using the half-life of HbCO with different treatment regimens. As noted above, HbCO may be a poor marker of the severity of CO poisoning. The half-life of HbCO is about 320 min by breathing room air, 60 min by breathing 100% NBO, and 23 min with 100% hyperbaric oxygen (HBO) at 2.8 atmospheres of pressure (2.8 ATA). Failure of mild symptoms to resolve after 4 h of NBO administration, if no other likely cause for the symptoms can be found, should lower the emergency clinician's threshold for the use of HBO therapy.

Mild CO Toxicity	Serious CO Toxicity
Weakness	Loss of consciousness or near syncope
Nausea	Confusion (moderately abnormal CONSB)
Dizziness	Focal neurologic changes
Headache	Myocardial ischemia
Mildly abnormal CONSB	Persisting hypotension
(with patient on room air	Persisting acidosis
while testing)	Pregnant mother with HbCO >15%
	Concurrent injury or intoxication
100% NBO for 4 h	HBO 90-min treatment session
Reassess; if symptoms persist, consider HBO versus continued NBO	Reassess after first treatment; if symptoms persist, repeat HBO in 3–6 h

Key: CONSB, CO neuropsychometric screening battery; NBO, normobaric oxygen; HBO, hyperbaric oxygen.

TABLE 198-1   Treatment Recommendations for CO Toxicity

Major symptoms (any history of loss of consciousness, amnesia, or myocardial ischemia) have traditionally been an indication for initial HBO treatment. [1,14] While dramatic improvement in symptoms and signs is generally seen, there is continued debate as to whether HBO is better than NBO with regard to short- and long-term outcomes.[19] Prospective, randomized studies comparing HBO and NBO have yielded conflicting results, possibly due to different entry criteria, the intensity of the outcome measure, and the duration of follow-up.[20,21 and 22] There appears to be some benefit to HBO in reducing neurophysiologic sequelae, but that difference may be detectable only with specific testing and the benefit may disappear after 12 months of follow-up.

While the patient is being prepared for referral to a hyperbaric chamber, he or she should be maintained on 100% NBO. Traditional recommendations for HBO treatment for CO poisoning have sometimes stressed the use of HbCO criteria. This approach is no longer advocated because of the poor correlation between clinical symptoms, morbidity, mortality, and ED HbCO levels. In addition, there is no evidence that HBO treatment based on HbCO level alone is beneficial.

The added mortality or morbidity incurred by transport to an HBO treatment facility has been established to occur in less than 5 percent of cases so handled. Both monoplace and multiplace hyperbaric chambers have critical care capability for ventilator support of endotracheally intubated patients, blood pressure monitoring, central venous manometry, and cardiac monitoring. U.S. emergency physicians can find the location of the nearest hyperbaric chamber by calling the Divers Alert Network (DAN), Duke University, Durham, NC, at 1-919-684-8111.

Standard HBO treatment for CO intoxication uses 100% oxygen at 2.4 to 2.8 ATA for 90 min. Most patients with moderate symptoms respond to one treatment, although some may have persistent symptoms that require one or two more treatments during the first 24 h to fully resolve. Treatment costs for HBO are approximately $500 per session, in comparison to about $150 to $200 for 4 h of NBO in an ED.

In addition to enhancing the elimination of CO from the body, HBO treatment has several theoretical advantages over NBO treatment. HBO improves oxygen delivery to ischemic tissue and CO elimination from hemoglobin. HBO, not NBO, lessens CO-induced reperfusion injury by truncating lipid peroxidation and lessening leukocyte endothelial adherence in microvasculature. [9,10]

Complications of HBO treatment include a very low incidence of oxygen-induced seizures (approximately 1 per 1000 patients), ear and sinus barotrauma, pulmonary barotrauma, and vascular gas embolism. Pregnancy is not a contraindication to HBO treatment. The only absolute contraindication to HBO treatment is an untreated pneumothorax.

DISPOSITION

CO-intoxicated patients with mild symptoms (headache, nausea, flulike symptoms, weakness, and dizziness) that remit after 4 h of 100% NBO may be discharged with the proviso that they return for evaluation if symptoms return. Patients should be reevaluated in about 24 to 48 h. If patients with minor symptoms do not improve after 4 h of NBO therapy but the symptoms remit after a single HBO treatment, then the patient can be discharged with the same instructions. If symptoms do not remit, the patient should be admitted with appropriate neurologic consultation.

CO-intoxicated patients with the history of loss of consciousness, amnesia, or seizure should be admitted even if symptoms improve with HBO treatment. CO-intoxicated pregnant patients should be admitted for fetal monitoring. CO-intoxicated patients with evidence of myocardial ischemia should be admitted for evaluation and management.

A subset of CO patients have "interval CO injury" or delayed development of neurologic symptomatology from 2 days to 1 month after initial improvement. Discharge instructions should include this information.

Amelioration of neurologic residual injury with delayed treatment has occurred up to at least 20 days postinjury with HBO treatment. A short series of daily "tailing"

low-dose HBO treatments has been anecdotally used to resolve or ameliorate lingering residual neurologic injury.

199 RADIATION INJURIES

Pamela L. Piggott

INTRODUCTION

Since 1978, the US Joint Commission on Accreditation of Healthcare Organizations (JCAHO) has required that all hospitals have an active plan to manage radiation accidents. Casualties from radiation accidents are rare events in comparison with other types of hazardous material accidents. However, with today's widespread use of radiation technology in medicine, research, industry, power production, and national defense, there is a growing potential for radiation injuries. Of further importance is the potential of large numbers of casualties from a terrorist attack employing nuclear weapons. An understanding of basic radiation physics and pathogenesis of injury will aid the emergency physician in the triage and initial management of radiation injuries.

The emergency physician must also be prepared for the potential situation in which an individual has gained possession of a radiation source without being aware of its hazard and the individual develops injury. A significant case of this occurred in 1987 in Guiana, Brazil, when a teletherapy source of Cs-137 was released into the public domain. Two weeks elapsed before the radiation accident was fully discovered. Patients with gastrointestinal symptoms were initially misdiagnosed as having a food allergy. One patient with severe radiation skin injury was referred to a specialty center for suspected tropical disease infection. This incident resulted in over 200 contaminations, 20 significant exposures, and 4 deaths. The ability to recognize signs and symptoms of radiation injury will enable the physician to deliver more prompt and effective treatment to these types of patients.

INCIDENCE OF RADIATION ACCIDENTS

The most recognized and comprehensive record of radiation accidents is the registry maintained by an asset of the US Department of Energy, the Radiation Emergency Assistance Center/Training Site (REACTS). Since the inception of the registry in 1944, 403 radiation accidents have been recorded worldwide with victims totaling 133,617 individuals; 2965 with significant exposure and 120 fatalities (Table 199-1). The 1986 Chernobyl accident accounts for 116,500 individuals and 28 acute fatalities. The most frequent radiation accident is one of high-dose local exposure, usually to the hands, from a radiation device. The majority of these accidents have occurred in the industrial setting with inadvertent exposure from radiation devices used in radiography to verify integrity of metals such a pipe welds. [1]

Location	Number of Accidents	Persons Involved	Significant Exposure*	Fatalities
US	243	1359	786	31
Outside US	160	132,258	2179	89
	403	133,617	2965	120

*A significant radiation exposure is one in which an individual receives one or more of the following: whole body dose of 0.25 Sv (25 rem) of more, skin dose of 6 Sv (600 rem) or more, other tissue dose of 0.75 Sv (75 rem) or more, or internal contamination level equal to or greater than half of its maximum permissible body burden.

FUNDAMENTALS OF RADIATION PHYSICS

Nonionizing and Ionizing Radiation

The electromagnetic radiation spectrum includes long wavelength, low frequency, low-energy forms of nonionizing radiation and progresses to short wavelength, high frequency, high-energy forms of ionizing radiation. "Ionizing" refers to the ability of high-energy radiation to displace electrons from atoms and cause matter through which it passes to become electrically charged. Nonionizing forms include ultraviolet rays, visible rays, infrared rays, microwaves, and radio waves. Lasers, ultrasound, and nuclear magnetic resonance systems are other examples of nonionizing radiation used in the medical field. X-rays and gamma waves are ionizing forms of electromagnetic radiation.

Ionizing radiation is emitted from unstable forms of elements called radioisotopes. An isotope is a variation of an element with a different number of neutrons in the nucleus. Because its number of protons identifies an element, all isotopes of an element have the same number of protons and thus the same atomic number. However, the different numbers of neutrons give isotopes of the same element different atomic weights.

Some isotopes are unstable and spontaneously transform in order to reach a more stable configuration. This transformation is a process called decay or disintegration and may involve the release of ionizing radiation. An isotope that emits ionizing radiation during its decay is referred to as a radioisotope. Radioisotope is a general term for radioactive isotopes of any element and radionuclide is a term that refers to a radioactive isotope of a specific element.

Biological Effect of Ionizing Radiation

The biological effect of ionizing radiation occurs at the cellular level. DNA and other macromolecules of the cell may be directly ionized by radiation or indirectly damaged by highly reactive free radicals created by ionization of cellular water. High levels of radiation exposure may cause direct cell death. More commonly, lower levels of radiation interrupt the cell's reproductive process by damaging the cell's mitotic capability, making it unable to divide. Injury occurs at the time of exposure but

the onset of clinical manifestation of radiation injury varies among cell type. Short-lived cells, such as blood cells, are quickly depleted and injury may become evident before new cells are generated. Longer-lived cells, such as the lens of the eye, regenerate slowly and thus injury may not become apparent for years after the exposure.

Radiosensitivity is the response of cells to acute manifestations of radiation injury. In general, poorly differentiated cells and cells with a short life span and high turnover rate are most vulnerable to the detrimental effects of radiation. Rapidly proliferating cells, such as those of the hematopoietic, gastrointestinal, and reproductive systems are more radiosensitive than the more slowly dividing cells of the nervous system and musculoskeletal system.

Types of Ionizing Radiation

Radiation is emitted as either particles or waves. Particulate radiation includes alpha, beta, and neutrons, whereas gamma and x-rays are electromagnetic waves (Table 199-2).

Type (Symbol)	Mass*	Charge	Penetration	Shield	Hazard	Source
Alpha (α)	4	+2	Few cm in air	Paper, Keratin layer of skin	Internal contamination only	Transuranic elements, i.e., plutonium found in nuclear weapons and isotope production facilities
Beta (β)	1/1836	−1	~4 mm into skin	Clothing	Skin and internal contamination	Most radioisotopes decay by β occasionally following by γ emission
Neutron (N)	1	0	Variable	Material of high hydrogen content	Whole-body irradiation	Critically accidents around nuclear power production facilities or nuclear weapons
Gamma (γ)	0	0	Several cm in tissue	Concrete Lead	Whole-body irradiation	Most radioisotopes emit γ following β decay

*Approximate measurement in atomic mass units (AMU).

TABLE 199-2   Types of Radiation

The biological effect of these forms of radiation is a function of the mass, charge, and energy that the type of radiation possesses. Linear Energy Transfer (LET) describes the rate at which radiation deposits its energy as it travels through matter. In general, particulate radiation has a high LET and electromagnetic radiation has a low LET. High LET radiation interacts readily with matter, creating a dense number of ionizations in the matter through which it passes. Thus, high LET radiation dissipates its energy quickly and does not penetrate deeply. This intense ionization in a concentrated area creates a potential for significant biological damage when high LET radiation is deposited internally. Conversely, low LET radiation interacts less readily with matter, creating less ionization along its traveled path. These properties enable low LET radiation to penetrate deeply into body tissue. Exposure to an external source of low LET radiation creates a potential for significant biological damage.

ALPHA PARTICLES   Alpha radiation is a heavy, highly charged particle composed of 2 protons and 2 neutrons. Because of its large mass and charge, alpha particles travel at a low velocity and interact readily with matter. Alpha particles have the highest LET of the different types of radiation and therefore deposit a large amount of energy in a small volume of tissue. However, an alpha particle dissipates its energy quickly, traveling only a few centimeters in air. Alpha radiation is easily shielded and cannot penetrate paper. The keratin layer of skin also blocks alpha particles. Thus alpha radiation possesses a significant biological hazard only when internalized. Heavy radioisotopes with an atomic number above 82, such as uranium and plutonium, are sources of alpha particle emission.

BETA PARTICLES   Beta particles have a smaller mass and charge and generally have a greater velocity than alpha particles. When compared to alpha, beta particles have a lower LET, interacting with matter to a lesser extent and creating less ionization along the path it travels. These properties enable beta radiation to travel further and penetrate deeper than alpha radiation. Beta radiation penetrates approximately 8 mm into exposed skin and can cause serious burns. Like alpha, beta is also a hazard if internally deposited but to a lesser extent. Most radioisotopes decay by beta radiation followed by gamma emission.

NEUTRONS   Neutrons are electrically neutral particles with a wide range of energy, velocity, and penetration power. Exposure to neutrons is unique. Unlike irradiation by other forms, high-level neutron exposure can induce radioactivity. That is, neutron irradiation can cause previously stable atoms of the absorbing material to become radioactive. In human tissue, the induced radioactive isotope is primarily Na-24, which can be detected in blood and urine specimens. In peacetime, neutron exposure is unlikely and sources of neutrons are limited primarily to nuclear power plants, particle accelerators, and weapon assembly sites.

GAMMA AND X-RAYS   Gamma and x-rays are electromagnetic waves with no mass and no charge that travel at the speed of light. These rays have a low LET, creating sparse ion pairs as they travel through tissue. X-rays are generated by excitation of the orbital electrons while gamma is a photon emitted from the nucleus. X-rays have longer wavelengths, lower frequency, and lower energy than gamma rays. Gamma rays are the most penetrating type of ionizing radiation and travel several meters in air and many centimeters into tissue. Exposure to an external source of gamma or high-energy x-rays presents a significant whole-body radiation hazard and high doses may result in acute radiation syndrome.

Units of Measure

Radiation can be measured as activity, exposure, or dose (Table 199-3). Conventional units include the curie, roentgen, rad, and rem. The International System (SI), is now more widely used and includes the becquerel, gray, and sievert.

Description	Conventional Units	SI Unit	Conversion
Activity Units of activity describe the amount of radioactivity present. These units reflect the rate of decay or the number of disintegrations occurring per second (dps). 1 Ci = 3.7 × 10¹⁰ dps; 1 Bq = 1 dps.	Curie (Ci)	Becquerel (Bq)	1 Bq = 2.7 × 10⁻¹¹ Ci; 1 Ci = 3.7 × 10¹⁰ Bq
Exposure Units of exposure measure the amount of X or gamma radiation that produces a given number of ionizations in air.	Roentgen (R)	coul/kg	1 R = 2.58 × 10⁻⁴ coul/kg
Absorbed Dose Units of absorbed dose can be applied to any type of radiation and reflects the energy imparted to matter.	Rad (r)	Gray (Gy)	1 rad = 0.01 Gy; 1 Gy = 100 rad
Dose Equivalent Units that provide a common unit of measure for the different types of radiation. These units are calculated by multiplying the absorbed dose to modifying factors that take into account the different biological effect of different radiation types.	Rem	Sievert (Sv)	1 rem = 0.001 Sv; 1 Sv = 100 rem
Internalized Radiation Term that reflects the amount of radiation that will be delivered to the body from internally deposited radioisotopes.	Body burden	N/A	

TABLE 199-3   Radiation Units of Measure

The curie (Ci) and becquerel (Bq) are units of activity and describe the amount of radioactivity present. A radioisotope's activity is a function of its rate of decay or number of disintegrations per second. The roentgen (R) is a unit of exposure and measures the amount of x or gamma radiation that produces a given number of ionizations in air. The roentgen is not applicable to particulate types of radiation. Many radiation survey instruments record exposure rate per hour of x or gamma radiation. The SI equivalent of roentgen is coulomb per kilogram (coul/kg). The rad (r) and gray (Gy) are units of absorbed dose and reflect the amount of energy that the radiation imparts to matter through which it passes. These units are used for photon as well as particulate radiation and are not restricted to measurement in air.

Because the different types of radiation have different magnitudes of biological effect on man, units of dose-equivalent are used to provide a common scale of measurement for the different types of radiation. The rem and sievert (Sv) are units of dose-equivalent and are obtained by multiplying the absorbed dose by modifying factors. Differentiation between units of absorbed dose and dose equivalent is most important with high LET radiation, particularly alpha radiation. Because

of the large amount of energy that alpha particles deposit in a concentrated area, alpha's potential for biological damage is greater. The dose equivalent of alpha radiation is approximately 20 times the absorbed dose. In other words, one rad (or gray) of alpha radiation is approximately equivalent to 20 rem (or sievert).

For beta, x, and gamma radiation, the dose equivalent is essentially equal to the absorbed dose. In simplified terms, a rad (or gray) of beta, x, or gamma radiation is roughly equivalent to a rem (or sievert). For these types of low LET radiation, units of absorbed dose and dose-equivalent are often used interchangeably.

Body burden is used in reference to internally deposited radioactive material. Different radionuclides will deliver varying amounts of radiation to the body when internalized. The amount of radioactivity that may be present in the body for a working lifetime and pose no reasonable expectation of health risk is referred to as the Maximum Permissible Body Burden (MPBB). The amount of internally deposited radioactive material is quantified as a percentage of the MPBB that has been established for the particular radionuclide. The MPBB is based on continuous exposure in a working lifetime, thus the MPBB must be interpreted with caution in an accident setting involving acute exposure. Annual Limit of Intake (ALI) is a newer term that is also used to quantify internally deposited radioactive material.

Radiation Monitoring Equipment

Common radiation monitoring equipment includes dosimeter and survey meters (Table 199-4). Dosimeters are small devices that are typically worn on the upper torso to record the cumulative amount of radiation an individual receives while wearing the device. Survey instruments are rate meters that record the amount of radiation detected in an area per unit of time.

Equipment Type	Device	Common Type of Measurement	Units Commonly Recorded
Dosimeter	TLD or film badge	Cumulative dose of beta, x, and gamma	Rem or Sievert
Dosimeter	Pocket dosimeter	Cumulative exposure to x and gamma	mR
Survey meter	GM tube	Low exposure rates of x, gamma, and beta	cpm*
Survey meter	Ion chamber	Higher exposure rates of x and gamma	mR/h

*2500 cpm is approximately 1 mR/h.

TABLE 199-4   Radiation Monitoring Equipment

PERSONAL DOSIMETERS   A thermoluminescent dosimeter (TLD), or film badge, is used to provide permanent records of cumulative-dose received. Most of these devices measure beta, x, and gamma radiation. The dose is recorded in rem or sievert. Dose measurements are not immediately available to the wearer because both of these devices require processing. Self-reading pocket dosimeters may be used in addition to TLDs. These devices provide immediate estimates of cumulative exposure of x and gamma radiation. Most pocket dosimeters can be directly read when held up to a light source. Estimates are typically recorded in milliroentgen (mR).

RADIATION SURVEY METERS   Ion chambers are common types of survey meters for recording exposure rates of x and gamma radiation. Some types of ion chambers are equipped to also detect beta radiation with a Mylar (Dupont) window beneath a removable shield. These instruments are usually calibrated in mR/h. Geiger-Müeller (GM) instruments are commonly used to perform surveys for external contamination. These instruments detect lower exposure rates of x and gamma radiation, as well as beta radiation. With special instrument probes, alpha radiation can also be detected. The units recorded are typically counts per minute (cpm). For comparison, 2500 cpm is approximately equal to 1 mR/h.

RADIATION ACCIDENT PREPARATION

Every EMS system should have a prehospital plan for the evacuation of victims from a radiation disaster. The scene is first evaluated for safety and containment of contamination, and radiation counters provided for prehospital personnel. HAZMAT is often the responsible agency. Scene safety must be assured before evacuation begins. Every hospital should have a written protocol detailing instructions for receiving and treating radiation accident victims. The initial medical evaluation and treatment of the victims often falls under the purview of the emergency physician, so that the emergency physician should take an active role in the development of the hospital's radiation accident plan. Several publications are available to provide specific detailed guidance for the development of an Emergency Department Radiation Accident Protocol, as well as prehospital management of radiation accident victims. [2,3]

Emergency Department Notification

Local facilities that may potentially refer a radiation accident victim to the emergency department should be identified in advance and instructed to provide as much advance notification of potential incidents as possible to allow adequate time for mobilization of resources and the physical preparation of the emergency department. When receiving notification of a radiation accident, the emergency physician should request information that will facilitate the necessary preparation for receiving and treating the patient. Useful information to obtain includes:

1. Circumstances of the accident
2. Number of victims
3. Medical condition and physical injuries of the victims
4. Type and extent of radiological insult: irradiated, externally contaminated, or internally contaminated
5. Identification of the radioactive material
6. Exposure to other hazardous material that may be chemically toxic or corrosive.

This notification should serve to activate the Emergency Department Radiation Accident Protocol. The protocol should clearly identify the members and individual responsibilities of the radiation emergency response team as well as the location and contents of the radiation emergency supply kit. Additionally, the protocol should include specific details for the physical preparation of the emergency department and staff that is necessary to safely receive and treat a radiation accident victim. Such preparations, outlined in Table 199-5, are time-consuming and should be initiated prior to the patient's arrival.

TABLE 199-5   Key Contamination Control Principles

Initial activation of the protocol should include requesting assistance from predetermined local radiation specialists and, ideally, health physics professionals. Radiation specialists may assist by monitoring radiation dose of personnel, surveying personnel and areas for contamination, directing contamination control and decontamination efforts, and disposing of contaminated wastes. If faced with a severe or extensive radiological accident, additional sources of assistance are provided at the end of this chapter.

Triage and Treatment Philosophies

Managing hazardous material accidents of *any* type requires health care providers to perform the following initial key actions:

- secure the safety of the accident scene
- provide lifesaving emergency care
- limit exposure to the hazardous substance
- contain the spread of the hazardous substance

Additional precautions are required when managing radiation accidents because, unlike hazardous material of other types, radiation can be detected only by monitoring devices. After scene safety is secured and emergent resuscitation and stabilization is provided, medical management of these patients must employ the use of protective equipment and monitoring devices. Practices of dose reduction, contamination control, and decontamination are necessary in order to protect the safety of patients, health care providers, and the environment.

Radiation accidents can be most effectively managed if the patients are separated into one of the following three situations: (1) externally contaminated patients, (2) internally contaminated patients, or (3) externally irradiated patients. Each patient type requires specific treatment considerations, which are discussed below and illustrated in Table 199-6. If there are multiple casualties, triage is based on the patient's acute medical condition. If all patients are medically stable, the order listed above is the suggested priority for providing treatment.

TABLE 199-6   Initial Medical Management of Radiation Accident Victims

CLINICAL PRESENTATION AND MANAGEMENT

Externally Contaminated Patients

A patient is externally contaminated when radioactive materials are physically deposited onto the patient's skin or clothing. All victims of radiation accidents should be handled as if contaminated until known otherwise. Upon arrival to the hospital, all patients should be surveyed for contamination. If radiation-monitoring devices are not available, patients should be routinely decontaminated and then surveyed for contamination when monitoring equipment is obtained.

The dose from external contamination to either the patient or the attending medical staff is rarely significant. Spreading the contamination in the environment and the potential of internalization are the main hazards with external contamination. Thus special precautions are required for receiving and treating these patients. The hospital's radiation response team should be trained in radiation monitoring and decontamination techniques. Specific contamination control principles and physical decontamination techniques are required for the care of these patients (Table 199-5 and Table 199-7).

TABLE 199-7   Key Decontamination Techniques

It is not immediately crucial to know the identity of the radionuclide, however it is important to determine whether the nuclide emits beta-gamma radiation and/or alpha radiation. Commonly used radiation survey meters easily detect beta and gamma radiation. Detection of alpha radiation requires special instrument probes and careful monitoring techniques. Alpha radiation is shielded by any moisture, including perspiration and blood. Therefore, only trained individuals should perform surveys for alpha-emitting contamination.

Internally Contaminated Patients

Radioactive material gains entry into the body by three principal routes: inhalation, ingestion, or absorption from contaminated mucous membranes or abraded skin. Misadministration of a radiopharmaceutical is a potential source of internal contamination that can occur in the hospital setting. Internal contamination becomes a major concern of the population if large amounts of radioactive material are released into the atmosphere as a result of nuclear weapon detonation, large-scale nuclear power plant accident, or even a volcanic eruption. Such events may result in inhalation of airborne radioactive material or ingestion of radioactive material deposited onto agricultural land with subsequent transfer into the food chain.

Internal contamination is medically significant because internally deposited radioactive material will continue to irradiate tissues until it decays to a stable isotope or is biologically eliminated. As with other types of radiation exposure, the dose received depends on the amount and energy of the radioactive material and the time exposed. Additionally, the route of intake into the body, the biochemical form, and the physical and biological half-life of the particular radionuclide affect the dose received from internal contamination. The biochemical nature of the radionuclide determines if it is disseminated throughout the body or concentrated in a specific

organ. The term critical organ is used to describe the organ that receives the highest dose of radiation or is the site of the most significant biological damage.

IDENTIFICATION AND MEASUREMENT   In contrast to external contamination, identification of the specific radionuclides that become internalized is important for determining the method of treatment. When the substance is not known, laboratory identification is possible. Internally deposited radionuclides are identified by radioanalysis of substances excreted from the body. Radiochemistry laboratories identify and quantify the specific radionuclides by analyzing swabs from nares, oropharynx, and wounds, as well as sputum, urine, and fecal specimens. This technique of internal dose assessment is referred to as an excretion method or bioassay measurement. Internal dose assessment by this method requires that all body excreta from internally contaminated patients be collected. The collection should continue for several days because repeated measurements are used to monitor the excretion rates of the contamination.

Radioactivity within the body can also be measured in vivo by a device called a whole-body counter. These detectors predominately measure gamma-emitting radiation and some high-energy beta radiation. Internalized alpha and lower-energy beta-emitting radiation do not escape from the body and are not detected by these devices. Whole-body counters are very sensitive and give false measurements if external contamination is present on the body. For this reason and because these detectors are not readily accessible, whole body counters are generally not practical in the acute setting of a radiation accident.

GENERAL TREATMENT   When the contaminating radionuclide is not known, radiochemical laboratory identification of radioisotopes may take several days. Prior to obtaining identification, methods can be initiated for removal of the most commonly encountered radionuclides that are suspected for the particular accident type. As with other hazardous material, treatment is aimed at reducing absorption or hastening elimination. After all swabs have been obtained, wounds should be irrigated with physiological saline.

Pulmonary clearance of inhaled radioactive particles is not effectively enhanced by medications. If large quantities of insoluble radioactive material have been inhaled, bronchopulmonary lavage may be considered. This treatment carries the associated risk of general anesthesia and is performed more commonly in Britain than in this country.

Reduction in gastrointestinal absorption may be accomplished with gastric lavage, emetics, and purgatives. Additionally, antacids containing aluminum cause many metals to precipitate as insoluble hydroxides. Cathartics can then be administered to decrease the transit time of these precipitants.

DECORPORATION TREATMENT   Once the radioactive material crosses into the extracellular fluid, incorporation has occurred and elimination is more difficult. Methods of decorporation include blocking agents, isotopic dilution, displacement, mobilizing agents, and chelation. Treatment with blocking agents reduces the uptake of a radioisotope at an organ or metabolic site by saturating the site with a stable form of the isotope. Isotopic dilution therapy involves administering large quantities of a stable form of the isotope, thus diluting the concentration of the radioisotope. In displacement treatment, a different but similar stable element is administered that will act as a competitor with the radioisotope for an uptake site. Mobilizing agents induce body tissues to release radioisotopes by increasing the natural turnover process. Chelating agents are organic compounds that provide an ion exchange matrix. The exchanging of inorganic ions results in stable nonionized ring complexes that can be excreted.

Frequently treated causes of internal contamination are radioactive forms of iodine, plutonium, cesium, and hydrogen (Table 199-8). Of particular importance and effectiveness are the treatments discussed below for radioiodine and alpha-emitting contamination such as plutonium.

TABLE 199-8   Commonly Treated Forms of Internal Contamination

RADIOIODINE   Inhalation or ingestion of radioiodine is particularly hazardous to the thyroid with a potential risk of causing hypothyroidism or thyroid cancer. I-131 is the predominant internal contaminate resulting from incidents that involve the release of nuclear fission products such as a nuclear reactor accident or nuclear weapons test. Studies on the health effects of the Chernobyl accident have shown that populations in heavily contaminated areas have an increase in thyroid cancer presumed to have resulted from radioiodine exposure. The number of thyroid cancers reported in these areas continues to increase, with the highest prevalence in individuals who were under the age of 10 years at the time of the accident. [4]

Rapid detection of radioiodine uptake is essential because treatment is most beneficial when administered within 12 hours. Radioiodine is a soluble nuclide that is detected in the urine immediately after exposure. Thus urine excretion measurements are used to provide early identification of radioiodine uptake. A more rapid, but less sensitive, method is direct measurement with a survey meter held over the thyroid gland.

Early administration of stable potassium iodine (KI) is recommended for high levels of accidental radioiodine exposure. Oral administration of 300 mg of stable iodine (390 mg of KI) within one hour of exposure is approximately 90 percent effective at blocking the thyroid uptake of radioiodine. KI administered six hours after exposure reduces thyroid uptake by approximately 50 percent. Little protective effect is seen when KI is given after 12 h of exposure. KI should be continued daily for 7 to 14 days to prevent recycling of radioiodine. [5] Administration of antithyroid medications, such as propylthiouracil or methimazole, may be considered if the time since exposure is more than 12 h.[6] In the event of widespread release of radioiodine, the FDA has approved the use of nonprescription KI. State and local officials are responsible for the procurement and distribution of KI to the general public.

ALPHA CONTAMINATION   Early treatment is recommended for contamination with alpha-emitting radionuclides such as Pu-239. Alpha radiation has a high LET with potential for significant damage when internally deposited. This internal contamination hazard is a result of alpha's deposition of large amounts of energy in a short range and thus causing intense ionization in a concentrated area. This potential damage is made worse by the fact that many of the radioisotopes that emit alpha radiation have very long half-lives.

Chelating agents such as calcium and zinc salts of diethylenetriamine pentaacetic acid (Ca-DTPA and Zn-DTPA, respectively) are effective treatments for contamination with heavy metals and rare earths that emit alpha radiation. If alpha-emitting contamination is detected in wounds or in the nares or oropharynx, treatment with DTPA should be initiated promptly, ideally within 1 to 2 h after contamination has occurred. Potential contraindications for the use of DTPA are severe renal dysfunction, thrombocytopenia, or leukopenia. DTPA is administered systemically by slow IV push or by aerosol administration. Ca-DTPA has been shown to be more effective in animal studies and is the preferred form of drug for the initial one to two days of treatment. Zn-DTPA is less toxic and recommended for treatments of longer duration and of pregnant females. For aerosol administration, Ca-DTPA is preferred because of the metallic taste associated with Zn-DTPA. Most DTPA solutions in nuclear medicine departments are a too dilute concentration for effective decorporation. DTPA for this purpose can be obtained from Oak Ridge Associated Universities, REACTS, Oak Ridge, TN 37831.

The success of decorporation techniques depends on early administration. The risks associated with therapy must be weighed against the risk of untreated internal radiation exposure. Assistance from expert consultants should be requested prior to beginning decorporation therapy.

Externally Irradiated Patients

Several general concepts are essential for understanding the radiation injury resulting from exposure to an external source:

1. An acute dose of radiation results in more biological damage than the same radiation dose delivered over a more protracted period of time.
2. Biological injury from radiation occurs at the time of exposure and the clinical signs and symptoms manifest over time.
3. The elapsed time from exposure to the onset of symptoms is inversely related to the radiation dose received.
4. Exposure to penetrating types of radiation (gamma, x-ray, and neutron) results in a whole-body dose. Acute high-level irradiation to a significant portion of the body may result in acute radiation syndrome. Partial-body irradiation may result in local radiation injury.
5. Nonpenetrating types of radiation, alpha and beta, do not deliver a whole-body dose.

Whole-Body Irradiation/Acute Radiation Syndrome

Characteristic and relatively predictable signs and symptoms develop when a significant portion of the body is exposed to a high level of penetrating radiation over a short period of time, typically less that 24 hours. [7] These signs and symptoms are collectively referred to as acute radiation syndrome (ARS) (Table 199-9). A whole-body gamma dose in excess of 2 Gy (200 rad) is the primary cause of acute radiation syndrome. Alpha and low-energy beta radiation lack sufficient energy to penetrate the skin and deliver a whole-body radiation dose. Neutron exposure is rare, but high-level neutron irradiation is also capable of producing ARS. Additionally, there are a few reports of ARS following significant amounts of internal radioactive contamination.

Approximate Dose	Onset of Prodrome	Duration of Latent Phase	Manifest Illness
>2 Gy (200 rad)	Within 2 days	1–3 weeks	Hematopoietic syndrome with pancytopenia, infection, and hemorrhage.
>6 Gy (600 rad)	Within hours	<1 week	GI syndrome with dehydration, electrolyte abnormalities, GI bleeding, and fulminant enterocolitis.
>20 Gy (2000 rad)	Within minutes	None	CV/CNS syndrome with refractory hypotension and circulatory collapse. Fatal within 24–72 h.

TABLE 199-9   Acute Radiation Syndrome

Four distinct phases are seen in the unfolding of ARS: prodromal phase; latent phase; manifested illness phase; and recovery phase or death. The prodromal phase is a transient period of self-limiting symptoms that may occur within minutes, hours, or days after exposure. The acuity of onset and the duration of this phase are directly related to the dose received. The prodromal phase is an autonomic nervous system response that initiates gastrointestinal symptoms such as anorexia, nausea, vomiting, and, with high doses, diarrhea. In addition, neuromuscular symptoms often accompany the autonomic response and may include hypotension, pyrexia, diaphoresis, cephalgia, and fatigue. The latent phase is a symptom-free interval that follows the resolution of the prodromal phase. Shorter latent phases correspond to higher levels of dose received. The latent period may last 1 to 3 weeks with a dose of less than 4 Gy (400 rad), but the latent period may last only a few hours when a dose above 15 Gy (1500 rads) is received.

The manifest illness phase is often divided into three dose-dependent subsyndromes. In ascending order of severity, these syndromes are clinically related to injury of the hematopoietic, gastrointestinal, and cardiovascular/central nervous systems. The toxic effects to these organ systems are not discrete. There is considerable overlap as well as additive detrimental effects among these syndromes.

HEMATOPOIETIC SYNDROME   The hematopoietic system is the first organ system to manifest injury from whole-body irradiation and symptoms are seen from doses above 1.5 to 2 Gy (150 to 200 rad). Self-limiting prodromal symptoms begin within several hours or days and typically resolve within 48 hours. An asymptomatic latent period follows and typically lasts for one to three weeks. Radiation destroys circulating lymphocytes and damages stem cells in the bone marrow and lymphatic system. The rapid decline in lymphocytes is a hallmark of the hematopoietic syndrome and is one of the best early indicators of the extent of radiation injury. Granulocytes, and to a lesser extent, platelet counts, display an initial rise followed by an accelerated decrease reaching a nadir at about 30 days. The red blood cell population also decreases in concentration with resultant mild anemia, but to a lesser extent than other blood cell lines. The kinetics of blood cells are discussed below in more detail in reference to dose estimation. The effects of this syndrome result in pancytopenia and immunosuppression with subsequent hemorrhage and infection as the principal causes of morbidity and mortality. Survival is possible with extensive medical intervention.

GASTROINTESTINAL SYNDROME   At doses higher than those resulting in the hematopoietic syndrome, toxicity to the gastrointestinal tract occurs. Gastrointestinal syndrome is the second subsyndrome of the manifest illness phase of ARS and may occur after doses above 6 to 7 Gy (600 to 700 rad) are received. This syndrome is distinguished from the hematopoietic syndrome by the onset of nausea, vomiting, and, often, diarrhea within hours after exposure. These prodromal symptoms are followed by a short latent period of one week or less. Reappearance of gastrointestinal symptoms then occurs with severe nausea, vomiting, diarrhea, and abdominal pain. There is damage of the intestinal mucosal barrier with massive fluid losses resulting in profound dehydration and electrolyte disturbances. The denuded gastrointestinal mucosa allows enteric flora to disseminate into the bloodstream. Declines in blood cell populations are similar to that which occurs with the hematopoietic syndrome, but abnormalities occur sooner and with greater magnitude. With the concurrent immunocompromised state, a fulminating enterocolitis follows. There are few documented cases of gastrointestinal syndrome in humans, all of which resulted in fatalities.

CARDIOVASCULAR AND CENTRAL NERVOUS SYSTEM SYNDROME   The cardiovascular and central nervous system syndrome is the third subsyndrome of the manifest illness phase of ARS that occurs after doses above 20 to 30 Gy (2000 to 3000 rad) are received. This syndrome presents with immediate prostration, nausea, vomiting, explosive, bloody diarrhea as well as hypotension. Alterations in consciousness including lethargy, disorientation, ataxia, tremors and convulsions occur within hours after exposure. Hypotension is persistent and refractory to treatment. This syndrome is universally fatal with death occurring within 24 to 72 hours, predominantly due to circulatory collapse. The lymphocyte count promptly falls to near-zero levels. Granulocytosis develops early and persists until death.

In addition to these organ system injuries of the manifest illness syndromes, radiation doses above 8 to 9 Gy (800 to 900 rad), may damage the pulmonary system with resulting pneumonitis, fibrosis, and interstitial edema. [8]

DOSE ESTIMATION   If the patient was not wearing a personal dose monitor (dosimeter) at the time of the accident, estimations of dose can be calculated from the circumstances of the accident. The dose received is a function of the individual's proximity to the source, the type and energy of the particular source, as well as the duration of exposure and extent of shielding. This information may not be available at the time of the patient's presentation to the emergency department and estimates of the radiation injury received must be obtained by assessing physical symptoms and laboratory data.

Hematological Data for Estimating Radiation Injury   The earliest laboratory indicator of biological damage from radiation is a marked decrease in peripheral lymphocytes, often within eight hours postexposure. The more precipitous the decline in lymphocytes, the greater the dose received. (Fig. 199-1). The lymphocyte count 24 hours postexposure is useful in predicting the patient's clinical course. If the lymphocyte count is maintained above 1200/μL, no clinical support is required. If the count falls below 500/μL, a severe clinical course can be anticipated. If the entire lymphocyte count is depleted within six hours, a fatal outcome is likely.
FIG. 199-1. Estimated radiation dose and degree of injury from early changes in lymphocyte counts. Approximate whole-body dose: Curve A—3.1 Gy (310 rad); Curve B—4.4 Gy (440 rad); Curve C—5.6 Gy (560 rad); Curve D—7.1 Gy (710 rad). (Reproduced from *Health Physics* 72:514, 1997 with permission from the Health Physics Society. Figure has been modified from its original version.)

Because circulating lymphocytes are very radiosensitive, dose estimation by lymphocyte count is less reliable with doses above 3 Gy (300 rad) and more accurate estimates can be obtained from the granulocyte pattern. In contrast to lymphocytes, circulating granulocytes are not directly killed by radiation. However, damage to blood progenitor cells in bone marrow results in a later decline in the granulocyte population. A transient increase in peripheral granulocytes is seen immediately after exposure due to a stress-related release of granulocytes from the bone marrow stores into the peripheral circulation. Granulocytopenia occurs after these stores are mobilized and then localize in radiation damaged tissues, reaching a nadir at about 30 days after exposure. Granulocytes may show a transient rise about 10 to 15 days postexposure when damaged stem cells begin proliferation but die before reaching their full reproductive capability. Absence of this transient rise in granulocyte numbers indicates exposure above 5 Gy (500 rad) and is a poor prognostic sign. [9]

Platelet counts may slightly increase in the first few days after exposure and then fall to a nadir at about 30 days. The red blood cell population shows a milder decrease in concentration with resultant mild anemia. The decrease in the red cell line is less pronounced than other hematopoietic cells and reflects the red cells' longer life span in the peripheral circulation (Fig. 199-2).
FIG. 199-2. Typical hematological course and clinical stages after sublethal (~300 rad) exposure to total body irradiation. (Reprinted with permission from *Radiobiological Factors in Manned Space Flight,* copyright 1965 by the National Academy of Sciences. Washington, DC, National Academy Press, 1965.)

Dose Estimation by Cytogenetic Analysis   Cytogenetic analysis of circulating lymphocytes is another method of dose estimation. Radiation induces some characteristic chromosome aberrations, particularly rings and dicentrics, in a dose-dependent manner. The frequency of these abnormalities can be scored in cytogenetic laboratories to obtain estimates of radiation dose received. This process is technically challenging, time-consuming, and expensive but is the most sensitive biological measurement for quantifying dose from whole-body irradiation. [9]

Clinical Symptoms for Estimating Radiation Injury   The absence or time of onset of nausea and vomiting are useful for assessing the injury severity. Diarrhea is a less useful symptom unless there is prompt, explosive, bloody diarrhea, which indicates a likely fatal outcome. Individuals who have received doses less than 1 Gy (100 rad) seldom experience nausea or vomiting. Less than 1 Gy is a reliable dose estimate for individuals who remain asymptomatic 24 hours postexposure; hospital admission for these individuals is generally unnecessary. [10]

LETHAL DOSE   The LD50/60 from exposure to ionizing radiation is defined as the dose of penetrating ionizing radiation that will result in the deaths of 50 percent of the exposed population within 60 days. Three values are commonly cited for human survival. The most commonly cited value is LD50/60 of approximately 4.5 Gy (450 rad). This value assumes intensive medical therapy is provided, including antibiotics, blood products, and reverse isolation. With only minimal treatment, such as basic first aid, the LD50/60 falls to approximately 3.4 Gy (340 rad). Victims of the Chernobyl nuclear accident have demonstrated that humans can survive radiation doses greater than anticipated. Intensive medical support to Chernobyl victims provided a high survival rate in individuals receiving less than 6 Gy (600 rad). With newer advances in medical treatment, such as stem cell transplantation and cytokine administration, it may be possible to raise the LD50/60 to 11 Gy (1100 rad). [11]

TREATMENT OF WHOLE-BODY IRRADIATION   The patient who has only been exposed to an external source of penetrating radiation is not radioactive or contaminated and therefore requires no special precautions for handling or treating. A rare exception is exposure to high-level neutron irradiation, which can induce radioactivity. In the unlikely event of a criticality accident, neutron exposure becomes a concern. Patient specimens of blood and urine should be collected and assayed for induced radioactivity in the body, predominately Na-24. In addition, all metal objects on the patient's body or clothing should be monitored for potential radioactivity, including jewelry, coins, dental fillings, wristwatches, and buttons.

Initial treatment of the irradiated patient is directed toward alleviating the symptoms of the prodromal phase and may include the use of antiemetics and anxiolytics. Pain management may be required if there is associated trauma. Medical treatment has been unsuccessful in the few documented cases of high radiation doses that cause major damage to the GI or CV/CNS systems. Survival is possible for individuals with lower radiation doses resulting in the hematopoietic form of ARS.

The ultimate treatment goal is to provide support during the period of deficient defenses against infection and hemorrhage until marrow recovery occurs. Supportive treatment may include IV fluids, blood products, and total parenteral nutrition, as well as reverse isolation, prophylactic antibiotics, and antifungal medications. The patient, as well as family members who may be potential blood donors, should undergo HLA typing in preparation of white cell and platelet transfusions if marrow suppression becomes severe. The most severe marrow depression occurs at two to three weeks after exposure. Spontaneous recovery of granulocytes and platelets is quite rapid after the fifth week.

Bone marrow transplantation may be considered for patients who have received doses above 8 or 9 Gy (800 to 900 rad). [12] Bone marrow transplantation is advocated only for patients who are likely to die from radiation-induced myelosuppression if they have a well-matched donor and do not have irreversible damage to other major organ systems. Transplantation was provided for 13 victims of the Chernobyl accident who had received a dose greater than 5.6 Gy (560 rad). Within the following 3 months, 11 of these 13 patients died. The causes of these deaths were multifactorial and included graft-versus-host disease, burns, traumatic injury, radiation pneumonitis, ARDS, and renal and hepatic failure.

Other treatment modalities for myelosuppression that do not carry a risk of graft-versus-host disease are being studied. The administration of hematopoietic growth factors is currently under intense clinical investigation. Hematopoietic growth factors are cytokines such as erythropoietin, interleukins, and colony-stimulating factors. These proteins have been shown to stimulate the proliferation and differentiation of the surviving stem cells and thus accelerate reconstitution of the bone marrow. These growth factors are most efficacious in animal models when administered immediately after irradiation and demonstrates the importance of early dose

estimation. Patients in whom the estimated dose is high enough to cause severe marrow damage may benefit from prompt administration of these growth factors.

Obtaining data and specimens for dose estimation is therefore a crucial aspect of planning therapy and predicting the patient's clinical course. The time of onset of all clinical symptoms should be carefully observed and documented. Serial blood specimens should be obtained for hematological and cytogenetic dose assessment.

If significant radiation dose was received, the patient should have long-term periodic follow-up for potential delayed effects of radiation damage such as cataracts, infertility, thyroid dysfunction, leukemia, or other neoplasms.

Local Radiation Injury

The majority of radiation accidents in the United States result in local radiation injury from partial-body exposure. In contrast to whole-body irradiation, partial-body irradiation rarely causes systemic manifestations. A rare exception is the development of ARS following partial-body irradiation that affects a significant amount of the bone marrow. Most commonly, a portion of the extremities is affected and the clinical picture consists of cutaneous changes.

Local radiation injury from doses above 2 to 3 Gy (200 to 300 rad) may result in erythema with associated hyperesthesia and itching. These signs occur within hours after exposure and are transient. Depending on the dose received, the erythema may reappear. Early onset of the initial erythema and quick reappearance of erythema correspond to higher doses. With doses below 3 Gy (300 rad), the erythema may not reappear. Doses of 6 Gy (600 rad) result in reoccurrence of significant erythema in 1 to 3 weeks. Much higher doses may result in prompt and persistent erythema.[10]

Other cutaneous changes resulting from local radiation injury include epilation, desquamation, and necrosis. Epilation or alopecia begins within 2 to 3 weeks after doses of 3 Gy (300 rad) are received. Epilation may be complete after doses above 5 Gy (5 rad) and may be permanent after doses above 6 Gy (600 rad). Doses of 12 to 15 Gy (1200 to 1500 rad) result in dry desquamation within 2 to 3 weeks. Doses in excess of 25 Gy (2500 rad) result in wet desquamation, blistering bulla, and ulceration within 3 to 5 weeks. Radionecrosis is seen after doses above 50 Gy (5000 rad). [13]

These skin manifestations may appear similar to thermal burns. However, unlike thermal burns, cutaneous radiation injury may be associated with waves of transient erythema described above, as well as with a delayed onset of pain, followed by a more prolonged and severe pain. Another important distinction of radiation injury is that the clinical changes evolved over a more prolonged time period. The exception is very high doses on the order of 50 Gy (5000 rad) that result in prompt transdermal injury resembling a thermal third-degree burn. The pain is immediate and excruciating. Surgical resection and grafting may be required.

Emergency department care of cutaneous radiation injury is limited to analgesics, routine burn care, and, if indicated, surgical referral. Physical therapy and splinting may be useful for preventing contractures and preserving joint range of motion. These patients must be carefully monitored for hemorrhage, infection and necrosis. In addition, prolonged observation is needed for later neoplastic changes of the skin.

Prenatal Exposures

When a pregnant female is exposed to ionizing radiation special consideration must be given to the radiosensitive unborn child. [14,15] Fetal cells are largely undifferentiated and highly proliferative and thus have increased radiosensitivity depending on the phase of gestation (Fig. 199-3). At 0 to 2 weeks postconception, there is an all-or-none phenomenon. Irradiation during this time usually results in death with resorption of the conceptus or no observable damage. This phenomenon is a result of the pluripotential of the early blastomeres that allows injured cells to be replaced by remaining cells when the damage is not extensive. After two weeks gestation, organogenesis begins and the embryo is at risk of congenital malformations. The risk of injury is greatest for the particular organ system that is under development at the time of radiation exposure. After seven weeks, the fetal period begins. Major organogenesis is complete, with the exception of the CNS. The CNS has continued susceptibility to radiation injury during the early fetal period. [15]
FIG. 199-3. The various adverse effects associated with radiation and their relative incidence at different stages of gestation. (Reprinted with permission from *Medical Effects of Ionizing Radiation,* 2d ed. Philadelphia, WB Saunders, 1995.)

Data of radiation-induced anomalies in humans has been derived from Japanese atomic bomb survivors who received radiation exposure in utero. The most common injuries are related to the CNS, particularly microcephaly and mental retardation. Other malformations, such as growth retardation and ocular defects, have been reported less frequently. Radiation exposure during 8 to 15 weeks' gestation correlates with the most significant CNS injury. This increased radiosensitivity is due to the extensive proliferation and migration of neuronal cells at this time. [15] Both human and animal studies indicate that a minimum fetal exposure of 0.1 to 0.2 Gy (10 to 20 rad) is required for injury.[15] Official agencies, including the National Council on Radiation Protection (NCRP), recommend that the dose to an unborn child be limited to 500 millirem (5 milliSv). [16] Below this limit, the risks to the unborn child exposed with radiation do not exceed the baseline rate of birth defects seen in infants not exposed to radiation.[17]

If a fetal dose is above 500 millirem (5 milliSv), particularly during the vulnerable period of 8 to 15 weeks' gestation, risks such as CNS damage or growth defects, must be considered. In such a case, a physician with expertise in radiation injury should be consulted to provide counseling to the expecting parents.

DOSE REDUCTION TECHNIQUES

When working in a radiation area, the dose received is decreased by three principal means: shielding the radiation source, minimizing the time in the radiation area, and increasing the distance from the radiation source. The exposure rate in an area decreases by the square of the distance from the source. This concept is referred to as the inverse square law and is a very effective technique of dose reduction. For example, increasing the distance from the source by a factor of 4 decreased the exposure rate by a factor of 16.

SOURCES OF ASSISTANCE

Emergency department personnel should be familiar with authorities that can provide advice and assistance when radiation accidents occur. Radiation emergency call lists may be prepared in advance and include the following contacts:

1. Local facilities which staff medical and health physics professionals trained in radiation accidents.
2. Local civil defense or disaster offices.
3. State radiological health office (title may vary by state).
4. Federal Emergency Management Agency (FEMA)
5. US Department of Energy (DOE). Seven assets of DOE are dedicated to radiological emergency response: Aerial Measuring System (AMS), Atmospheric Release Advisory Capability (ARAC), Accident Response Group (ARG), Federal Radiological Monitoring and Assessment Center (FRMAC), Nuclear Emergency

Search Team (NEST), Radiological Assistance Program (RAP), and Radiation Emergency Assistance Center/Training Site (REACTS). These assets provide expert technical support throughout the U.S. in response to radiation accidents, nuclear weapons incidents, lost or stolen radioactive materials, or acts of nuclear terrorism.

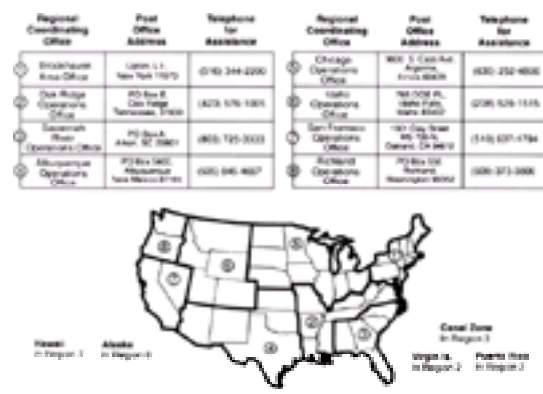
RAP has 8 regional coordinating offices that provide assistance in preparing for radiological emergencies and provide radiological assessments of accidents (Fig. 199-4).


FIG. 199-4. Regional coordinating offices for Department of Energy Radiological Assistance Program. (Courtesy of the United States Department of Energy Regional Coordinating Offices.)

REACTS is the medical asset of DOE Radiological Emergency Response that provides training programs, consultation assistance, and treatment capabilities. REACTS has the capability to dispatch an emergency response team of health professionals to assist at an accident site. After initial treatment and decontamination actions are complete, REACTS may also accept severely contaminated or irradiated patients for transfer to its facilities for more definitive care. REACTS daytime phone is (423) 576-3131. REACTS 24-hour emergency number is (423) 481-1000.

200 MUSHROOM POISONING

Sandra M. Schneider
Anne Brayer

Mushrooms are one of the more common toxic exposures, with over 12,000 mushroom exposures reported to poison centers in 1996, or roughly 5 for every 100,000 population.[1] Over 95 percent of these ingestions were unintentional, with nearly 70 percent occurring in children under the age of 6. Most ingestions resulted in little or no gastrointestinal (GI) toxicity.

Depending on the type of mushroom, adverse effects from ingestion range from mild GI symptoms to major cytotoxic effects resulting in organ failure and death. Toxicity may also vary based on the amount ingested, the age of the mushroom, the season, the geographic location, and the way in which the mushroom has been prepared prior to ingestion. Individuals also vary in their response to any given mushroom ingestion, so that one person may show significant effects while others may be asymptomatic ingesting the same mushroom (Table 200-1).

TABLE 200-1   Mushrooms: Symptoms, Toxicity, and Treatment

Mushroom toxicity is divided into early toxicity (within 1 h after ingestion) and delayed toxicity (6 h to 20 days). In general, if toxicity begins within 2 h of ingestion of a mushroom, the clinical course will most likely be benign. If symptoms begin 6 h or later after ingestion, however, in general the clinical course will be more serious and potentially fatal. Nearly all fatalities in the United States occur from the ingestion of the *Amanita* species (*Amanita phalloides, Amanita virosa,* and *Amanita verna*).

Mushroom poisoning occurs among four main groups of individuals: young children who ingest mushrooms inadvertently, wild-mushroom foragers, individuals attempting suicide or homicide, and individuals looking for a hallucinatory "high." Identification of the mushroom ingested may be difficult and time consuming. In all cases, treatment should be directed by a patient's symptoms rather than by attempts at mushroom identification. Very often, foragers will mix different species of mushrooms together, so it is not always clear that the species being identified is the same one that was ingested. Treatment of the patients should always be based on presenting symptoms.

Identification of the *Amanita* species may be helpful; however, there are many *Amanita* mushrooms that are nontoxic. *Amanita* species generally have warts on the cap (remnants of the membrane covering the emerging mushroom), which often give it a spotted appearance. The gills are "free," ending before the stem begins. The stem characteristically has a membrane ring around it and widens as it enters the soil. In most cases, the stem of the mushroom is contained in a cup or volva, which may be underground.

This chapter deals with each of the major toxic groups separately, as their toxicity, clinical features, and treatment vary significantly.

EARLY-ONSET GASTROINTESTINAL SYMPTOMS

Pathophysiology

The most commonly ingested toxic mushrooms are those that cause GI irritation. These mushrooms can be of many types. In North America, *Chlorophyllum molybdites* is particularly common and is sometimes mistaken for an *Amanita.* Many of the so-called little brown mushrooms (LBMs) found commonly in lawns, and often accidentally ingested by children, are in this category. The actual toxin varies with the species of mushroom, but most toxins are poorly described.

Clinical Features

Typically, patients will present with acute onset of vomiting and diarrhea less than 2 h after ingesting the mushroom. There may be intestinal cramping, chills, headaches, and myalgias. The diarrhea is usually watery, but occasionally may be bloody, with fecal leukocytes. Most commonly, symptoms are mild and self-limited. Infrequently, the vomiting and diarrhea may lead to significant dehydration and electrolyte imbalance. The history of ingestion is frequently offered by the patient, but in cases where it is not, the presentation may be confused with acute gastroenteritis or acute food poisoning.

Treatment

General treatment for toxic mushroom ingestion includes GI decontamination. Activated charcoal (0.5 to 1.0 g/kg orally or via nasogastric tube) is indicated for all ingestions unless toxic species can be ruled out. Treatment for ingestion of GI irritants is largely supportive, including IV fluid and electrolyte replacement when necessary. Judicious use of antiemetics is probably justified, but antidiarrheal agents are best withheld, because they may prolong the exposure to the toxin.

In most cases, the illness is self-limited, with symptoms resolving within 12 to 24 h. Rarely, symptoms may persist and hospitalization may be indicated for fluid and electrolyte replacement.

EARLY-ONSET NEUROLOGIC SYMPTOMS

Pathophysiology

There are several classes of mushrooms that can cause neurologic symptoms. These include the hallucinogenic mushrooms ("magic" mushrooms) that are intentionally ingested for their mind-altering qualities. These mushrooms contain psilocybin or psilocin toxins, which are neuroactive chemicals similar to lysergic acid diethylamide (LSD). They act on serotonin-dependent neurons in the central nervous system (CNS), causing effects similar to those of LSD. Mushrooms from the *Psilocybe* genus, which are the most commonly ingested in this class, are small brown mushrooms that commonly grow on dung in warmer climates and often turn a greenish blue when bruised or cut. They may also be cultivated at home from purchased spores. Nontoxic mushrooms may also be laced with phencyclidine (PCP) or LSD and sold as hallucinogenic mushrooms.

Clinical Features

The clinical symptoms usually present within 2 h of ingestion, with euphoria, a heightened imagination, a loss of time sensation, and visual distortions or hallucinations. There may be tachycardia and hypertension. Fever and seizures have rarely been reported. Symptoms typically last 4 to 6 h. There are infrequent reports of patients suffering from flashbacks for up to 4 months after ingestion.

Treatment

Treatment should be largely supportive. Placing the patient in a darkened quiet room, devoid of visual stimuli, and providing reassurance are often sufficient. If sedation is required, benzodiazepines such as diazepam (0.1 mg/kg for children and 5 mg for adults, administered intravenously) are preferred to phenothiazine derivatives because the latter can lower seizure threshold.

EARLY-ONSET ANTICHOLINERGIC SYMPTOMS

Pathophysiology

Mushrooms containing the isoxazole derivatives, ibotenic acid and muscimol, are known for their neurologic effects. *Amanita muscaria* is an easily identified member of this group. It has an orange or red cap with white warts (remnants of the universal veil present in young specimens) as well as a ring (annulus) and cup (volva) on the stem. *Amanita pantherina,* another member of the group, is 5 to 14 cm in length and diameter, with a white to brown cap and with the ring and cup on the stem. Both specimens grow under trees in woodlands throughout North America.

Clinical Features

Patients ingesting these mushrooms usually present with symptoms within 30 min of ingestion. Most commonly, the symptoms are anticholinergic, including tachycardia, hypertension, warm, dry skin and mucous membranes, and mydriasis. Dizziness, mild intoxication, ataxia, and difficulty with size, time, and place perceptions are common. Much less commonly, patients may present with cholinergic symptoms, including salivation, lacrimation, urination, defecation, GI hypermotility, and emesis. Seizures have been reported in children. Symptoms are typically self-limited, resolving within 3 to 4 h after ingestion.

Treatment

Treatment begins with GI decontamination. Syrup of ipecac may be appropriate if it can be administered within 30 to 60 min of ingestion, but caution is advised due to the potential for CNS depression and seizures. Activated charcoal administration is advised in most cases. In patients with significant vomiting and diarrhea, fluid and electrolyte replacement may be necessary. Patients who are agitated should be appropriately restrained. Sedation may be provided as necessary with benzodiazepines (diazepam or lorazepam) or phenobarbital. Seizures have been successfully treated with benzodiazepines.

For patients with severe anticholinergic symptoms, treatment with physostigmine may be considered. Physostigmine has been known to produce bradycardia, hypotension, and seizures, so administration should be reserved for severely symptomatic patients. The dosage is 1 to 2 mg IV slowly in adults and 0.5 mg in children. Patients should have continuous cardiorespiratory and blood pressure monitoring during administration. In the rare patients with cholinergic symptoms, administration of IV atropine may be considered (0.5 to 1 mg for adults and 0.01 mg/kg for children). Dosage should be titrated to clinical effect, using drying of pulmonary secretions as the end point. Atropine has been shown to cause worsening of CNS symptoms in patients who ingest isoxazole derivatives, so administration should be reserved for patients with severe cholinergic symptoms.

EARLY-ONSET MUSCARINIC SYMPTOMS

Pathophysiology

Mushrooms containing muscarine cause neurologic symptoms and muscarinic or cholinergic effects. The symptoms are characterized by the SLUDGE syndrome, with salivation, lacrimation, urination, defecation, GI hypermotility, and emesis. Mushrooms of the *Inocybe* and *Clitocybe* genus are common causes of muscarinic poisoning. The *Inocybe* mushrooms are small brown mushrooms with conical caps, typically found under hardwoods and conifers. The *Clitocybe* mushrooms are usually found individually on lawns and in parks, and are white to gray, with a cup-shaped cap. *Amanita muscaria,* despite its name, contains far less muscarine than these other families and only rarely causes cholinergic poisoning symptoms.

Clinical Features

In addition to the SLUDGE syndrome, patients with muscarine ingestions can present with diaphoresis, muscle fasciculations, miosis, bradycardia, and bronchorrhea. Symptoms typically present within 30 min of ingestion and spontaneously resolve in 4 to 12 h.

Treatment

In most cases, symptoms are mild and self-limited. Supportive care is often sufficient. Because emesis is a common presenting symptom, activated charcoal administration is often difficult. Patients with severe vomiting may require IV fluid and electrolyte replacement.

Atropine is an antidote for muscarinic symptoms and can be administered in severe cases. It can be effective in treating bradycardia and hypotension unresponsive to

IV fluids. Atropine is helpful in the treatment of diaphoresis, increased oral secretions, and bronchorrhea. It may also help reduce GI cramping, emesis, and diarrhea. The dose is 0.5 to 1.0 mg for adults and 0.01 mg/kg for children, administered intravenously. The dose can be repeated as necessary to control bronchorrhea, bradycardia, or hypotension. Large doses may be necessary to treat severe toxicity. Patients should be carefully monitored during administration. Oxygen and inhaled b agonists (albuterol or metaproterenol) are recommended for the treatment of patients with increased pulmonary secretions and bronchospasm.

DELAYED GASTROINTESTINAL SYMPTOMS

Pathophysiology

Two different mushrooms, *Gyromitra* and *Amanita,* cause significant toxicity, which characteristically presents several hours after ingestion. *Gyromitra esculenta* (the false morel) grows primarily in the spring in North America and is found in several other European countries. It has a brown convoluted top resembling a brain and is often mistaken for the tasty morel mushroom. Gyromitrin (*N*-methyl-*N*-formylhydrazone) is a volatile heat-labile toxin and primarily responsible for symptoms. Parboiling the mushroom can partially eliminate the toxin. Gyromitrin is hydrolyzed in the stomach to form *N*-methyl-*N*-formylhydrazine (MFH) and ʌ-methylhydrazine (MH). MH is chemically identical to rocket fuel, and workers exposed to MH develop CNS toxicity. MH binds to pyridoxine and thus interferes with enzymes that require pyridoxine as a cofactor. g-Aminobutyric acid (GABA) is lowered in the CNS, which may be a possible etiology for the seizures. MFH is converted into a free radical in the liver and causes local hepatic necrosis by blocking the activity of the P-450 system, glutathione, and other hepatic enzyme systems. [2] These two chemicals explain the CNS and hepatic dysfunction characteristic of gyromitrin toxicity. The etiology of the initial GI symptoms remains obscure.

Amanita phalloides, Amanita virosa, and *Amanita verna* commonly occur in the Northern Hemisphere and are particularly common in North Central Europe. Mushrooms of this species are found throughout the West Coast, Midwest, and in parts of the Northeast. Immigrants may mistake these mushrooms for edible varieties common in Eastern Asia. Mushrooms of the *Amanita* species are responsible for 95 percent of deaths associated with mushrooms.

Amanita phalloides contains several amatoxins and phallotoxins. Phallotoxins are bicyclic peptides that inactivate F-actin. Although this action has been of interest to basic scientists, phallotoxins do not appear to be active in human toxicity. Amatoxins are bicyclic octapeptides that are rapidly absorbed through the intestinal mucosa, carried to the liver, and undergo enterohepatic circulation. Recent human kinetic data show that a amanitin is cleared from the plasma within 48 h. [3] Concentrations in the plasma are quite small; amatoxins are not protein bound but actively transported into hepatocytes where they bind to RNA polymerase II and inhibit the formation of messenger RNA.[4] Some literature regarding studies with animals suggests that free radical formation may also be involved in toxicity. [5] Pathologic evidence of nuclear fragmentation and condensation of chromatin occur within 24 h.

Amanita virosa also contains five distinct virotoxins, which like phallotoxins do not appear to have clinical significance in humans because they are not absorbed from the GI tract. *Lepiota* mushrooms contain a high concentration of amatoxin (higher than *Amanita phalloides*) and have recently been described as causing symptoms identical to those seen with *Amanita phalloides.*[6]

The diagnosis of gyromitrin toxicity is generally assumed from the clinical features and the identification of the mushroom, either by the patient or from samples. Identification of *Amanita* species generally requires a trained mycologist. The Meixner colorimetric test is used to look for the presence of amatoxin. Although it is sensitive, it is not very specific, as other nontoxic mushrooms may test positive. Thin-layer chromatography, high-performance liquid chromatography, and radioimmunoassay have been developed to detect amatoxin. Amatoxin can be detected in plasma, urine, GI contents, and feces. However, its presence merely confirms amatoxin poisoning. Levels do not appear to correlate with clinical severity, and many patients do not have amatoxin detected, presumably because of rapid clearance.

Clinical Features

The distinct characteristic of these mushrooms is the onset of intense GI symptoms (nausea, vomiting, and diarrhea) 6 to 24 h after ingestion. At least with the *Amanita* species, the later the onset of the GI symptoms, the milder is the disease. After resolution of the initial GI symptoms, patients may develop hepatic injury.

Patients who ingest a gyromitrin-containing mushroom typically have a delayed onset of GI symptoms, which appear 6 to 8 h after ingestion. Initial GI symptoms are accompanied by neurologic symptoms, including dizziness and headache. In a mild ingestion, patients will have neurologic symptoms for several days and recover without difficulty. In severe cases, however, hepatic failure becomes symptomatic on day 3 and may result in death by as soon as day 7. Hypovolemia is common in the first phase of toxicity. Hypoglycemia occurs during the GI phase and again in the acute hepatic failure phase. Seizures, lack of coordination, and muscle cramps may occur.

Patients who ingest amatoxin-containing mushrooms also have delayed onset of GI symptoms (6 to 24 h). The gastroenteritis is intense, often requiring fluid and electrolyte replacement. Hypovolemia and hypoglycemia are quite common during the early GI phase. The gastroenteritis generally subsides after 12 h, and patients may again feel well. Hepatic failure becomes symptomatic on day 3 or 4, and death may follow as soon as day 7. Patients rapidly develop jaundice and right upper quadrant pain, and may develop a decreased level of consciousness, an elevated ammonia level, and cerebral edema. Liver enzymes, bilirubin, and prothrombin time rapidly become abnormal. Renal failure occurs either as a direct result of the toxin or as part of the hepatorenal syndrome.

In both toxicities, serum transaminases begin to increase 36 to 72 h after ingestion. Levels may be quite elevated. Prothrombin time may be elevated and unresponsive to vitamin K or fresh frozen plasma replacement. Amylase and lipase elevation suggests acute pancreatitis, although symptomatic pancreatitis is rare. Abnormal laboratory test findings in amatoxin poisoning include a decrease in neutrophils, lymphocytes, and platelets, and abnormal thyroid function. Hypophosphatemia (primarily noted in children), hypocalcemia, and elevated insulin levels occur. None of these laboratory abnormalities correlate with clinical disease, and their cause is unknown.

Pathologic changes are well described. Patients who ingest gyromitrin show diffuse hepatocellular damage and interstitial nephritis. Patients who ingest amatoxins show fatty degeneration of the liver, with intranuclear collection of lipids and extensive hepatic necrosis. Electron microscopy shows vacuolization of the mitochondria and clumping of the chromatin in the nucleoli. There are extensive lipid peroxidation changes in both the nucleus and the cytoplasm.

Several cases of mushroom toxicity during pregnancy have been reported. Aside from a slightly lower birth weight, compared with normal controls, all of these pregnancies have been completed without difficulty. [7] The babies appeared to be healthy and neurologically normal. This is in keeping with the findings that amatoxin do not cross the placental barrier.

The mortality rate from *Gyromitra* ingestion is estimated at 15 to 35 percent. Although, historically amatoxin hepatic failure had a mortality rate as high as 50 percent, more recently mortality has been reduced to 10 to 15 percent, based on improved care for hepatic failure. Liver transplant is often successful in patients with fulminant hepatic failure.

Patients who survive severe hepatic failure from amatoxin may develop signs of chronic active hepatitis with persistent elevation in liver transaminases, development of anti-smooth muscle antibodies, and cryoglobulins; the long-term consequences are unclear. No prolonged effects from gyromitrin toxicity have been reported.

Treatment

Most patients present with GI symptoms. Initial symptoms are severe vomiting and diarrhea. If a patient presents within a few hours of ingestion, gastric decontamination is indicated. Repeated doses of charcoal may be effective, particularly in the presence of amatoxin (as it undergoes enterohepatic circulation), at least for the first 24 h, but no clinical studies have shown the efficacy of charcoal for gyromitrin or amatoxin. Fluid and electrolyte replacement is mandatory. Glucose should be monitored and replaced, if necessary. Hypoglycemia still represents one of the most common causes of death in early mushroom toxicity.

All patients who have ingested amatoxin- or gyromitrin-containing mushrooms should be closely monitored for 48 h for the development of hepatic failure. Liver enzymes and prothrombin time should be monitored several times a day. Patients should be treated with a low-protein diet and receive standard supportive therapy for hepatic failure. Fresh frozen plasma and vitamin K can be used for the treatment of prolonged prothrombin time; in many cases, however, coagulopathy does not respond to treatment.

Patients who develop hepatic failure should be monitored closely and, in severe cases, preparations made for liver transplant. Although, no firm criteria exist to determine which patients will require liver transplant, clinical studies of amatoxin suggest aspartate aminotransferase (AST) levels greater than 2000 IU, grade 2 hepatic encephalopathy, and prothrombin time greater than 50 s despite therapy are indicative of the need for emergency liver transplant. [8] Many patients have met this criteria and survived without a hepatic transplant, and many patients have died without achieving these "target" values. Liver transplant, however, does provide the only option for patients in fulminant hepatic failure and has been quite successful. Recently, a child was given a temporary liver transplant, which allowed time for her own liver to regenerate. The transplanted liver was then removed.

Gyromitrin-Specific Treatment

The neurologic symptoms associated with gyromitrin are successfully treated with high-dose pyridoxine. Pyridoxine provides the cofactor required for the regeneration of GABA. High doses of pyridoxine (25 mg/kg up to a maximum of 25 g/day) are recommended, but doses of pyridoxine in excess of 40 g have been associated with severe peripheral neuropathy. [9] Pyridoxine does not affect the development or course of hepatic failure, and there is no specific therapy for gyromitrin-induced hepatic failure.

Amatoxin-Specific Treatment

Historically, there have been many anecdotal and largely ineffective treatments used to counteract this deadly toxin. Because 80 percent of the toxin is eliminated in the urine, forced diuresis may have some theoretical basis, but no clinical trials have shown efficacy. Amatoxins are dialyzable, and both hemodialysis and hemoperfusion had been a standard for therapy. However, because of the small plasma concentration, early binding in the liver, and rapid clearance from the plasma (within 48 h), hemodialysis and hemoperfusion are of limited usefulness. Many patients who receive hemodialysis actually do worse than patients treated with other forms of therapy. Attempts to interrupt enterohepatic circulation have also been tried but are of limited usefulness. Although high concentrations of amatoxin are excreted into bile, the small amount of liquid produced does not yield a large amount of the amatoxin extracted.

Thioctic acid, which has been used for many years in Europe, is a known free radical scavenger and may be effective in the treatment of acute hepatic failure of undifferentiated cause. Thioctic acid and glutathione appear to protect against microsomal lipid peroxidation and therefore may be of theoretical use in amatoxin poisoning. Animal and human studies, however, have not shown thioctic acid to be effective.

For patients in the United States, penicillin appears to be the most effective therapy. High doses of penicillin appear to block the uptake of amatoxin into the liver by its shared active transport system. [10] In addition, penicillin increases renal excretion of the toxin. Other antibiotics, such as rifampin and cephalosporins, have a similar effect in animal studies. Huge doses of penicillin G [300,000 to 1,000,000 U/kg/day] are required to decrease toxicity. Such doses are associated with seizures, and patients should be appropriately monitored. Penicillin should be started very soon after ingestion, if amatoxin ingestion is suspected. Penicillin-allergic patients either should not be treated with penicillin or should undergo desensitization.

Silymarin (silybinin), which has been used successfully in Europe to treat amatoxin ingestion, acts as a free radical scavenger and may interrupt the enterohepatic circulation of amatoxin when given orally. It is not available in the United States, but a recent study in Europe showed success in patients with amatoxin poisoning. [11]

Hyperbaric oxygen, which has been used in Europe as a treatment for amatoxin poisoning, [12] has been shown to be beneficial in other cases of hepatic failure, perhaps by increasing hepatic regeneration and interfering with free radical formation as well. No controlled studies exist, and animal studies have produced conflicting results.

There have been animal studies of other therapies that have not been yet definitively tested in humans. High-dose cimetidine (10 g/day) has been shown to be effective in animals and recently has been used successfully in humans. [5] Vitamin C, zinc, and thiol compounds have also been useful in animal models. Fab monoclonal antibodies have been developed against amatoxin. [13] Although successful in reducing hepatic failure, severe renal toxicity has developed. Theoretically, such Fab antibodies could be used with plasmapheresis to remove the antibody-antigen complexes.

DELAYED-ONSET RENAL FAILURE

Pathophysiology

Orellanine and ortinarin A and B are nephrotoxic compounds found in species of *Cortinarius* (*C. orellanus, C. speciosissimus,* and *C. gentilis*). These toxins are heat stable, and their mechanisms of action are unknown. Mushrooms of this species are found primarily in Europe and do not represent a significant problem in the United States. Recently, a similar delayed onset of renal toxicity was reported following the ingestion of *Amanita smithiana*.[14] This mushroom is commonly mistaken for pine mushrooms and grows commonly in the Pacific Northwest. Nephrotoxins in this mushroom are norleucine (aminohexadrenoic acid) and chlorocrotylglycine.

Clinical Features

Patients who ingest mushrooms containing nephrotoxins are generally asymptomatic. Occasionally, paresthesias, abnormal taste, and cognitive dysfunction are reported. Symptoms of renal failure begin between 3 and 20 days following ingestion. There is some evidence to suggest that patients who ingest *Amanita smithiana* may develop renal failure earlier. Many patients who ingest these mushrooms have no evidence of renal dysfunction, suggesting host variability. Supportive hemodialysis may be required in as many as 30 to 50 percent of patients, but 50 percent of patients will have spontaneous return of normal renal function. [15,16]

Ultrasonography shows enlarged kidneys. Renal biopsy shows mononuclear inflammatory infiltrate and signs of acute tubular damage with cell necrosis, cell shedding into the lumen, and de-differentiation of the proximal tubular epithelia. Electron microscopy show mitochondrial swelling, apical cytoplastic vacuolization, and a distortion of the brush border. These findings are consistent in both human and animal models. [16] The toxin appears to bind to tubular cells and can be detected in biopsy specimens as late as 180 days after ingestion.

Treatment

There is no specific treatment for patients who develop renal failure from *Cortinarius* or *Amanita smithiana*. Urine output and electrolyte, calcium, magnesium, blood urea nitrogen, and creatinine levels should be monitored. Hemodialysis support is indicated for refractory hyperkalemia, refractory acidosis, uremic symptoms, or severe renal dysfunction. As spontaneous improvement is reported, renal transplant should be withheld for several months to monitor patient response. Renal transplant has been used in several patients with good success.

DELAYED ONSET ACCOMPANYING ALCOHOL INGESTION

Pathophysiology

Perhaps the most interesting, but clinically least important, is a mushroom toxin contained in the *Coprinus* genus. This mushroom, which is very common in North America, is known as the "inky-cap" or "shaggy mane." It is a tall, white, thin mushroom with a shaggy cap. As the mushroom ages, the cap liquefies and blackens, and black liquid drips from the necrosing cap. The mushroom contains coprine, which is chemically related to disulfiram. Coprine inhibits alcohol dehydrogenase with the onset of activity 2 h after ingestion, and activity may last up to 72 h. If alcohol is consumed during this "sensitive" period, patients will develop a typical disulfiram reaction. Mushrooms ingested at the same time as alcohol produce no toxicity.

Clinical Features

Because of the delay between mushroom consumption and alcohol consumption, few patients will link their symptoms to the ingestion of a mushroom. Patients present with facial flushing, diaphoresis, headache, tachycardia, nausea, and vomiting. Most symptoms are mild.

Treatment

Because alcohol is readily absorbed from the GI tract, GI decontamination has no role. Likewise, charcoal would not be expected to have great benefit. Patients occasionally become hypotensive and respond to IV fluids or, in refractory cases, norepinephrine. Supraventricular tachycardia is rare but responds to propranolol. Patients should be educated about the link between the alcohol and mushroom ingestion.

201 POISONOUS PLANTS

Mark A. Hostetler
Sandra M. Schneider

Poisonous and injurious plants number in the hundreds and have a wide variety of toxicities. Rather than attempting a comprehensive listing, this chapter focuses on the most important plant-related encounters clinically relevant to emergency medicine. It includes descriptions of the most prevalent and poisonous plants (Table 201-1 and Table 201-2), those plants most commonly mistaken for being poisonous (Table 201-3), the most severely poisonous plants, and those most frequently encountered during the holiday season. [1,2 and 3] Individual plants are discussed in terms of their pathophysiology, clinical features, and treatment.

TABLE 201-1   Most Commonly Encountered Plants (in Descending Order)

Castor bean (*Ricinus communis*)

Foxglove (*Digitalis purpurea*)

Jequirity bean (*Abrus precatorius*)

Oleander (*Nerium oleander*)

Poison hemlock (*Conium maculatum*)

Water hemlock (*Cicuta maculata*)

Yew (*Taxus* species)

TABLE 201-2   Most Toxic Plants

African violet (*Episcia reptans*)

Coleus (*Coleus X hydrus*)

Dracaena species

Ficus species (climbing or weeping fig)

Jade plant (*Crassula argentea*)

Honeysuckle (*Lonicera* species)

Pyracantha species

Rubber tree plant (*Ficus elasticus*)

Schefflera species (*Brassaia actinophylla*, umbrella plant)

Spider plant (*Chlorophytum comosum*)

Wandering jew (*Tradescantia albiflora*)

TABLE 201-3   Nonpoisonous Plants Commonly Mistaken for Being Poisonous

EPIDEMIOLOGY

According to statistics gathered by the American Association of Poison Control Centers (AAPCC), plants are the fourth most common reason for poison center notification and account for 5 to 10 percent of all calls received. [3] This high rank is a reflection of their wide availability rather than any unusually high level of innate toxicity. Children under 6 years of age account for 70 to 80 percent of all plant-related exposures, the vast majority of which (96 percent) are unintentional. The most common plant-related call received by a poison control center is for completely nontoxic plants (21 percent) and, on average, fewer than 10 percent of patients require treatment in a health care facility. Of those suffering any sequelae, minimally bothersome effects are most common and occur in 10 percent of all ingestions. Dermatitis and gastrointestinal irritation are most common and occur in approximately 20 percent of patients. Moderate effects of a more systemic nature occur in 1 percent. Severe effects associated with life-threatening or disabling injuries are extremely uncommon and occur in only 0.04 percent. Death due to plant-related exposures are rare, and occur at a rate of less than 0.001 percent.

Toddlers experience the world by first putting it into their mouth. Since 80 percent of the exposures occur among toddlers younger than age 6 years, and most within the home, prevention is paramount. All poisonous and injurious plants must be kept out the reach of toddlers and preschoolers. Homes should be purged of all potentially toxic plants just as they are for medications and cleaning supplies, and children should be specifically instructed never to eat plants or wild berries.

TREATMENT

Most plant-related exposures require no treatment, and those that do often can be managed by simple decontamination procedures. Those patients with a potentially serious exposure who are asymptomatic should be observed in the emergency department for at least 4 to 6 h. If they remain asymptomatic, they may be discharged with appropriate instructions and follow-up. Symptomatic patients require ongoing monitoring and care and should be admitted to the hospital, because toxicity may continue to evolve. Few plants have specific antidotes.

It is recommended that all exposures be reported to the regional poison control center, which is the only national organization currently tracking all poisonous and injurious plants, and their input is invaluable. Poison centers are also helpful with plant identification. All exposures are potential toxicologic emergencies and should be treated accordingly, with appropriate consultation.

SEVERELY POISONOUS PLANTS

Castor Bean (*Ricinus communis*)

Ricin is a potent toxalbumin that inhibits protein synthesis and causes severe cytotoxic effects on multiple organ systems. It may be one of the most poisonous naturally occurring substances known. [4,5] Although present in all parts of the plant, it is concentrated most in the seeds. Beans are covered by a hard, relatively impervious outer shell that must be chewed or in some way broken in order for the ricin to result in toxicity.

Symptoms include delayed gastroenteritis, which may be severe and hemorrhagic, followed by delirium, seizures, coma, and death. Beans are particularly antigenic and may cause severe hypersensitivity and cutaneous and systemic allergic reactions.

Whole bowel irrigation (WBI) has been advocated to ensure rapid and complete decontamination of the GI tract. Rapid elimination of the bean before erosion of the outer shell occurs may decrease or prevent the release of potent toxins. Beans should be counted to assure complete recovery. Patients should be observed for at least 8 to 12 h. Once symptomatic, supportive care involves attention to fluid, glucose, and electrolyte replacement.

Foxglove (*Digitalis purpurea*)

Foxglove contains cardiac glycosides similar in structure and action to digitalis. Its toxicity lies somewhere between lily of the valley and oleander (see *oleander* below).

Jequirity Bean (*Abrus precatorius*)

Jequirity beans contain the toxalbumin abrin, one of the most lethal naturally occurring toxins known. [5] Children have died as a result of chewing alone (without swallowing) the beans. Chewing and swallowing just one bean may be lethal to an adult. Symptoms include a delayed gastroenteritis, which may be severe and hemorrhagic, followed by delirium, seizures, coma, and death. Like castor bean, recovery of the intact bean by WBI is preferred. Patients should be observed for at least 8 to 12 h. Treatment is otherwise supportive, with attention to fluid replacement and monitoring of electrolytes.

Oleander (*Nerium oleander*)

Similar in structure and effect to digitalis, all parts of the plant contain the cardiac glycosides oleandrin, oleandroside, nerioside, and digitoxigenin. Cardiac glycosides act by inhibiting the Na, K-ATPase pump and lead to hyperkalemia and a variety of dysrhythmias. Of all plants containing cardiac glycosides (lily of the valley, foxglove, and oleander), oleander is the most toxic.

These glycosides cross-react sufficiently such that a positive serum digoxin level will qualitatively confirm an ingestion. Quantitative levels are not accurate, however, and should not be used to quantify the amount of ingestion or potential toxicity. Effects include nausea, vomiting, diarrhea, abdominal pain, confusion, and cardiac dysrhythmias.

Potassium levels should be closely monitored. Hyperkalemia may be severe and refractory to the usual treatments (insulin, dextrose, bicarbonate), and may require hemodialysis. [6] Calcium is generally not recommended, as it may exacerbate the digitalis toxicity. In addition to GI decontamination and routine antidysrhythmic therapy, digoxin-specific Fab antibody fragments are recommended for patients with significant symptoms. [7]

Poison Hemlock (*Conium maculatum*)

All parts contain conine alkaloids similar in structure and effect to nicotine. Symptoms occur rapidly in 15 min to 1 h and begin with complaints of burning and dryness of the mouth. Tachycardia, triors, diaphoresis, mydriasis, profound muscle weakness, and seizures may develop. In severe cases, ascending paralysis, bradycardia, coma, and death occur. Although most cases are unintentional, there are some case reports of toxicity resulting from the intentional use by patients for a presumed narcotic-like effect. [8] Treatment consists of GI decontamination, activated charcoal, and supportive care which may include IV fluids, antidysrhythmics, and anticonvulsants.

Water Hilock (*Cicuta maculata*)

Cicutoxin, a highly unsaturated higher alcohol, is found in highest concentrations in the root, but all parts contain the poison. Its exact mechanism of action is unknown. One mouthful may be fatal in as soon as 15 min. Initial symptoms include nausea, vomiting, and abdominal pain, followed by delirium, seizures, and death. Seizures may be severe and refractory to conventional anticonvulsant therapy. The mortality rate may be as high as 30 percent. [9] GI decontamination is paramount. Treatment is otherwise supportive, with IV fluids, anticonvulsants, and bicarbonate if necessary for acidosis.

Yew (*Taxus* Species)

Yew contains taxine alkaloids in the leaves and seeds. Symptoms include nausea, vomiting, and abdominal pain, followed by seizures, cardiac dysrhythmias, coma, and occasionally death. Treatment consists of GI decontamination, activated charcoal, fluids, and antidysrhythmics as necessary.

COMMON POISONOUS AND INJURIOUS PLANTS

Aloe (*Aloe barbadensis*)

Sap from this common succulent house plant contains an anthraquinone that acts as a cathartic. Symptoms include abdominal pain and diarrhea within 6 to 12 h of ingestion. It may occasionally turn the urine red, and large doses may cause nephritis. There is no specific antidote. Intravenous (IV) fluids may be necessary to support GI fluid losses.

Azalea (*Rhododendron* Species)

Andromedotoxins are found in the leaves, flowers, and nectar. Symptoms produced include salivation, lacrimation, bradycardia, hypotension, progressive paralysis, and potentially (but rarely) death. Most cases display minimal toxicity. In addition to gastrointestinal (GI) decontamination, treatment consists of atropine for symptomatic bradycardia and fluids or pressors for hypotension.

Cactus

Needles or spines may ibed in the skin and cause direct mechanical injury. [10] Patients complain of pain and irritation at the site. Unlike other foreign bodies such as glass that are inert, spines contain proteinaceous material and should be rioved if possible. They may be rioved by applying a thin layer of rubber cient or other similar type substance. The substance is allowed to dry and then gently peeled off rioving the spines. Complications such as infection and granuloma formation occur, but are uncommon.[10]

Caladium

Toxicity is similar to dieffenbachia (calcium oxalate raphides), but less severe.

***Crocus* (Autumn Crocus)**

Colchicine is contained in all parts of the autumn crocus and glory lily. Colchicine causes a gastroenteritis that is delayed and severe, and is followed by severe multisysti organ failure. Common effects include coagulopathy, bone marrow suppression with granulocytopenia and thrombocytopenia, cardiac dysrhythmias, cardiogenic shock, adult respiratory distress syndrome, hepatic insufficiency, delirium, seizures, coma, and death. In addition to GI decontamination, treatment usually requires aggressive fluid resuscitation. Colchicine-specific Fab fragments are commercially available for severe poisonings.

***Dieffenbachia* (Dumbcane)**

Plants contain calcium oxalate crystals packaged into bundles known as raphides. In addition to the calcium oxalate crystals, these plants also contain preoteolytic enzymes with antitrypsin-like activity that stimulate the release of histamine and bradykinin. It riains unclear why some plants such as schefflera, which also contain calcium oxalate crystals, are completely nontoxic. Children who chew the leaves develop immediate burning and irritation of the oral mucosa. Cases of severe swelling, drooling, dysphagia, and respiratory compromise have been reported, but are not common. In a large retrospective study of 188 patients suffering oxalate exposure, all cases were minor and resolved with little or no treatment. [11] Diulcifying agents such as cold milk or ice cream may help. Analgesics may be necessary. Steroids may be beneficial for severe cases, although there have been no controlled trials.

Fava Beans

There are limited examples of genetic predispositions being associated with increased potential for toxicity. Among persons affected by glucose-6-phosphate dehydrogenase deficiency, 10 to 20 percent develop favism after consuming fava beans. Symptoms include GI upset, fever, and h4ache. Patients may develop hiolytic aniia, hioglobinuria, and jaundice. [12] There is no specific antidote.

Jimsonweed (*Datura* Species)

Jimsonweed (also known as thorn apple, devil's trumpet, or locoweed) is a wildly occurring weed infamous for its hallucinatory properties. Exposures most commonly are intentional and occur through experimentation. [13] All parts of the plant are toxic and contain atropine-like alkaloids (hyoscyamine, atropine, and scopalamine) capable of precipitating acute anticholinergic crises by competitive inhibition of cholinergic muscarinic receptors. [14]

Symptoms occur within 30 to 60 min and may last for up to 48 h because of delayed gastric motility. Symptoms include hyperthermia ("hot as a hare"), flushed skin ("red as a beet"), dry skin and mucus mibranes ("dry as a bone"), mydriasis ("blind as a bat"), and hallucinations or delirium ("mad as a hatter"). Tachycardia and urinary retention are also common.

Treatment includes GI decontamination with iesis or lavage, activated charcoal, and supportive care (IV fluids, external cooling, and restraints for patient protection). GI decontamination may be useful for up to 48 h after ingestion if the patient riains symptomatic. [14] Physostigmine, a cholinesterase inhibitor, antagonizes both the central and peripheral effects and may be required in 30 to 40 percent of cases. [13] It should be considered for severe cases exhibiting hyperthermia, seizures, or frank psychosis. An initial dose of 0.5 mg for children or 1.0 to 2.0 mg for adults is given slowly IV over 5 min. Repeat doses may be required. [13] See Chapter 177, "Anticholinergic and Antihistaminic Toxicity," for more discussion.

Lily of the Valley (*Convallaria majalis*)

In addition to ingestion of the plant itself, toxicity has been reported from drinking of water in which the freshly cut flowers were kept (see the *oleander* section).

Nettle (Stinging Nettle, Bull Nettle)

Nettles contain a specialized systi for injecting their toxins. Stinging hairs are connected to a bladder filled with various irritants (histamine, acetylcholine, 5-hydroxytryptamine). Handling of the plant stimulates the injection of these substances via the hair tube. An immediate burning response may last for hours. Treatment is symptomatic.

Nightshade, Common or Woody (*Solanum* species, Nightshade)

The glycoalkaloid solanine is present in all parts of the plant. Ingestion results in nausea, vomiting, diarrhea, and abdominal pain. Delirium, hallucinations and coma may also occur with larger doses. There is no specific treatment.

Nightshade, Deadly (*Atropa belladonna*)

This contains atropine-like substances with anticholinergic properties (see the *jimsonweed* section).

Peach, Apricot, Pear, Crab Apple, and *Hydrangea*

Amygdalin, a cyanogenic glycoside, is metabolized by the enzyme iulsin to hydrocyanic acid. In sufficient quantities, hydrocyanic acid may lead to acute cyanide toxicity. The requisite enzyme (iulsin) is present in the pits or seeds listed above and may be present to some degree in intestinal bacteria. Ingestion of large amounts of seeds or pits results in diaphoresis, nausea, vomiting, abdominal pain, and lethargy. Symptoms develop over hours. GI decontamination is needed. If symptomatic, antidotal therapy may be needed for cyanide toxicity (amyl nitrate, sodium nitrate, and sodium triosulfate). See Chapter 182, "Cyanide," for further discussion.

Pepper (*Capsicum*)

Capsicum causes irritation, burning, and pain upon contact with mucous mibranes as a result of depletion of substance P from terminal nerve endings. There is intense burning of the mucous mibranes with contact. Patients typically self-innoculate their eyes while preparing peppers. Police use pepper sprays to subdue combative individuals. In addition to cutaneous decontamination with copious amounts of water and a gentle hand soap, diulcifying agents such as cold milk or ice cream may help. Analgesics may be necessary.

Philodendron (Elephant's Ear)

All parts contain oxalate raphides and may produce symptoms similar to dieffenbachia, although less severe.

Pokeweed (*Phytolacca americana*)

All parts of the plant are toxic, but especially the roots, unripe berries, and seeds. Phytotoxins (phytolaccotoxin and phytolaccine) cause direct mucosal irritation and GI symptoms. Patients complain of burning in the mouth and throat, with abdominal pain, nausea, vomiting, and profuse diarrhea that may be foamy. [15] Severe intoxications may result in coma and death. Although their safety riains somewhat controversial, ripe berries are occasionally used in pies and the leaves boiled for greens. Treatment is GI decontamination with iesis or lavage, charcoal, and supportive care consisting of fluid-electrolyte replacient.

Pothos (Devil's Ivy, *Epiprinum*)

This plant has toxicity similar to dieffenbachia, but less severe.

Red/Yellow Sage (*Lantana*)

Leaves and unripe fruit contain the toxin lantadene. Patients develop dilated pupils, vomiting, diarrhea, weakness, and coma. Symptoms may be delayed for 2 to 6 h. Treatment is GI contamination and fluids for dehydration.

Solanum Species (Potato, Eggplant, Common Nightshade)

Solanine is contained in green potatoes and in the sprouts, and is destroyed by cooking. Delayed gastroenteritis may be seen (see *common nightshade* above).

Toxicodendron Species (Poison Ivy, Oak, and Sumac)

Plants contain the antigenic resin, urushiol. Once exposed, most, but not all, individuals develop sensitization as the antigenic resin binds with skin proteins and forms a complete antigen. Reexposure then stimulates a T-cell-mediated immune response. Reactions begin with itching, burning and redness developing over 12 to 48 h, and may progress to include varying degrees of vesiculobullous formation. Resin may riain after the plant has dried and may be aerosolized during burning. Antipruritic and topical therapies (oatmeal baths and topical steroids) are commonly used. Facial, genital or widespread involvient requires systiic steroids for 10 to 14 days. Patients should be advised to clean under their fingernails and wash all contaminated clothing. IvyBlock, a new product recently approved by the Food and Drug Administration, contains bentoquatam and binds urushiol to prevent absorption. Skin cleansers (such as Tecnu, Oak-N-Ivy Brand) may be used after the rash has begun to develop, up to 8 h after exposure, to decontaminate the skin. (See Chap. 239 for further discussion.)

COMMON HOLIDAY OR SEASONAL PLANTS (POISONOUS AND NONPOISONOUS)

Holly (*Ilex* Species)

The leaves are nontoxic, whereas the berries contain a variety of toxins known as saponins. Gastroenteritis is most common and may occur with as few as two or three berries, whereas 20 to 30 berries may be fatal. Treatment is GI decontamination followed by IV fluids to prevent dehydration.

Poinsettia (*Euphorbia pulcherrima*)

Poinsettia is a much maligned plant ubiquitous during the Christmas holidays. Originally implicated as being toxic, recent evidence suggests that at most it may occasionally cause some local irritation to skin, mouth, or conjunctiva. [16]

Mistletoe (*Phoradendron*)

All parts are poisonous and contain phoratoxin, a toxalbumin. Gastroenteritis may occur following ingestion of a large number of berries. Treatment is GI decontamination with fluid and electrolyte monitoring.

Easter Lily (*Lilium longiflorum*)

Toxicity has not been reported in humans.

William J. Brady
Richard A. Harrigan

Although there is no universally accepted definition of hypoglycemia, it is generally defined as (1) a serum glucose level of less than 50 mg/dL, (2) symptoms consistent with the diagnosis; and (3) resolution of symptoms following glucose administration. Up to 20 percent of patients with diabetes mellitus using insulin or oral hypoglycemic agents (OHAs) will experience symptoms of hypoglycemia in their lifetime, requiring emergency department (ED) evaluation and therapy. [1,2 and 3] If one considers all patients with altered mentation arriving at the ED, hypoglycemia is the underlying process in approximately 7 percent. In addition to diabetes, other clinical settings associated with hypoglycemia include sepsis, liver disease, alcohol intoxication, starvation, and certain toxic ingestions. Hypoglycemia should be considered in the differential diagnosis in any patient with altered mental status or focal neurologic signs. [4,5]

PATHOPHYSIOLOGY

Blood glucose homeostasis involves complex neural, metabolic, and hormonal interactions. The central nervous system (CNS) requires a continuous supply of carbohydrate fuel for normal function and utilizes about 150 g/day of glucose. The CNS has a small reservoir of glucose that is sufficient for only a few minutes of normal brain function. Despite these stringent demands, the body normally functions quite well in maintaining plasma glucose levels within a narrow range despite constant changes in glucose intake and/or utilization.

The primary glucoregulatory organs are the liver, the pancreas, adrenals, and pituitary gland. These organs maintain glucose control by the release and interaction of various hormonal agents, including insulin, glucagon, the catecholamines epinephrine and norepinephrine, cortisol and other glucocorticoids, and growth hormone. Insulin is the major metabolic regulatory factor, acting predominantly on the liver, skeletal muscle, and adipose tissue. Insulin suppresses endogenous glucose production, stimulates glucose utilization, and increases glucose storage in the form of glycogen, thus lowering the plasma glucose concentration.

The first defense against the development of hypoglycemia is a decrease in insulin secretion, but both glucagon and epinephrine are also important for the acute protection against hypoglycemia. Both of these counterregulatory hormones are the only agents capable of stimulating hepatic glucose production within minutes of their release into circulation, primarily via glycogenolysis—the release of glucose from its intracellular storage-depot glycogen. The effect of these two hormones beyond the immediate period after their release—ranging from several hours to several days—is felt predominantly through their effect on gluconeogenesis—the de novo production of glucose from other metabolic substrates. Glucagon is felt to be the major counterregulatory hormone while epinephrine is important under certain conditions, especially during glucagon deficiency and in the generation of warning symptoms of hypoglycemia. Epinephrine also stimulates hepatic glucose production as well and also limits glucose utilization. In contrast to glucagon and epinephrine, glucocorticoid and growth hormone responses are largely involved in the protection against prolonged hypoglycemia over days to weeks.

Hormonal responses are largely determined by glucose intake and vary between the fed and the fasting states. The fed state extends for up to 3 h after the ingestion of food. In the fed state, glucose absorption from the gut stimulates the release of insulin from the pancreas, causing a shift of carbohydrate from the circulation into the various tissues for either consumption or storage. In certain cases, after entry into the cell, glucose is immediately used for energy production via glycolysis, with the glycolytic products proceeding on to the tricarboxylic acid (TCA) cycle and down the electron transport chain, generating additional ATP. If the glucose is destined for fuel storage, it may take various forms, depending on the host tissue location: glycogen in the liver, triglycerides in adipose tissue, and protein in muscle. Insulin also acts on the liver to decrease glucose output by inhibiting glycogenolysis and gluconeogenesis. It inhibits lipolysis and promotes lipogenesis in adipose cells, and encourages the uptake of amino acids and inhibits proteolysis.

The fasting period is the interval between feedings, beginning approximately 4 h after eating and extending up to the next meal. In fasted individuals, the maintenance of normal blood glucose levels depends on an adequate supply of endogenous gluconeogenic substrates (amino acids, glycerol, and lactate), functionally intact hepatic glycogenolytic and gluconeogenic enzymatic systems, and normal endocrinologic function for integrating and modulating these processes. Hypoglycemia may result if any part of this system is disrupted. During fasting, relatively low insulin levels initiate the mobilization of these various stored fuels from host tissue sources. The most readily and rapidly available source of glucose is hepatic glycogen. Glucose is formed by glycogenolysis, which is potentiated in the liver by glucagon and epinephrine. The glycogen reserve is limited and will be depleted after 24 to 48 h of fasting in healthy patients and possibly earlier in malnourished individuals. With continuation of fasting (approximately 4 to 6 h), gluconeogenesis becomes the primary source of blood glucose required for CNS metabolism and other bodily processes. Gluconeogenesis, occurring primarily in the liver, uses various metabolic substrates to generate an additional glucose supply. Amino acids are mobilized from muscle tissue via proteolysis, which is facilitated by low insulin levels and mediated by cortisol and glucagon. Lactate, from recycled glucose, and glycerol, from lipolysis, are minor yet important substrates for gluconeogenesis. During nonprolonged overnight fasting, 90 percent of gluconeogenesis occurs via proteolysis with conversion of amino acids to glucose.

If fasting is prolonged beyond the functional capabilities of both gluconeogenesis and glycogenolysis, the mobilization of other fuel stores is initiated with a decline in plasma insulin levels, thus removing the insulin-mediated inhibitory action on lipolysis and proteolysis; alternative fuel stores are then mobilized. Fat stores in the form of triglycerides are a major source of energy. Lipolysis, potentiated by a relative decline in serum insulin levels and the presence of both epinephrine and growth hormone, produces free fatty acids (FFAs) and glycerol. Most tissues, except the CNS and cellular blood elements, use FFAs as a source of energy, simultaneously allowing the body to conserve glucose for brain metabolism and sparing protein from catabolism for gluconeogenesis. The released glycerol may also be converted to glucose in the liver.

Hypoglycemia unawareness—the development of low serum sugar values without the physiologic ability to react—places individuals at greater risk for coma and other neurologic sequelae. Extremes of age, comorbidity, medications, autonomic neuropathy, and the degree of serum sugar control are some factors affecting awareness of hypoglycemia. It has been suggested that elderly patients are more likely to experience hypoglycemia without an awareness of the event. As an example, the presence of previous stroke in older patients could increase the chance of unrecognized hypoglycemia. b-Adrenergic receptor antagonists block the effects of epinephrine, therefore contributing to patient unawareness of hypoglycemia. Further, patients with diabetes mellitus and autonomic neuropathy demonstrate blunted counterregulatory responses to hypoglycemia. [6] With increasingly rigid control of the serum glucose, patients with diabetes mellitus without neuropathy may also have reduced responsiveness of the counterregulatory hormones, potentiating an unawareness of hypoglycemia. [7] Such a clinical unawareness may result from either a lack of CNS recognition of hypoglycemia or impaired autonomic response to low serum sugar.

CLINICAL FEATURES

Table 202-1 lists common causes of hypoglycemia in adults. The most common causes treated in an urban ED were diabetic medical therapy, 54 percent; ethanol use, 48 percent; and sepsis, 12 percent. [4]

TABLE 202-1   Potential Etiologies of Hypoglycemia in Adults

Common scenarios in diabetic patients include inadequate food intake, increased physical exertion, incorrect medication dosing, or drug interactions. The characteristics of diabetic patients who are more likely to experience hypoglycemia include male gender, adolescent and very elderly age groups, African American heritage, a past history of hypoglycemia, "intensive" diabetic medical therapy, insulin use (compared with OHA therapy), polypharmacy (more than five agents), and recent hospitalization.[1,2 and 3]

The introduction of metformin, a biguanide, has added another medication to the list of agents encountered in diabetic patients. Metformin improves the end-organ sensitivity to insulin and acts via a number of mechanisms in diabetic patients, including a reduction in hepatic glucose output and enhanced peripheral glucose uptake. Metformin is considered an antihyperglycemia drug rather than a hypoglycemic agent such as the sulfonylureas and insulin. Hypoglycemia is rarely encountered in patients using only metformin.

The nonselective b-blocker agents impair glycogenolysis and the hyperepinephrinemic response to lowered serum sugar levels, thus predisposing individuals to hypoglycemia. Hypoglycemia resulting from the sole ingestion of such adrenergic-blocking agents is rare. [5]

Approximately 50 percent of patients treated for hypoglycemia in an urban ED were acutely intoxicated with ethanol or were chronic alcohol abusers. [4] Alcohol inhibits hepatic gluconeogenesis, which becomes problematic when a patient has not eaten for a prolonged period and the glycogen stores have been depleted by glycogenolysis. A 12-h fast is often sufficient for severely malnourished alcoholics to become hypoglycemic. Hypoglycemia has also been produced in healthy adults by infusing 75 g of alcohol after a 36-h fast. Rapid bedside serum glucose determinations should be performed on all patients with any mental status abnormality or evidence of alcohol use.

Sepsis may cause hypoglycemia by inhibition of gluconeogenesis and by increased responsiveness to insulin. Systemic hypoperfusion, often associated with sepsis, increases peripheral glucose utilization while metabolic acidosis decreases gluconeogenesis. The multiorgan failure associated with the sepsis syndrome not infrequently includes hepatic dysfunction and an increased potential for hypoglycemia.

Patients with hypoglycemia may have a wide array of symptoms and signs (Table 202-2). The clinical manifestations of hypoglycemia are divided into two broad categories: neuroglycopenic and hyperepinephrinemic (also known as the autonomic or sympathomimetic findings). As glucose is the main energy source for CNS function, it is not surprising that most episodes of symptomatic hypoglycemia include neurologic dysfunction. With a decline in serum sugar, the brain quickly exhausts its reserve supply of carbohydrate fuel, resulting in CNS dysfunction. This manifests most commonly by alterations in consciousness, such as lethargy, confusion, combativeness, agitation, and unresponsiveness. Other neuroglycopenic manifestations include seizures and focal neurologic deficits. A review of 125 cases of hypoglycemia in an urban ED showed that the neuroglycopenic findings predominated. [4] A depressed sensorium was noted in 52 percent of cases, with other mental status changes—agitation and combativeness—found in 30 percent of patients. Described less frequently, seizure activity and focal neurologic findings were encountered in 7 percent and 2 percent, respectively. [4]

Clinical Presentation	Frequency (%)
Depressed sensorium	52
Other mental status changes	30
Hyperepinephrinemic findings	8
Seizure	7
Focal neurologic findings	2

Source: From Malouf and Brust,[4] with permission.

TABLE 202-2   Frequency of Presenting Signs and Symptoms in Hypoglycemia

A rapid fall in blood glucose levels or the hypothalamic sensing of neuroglycopenia causes the release of the counterregulatory hormones, primarily the catecholamines epinephrine and norepinephrine. The release of the latter is responsible for the hyperepinephrinemic findings, including anxiety, nervousness, irritability, nausea, vomiting, palpitations, and tremor. Such signs and symptoms were noted in 8 percent of ED patients with hypoglycemia. [4]

The term "hyperepinephrinemic" is a misnomer in that cholinergic factors resulting from autonomic nervous system stimulation are also noted in certain patients. Stimulation of the cholinergic nervous system also occurs and may result in manifestations such as sweating, changes in pupillary size, bradycardia, and salivation.

The rapidity of onset of the hypoglycemic event determines in part the presentation. A gradual onset of hypoglycemia results from a relatively slow decrease in the serum glucose and the development of the neuroglycopenic signs and symptoms. Conversely, a sudden drop in the blood sugar level will produce anxiety, diaphoresis, tremor, and the other hyperepinephrinemic findings. In most cases of hypoglycemia, however, CNS dysfunction predominates with some degree of alteration in the level of awareness, accompanied by diaphoresis and tachycardia.

Hypoglycemia has been misdiagnosed as stroke, transient ischemic attack, seizure disorder, traumatic head injury, brain tumor, narcolepsy, multiple sclerosis, psychosis, sympathomimetic drug ingestion, hysteria, altered sleep patterns and nightmares, and depression. [6,7,8,910 and 11] Although uncommon, bradycardia has also been reported.[12]

DIAGNOSIS

Failure to determine the blood glucose level early in the evaluation can result in a delayed or missed diagnosis with associated morbidity due to CNS injury or unnecessary invasive procedures and therapies.[13] Always consider hypoglycemia as a potential cause of altered mentation and rapidly screen for it at the bedside, followed by replacement therapy, regardless of the presumed reason for a patient's condition. The use of bedside testing is preferred in that the result is immediately available to the clinician and its result may alter therapeutic and diagnostic plans. [13] The accuracy of bedside reflectance tests is acceptable though less reliable at extremely low and high glucose levels.

If possible, immediately prior to intravenous (IV) dextrose therapy, a serum sample should be obtained and sent to the lab for confirmation. Glucose values of whole

blood are approximately 15 percent less than serum or plasma. This discrepancy is due to the relatively low glucose concentration in red blood cells—with storage, equilibration occurs. Venous blood has a 10 percent lower glucose concentration when compared with either capillary or arterial blood. Finally, the collecting tube should contain fluoride to inhibit glycolysis in vitro before the sample is assayed.

TREATMENT

Initial management is the administration of 1 g/kg body weight dextrose, as 50% dextrose in water (D_{50}/W) in adults. This can be followed by the infusion of 10% dextrose at a rate to maintain the serum glucose above 100 mg/dL. Repeat bedside glucose determination should be done every 30 min for the first 2 h, to detect rebound hypoglycemia. The best replacement is oral, however. A total of 300 g (1200 cal) of carbohydrate should be given orally, as sodas, juices, sandwiches, or snacks. A total of 50 mL of 10_{50}W contains only 100 cal. Whereas some suggest that each ampule of glucose (50 g of a 50% dextrose solution) will raise the serum glucose by 60 mg/dL,[14] others feel that prediction of posttreatment levels is impossible. [15]

Glucagon, 1 mg intramuscularly or IV, can be used in diabetics or in those in whom IV access is unobtainable. Response to glucagon therapy is generally slower when compared with IV dextrose, requiring 7 to 10 min prior to normalization of mental status; additionally, the response to glucagon administration may be short-lived. The condition of alcoholics, the elderly, and others with depleted glycogen stores will generally not improve with glucagon. Fructose and other complex carbohydrates should not be used to correct hypoglycemia in that these sugars do not cross the blood-brain barrier effectively or require extensive metabolic conversion.

Persistent hyperglycemia, maintained by slow administration of dextrose, indicates that the infusion may be reduced and eventually withdrawn. Failure to respond to parenteral glucose administration should prompt consideration of other causes of hypoglycemia.

A total of 100 mg parenteral thiamine should be given in conjunction with glucose, because, historically, the administration of glucose without thiamine in severe nutritional deficiency states could precipitate Wernicke's encephalopathy. [16] Today, this is rare. Thiamine acts as a coenzyme in several reactions in intermediary metabolism, specifically in the conversions of pyruvate to acetyl coenzyme A (linking glycolysis to the TCA cycle) and a-ketoglutarate to succinate (a reaction in the TCA cycle). As thiamine reserves disappear, the reactions halt, removing the CNS's main source of ATP and causing the acute development of Wernicke's syndrome.

Steroid administration should be considered for hypoglycemia that is either resistant to aggressive glucose replacement therapy or associated with the signs of adrenal insufficiency (see Chap. 208). The dose is 100 to 200 mg hydrocortisone IV in adults.

Studies in the early 1980s suggested that hyperglycemia at the time of hospital admission is associated with poor neurologic recovery in stroke patients [17] and survivors of out-of-hospital cardiopulmonary arrest. [18] More recently, similar concern has been voiced regarding the association of worsened neurologic outcome and hyperglycemia in patients with acute head injury. [19,20] It is theorized that hyperglycemia accentuates local tissue damage by continued or increased anaerobic metabolism, lactate production, and intracellular acidosis. Acidosis may trigger a cascade that includes calcium entry into cells, lipolysis, and cytotoxic fatty acid release, culminating in neuronal death. The clinical significance has not been demonstrated, and this information should not alter the clinical management of hypoglycemia at this time.

DISPOSITION

Factors affecting disposition include (1) the patient's current mental status as well as the level of consciousness during observation in the ED, (2) serial determinations of the serum glucose, (3) both the timing and extent of the response to resuscitative therapy, (4) the need for additional replacement therapy, (5) etiology of the hypoglycemic event, (6) comorbidity, (7) the patient's social situation, (8) any psychiatric issues, and (9) the agent ingested.

Either continued or recurrent mental status alteration, recurrent hypoglycemia, or a downward trend in serial glucose values during ED observation despite adequate replacement therapy demands admission to the hospital. Also, any patient requiring large doses of dextrose as both bolus and infusion should be admitted. An inpatient disposition in a critical care setting is likely warranted in cases involving the following etiologies: massive insulin or OHA ingestion, marked malnutrition, sepsis, acute liver failure, or any other event associated with the tendency toward profound hypoglycemia. Further, patients without proper outpatient supervision should be admitted for observation. The case suitable for outpatient observation is characterized by a responsible adult who will monitor the patient's mental status every 3 h, coupled with a motivated patient who will perform serum glucose determinations frequently and who can maintain oral feeding. The suspected or known intentional ingestion of either insulin or OHA must be admitted for ongoing medical and psychiatric care.

The particular medication agent ingested must be strongly weighed in disposition decisions. Short-acting insulin preparations do not always demand hospitalization, whereas intermediate and long-acting preparations likely will require admission for ongoing observation and, at times, continued supportive care. Care must be exercised in large short-acting insulin exposures in that the pharmacodynamics of such insulin preparations are altered with massive doses. The expected short half-life may not be encountered. OHAs also represent an indication for hospitalization due to relatively long serum half-life with a prolonged tendency toward the development of hypoglycemia. Low serum glucose may develop as long as 16 h after ingestion, though the majority of patients will become symptomatic within 8 h of exposure.[21] A single tablet ingestion by a child can produce significant hypoglycemia. Finally, if any doubt exists as to the need for inpatient observation, admission for short-term observation is justified. If a patient is discharged, follow-up should be provided in 24 h with the primary care physician.

203 DIABETIC KETOACIDOSIS

Cary L. Lubkin

INTRODUCTION

Diabetic ketoacidosis (DKA) is an acute, life-threatening complication of diabetes mellitus. DKA occurs predominately in patients with type I or insulin-dependent diabetes mellitus, but is also well described in type II or non-insulin-dependent diabetes mellitus. [1] DKA accounts for 8 to 28 percent of all diabetic admissions, and has an incidence among diabetics in the United States of 3 to 8 episodes per 1000 patients. [2] Europe has a comparable incidence. Twenty to 30 percent of cases occur in patients with new-onset diabetes. There was a decline in mortality from DKA in the 1960s and 1970s because of early recognition, improved patient education, and advances in management. Better understanding of pathophysiology and an aggressive, uniform approach to diagnosis and management has reduced mortality to less than 5 percent of reported episodes. [3] However, mortality is higher in the elderly due to underlying renal disease or coexisting infection. [4]

PATHOPHYSIOLOGY

In simplest terms, DKA represents the body's response to cellular starvation, brought on by relative insulin deficiency and counterregulatory or catabolic hormone excess (Fig. 203-1).[5] Insulin is the only anabolic hormone and is responsible for the metabolism and storage of carbohydrates, fat, and protein. Counterregulatory hormones include glucagon, catecholamines, cortisol, and growth hormone. This lack of insulin and excess counterregulatory hormones results in hyperglycemia (due to excess production and underutilization of glucose, the resultant osmotic diuresis and decreased glomerular filtration rate), [2] ketone formation, and an anion gap metabolic acidosis.

FIG. 203-1. Pathogenesis of DKA, secondary to relative insulin deficiency and counterregulatory hormone excess.

Insulin

Ingested glucose is the primary stimulant of insulin release from the b cells of the pancreas. Insulin's main action occurs at the three principal tissues of energy storage and metabolism (i.e., liver, adipose tissue, and skeletal muscle). Insulin acts on the liver to facilitate the uptake of glucose and its conversion to glycogen while inhibiting glycogen breakdown (glycogenolysis) and suppressing gluconeogenesis. The net effect of these actions is to promote the storage of glucose in the form of glycogen. Insulin's effect on lipid metabolism is to increase lipogenesis in the liver and adipose cells by the production of triglycerides from free fatty acids and glycerol while inhibiting the breakdown of triglycerides. Insulin stimulates the uptake of amino acids into muscle cells with subsequent incorporation into muscle protein while preventing the release of amino acids from muscle and hepatic protein sources.

Deficiency in insulin secretion is the predominant lesion in diabetes mellitus and it may be partial or total. In the initial stages of diabetes mellitus, the secretory failure of b cells impairs fuel storage and may only be evident during a glucose-tolerance test. As the disease progresses and levels of insulin decrease, fuel stores are mobilized during fasting, resulting in hyperglycemia. When pancreatic b-cell reserve is present, hyperglycemia may trigger an increase in insulin and a return to normal glucose concentration. With further disease progression, hyperglycemia can no longer trigger an increase in insulin activity. Despite the presence of elevated intravascular glucose, in the absence of insulin the cells are unable to utilize glucose as a fuel source. The body responds by breakdown of protein and adipose stores to try and produce a usable intracellular fuel. Loss of the normal physiologic effects of insulin leads to secretion of catabolic hormones and resultant hyperglycemia and ketonemia.

Counterregulatory Hormones

The response to cellular starvation seen with insulin insufficiency is increased levels of glucagon, catecholamines, cortisone, and growth hormone. Glucagon is the primary counterregulatory hormone. The catabolic effects of these hormones includes increased gluconeogenesis and glycogenolysis, breakdown of fats into free fatty acids and glycerol, and proteolysis with increased levels of amino acids. Increased levels of glucogenic precursors, such as glycerol and amino acids, facilitate gluconeogenesis, worsening hyperglycemia.

Free fatty acids released in the periphery are bound to albumin and transported to the liver where they undergo conversion to ketone bodies. The primary ketone bodies b-hydroxybutyric acid (bHB) and acetoacetic acid (AcAc) account for the metabolic acidosis seen in DKA. The two are in equilibrium: AcAc + NADH $\rightleftharpoons$ 2; bHB + NAD. AcAc is metabolized to acetone, another major ketone body. Depletion of baseline hepatic glycogen stores tends to favor ketogenesis. Low insulin levels decrease the ability of the brain, cardiac, and skeletal muscle to use ketones as an energy source, also increasing ketonemia. Persistently elevated serum glucose eventually causes an osmotic diuresis. The resulting volume depletion worsens hyperglycemia and ketonemia. The renin angiotensin aldosterone system, activated by volume depletion, exacerbates renal potassium losses already occurring from osmotic diuresis. In the kidney, chloride is retained in exchange for the ketoanions being excreted. This loss of ketoanions represents a loss of potential bicarbonate. In the face of marked ketonuria a superimposed hyperchloremic acidosis is also present. The presence of a concurrent hyperchlorene acidosis can be detected by noting a [HCO$_3^-$] lower than explainable by the amount the anion gap has increased (see Chap. 21). As adipose tissue is broken down, prostaglandins PGI$_2$ and PGE$_2$ are produced. Both account for the paradoxical vasodilation that occurs despite

profound levels of volume depletion. They may be responsible for the fact that acute renal failure and extremity gangrene rarely develop in DKA despite depletion volume.

DKA IN PREGNANCY

Several physiologic changes in pregnant patients make them more prone to DKA. Maternal fasting serum glucoses are normally lower, which leads to relative insulin deficiency and an increase in baseline free fatty acid levels in the blood. Pregnant patients normally have increased levels of counterregulatory hormones. In addition, the chronic respiratory alkalosis seen in pregnancy leads to decreased bicarbonate levels due to a compensatory renal response resulting in a decrease in buffering capacity. Pregnant patients also have an increased incidence of vomiting and infections (e.g., urinary tract infections, sinusitis, otitis media), which are frequent precipitants of DKA. In addition, DKA is triggered at lower sugar levels in the pregnant population. [6] Maternal acidosis causes fetal acidosis and also decreases uterine blood flow and fetal oxygenation. Maternal hypokalemia can also lead to fetal dysrhythmias and death.

CAUSES OF DIABETIC KETOACIDOSIS

Factors known to precipitate DKA include omission of daily insulin injections and a variety of stressful events, such as infection, stroke, myocardial infarction, trauma, pregnancy, hyperthyroidism, pancreatitis, pulmonary embolism, surgery, and steroid usage. Recent studies have shown that errors in insulin usage are a much more common precipitant than previously thought, especially in the younger population. [7] In approximately 25 percent of patients, no clear precipitating cause is found. [8]

CLINICAL PRESENTATION

The clinical manifestations of DKA are directly related to the three primary metabolic derangements—hyperglycemia, volume depletion, and acidosis. Hyperglycemia causes an increased osmotic load with movement of intracellular water into the vascular compartment. The ensuing osmotic diuresis gradually leads to volume loss in addition to renal losses of sodium, chloride, potassium, phosphorous, calcium, and magnesium. Initially, patients may compensate by increasing their fluid intake. In this initial period, polyuria and polydipsia are usually the only symptoms until ketonemia and acidosis develop. As the acidosis progresses, the patient develops a compensatory augmented ventilatory response. Increased ventilation is physiologically stimulated by acidemia to diminish the P_{CO_2} and thus counter the metabolic acidosis. The acidosis combined with the effects of prostaglandin I_2 and E_2 lead to the peripheral vasodilation despite profound levels of volume depletion. Prostaglandin release is also felt to play a role in the often unexplained nausea, vomiting, and abdominal pain that are frequently seen at presentation, especially in children. Vomiting, which may be a maladaptive physiologic response to diminish the acid load, unfortunately exacerbates the renal potassium losses and contributes to rapidly progressive volume loss, weakness, and weight loss. As volume depletion progresses, poor absorption of subcutaneous insulin renders it ineffective. Mental confusion or coma may be present at the time of presentation; these symptoms are much more likely with serum osmolarity >340 mOsm/L. If the serum osmolarity is <340 mOsm/L in a comatose patient, another cause of the coma should be sought.

Abnormal vital signs may be the only significant physical findings at the time of presentation. Tachycardia and either significant orthostasis or hypotension are usually present. Poor skin turgor denotes significant volume depletion. With severe acidemia, both the rate and depth of respirations are elevated secondary to compensatory hyperventilation (Kussmaul respirations). Acetone produces the characteristic fruity odor on the breath found in some patients. The absence of fever does not exclude infection as a source of the patient's ketoacidosis. Hypothermia is occasionally present.

Abdominal pain and tenderness can be due to gastric dilatation, ileus, or pancreatitis. Due to the frequency of abdominal pain and the presence of an elevated serum amylase in both DKA and pancreatitis, distinguishing the diagnoses may be difficult. Elevated serum lipase is more specific to pancreatitis and should be used to differentiate the two conditions.

LABORATORY

Almost all patients with DKA present with blood glucose greater than 300 mg/dL. Patients who present just after receiving insulin or who have impaired gluconeogenesis (e.g., in alcohol abuse or liver failure) may have lower initial serum glucose levels. [2] Elevated serum levels of bHB and AcAc cause acidosis and ketonuria. The nitroprusside reagent normally used to detect urine and serum ketones only detects AcAc. Acetone is only weakly reactive and bHB not at all. NADH accumulation in mitochondria, as may occur with lactic acidosis or alcohol metabolism, favors the bHB side of the equation noted earlier. The enzymatic test for bHB is reliable but not widely available. Paradoxically, ketone levels will increase as the patient is being treated and improve as the body converts the more acidic bHB to AcAc. Therefore, ketones need only be checked initially. Serum electrolytes should be carefully examined for multiple metabolic abnormalities. Elevated serum ketones lead to a high anion gap metabolic acidosis. Hyperchloremic acidosis also occurs on the basis of ketoanion exchange for chloride in the urine; this is especially true in patients who maintain good hydration status and thus their glomerular filtration rate despite ketoacidosis. Metabolic alkalosis also can occur due to vomiting, osmotic diuresis, and concomitant diuretic use. Some patients with DKA may present with "normal" appearing $[HCO_3^-]$ or even alkalemia if these other processes are severe enough to mask the acidosis. In such situations, an elevated anion gap may be the only clue to the presence of an underlying metabolic acidosis otherwise masked by the concomitant volume contraction-related metabolic alkalosis.

Arterial blood gases (ABG) have traditionally been used to help determine precise acid-base status in order to direct treatment. A very low P_{CO_2} usually reflects respiratory compensation for metabolic acidosis, but may also reflect a primary respiratory alkalosis, which may be an early indication of pulmonary disease (e.g., pneumonia, pulmonary embolus) as a possible trigger of the DKA. Chapter 21 details how compensatory changes in P_{CO_2} can be distinguished from a primary respiratory alkalosis. Recent studies have shown a strong correlation between venous and arterial pH in patients with DKA. [9] Venous pH obtained during routine phlebotomy can potentially be used to avoid ABGs, which are painful and may cause arterial vascular complications.

Total body potassium is depleted by renal losses. However, measured serum potassium is normal or elevated in most patients [10] because of two important factors: extracellular shift of potassium secondary to acidemia and increased intravascular osmolarity caused by hyperglycemia. [11] Prerenal azotemia also contributes by interfering with kaliuresis. Osmotic diuresis leads to excessive renal losses of sodium chloride in the urine. However, the presence of hyperglycemia tends to artificially lower the serum sodium levels. The standard correction is by adding 1.6 meq to the reported sodium value for every 100 mg of glucose over 100 mg/dL. Osmotic diuresis also causes urinary losses and total body depletion of phosphorous, calcium, and magnesium. Be aware that hemoconcentration frequently leads to initial artificially elevated levels. As therapy progresses lower serum levels of each will be evident.

Serum creatinine will frequently be artificially elevated because AcAc interferes with the laboratory assay. Liver function studies may be elevated because of fatty infiltration of the liver, which corrects as the acidosis is treated. CPK and amylase are also frequently elevated at the time of presentation. Leukocytosis is often present because of hemoconcentration and stress. However, an elevated band count of 10 or more has been shown to reliably predict infection in this population. [12]

Electrocardiographic changes of hyperkalemia or hypokalemia may be seen. These changes are often very transient because of the rapidly changing metabolic status. The cardiogram should also be evaluated for ischemia as myocardial infarction may precipitate DKA. The underlying rhythm is usually sinus tachycardia.

DIFFERENTIAL DIAGNOSIS

Although the exact definition of DKA is variable, most experts agree that a blood glucose greater than 250 mg/dL, bicarbonate level less than 15 meq/L, and an arterial pH of less than 7.3 with moderate ketonemia constitute the disease. [2]

The differential diagnosis of metabolic coma in a diabetic patient includes hypoglycemia, nonketotic hyperosmotic coma, alcoholic ketoacidosis, lactic acidosis, and other causes of wide anion gap acidosis. A rapid differentiation can be made in the emergency department using glucose reagent strips, urine dipsticks for ketones, and blood gas analysis. As an initial rapid diagnostic step, the finding of elevated glucose with the concomitant detection of ketones by near-patient testing methods, and the presence of metabolic acidosis on venous or arterial blood gas analysis, has few rival diagnoses other than DKA. However, evaluation of the anion gap is usually superior to pH or $[HCO_3^-]$ determination alone, because any "widening" of the anion gap is independent of potentially masking effects of concurrent other acid/base disturbances. The clinician who is not well acquainted with the nuances of blood gas interpretation (Chap. 21), will be confused when the pH and $[HCO_3^-]$ are not much altered from normal. Although the pH and $[HCO_3^-]$ are usually examined to determine the presence of an acidosis, both can be affected by concurrent acid/base disturbances as may occur when metabolic alkalosis is also present (pH and $[HCO_3^-]$ affected) or when respiratory alkalosis is also present (pH affected). Patients with hyperosmolar, nonketotic coma tend to be older, have a more prolonged course, and have prominent mental status changes. Their serum glucose levels

are generally much higher (>1000 mg/dL), and they have little to no anion gap metabolic acidosis.

The differential diagnosis of DKA includes any entity that causes a high anion gap metabolic acidosis. These include alcoholic or starvation ketoacidosis, uremia, lactic acidosis, and various ingestions (e.g., methanol, ethylene glycol, and aspirin). The ketosis in alcoholic ketoacidosis and starvation ketosis tends to be milder and glucose is usually low or normal. bHB predominates in alcoholic ketoacidosis so the urinary ketone test may be negative. If an ingestion is suspected, serum osmolarity or drug-level testing is required. Depending on the hemodynamic status, lactic acidosis (poor perfusion) may occur simultaneously with DKA; in these cases, serum lactate levels are indicated. The absence of, or presence of, only moderate ketonemia should elicit a search for lactic acidosis, as its presence favors the undetected bHOB as the predominant ketone.

TREATMENT

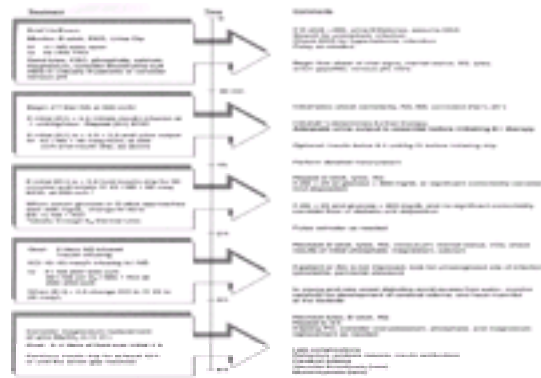
The diagnosis of DKA should be suspected at triage, and aggressive fluid therapy initiated prior to lab results (Fig. 203-2).[15] Patients should immediately be placed on a monitor in an acute care room and have at least one large-bore (16- to 18-gauge) intravenous line of 0.9% saline (NS) running, a second intravenous line of 0.45% normal saline at KVO (keep vein open), and have a rapid finger stick blood sugar, urine dipstick, and EKG performed. A CBC, electrolytes, phosphate, magnesium, calcium, blood cultures, and other laboratory tests should be sent as indicated. Arterial blood gases are optional, and are only required for the diagnosis and monitoring of critically ill patients. Consider utilizing venous pH (approximately 0.03 lower then arterial pH) [9] for monitoring. The goals of therapy include volume repletion, reversal of the metabolic consequences of insulin insufficiency, correction of electrolyte and acid-base imbalance, recognition and treatment of precipitating causes, and avoidance of complications. Metabolic disturbances should be corrected at the rate of occurrence, or over 24 to 36 h.


FIG. 203-2. Time line for the typical adult patient with suspected DKA.

A variety of therapeutic approaches have been advocated in the literature. Meeting the goals of safely replacing deficits and supplying missing insulin requires frequent (every one to two hours) monitoring of electrolytes (glucose, potassium, anion gap), vital signs, level of consciousness, and volume input/output until recovery is well established. Resolving hyperglycemia alone is not the end point of therapy. Concomitant resolution of the metabolic acidosis (or inhibition of ketoacid production) signifies resolution of DKA. Normalization of the anion gap usually requires 8 to 16 h, and reflects clearance of ketoacids. The order of therapeutic priorities is fluid, insulin, potassium, phosphate, magnesium, and bicarbonate.

Fluid Administration

Rapid fluid administration is the single most important initial step in the treatment of DKA. [3] Fluid helps restore intravascular volume and normal tonicity, perfuse vital organs, improve glomerular filtration rate (GFR), and lower serum glucose and ketones. The average adult patient has a water deficit of 100 mL/kg (5 to 10 L) and a sodium deficit of 7 to 10 meq/kg.[3] NS is the most frequently recommended fluid for initial rehydration even though the extracellular fluid of the patient is initially hypertonic. NS does not provide "free water" to correct intracellular dehydration, but it does prevent an excessively rapid fall in extracellular osmolarity and excessive transfer of water into the central nervous system (CNS). After initial resuscitation with NS, most authors favor alternating the administration of NS with half-normal saline, or utilizing two intravenous lines—one NS and one-half NS.

Based on clinical suspicion alone and prior to initial electrolyte results, the first liter of NS should be administered well within the first 30 min unless there are mitigating circumstances. In general, the first 2 L are administered rapidly over 0 to 2 h, the next 2 L over 2 to 6 h, and 2 L more over 6 to 12 h. This replaces approximately 50 percent of the total water deficit over the first 12 h, with the remaining 50 percent water deficit to be replaced over the subsequent 12 h. The blood glucose and ketone body concentration begin to fall after fluid administration and before implementation of any other therapeutic modality. [13] Hydration alone will reduce the glucose concentration by 17 to 80 percent over 12 to 14 h. [14] Tissue perfusion is restored with rehydration, improving the effectiveness of insulin. The subsequent rise in GFR allows for glucose and ketone body clearance, lowering serum glucose concentration and osmolarity. The patient's blood glucose needs to be carefully monitored, and 5% dextrose added to the rehydration solution when the glucose is 250 to 300 mg/dL.

The fluid should be changed to a hypotonic solution after the initial replacement of intravascular volume with normal saline. Patients presenting without extreme volume depletion can be safely managed with a modest fluid replacement regimen (500 cc/h for 4 h). [15] Monitoring central venous pressure or pulmonary artery wedge pressure should be considered during fluid replacement in elderly patients or in those with heart disease. Although the most common pitfall is failure to give adequate volume replacement,[3] excess fluid may contribute to the development of adult respiratory distress syndrome and cerebral edema.

Insulin

Initial hydration reduces the level of counterregulatory hormones, replaces vital fluid and electrolytes, and importantly, makes cells more responsive to insulin. In the early 1970s the dose, rate, and method of insulin administration in DKA was studied extensively. It is generally accepted that the "ideal way" to administer insulin is by continuous infusion of small doses of regular insulin through an infusion pump. [5,13,14,16] This approach appears to be more physiologic, helps produce a more linear fall in serum glucose and ketone bodies, and is associated with less-severe metabolic complications (hypoglycemia, hypokalemia, and hypophosphatemia).

Low-dose insulin administration by an infusion pump is simple, safe, and effective. Continuous insulin administration ensures that a steady blood concentration is maintained, and this technique allows flexibility in adjusting the insulin dose. Insulin inhibits gluconeogenesis, lipolysis, catabolic hormone secretion, and the production of ketoacids, in addition to promoting potassium, glucose, and phosphate uptake in tissues. After the initial fluid bolus, insulin is administered at 0.1 U/kg/h. Recent reviews have different recommendations regarding the use of an insulin-loading or -priming dose. [2,3,8] The effect of insulin begins almost immediately after the initiation of the infusion, and a loading dose has not been proven necessary. An intravenous loading dose of 0.1 U/kg is optional. The half-life of insulin given intravenously is 4 to 5 min, with an effective biologic half-life at the tissue level of approximately 20 to 30 min. Because insulin binds to plastic tubing, the first 25 mL of a prepared insulin solution (100 U of regular insulin in 100 mL of normal saline) should be wasted, and the drip plugged into an established intravenous line on an infusion pump at the port closest to the skin. Serious complications with continuous intravenous low-dose insulin infusions are minimal. Frequent monitoring is required to ensure that insulin is being administered in the desired amount.

Intramuscular or subcutaneous administration of regular insulin in DKA is to be discouraged. [5] Insulin absorption may be erratic in the volume-depleted, vasoconstricted patient, delaying the achievement of adequate insulin levels. Furthermore delayed absorption can produce deposits of insulin that may be later absorbed, causing hypoglycemia.

The incidence of nonresponders to low-dose continuous intravenous insulin administration is 1 to 2 percent. Infection is the primary reason for failure to respond. If the patient fails to respond to low-dose insulin therapy in the first hour (assuming adequate hydration), the infusion rate should be doubled or an intravenous bolus (0.2 to 0.4 U/kg) administered.

The insulin infusion should continue until ketonemia has cleared, [5] and the anion gap has normalized. As previously noted, there is conversion from bHB to AcAc, with

"increasing ketones" measurable in the serum and urine. Therefore, the anion gap is the more accurate determinant of ongoing recovery. Resolution of hyperglycemia usually occurs earlier than the anion gap [14] and it may be necessary to administer glucose from the beginning of insulin therapy, or shortly after its institution. In most patients, continuous intravenous insulin therapy should continue for at least 12 h (or until resolution of the anion gap), and an overlap period in which subcutaneous insulin is given should precede discontinuation of the insulin infusion. In the rare patient with initial hypokalemia (<3.5 meq), insulin can precipitate life-threatening hypokalemic effects.[14] Parenteral potassium should be started in these patients (10 to 15 meq/h) for at least 30 min prior to insulin.

Potassium

Patients in DKA usually present with profound total body potassium deficits in the range of 3 to 5 meq/kg. [3] This deficiency is created by insulin deficiency, metabolic acidosis, osmotic diuresis, and frequent vomiting. Only 2 percent of total body potassium is intravascular, and the initial serum concentration is usually normal or high because of the intracellular exchange of potassium for hydrogen ions during acidosis, total body fluid deficit, and diminished renal function. Initial hypokalemia indicates severe total body potassium depletion, and large amounts of potassium are necessary for replacement in the first 24 to 36 h.

The goals of potassium replacement are to maintain a normal extracellular potassium concentration during the acute phases of therapy and to replace the intracellular deficit over a period of days. During initial therapy for DKA, the serum potassium concentration may fall rapidly, primarily due to the action of insulin promoting reentry of potassium into cells and, to a lesser degree, to the dilution of extracellular fluid, correction of acidosis, and increased urinary loss of potassium. If these changes occur too rapidly, precipitous hypokalemia may result in fatal cardiac arrhythmias, respiratory paralysis, paralytic ileus, and rhabdomyolysis. The development of severe hypokalemia is potentially the most life-threatening electrolyte derangement during the treatment of DKA. [3] This complication is avoidable if the pathophysiology is understood and the effects of therapy frequently monitored.

Early potassium replacement is now a standard modality of care. Potassium is not added blindly to the first liter of NS administered to restore circulation, because giving potassium rapidly to a patient in a hyperkalemic potentiating state (i.e., acidemia, insulin deficiency) may dangerously increase extracellular potassium and precipitate fatal ventricular tachycardia or fibrillation. The patient's initial EKG often provides early evidence of hyperkalemia, progressively manifested by peaked T waves, prolonged PR interval, absent P wave, increasing QRS interval, and, lastly, a sine-wave pattern. The initial measurement of serum electrolytes and presence of urine output determine initial potassium therapy. As a general guideline, initial serum potassium greater than 3.5 meq/L and less than 5.5 meq/L (prior to fluid resuscitation and insulin) coupled with urine output calls for 10 meq KCl/h replacement in intravenous fluid for at least four hours. Because the most rapid changes occur during the first few hours of therapy, plasma potassium is initially measured every one to two hours. If oliguria is present (fortunately this is rare secondary to the protective osmotic diuresis) renal function must be evaluated and potassium replacement must be decreased. An initial serum potassium greater than 5.5 meq/L usually reflects a more profound acidemia. Intravenous potassium replacement is withheld until the serum potassium is documented to be below 5.5 meq/L and urine output is established. Fluid and insulin therapy alone will usually lower the serum potassium rapidly. Initial hypokalemia (<3.5 meq/L) necessitates more aggressive replacement prior to insulin therapy. Intravenous potassium should be given at 15 to 20 meq/h, with insulin initiated 30 min later. There is no documented advantage using potassium phosphate over potassium chloride; excessive use of potassium phosphate may result in metastatic precipitation of calcium phosphate in tissues.

The goal is to maintain serum potassium levels within the normal range of 4 to 5 meq/L and avoid life-threatening hyper- or hypokalemia. Oral potassium replacement is safe and effective, and should be utilized as soon as the patient can tolerate oral fluids. During the first 24 h, potassium chloride 100 to 200 meq is usually required. Occasionally, as much as 500 meq is necessary.

Phosphate

Phosphate plays an integral role in the conversion of energy from adenosine triphosphate (ATP) and in the delivery of oxygen at the tissue level through 2,3-diphosphoglyceric acid (2,3-DPG). In addition, many important enzymes, cofactors, and biochemical intermediates depend upon phosphate. Phosphate is primarily intracellular, and shifts to the extracellular compartment during DKA. Serum levels are often normal or increased upon presentation, and do not reflect the total body phosphate deficits secondary to enhanced urinary losses. [8] Phosphate (similar to glucose and potassium) reenters the intracellular space during insulin therapy, resulting in low phosphate concentrations. Hypophosphatemia is usually most severe 24 to 48 h after the start of insulin therapy. Acute phosphate deficiency (<1.0 mg/dL) has been associated with a variety of clinical disorders, including hypoxia, rhabdomyolysis, hemolysis, respiratory failure, and cardiac dysfunction. Fortunately, all are extremely rare during therapy of DKA. [5]

The role of phosphate replacement during the treatment of DKA remains controversial. No clinical trial has demonstrated significant benefits from routine intravenous phosphate therapy.[8,14] In general, intravenous therapy should be withheld unless the serum phosphate concentration is less than 1 mg/dL. Hypophosphatemia can be corrected safely and effectively with oral replenishment, which may cause diarrhea.

There is no established role for initiating intravenous potassium phosphate in the ED. Significant hypophosphatemia tends to develop only many hours into therapy, after the patient is already admitted. Several undesirable side effects from intravenous phosphate administration have been reported. These include hyperphosphatemia, hypocalcemia, hypomagnesemia, metastatic soft tissue calcifications, and hypernatremia and volume loss from osmotic diuresis. If deemed necessary (phosphate <1.0 mg/dL early in therapy and/or patient vomiting), intravenous phosphate replacement should be done by, or in consult with, experienced physicians in an ICU setting. Serum phosphate, calcium, and magnesium levels should be monitored during therapy of DKA; but, again, the case for routine early parenteral phosphate replacement has not been made.

Magnesium

Ongoing osmotic diuresis may cause significant depletion of magnesium stores (from bone) and hypomagnesemia. Hypomagnesemia may inhibit parathyroid hormone secretion, causing hypocalcemia and hyperphosphatemia. Symptomatic hypomagnesemia in DKA (hyperreflexia, positive Chvostek or Trousseau signs) is rare, as is the need for intravenous therapy. If serum magnesium is <1.2 mg/dL or symptoms are suggestive of hypomagnesemia, magnesium can be given orally in the form of magnesium oxide or parenterally as magnesium sulfate. It is recommended to monitor serum magnesium and calcium on presentation and 24 h into therapy unless symptoms suggestive of hypomagnesemia or hypocalcemia occur.

Bicarbonate

The role of bicarbonate in DKA has been debated for decades. Arbitrary initial pH levels to utilize bicarbonate are still currently recommended in many texts. To date, not a single study clearly demonstrates improved clinical outcome using bicarbonate in the treatment of DKA. Acidotic patients routinely recover from DKA without alkali therapy. Routine use of supplemental bicarbonate in the treatment of DKA is not recommended. [8,17,18]

Severe metabolic acidosis is associated with numerous cardiovascular (impaired contractility, vasodilation, hypotension) and neurologic (cerebral vasodilation and coma) complications.[14] Theoretical advantages of bicarbonate include improved myocardial contractility, elevated ventricular fibrillation threshold, improved catecholamine tissue response and decreased work of breathing. [17] These theoretical advantages appear outweighed by the possible disadvantages of bicarbonate administration in DKA of severe and worsening hypokalemia; paradoxical central nervous system acidosis; worsening intracellular acidosis; impaired oxyhemoglobin dissociation; rebound alkalosis; hypertonicity and sodium overload; delayed recovery from ketosis; [18] elevation of lactate levels;[17] and possible precipitation of cerebral edema.[14] During routine therapy of DKA hydrogen ion production ceases when ketogenesis stops; excessive hydrogen ions are eliminated through the urine and respiratory tract. Ketone body metabolism results in the endogenous production of alkali. Children with initial pH values as low as 6.73 have been shown to promptly recover from DKA without bicarbonate.[17]

Severe acidosis (pH <7.0) and worsening pH despite aggressive therapy for DKA should prompt the clinician to rule out other causes of metabolic acidosis (i.e., lactate from sepsis or bowel infarction, methanol ingestion, etc.). The potential benefits of bicarbonate in the elderly with cardiovascular instability and DKA must be balanced against the potential disadvantages. [8]

COMPLICATIONS AND MORTALITY

Complications can be categorized as those occurring secondary to the acute disease, early complications related to therapy, and late complications. A critically ill, lethargic patient is at risk for aspiration, and airway protection and evacuation of gastric contents may be indicated. In general, the greater the presenting serum osmolarity, blood urea nitrogen, and blood glucose concentration, the greater the mortality. There is also increased mortality for patients presenting with a serum

bicarbonate level of less than 10 mEq/L.

Of the factors responsible for precipitating DKA, infection and myocardial infarction are the main contributors to high mortality. Half the patients with DKA die when myocardial infarction is the precipitating event. Additional factors that reduce the chances of survival include old age, severe hypotension, prolonged and severe coma, and underlying renal and cardiovascular disease. Severe volume depletion leaves the elderly at risk for vascular stasis and deep vein thrombosis. Prophylactic heparin should be instituted in high-risk patients as inpatients.

Major complications related to therapy of DKA include hypoglycemia, hypokalemia, hypophosphatemia, ARDS, and cerebral edema. The goal of therapy is to produce a gradual return to normal metabolic balance. Rapid shifts of water, electrolytes and other solutes can be avoided by using isotonic saline as the initial intravenous fluid, using continuous intravenous low-dose insulin, replacing potassium early, and avoiding bicarbonate. Above all, a basic understanding of the pathophysiology of DKA, constant monitoring of the patient, and attention to detail are essential to prevent complications of therapy.

ARDS is a rare complication of therapy. Aggressive fluid therapy decreases plasma oncotic pressure and raises left atrial end diastolic pressure, favoring a shift of fluid across the pulmonary capillary membrane. Fortunately, widening of the alveolar arterial gradient, hypoxia, and chest radiograph changes are very rare. Elderly patients who present with rales on chest exam may be at increased risk and should be monitored closely for this complication with continuous pulse oximetry and serial exams; they should also receive lower rates of fluid. [3]

The development of cerebral edema during the treatment of DKA, especially in young patients, is a potentially catastrophic complication. [13] Cerebral edema tends to occur during the first 24 h of therapy when the patient appears to be improving clinically and biochemically. [8] The true incidence of clinically apparent cerebral edema is unknown, but estimated to be 0.7 to 1.0 per 100 episodes of DKA in children. [8] Cerebral edema complicating DKA has a reported mortality of 70 percent. One hypothesis is that the osmotic diuresis promotes loss of water and sodium from both intra- and extracellular spaces. Hyperglycemia leads to a hyperosmolar extracellular state. Brain cells enzymatically produce osmotically active particles, or idiogenic osmoles that protect cells from further loss of water and shrinkage. During therapy with intravenous fluid and insulin, water moves into brain cells faster then idiogenic osmoles can dissipate, promoting cellular swelling. [8,14] Subclinical brain swelling has been reported in asymptomatic children during treatment of DKA. [14]

Multiple studies and reviews have found no specific presentation or treatment variables that predict or contribute to the development of cerebral edema. [14] Young age and new-onset diabetes are the only identified potential risk factors. Excessive initial fluid administration of greater than 4 L/m^2 body surface area per day has been associated with cerebral edema. [14] Initial "corrected" hypernatremia may be a risk factor in children as well. Recent data suggests that children who develop cerebral edema initially may have a relatively normal serum osmolarity and subsequently develop progressive hyponatremia and/or a trend of declining serum sodium before developing cerebral edema. [19] Approximately one-half of the patients who developed cerebral edema had premonitory symptoms of severe headache; incontinence; change in arousal or behavior; pupillary changes; blood pressure changes; seizures; bradycardia; or disturbed temperature regulation. Any change in neurologic function early in therapy should prompt the clinician to immediately administer mannitol at 1 to 2 g/kg body weight, which should be at the bedside of high-risk patients. Mannitol should be given prior to obtaining confirmatory CT scans, [8] as serious morbidity and mortality may be prevented. Other aggressive measures such as intubation, hyperventilation, and fluid restriction may be necessary. Gradual replacement of water and sodium deficits and slow correction of hyperglycemia may lessen the risk.

It is important to monitor for late complications of DKA. Metabolic acidosis refractory to routine therapy may be secondary to unrecognized infection (lactic acidosis), insulin antibodies, or improper preparation or administration of the insulin drip. Shock, unresponsive to aggressive fluid therapy suggests gram-negative bacteremia or silent myocardial infarction. Hyperchloremic non-anion gap metabolic acidosis develops in virtually every patient during therapy due to rapid volume expansion in the face of reduced HCO_3^- content. Also, bicarbonate equivalents are excreted in the urine as ketones and replaced with chloride provided by the normal saline. This emphasizes the importance of monitoring the anion gap during therapy, not the bicarbonate concentration. The non-anion gap metabolic acidosis (should it be present) resolves during recovery as bicarbonate is regenerated and excess chloride excreted in the urine.

Late vascular thrombosis may occur in any muscular artery, though cerebral vessels appear to be most susceptible. [5] Volume depletion, low cardiac output, increased blood viscosity, and underlying atherosclerosis may predispose the elderly to this rare complication. Thrombosis may occur several hours or days after institution of therapy, and after resolution of ketoacidosis. [13]

Mortality in DKA results mainly from sepsis or pulmonary and cardiovascular complications in the elderly, and fatal cerebral edema in children and young adults (<28 years old). [8] Age-adjusted death rates per 100,000 diabetic population for DKA and DKA-related deaths declined between 1980 and 1987, increased in 1988 and 1989, and then began decreasing again in 1990. Overall, both the age-adjusted DKA death rate and the DKA-related death rate were 34 percent lower in 1994 than in 1980. The highest death rates were among persons aged >75 years, followed by persons aged <45 years. Among race-sex groups, DKA death rates were highest among black males, followed by black females, and then by whites. In 1994, the age-adjusted DKA death rate for black males was almost twice that for white males. [20]

DISPOSITION

The great majority of patients require hospitalization in a monitored setting, where there is nursing experience with insulin drips. In most institutions patients are initially cared for in an intensive care or intermediate intensive care unit. A select group of patients with an initial anion gap <25, glucose <800 mg/dL, and no comorbidity may be safely managed on an inpatient unit with nursing expertise utilizing insulin drips and managing diabetic patients. Patients presenting early in the course of their illness, who can tolerate oral liquids may be safely managed in the ED or observation unit and discharged after four to six hours of therapy. [3]

204 ALCOHOLIC KETOACIDOSIS

William A. Woods
Debra G. Perina

Alcoholic ketoacidosis (AKA) is a wide anion-gap acidosis most often associated with acute cessation of alcohol consumption after chronic alcohol abuse. The metabolism of alcohol with little or no glucose sources results in the elevated levels of ketoacids that typically produce the metabolic acidosis present in this illness. Although usually seen in chronic alcoholics, ketoacidosis has been described in first-time drinkers who binge drink, particularly in association with volume depletion from poor oral intake and vomiting.

PATHOPHYSIOLOGY

AKA occurs in the setting of a large quantity of alcohol ingestion and relative starvation. Starvation decreases glycogen and insulin stores and increases catecholamines, glucagon, growth hormone, and cortisol. As glycogen stores decrease, insulin production is retarded, resulting in increased lipolysis, increased hepatic ketogenesis, and peripheral use of ketones. Elevated levels of catecholamines, glucagon, growth hormone, and cortisol also stimulate lipolysis and hepatic ketogenesis. Both of these metabolic pathways lead to ketoacidosis.

Three types of ketones are produced in varying amounts: b-hydroxybutyrate (bHB), acetoacetate, and acetone (Fig. 204-1). Acetone, a metabolite of acetoacetate and a nonacidotic ketone, is rapidly excreted in urine. bHB and acetoacetate are the predominant primary ketones producing the acidosis seen in this illness, with bHB usually in greater concentration. The usual ratio of these ketones in healthy patients is 1:1. The ratio of these ketones is 5:1 to 10:1 in patients with AKA. The lack of nicotinamide adenosine dinucleotide (NAD), a necessary cofactor used to form acetoacetate from bHB, is thought to be the principle cause of this disparity.

FIG. 204-1. Ethanol metabolism.

The enzyme alcohol dehydrogenase metabolizes alcohol to acetaldehyde and acetate. Acetaldehyde is metabolized by the enzyme aldehyde dehydrogenase to acetyl coenzyme A, which forms free fatty acids, ketone bodies, and enters the Krebs cycle for glucose metabolism (Fig. 204-1). Under normal metabolic conditions, the majority of acetyl coenzyme A enters the Krebs cycle, and few ketone bodies are produced. NAD is a necessary cofactor for this step and is continually renewed through mitochondrial oxidation.

Under conditions of relative starvation, as seen in AKA, there is a relative insulin deficiency, whose release is further inhibited by the a-adrenergic response to volume contraction. Thus, glucose is not available for utilization in the Krebs cycle and the equation shifts to production of ketone bodies. In addition, the rate of NAD oxygenation by mitochondria also declines, resulting in a deficiency of this cofactor to metabolize alcohol and acetaldehyde, which further stimulates ketone body production (Fig. 204-1). The resulting deficiency of NAD can persist for several days after alcohol consumption has ceased. Hepatic gluconeogenesis is also decreased, due to the lack of available NAD cofactor for metabolism, along with decreased glycogen stores. Thus, AKA occurs in the setting of increased ketone production and an increased ratio of NADH (the reduced form of NAD) to NAD.

Additional mechanisms that contribute to ketone production include alcohol-induced mitochondrial structural changes and mitochondrial phosphorus depletion. Hypophosphatemia also inhibits the utilization of NADH and increases ketone body formation. Finally, acute vomiting and starvation superimposed on chronic malnutrition also contributes to the ketoacidosis state.

EPIDEMIOLOGY

There are no gender differences. The age of presentation is variable but usually between 20 to 60 years. Patients often experience repeated episodes of ketoacidosis, with 23 percent of patients having more than one episode of AKA in one series. The true incidence of this illness is unknown, but most likely mirrors the incidence of alcoholism in the population. [1] This illness may be more prevalent than previously suspected. One study indicated that analysis of serum chemistries of alcoholics arriving at emergency departments with complaints related to excessive alcohol intake incidentally found ketoacidosis in 25 percent of patients. Although with proper treatment this illness is self-limited, poor outcomes can occur. Medical examiner literature notes that 10 percent of deaths in known alcoholics are from AKA.[2]

CLINICAL FEATURES

AKA typically occurs after an acute decrease in alcohol intake in association with several days of poor food intake or vomiting. It is most commonly seen after a patient has had an episode of heavy drinking followed by decreases in alcohol and food intake. The nausea, vomiting, and abdominal pain that may be associated with gastritis or pancreatitis may exacerbate the progression of the illness. As anorexia continues, the symptoms worsen, leading the patient to seek health care. Symptoms, listed in Table 204-1, are nonspecific, making diagnosis difficult without laboratory studies as confirmation.

Symptoms,	%	Signs/Anion Gap,	%
Nausea	76	Tachycardia	56
Vomiting	73	Tachypnea	49
Abdominal pain	62	Abdominal tenderness	43
Shortness of breath	20	Heme-positive stool	18
Tremulousness	20	Hepatomegaly	18
Hematemesis	19	Altered mental status	15
Dizziness	19	Hypotension	12

Source: From Wrenn et al[?] and Soffer and Hamburger,[4] with permission.

TABLE 204-1 Common Symptoms and Signs in Alcoholic Ketoacidosis

There are no specific physical findings associated solely with AKA. The most common findings are tachycardia, tachypnea, and diffuse, mild to moderate abdominal tenderness. Volume depletion resulting from anorexia, diaphoresis, and vomiting causes the frequently seen tachycardia and hypotension. Most patients are awake at presentation. Mental status changes in patients with ketoacidosis should alert clinicians to other potential causes, such as toxic ingestion, hypoglycemia, alcohol-withdrawal seizures, postictal state, or unrecognized head injury.

LABORATORY

Alcohol levels are usually low or undetectable at the time of presentation, but some patients may present with an elevated blood alcohol level, making diagnosis more challenging. An elevated anion gap caused by ketones is essential for diagnosing AKA. As bHB predominates, the degree of ketonemia may not be appreciated, depending on the method of ketone detection (see Chap. 203 for a complete discussion). The initial anion gap is usually 16 to 33, with a mean of 21. Patients frequently have mild hypophosphatemia, hyponatremia, and/or hypokalemia. Most patients will also have elevated bilirubin and liver enzymes due to a long history of chronic ethanol use. Blood urea nitrogen and creatinine kinase levels are frequently elevated due to relative volume depletion. Serum lactate levels can be mildly elevated. Glucose levels are most often only mildly elevated, but a subset of patients will have hypoglycemia. On rare occasions, the glucose level may be greater than 200 mg/dL.

Acid-Base Balance

Serum pH is typically acidemic, but the pH may be normal or even alkalemic early in the course of the illness. In one study, 15 percent of patients were alkalemic, 30 percent had normal pH, and 55 percent had acidemia.[1] The degree of acidosis is typically less than that seen in patients with diabetic ketoacidosis. If the acidosis is mild and the patient also has a primary respiratory alkalosis (i.e., due to fever, sepsis, or alcohol withdrawal), then the pH may be normal or even alkalemic. Similarly, contraction metabolic alkalosis may mask the presence of a concurrent wide anion-gap acidosis and result in a "normal" or even elevated [HCO_3^-], rendering the pH normal or alkalemic. Since volume loss, whether due to poor volume intake or vomiting, is virtually always present in AKA, some degree of metabolic alkalosis is sure to exist.

Without routine evaluation of the anion gap in every patient at risk for AKA, the diagnosis can be easily missed. An anion gap greater than the patient's baseline (or greater than 15 in any case) signifies the presence of a wide anion-gap acidosis regardless of the actual [HCO_3^-] concentration or the pH, even if the patient is alkalemic. For example, a common serum chemistry result in a patient with AKA may be along the following lines: [Na^+], 145, [Cl], 95, [K^+], 4.1, and [HCO_3^-], 25. In this example, the anion gap (25, excluding K^+) is elevated by at least 10, yet the [HCO_3^-] and electrolyte levels are normal. The only explanation is that a mixed acid-base abnormality of approximately equal but opposing magnitudes exists. Arterial blood-gas determination is not needed to arrive at the correct diagnosis for this relatively complicated acid-base disturbance. (For a more detailed discussion, the reader is referred to Chap. 21, "Acid-Base Disorders.")

Ketones

Ketone bodies may be detected by the serum and urine nitroprusside test, which is the standard test for ketone detection. While bHB is the predominant ketone present in AKA, acetoacetate is the ketone normally detected by the nitroprusside test. As patients with AKA may have elevated acetoacetate levels, it is important not to develop a false sense of security with a negative or only weakly positive test. As treatment progresses and NAD levels increase, the acetoacetate levels may actually increase and the nitroprusside test will reflect an increasingly positive reaction. This natural progression should be expected and does not indicate a worsening of the patient's condition. The clinical application of this test is thus quite variable. Most authors suggest measuring bHB and acetoacetate levels only if the diagnosis is unclear or other ways are not available to follow the patient's response to therapy.[3]

DIAGNOSIS

The diagnosis is established in the classic presentation of the chronic alcoholic, with recent anorexia, vomiting, abdominal pain, unexplained metabolic acidosis with a positive nitroprusside test, elevated anion gap, and a low or mildly elevated serum glucose level. However, this presentation is uncommon. Establishing this diagnosis can be difficult for several reasons. First, the blood alcohol level may be zero, and the patient may not voluntarily provide the history of alcohol consumption. Second, urine nitroprusside testing may be negative or weakly positive, despite significant ketoacidosis. Third, the pH may vary from reflecting significant acidemia to mild alkalemia, depending on how advanced the pathophysiology is and the degree of ketone body production, as explained above.

Initial laboratory studies usually include determination of electrolyte, blood urea nitrogen, creatinine, white blood cell, hematocrit, hepatic and pancreatic enzyme levels, and urinalysis. The anion gap should be calculated. Determination of serum lactic acid level and serum osmolarity may also be helpful. Further laboratory studies may be needed to delineate the cause of the increased anion-gap acidosis if other ingestions besides ethanol are suspected (see the following section on differential diagnosis). An arterial blood-gas determination is unnecessary unless a primary respiratory acid-base disturbance is suspected (Table 204-2).

TABLE 204-2 Diagnostic Criteria for Alcoholic Ketoacidosis

Differential Diagnosis

The differential diagnosis for AKA is very broad. It is essentially the differential diagnosis of wide anion-gap metabolic acidosis. Lactic acidosis, uremia, and ingestants (particularly methanol and ethylene glycol) should be considered. A mild lactic acidosis is occasionally present in AKA related to ethanol metabolism, but it

is comparatively inconsequential. A significant lactic acidosis always stems from another cause. Lactic acidosis related to anaerobic metabolism (e.g., hypotension, sepsis, or tissue ischemia) or associated with methanol, ethylene glycol, and salicylic acid are usually markedly more severe and less readily masked by concurrent metabolic alkalosis. Both salicylic acid poisoning and sepsis (related lactic acidosis) often present with triple acid-base disturbances (metabolic acidosis, metabolic alkalosis, and primary respiratory alkalosis). Renal failure as a potential etiology can be ascertained from the serum chemistries. Diabetic ketoacidosis has a blood sugar level greater than 300 mg/dL. Finally, a differentiation from starvation ketosis is an academic exercise and unimportant, because underlying pathophysiology, treatment, and implications are similar. Isopropyl alcohol ingestion results in production of ketones and is on occasion associated with a mild lactic acidosis on a similar basis as is found in AKA. The presence of an osmolal gap (which is also a feature of methanol and ethylene glycol poisoning) may be differentiating. However, ethanol is osmotically active and, if present, will also contribute to an osmolal gap. If the blood alcohol level is known, then its contribution to any osmolal gap can be calculated. If the entire osmolal gap cannot be attributed to the ethanol level, then isopropyl alcohol (mild or no acidosis), methanol, or ethylene glycol (severe acidosis) may well be the explanation. Each 100 mg/dL of ethanol raises the osmolal gap by 22. (A full discussion on the diagnostic approach to distinguish various wide anion-gap type acidosis is found in Chap. 21, "Acid-Base Disorders." Details of osmolal gap are discussed in Chap. 23, "Fluids and Electrolyte Problems.")

Patients with AKA often have concurrent illnesses that may have promoted the alcohol cessation and anorexia. Thus, a thorough investigation for underlying illnesses should be performed. Common concurrent illnesses are pancreatitis, gastritis or upper gastrointestinal bleeding, seizures, alcohol withdrawal, sepsis, and hepatitis.

TREATMENT

Treatment of AKA is symptomatic. Therapy is aimed at both glucose administration and volume repletion. Ketoacidosis can be treated with only saline administration, but the addition of glucose hastens recovery. Glucose stimulates insulin production, which stops lipolysis and halts the further formation of ketones. Glucose also increases the oxidation of NADH to NAD, thereby further stopping ketone production. Patients with AKA are not hyperosmolar, and cerebral edema is of less concern with large volumes of fluid resuscitation. Even with vigorous fluid resuscitation, no cases of cerebral edema have been reported among those being treated for AKA.

Insulin is of no proven benefit and can be dangerous because patients often have depleted glycogen stores and normal glucose levels. Sodium bicarbonate is not indicated unless patients are severely acidemic, with a pH of 7.1 or lower. As noted, this level of acidemia is unlikely to be explained by AKA alone. A vigorous search for an alternate explanation must be undertaken. Hypophosphatemia is frequently seen in chronic alcoholic patients and can retard the resolution of acidosis, as phosphorus is necessary for mitochondrial utilization of glucose to produce NADH oxidation. However, phosphate replacement is generally unwarranted as part of this treatment in the ED, unless very low levels are encountered (less than 1.0 mg/dL). Oral replenishment is safe and effective. Nitroprusside tests correlated with clinical status may be used to help guide therapy, as an increasingly positive reaction signifies improvement. To prevent precipitation of Wernicke disease, all patients should receive 50 to 100 mg of thiamine prior to the administration of glucose. Concomitant administration of magnesium sulfate and multivitamins should be considered and guided by laboratory results. Acidosis may clear within 12 to 24 h. Patients whose course is uncomplicated may be safely discharged home if there is resolution of acidosis over time and the patient is able to tolerate oral fluids. Those patients with a complicated course, underlying illnesses, or persistent acidosis should be admitted for further evaluation and treatment.

205 HYPEROSMOLAR HYPERGLYCEMIC NONKETOTIC SYNDROME

Charles S. Graffeo

The disease process discussed in this chapter is frequently referred to as *nonketotic hyperosmolar coma* to characterize the syndrome of severe hyperglycemia, hyperosmolarity, and a relative lack of ketonemia in patients with poorly controlled or undiagnosed type 2 diabetes mellitus. The literature is replete with a score of other acronyms for this syndrome. The nomenclature used by the American Diabetes Association, *hyperosmolar nonketotic state* (HNS) and *hyperosmolar hyperglycemic nonketotic syndrome* (HHNS) are both commonly used and more appropriate. This chapter uses the HHNS designation. Placing emphasis on the presence or lack of coma, is likely to underestimate the severity of disease, and thus "coma" should be excluded from the nomenclature. In fact, although patients may present with a host of symptoms referable to the central nervous system, less than ten percent actually present with coma.[1] What is more typical, is a broad range of clinical presentations that correlate with the degree of serum osmolarity, volume depletion, underlying medical illness and severity of precipitating factors such as acute infection.

In general, HHNS is "defined" by extreme hyperglycemia with serum glucose usually greater than 400 mg/dL, an elevated calculated plasma osmolality of greater than 315 mosm/kg, serum bicarbonate greater than 15, an arterial ph of >7.3, and serum negative for ketones in a 1:2 dilution. These values, however, are fairly arbitrary and, depending on the severity of disease, serum glucose measurements may be well over a thousand. A profound metabolic acidosis and even mild degrees of ketonemia may both be found in HHNS. The importance of recognizing the potential for a variety mixed acid-base patterns in patients presenting with HHNS cannot be overemphasized.

Many authors propose that HHNS and diabetic ketoacidosis (DKA) should be viewed as similar disease processes with the fundamental difference being in the metabolism of lipids during a period of relative insulin deficiency. Shared features of both include hyperglycemia, hyperosmolarity, severe volume depletion, electrolyte disturbances and, sometimes, acidosis. The acidosis associated with HHNS may be due to tissue hypoperfusion (lactic acidosis), a mild starvation ketosis, and azotemia, in various combinations. In contrast, patients with DKA at similar levels of tissue perfusion also have much higher levels of circulating ketone bodies, which contribute additional anions, resulting in a more profound acidosis.

Early identification is the most effective means of preventing serious diabetes complications, including HHNS. Mild elevations of serum glucose identified on emergency department laboratory panels should not be ignored. Patients with evidence of hyperglycemia should be made aware of this potentially significant finding and referred for evaluation. The diagnostic criteria for diabetes should be used for the identification of undiagnosed diabetes (Table 205-1).[2]

1. Symptoms of diabetes plus a casual plasma glucose concentration >
   200 mg/dL. *Casual* is defined as any time of day without regard to
   the time since last meal. Symptoms include polyuria, polydipsia, and
   unexplained weight loss.
2. Fasting plasma glucose ≥ 126 mg/dL. *Fasting* is defined as no caloric
   intake for at least 8 h.
3. 2-h postglucose (PG) tolerance test, 2-hPG value of ≥ 200.

Impaired fasting glucose
1. Fasting plasma glucose ≥ 110 and < 126 mg/dL.
2. 2-hPG ≥ 140 and < 200 mg/dL. = impaired glucose tolerance.

Classification of Diabetes Mellitus,[1] with permission.

TABLE 205-1   American Diabetes Association Diagnostic Criteria for Diabetes and Impaired Fasting Glucose

EPIDEMIOLOGY

The basic epidemiology of diabetes is discussed in Chap. 209. Although HHNS occurs much less frequently than DKA, mortality rates are much higher. Reported range of mortality in HHNS is 15 to 35 percent versus approximately 5 percent in DKA.[3]

PATHOPHYSIOLOGY

The basic pathophysiology of diabetes is discussed in Chap. 209. The development of HHNS is attributed to three main factors: (1) decreased insulin utilization, (2) increased hepatic gluconeogenesis and glycogenolysis, and (3) impaired renal excretion of glucose.

During a state of poorly controlled type 2 diabetes mellitus, inadequate tissue utilization of glucose caused by insulin resistance results in hyperglycemia. In the absence of an adequate peripheral response to insulin, hepatic glycogenolysis and gluconeogenesis occurs, further elevating serum glucose. As serum glucose concentration increases, it creates an osmotic gradient that draws water out of the intracellular space and into the intravascular compartment. This initial increase in intravascular volume is accompanied by a temporary increase in the glomerular filtration rate (GFR). As serum glucose concentration exceeds approximately 180 mg/dL, the renal reabsorbtive capacity for glucose is exceeded, and glucosuria and a profound osmotic diuresis occur.

Patients with free access to water are often able to prevent profound volume depletion by replacing lost water with large free water intake. If this water requirement is not met (as may occur in a nonambulatory nursing home patient), volume depletion occurs. During osmotic diuresis, urine produced is markedly hypotonic. Still significant urinary loss of sodium and potassium, as well as more modest loss of calcium, phosphate, magnesium, and urea, also occur. As volume concentration progresses, renal perfusion decreases and the GFR is reduced. Renal tubular excretion of glucose is consequently impaired, which further worsens the hyperglycemia. A sustained osmotic diuresis may result in total body water losses that often exceed 20 percent of total body weight or approximately 9 L in a 70-kg patient.

The reason for the absence of ketoacidosis in HHNS is not clearly understood. Though some degree of a starvation ketosis does occur, clinically significant ketoacidosis does not. This lack of ketoacidosis in HHNS has been attributed to three possible mechanisms: (1) lower levels of counterregulatory hormones, (2) higher levels of endogenous insulin, which strongly inhibits lipolysis, and (3) inhibition of lipolysis by the hyperosmolar state.

There is controversy about the role that counterregulatory hormones glucagon, cortisol, growth hormone, and epinephrine play in HHNS. When compared with DKA, glucagon and growth hormone levels have been shown to be lower, which may help prevent lipolysis. When compared with DKA, significantly higher levels of insulin are found in the peripheral and portal circulation in HHNS. Though these levels of insulin are insufficient to overcome hyperglycemia, they appear to be sufficient to inhibit lipolysis.[4] Finally, there have also been limited experimental animal studies that have shown that both the hyperosmolar state and severe hyperglycemia inhibit

lipolysis in adipose tissue.[5]

CLINICAL FEATURES

The typical patient with HHNS is usually elderly, who is often referred by a caretaker for abnormalities in vital signs and or mental status; with complaints which include weakness, anorexia, or fatigue. Many will have either undiagnosed or poorly controlled type 2 diabetes. These patients often have some level of baseline cognitive impairment, and self-referral for medical treatment is rare. In general, any patient with hyperglycemia, an impaired means of communication, and limited access to unassisted free water intake is at risk for HHNS. The presence of renal insufficiency or cardiovascular disease is common to this patient population. The medications such as diuretics that are commonly used to treat these underlying chronic problems, predisposes to the development of HHNS.

Usually some precipitating event causes a patient to develop an insidious state of progressive hyperglycemia and hyperosmolarity, which goes unchecked. By far, acute infection is the most common precipitating cause of HHNS. Urinary tract infection and pneumonia are most common, though uremia, viral illness, and a host of metabolic and iatrogenic causes have been identified (Table 205-2). Similarly, several drugs may predispose or contribute to hyperglycemia, volume depletion, or other effects leading to HHNS (Table 205-3).

Diabetes	Infection
Parental or enteral alimentation	Myocardial infarction
Gastrointestinal hemorrhage	Severe burns
Pulmonary emboli	Renal insufficiency
Pancreatitis	Peritoneal or hemodialysis
Heat related illness	Cerebrovascular events
Mesenteric ischemia	Rhabdomyolysis

TABLE 205-3   Drugs That May Predispose Individuals to the Development of HHNS

Physical Findings

The physical manifestations associated with HHNS are nonspecific. Generally, clinical signs of volume depletion such as poor skin turgor, dry mucous membranes, sunken eyeballs, and orthostatic hypotension, will correlate with degree of hyperglycemia and hyperosmolality and duration of physiologic imbalance.

A wide range of findings from subtle changes in vital signs and cognition to clear evidence of profound shock and coma may occur. HHNS may unexpectedly be found in patients who present with concurrent medical insults such as an acute cerebrovascular accident (CVA), severe burns, myocardial infarction, infection, pancreatitis, or other acute illness (Table 205-3). Up to 15 percent may present with seizures. These are typically focal, though generalized seizures, which are often resistant to anticonvulsants, may occur.[6]

Other central nervous system (CNS) symptoms may include tremor, clonus, hyperreflexia or hyporeflexia, a positive plantar response, reversible hemiplegia, or hemisensory defects (without CVA or structural intracerebral lesion). The degree of lethargy and coma is proportional to the level of osmolality. [7,8] Those with coma tend to have higher osmolarity, hyperglycemia, and greater volume contraction. In view of the age of the patient population, it is not surprising that the misdiagnosis of stroke or organic brain disease is common.

Laboratory

The laboratory parameters used to define HHNS—glucose >400, osmolarity >315, ph >7.3, and negative serum ketones—are fairly arbitrary. Those values are found in the American Diabetes Association position statement for Hospital Admission Guidelines for Diabetes Mellitus. [9] Depending on concurrent illness and duration of disease, a "mixed disorder" with metabolic acidosis may be found. Essential laboratory tests should include serum glucose, electrolytes, calculated and measured serum osmolality, blood urea nitrogen (BUN), ketones, and creatinine, as well as cell blood count. In view of the frequency of precipitating causes and underlying medical conditions associated with HHNS, a broad range of ancillary studies should be considered. These should include blood cultures, sputum collection, urinalysis and culture, liver and pancreatic enzyme determinations, cardiac enzymes, thyroid function, and coagulation profiles. Other ancillary studies such as chest x-ray, electrocardiogram, computed tomography, and lumbar puncture and toxicologic studies should be considered. Arterial blood-gas determination is of added value only if there is suspicion of a respiratory component to the acid-base abnormality, as both P_{CO_2} and pH can be predicted from HCO_3^- concentration obtained in venous electrolytes (see Chap. 21, "Acid-Base Disorders").

In general, electrolyte abnormalities reflect a contraction alkalosis with varying degrees of wide-anion-gap metabolic acidosis. Initial serum electrolyte determinations can be reported as seemingly normal because the metabolic alkalosis and acidosis may largely cancel out each other's effect. A lack of careful analysis of serum chemistries may lead to a delayed appreciation of the severity of the underlying abnormalities, including volume loss. The only clue to a serious derangement may be the widened anion gap. Serum sodium is suggestive but not a reliable indicator of degree of volume contraction. Although the patient is certainly total body sodium depleted, the serum sodium (even corrected for the glucose elevation) may be low, normal, or elevated. Measured serum sodium, however, is often reported as low due to the dilutional effect of hyperglycemia. It is important to correct for this effect. Serum sodium decreases by approximately 1.6 meq per every 100 mg/dL increase in serum glucose above 100 mg/dL or

$$\text{corrected } [Na^+] = \text{measured } [Na^+] + \frac{1.6 \times [\text{glucose} - 100]}{100}$$

Elevated corrected serum sodium during severe hyperglycemia is usually explainable only by significant volume contraction. Normal sodium level or hyponatremia usually (but not invariably) suggests modest dehydration.

Serum osmolality has also been shown to correlate with severity of disease as well as neurologic impairment and coma. A calculated effective serum osmolality

excludes osmotically inactive urea, which is usually included in laboratory measures of osmolarity. The formula for calculated effective osmolality is

$$2([Na^+] + [K^+]) = \frac{glucose}{18}$$

Normal serum osmolality range is approximately 275 to 295 mosm/kg. Values above 300 mosm are usually clinically indicative of significant hyperosmolality.

Hypokalemia probably poses the most immediate electrolyte-based risk and should be anticipated. Losses of 300 to 600 meq are not uncommon. Initial values may be reported as normal during a period of severe volume contraction. Again, the patient is surely total body potassium depleted, but acid-base abnormalities may conspire to mask or augment the deficit. As intravascular volume is replaced, potassium losses become more apparent. Patients who have low serum K^+ during the period of severe volume contraction are at greatest risk for dysrhythmia. The importance of K^+ replacement during periods of rehydration and insulin therapy cannot be overemphasized.

Both prerenal azotemia and renal azotemia are common with plasma BUN-creatinine ratios often exceeding 30:1. Leukocytosis is variable and, when present, is usually due to infection or hemoconcentration. Hypophosphatemia may occur during periods of prolonged hyperglycemia. Acute consequences such as CNS abnormalities, cardiac dysfunction, and rhabdomyolysis are rare and usually associated with serum phosphate levels below 1.0 mg/dL. Routine replacement of phosphate or magnesium, unless severe, is usually unnecessary. Both electrolytes tend to normalize as the metabolic derangement is addressed. When necessary, gradual replacement minimizes the risks of complications such as renal failure. Metabolic acidosis is a wide-anion-gap type often due to poor tissue perfusion resulting in lactic acidosis, uremia, mild starvation ketosis, or all three.

TREATMENT

The treatment of HHNS consists of correction of hypovolemia, treatment of precipitating causes, correction of electrolyte abnormalities, and correction of hyperglycemia. Rapid treatment is reserved only for potentially life-threatening electrolyte abnormalities. Hydration and restoration of euglycemia should be done slowly.

Fluid Resuscitation

Initial fluid resuscitation should be aimed at reestablishing adequate tissue perfusion and decreasing serum glucose. Replacement of intravascular fluid losses alone can account for reductions in serum glucose on average 35–70 mg/h or up to 80 percent initial values. The expansion of intravascular volume decreases serum osmolarity, inhibits counterregulatory hormones, and improves renal excretion of glucose.

The average fluid deficit in HHNS is in the range of 20 to 25 percent of total body water (TBW) or 8 to 12 L. In the elderly, about 50 percent of body weight is due to TBW. By using patient's usual current weight in kilograms, normal TBW and water deficit can be calculated. One-half of the fluid deficit should be replaced over the initial 12 h and the balance over the next 24 h. The actual rate of fluid administration should be individualized for each patient based on the presence of renal and cardiac impairment. Initial rates of 500 to 1500 mL/h during the first 2 h, followed by rates of 250 to 500 mL/h are usually well tolerated. In fact, the initial liter of fluid can usually be infused "wide open" without risk of adverse sequelae in almost all patients. Patients with cardiac disease may require the more conservative rate of volume repletion. Renal and cardiovascular function should be carefully monitored. Central venous and urinary tract catheterization should be considered in patients with preexisting renal or cardiac disease.

Most authors agree that the use of isotonic saline (0.9% NaCl) is the most appropriate initial crystalloid for the replacement of intravascular volume. It is hypotonic to the patient's serum osmolarity and will more rapidly restore plasma volume. Once hypotension, tachycardia, and urinary output improve, half-normal saline (0.45% NaCl) can be used to replace the remaining free water deficit.

A limited number of reports of cerebral edema occurring during or soon after the resuscitation phase of patients with both DKA and HHNS have been described. [10,11] Most cases have occurred in children, and the mechanism is unclear. If changes in mental status occur during treatment, fluid should be stopped and head computed tomography obtained. Mannitol (1 g/kg IV bolus) can be given but effectiveness is unclear.

Electrolytes

Potassium deficits and shifts by far pose the most immediate electrolyte-based risk. On average, potassium losses range from 3 to 5 meq/kg, though deficits as high as 10 meq/kg body weight have been reported. Despite these total body deficits, initial serum laboratory measurements may be normal. Serum potassium may even be high in the presence of acidemia. Patients whose initial serum potassium measurements are low are at highest risk for cardiac dysrhythmia and respiratory arrest and should be treated with urgency. Insulin therapy will likely correct acidemia while increasing renal potassium losses as GFR is restored. Also, insulin therapy may cause precipitous shift of potassium into the cell. Usually well within the first 12 h of therapy, most patients will be hypokalemic if replacement therapy has not begun.

With adequate urinary output, potassium replacement should begin at serum K^+ of 4.5 to 5.0 meq/L. In general, potassium should be replaced at a rate of 10 to 20 meq/h, though life-threatening hypokalemia may warrant utilizing infusion rates of up to 60 meq/h. Some authors feel that potassium infusion through a central venous catheter poses risk for conduction defects and should be avoided. If properly diluted, peripheral infusions of potassium through two peripheral intravenous lines are well tolerated. Monitoring of serum potassium should occur every hour until a steady state has been achieved.

Sodium deficits are replenished fairly rapidly, considering the amount of normal saline and half-normal saline given during fluid replacement. Phosphate and magnesium levels should be measured. In cases of severe hypophosphatemia or hypomagnesemia, replacement therapy is indicated.

Insulin

The absorption of insulin by intramuscular or subcutaneous route is unreliable in patients with HHNS, and a continuous infusion of regular insulin should be given. Infusion rates should begin at 0.1 (units/kg)/h after an initial bolus of 0.1 units/kg. Insulin for infusion should be mixed in a 1:1 ratio (e.g., 250 units or regular insulin in 250 mL of 0.9% NaCl). Pump infusion rates will thus correlate exactly to hourly rate of units of insulin. Steady states utilizing infusion pumps occur within 30 min of infusion. This usually results in a decrease in the plasma concentration of glucose of 80 to 150 (mg/dL)/h. Some patients will demonstrate insulin resistance and require higher doses of insulin. Once serum glucose decreases to less than 300 mg/dL, the intravenous solution should be changed to D_5W 0.45 percent NaCl and the insulin infusion should be reduced to half or 0.05 (units/kg)/h.

Initial volume replacement should always precede the initiation of an insulin drip in HHNS. If insulin is utilized prior to rehydration, intravascular volume may be further depleted. Insulin will cause a shift of osmotically active glucose into the intracellular space, bringing free water with it. This will further deplete the intravascular compartment and may precipitate vascular collapse. Another relative contraindication to the early use of insulin in HHNS is hypokalemia. Insulin promotes transport of potassium into cells and it should be withheld until the potassium level is known and hypokalemia has been treated.

DISPOSITION

Most patients with HHNS require intensive care monitoring for the first 24 h. Patients requiring ongoing replacement of potassium should have continuous cardiac monitoring until those losses are replenished and serum potassium has stabilized.

Some patients may actually meet the criteria for HHNS, have mild symptoms, and have a negative evaluation for comorbidity. In cases when a reliable discharge plan can be arranged, outpatient treatment may be acceptable following appropriate emergency department care. If there is any doubt, the patient should be admitted.

Horace K. Liang

Hyperthyroid states may result from various disorders. Manifestations of disease may range from subtle, nonspecific complaints to life-threatening emergencies. Recognition and appropriate empiric treatment of thyroid storm is life saving.

NORMAL THYROID STATE

Regulation of synthesis and release of thyroid hormone is under the control of the anterior pituitary gland via thyroid-stiumulating hormone (TSH), or thyrotropin. Regulation of TSH in turn is by hypothalamic thyrotropin-releasing hormone (TRH) and also by means of a feedback loop to the pituitary gland by circulating thyroxine (T_4) and triiodothyrinine (T_3) levels. Thyroid hormone production depends on adequate iodine intake and synthesis of thyroglobulin. Following release from the thyroid, thyroid hormones are reversibly bound to various circulating plasma proteins, of which thyronine-binding globulin (TBG) is the major constituent. The free, unbound portions of the hormone are biologically active. Normally, T_4 is the predominant circulating hormone. T_4 is peripherally deiodinated to T_3 and is responsible for producing 80 percent of the circulating T_3 hormone. Free T_3 is biologically more active than T_4 but has a shorter half-life (1 day versus 1 week).

Thyroid hormone exerts its action on a wide host of metabolic processes. It appears that thyroid hormone is active mainly at the cellular level and mediated by nuclear receptors for T_3. Binding of these receptors modulates expression of specific target genes and subsequent protein synthesis. [1] Thyroid hormone may also mediate cellular metabolism.

HYPERTHYROIDISM

Hyperthyroidism occurs at all ages but is less common under the age of 15. It is 10 times more common in women than in men, with an annual incidence of about 1 per 1000 women.[2] Causes of hyperthyroidism are shown in Table 206-1. Graves disease is by far the most common cause, accounting for more than 80 percent of cases of hyperthyroidism in the United States.[3] Toxic multinodular and toxic (adenoma) nodular goiters are the next most frequent causes. Graves' disease is common in the third and fourth decades of life. It is characterized by hyperthyroidism due to an autoimmune activation of TSH, diffuse goiter, ophthalmopathy, and dermopathy. In contrast, toxic multinodular goiter usually occurs in a somewhat older population, commonly with a previous history of simple goiter. [2] Often, these patients have milder symptoms of thyrotoxicosis. Less common causes of hyperthyroidism are thyroiditis, pituitary tumors, metastatic thyroid cancer, and dermoid tumors or teratomas of the ovary. Medication-induced hyperthyroidism may be due to iodine ingestion, lithium therapy, or thyroid medication (thyrotoxicosis facticia). Amiodarone-induced thyrotoxicosis has been reported to be between 1 and 23 percent. [4]

Primary hyperthyroidism
  Graves' disease (toxic diffuse goiter)
  Toxic multinodular goiter
  Toxic nodular (adenoma) goiter
  Iodine intake (jodbasedow disease)
Central hyperthyroidism
  Pituitary adenoma

Thyroiditis
  Subacute painful (de Quervain's disease)
  Silent subacute
  Postpartum
  Radiation thyroiditis
Nonthyroidal disease
  Ectopic thyroid tissue (struma ovarii)
  Metastatic thyroid cancer

Drug induced
  Lithium
  Iodine (including radiographic contrast material)
  Amiodarone
  Excessive thyroid hormone ingestion (thyrotoxicosis facticia)

TABLE 206-1   Causes of Thyrotoxicosis

Classically, patients with hyperthyroidism may complain of heat intolerance, palpitations, weight loss, sweating, tremor, nervousness, weakness, and fatigue (Table 206-2). An individual with hyperthyroidism who is exhibiting only mild symptoms may be safely referred for further evaluation as an outpatient. Clinical suspicion of hyperthyroidism is confirmed by thyroid function tests. An elevated free T_4 and a low or undetectable TSH level is consistent with a diagnosis of hyperthyroidism. In some cases of Graves' disease, the T_4 level may be normal and the TSH level decreased but the patient appears to be thyrotoxic. A T_3 level should be determined to rule out T_3 toxicosis. Patients with hyperthyroidism secondary to pituitary adenomas will have elevated TSH.

Symptoms	Signs
Weakness	Goiter or thyroid bruit
Fatigue	Hyperkinesis
Heat intolerance	Ophthalmopathy
Nervousness	Lid retraction or stare
Increased sweating	Lid lag
Tremor	Tremor
Palpitation	Warm, moist skin
Increased appetite	Muscle weakness
Weight loss	Hyperreflexia
Hyperdefecation	Tachycardia or arrhythmia
Dyspnea	Systolic hypertension
Menstrual abnormalities	Widened pulse pressure

Source: From Tietgens and Leinung,[19] with permission.

TABLE 206-2   Signs and Symptoms of Symptoms of Hyperthyroidism

Palliative treatment for mild hyperthyroidism can be accomplished by using various b-blocker medications, the most common of which is propranolol. The goals of therapy include decreased heart rate, decreased tremor, increased muscle strength, and overall improvement in the patient's sense of well-being. [5] Treatment of Graves' disease may include long-term antithyroid medication, propylthiouracil or methimazole (MMI), radioiodine (iodine 131), or surgical ablation (subtotal thyroidectomy). Toxic multinodular goiter and solitary adenomas may also be treated with radioiodine. Hyperthyroidism due to thyroiditis is usually self-limited, and specific therapy is rarely needed. Common causes of thyroidtis are subacute (painful) thyroiditis (due to viral causes), silent thyroiditis (lymphocytic infiltrate), and postpartum thyroiditis (transient immune destruction). Thyrotoxicosis factitia may be suspected with the absence of thyromegaly, low serum thyroglobulin levels, and decreased or absent radioactive uptake with thyroid scanning. Hyperthyroidism during pregnancy is almost always due to Graves' disease. Often, Graves' disease improves with progression of gestation. The lowest dose of medication should be used in order to maintain a euthyroid state. Treatment options include propylthiouracil (PTU) (it causes fewer fetal anomalies than does MMI), but neonatal goiter has been reported with its use. The use of b blockers has been

controversial.[6] Administration of radioiodine is contraindicated in pregnant women. [7]

THYROID STORM

The life-threatening hypermetabolic state due to hyperthyroidism is termed thyroid storm. It is a rare occurrence but constitutes a medical emergency. The presentation is usually dramatic. The diagnosis is based on clinical suspicion, treatment is empirically initiated, and the patient is admitted to an appropriately monitored setting. The differential diagnosis is listed in Table 206-3. Classically, thyroid storm occurs as a result of previously unrecognized or poorly treated hyperthyroidism. Etiologies that precipitate thyroid storm are often recognized (Table 206-4), but the pathophysiology is not clearly understood. Most studies have not demonstrated differences in thyroid hormone levels between patients with symptomatic, uncomplicated hyperthyroidism and those with thyroid storm. Some studies have noted higher levels of free T_4 in individuals who have presented with thyroid storm. Enhanced sympathetic nervous system activity explains many of the presenting clinical findings of thyroid storm. Despite treatment, mortality rates are high (20 to 50 percent). The signs and symptoms of thyroid storm are listed in Table 206-5. The hallmarks of this disease are fever, tachycardia out of proportion to the fever, and changes in normal mental status (confusion, delirium, seizure, or coma). Burch has described a diagnostic point scale based on clinical presentation in order to distinguish among uncomplicated thyrotoxicosis, impending thyroid storm, and established thyrotoxic storm.[8]

Sepsis
Sympathomimetic ingestion (e.g., cocaine, amphetamine)
Heat stroke
Delirium tremens
Malignant hyperthermia
Malignant neuroleptic syndrome
Hypothalamic stroke
Pheochromocytosis
Medication withdrawal

TABLE 206-5   Presenting Signs and Symptoms of Thyroid Storm

Laboratory analysis is usually not helpful. Thyroid function tests are not routinely readily available to emergency physicians. Nonspecific laboratory findings may include leukocytosis, hyperglycemia, increased transaminase levels, and increased bilirubin levels.

Treatment

Initial treatment of thyroid storm consists of stabilization, airway protection, oxygenation, intravenous fluids, and monitoring. Specific therapy is outlined in Table 206-6. b blockers are used to treat the severe adrenergic symptoms. Utilizing propranolol has the additional benefit of inhibiting peripheral conversion of T $_4$ to T_3. If there is a contraindication to propranolol administration (e.g., asthma, congestive heart failure, or chronic obstructive pulmonary disease), a selective b $_1$ medication (e.g., esmolol) may be substituted. Guanethidine (inhibits norepinephrine release at the sympathetic junction) or reserpine (depletes stored catecholamines both centrally and peripherally including the adrenal medulla) may be considered as alternative therapy. An additional treatment goal is to decrease synthesis of hormone by the administration of PTU or MMI. PTU also decreases T_4 to T_3 conversion. After PTU administration has been initiated, treatment is directed toward decreasing the release of preformed thyroid hormone by the administration of iodine. It is important to not administer iodine until the synthetic pathway has been blocked. Otherwise, the addition of iodine will promote further hormone production. Various iodine-containing preparations, including iodine-containing radiographic contrast material (iopodate [Oragrafin] and ipanoate [Telepaque]) have been utilized for this purpose. Administration of lithium should be considered in patients with a prior history of iodine allergies. Note that many of the drugs used to treat thyroid storm are oral preparations and subsequently may need to be administered via orogastric tube. In cases where clinical deterioration occurs despite appropriate therapy, direct removal of circulating thyroid hormone has been accomplished by exchange transfusion,[9] plasma transfusion,[10] plasmapheresis, and charcoal plasmaperfusion. [11] Other therapeutic goals include treatment of hyperthermia with cooling blankets, ice packs, and antipyretics (acetaminophen). Avoidance of salicylates has been recommended because of displacement of T $_4$ from TBG, thereby increasing free T_4 levels. The empiric use of corticosteroids has been suggested to treat the potential adrenal insufficiency that may occur with such a hypermetabolic state.

TABLE 206-6   Treatment of Thyroid Storm

Comorbid factors that may have precipitated thyroid storm must also be treated. Electrocardiograms, chest radiographs, urinalysis, blood cultures, and administration of empiric antibiotics should always be considered in patients presenting in thyroid storm. Standard therapy for heart failure due to ischemic or hypertensive heart disease may be utilized. All patients should be admitted to an appropriately monitored setting for further evaluation and care. Definitive therapy is usually via radioiodine administration once the patient is stable and euthyroid.

207 HYPOTHYROIDISM AND MYXEDEMA COMA

Horace K. Liang

Hypothyroidism
Myxedema Coma

Treatment

Chapter References

Hypothyroidism arises from many etiologies. The severe manifestation of extreme hypothyroidism—myxedema coma—is a rare, potentially life-threatening illness. Correct diagnosis requires a high degree of clinical suspicion, and initiation of treatment is an empiric decision.

HYPOTHYROIDISM

Normal thyroid physiology is discussed in Chapter 206, "Hyperthyroidism and Thyroid Storm." Hypothyroidism occurs when there is insufficient hormone production or secretion. A general hypometabolic state is the principle feature of this disease. Hypothyroidism occurs more frequently among women than men. The prevalence of hypothyroidism among women ranges from 0.6 to 5.9 percent.[1] The most common etiologies of hypothyroidism are primary thyroid failure due to autoimmune diseases (of which Hashimoto thyroiditis is most common), idiopathic causes, postablative therapy, and iodine deficiency. [2] Hypothyroidism may be transient as in some cases of thyroiditis. The pathophysiology of this entity is unclear but may be viral in origin. Postpartum thyroiditis occurs within 3 to 6 months postpartum and reportedly occurs in 2 to 16 percent of women.[1] Secondary (due to pituitary tumors, infiltrative disease, or hemorrhage) or tertiary (hypothalamic disease) etiologies of hypothyroidism are less common (Table 207-1). Several medications have been reported to induce hypothyroidism. Amiodarone-associated hypothyroidism has been reported to occur in from 1 percent to as many as 32 percent of patients. [3] The mechanism is probably due to the large amount of iodine that is released by the metabolism of the drug, which then inhibits thyroid hormone synthesis and release. Lithium acts similarly to iodine and decreases thyroid hormone release. [4] When initiating lithium therapy, especially in patients with prior hypothyroidism, thyroid function must be carefully monitored.

```
Primary
    Autoimmune etiologies (Hashimoto thyroiditis)
    Idiopathic
    Postablation (surgical, radioiodine)
    Postexternal radiation
    Iodine deficiency
    Thyroiditis (subacute, silent, postpartum)*
    Infiltrative disease (lymphoma, sarcoid, amyloidosis, tuberculosis)
    Congenital

Secondary (pituitary)
    Panhypopituitarism

Tertiary (hypothalamic)
    Neoplasma
    Infiltrative

Drugs
    Amiodarone
    Lithium
    Iodine (in patients with preexisting autoimmune disease)
    Antithyroid medication

*Self-limited etiologies, often preceded by a hyperthyroid phase.
```

TABLE 207-1   Etiologies of Hypothyroidism

Primary hypothyroidism usually has an insidious onset. Clinical signs and symptoms of hypothyroid patients are listed in Table 207-2. Individuals with suspected uncomplicated hypothyroidism may be evaluated as outpatients. Typical laboratory findings in primary hypothyroidism include low thyroxine (T_4) and high thyrotropin (thyroid-stimulating hormone or TSH). Triiodothyronine (T_3) is an unreliable indicator of hypothyroidism and is not routinely measured. There is little urgent need for performing thyroid function tests, and typically they are not available during an emergency department visit. However, obtaining blood for testing in the emergency department may be helpful to a patient's health provider in follow-up care. In many cases, elderly patients with hypothyroidism may exhibit a paucity of symptoms. Because of the high prevalence of hypothyroidism in women over age 60, it is recommended that they be routinely screened with a serum TSH measurement. [5,6]

Fatigue	Hoarseness
Weight gain	Hypothermia
Cold intolerance	Periorbital puffiness
Depression	Delayed relaxation of ankle jerks
Menstrual irregularities	Loss of outer third of eyebrow
Constipation	Cool, rough, dry skin
Joint pain	Nonpitting edema
Muscle cramps	Bradycardia
Infertility	Peripheral neuropathy

TABLE 207-2   Symptoms and Signs of Hypothyroidism

Primary uncomplicated hypothyroidism is treated with T_4 administration. Initiation of oral therapy begins at a dose of 50 to 100 μg/day and is gradually increased. The average daily adult dose is 75 to 150 μg. Elderly patients with underlying heart disease are treated with lower initial dosages. Therapy is monitored to ensure that appropriate serum thyrotropin levels are achieved after 6 to 8 weeks following initiation of therapy. If hypothyroidism is due to less common secondary etiologies, initiation of thyroid hormone replacement may exacerbate preexisting adrenal insufficiency. Therefore, the etiology of hypothyroidism (primary versus secondary failure) should be determined prior to initiating T_4 replacement. Initiation of therapy in the emergency department is rarely warranted for simple hypothyroidism. Clinical clues that may differentiate primary and secondary hypothyroidism are listed in Table 207-3.

Primary	Secondary
Previous thyroid operation	No prior thyroid operation
Obese	Less obese
Goiter present	No goiter present
Hypothermia more common	Hypothermia less common
Voice coarse	Voice less coarse
Pubic hair present	Pubic hair absent
Skin dry and coarse	Skin fine and soft
Heart increased in size	Heart usually normal
Normal menses and lactation	Traumatic delivery, no lactation, amenorrhea
Sella turcica normal	Sella turcica may be increased in size
Serum TSH increased	Serum TSH decreased
Plasma cortisol normal	Plasma cortisol decreased
No response to TSH	Good response to TSH
Good response to levothyroxine without steroids	Poor response to levothyroxine without steroids

Abbreviation: TSH, thyroid-stimulating hormone.

TABLE 207-3   Differentiation of Primary and Secondary Hypothyroidism[7]

MYXEDEMA COMA

Myxedema coma describes a rare, clinical state in which an individual with long-standing preexisting hypothyroidism presents with life-threatening decompensation. [7] In reality, few patients present comatose with severe myxedema. Affected patients are commonly in the geriatric population. Various etiologies may be a precipitant to this syndrome (Table 207-4). The clinical presentation is one of a severe decompensated metabolic state that may include an alteration in mental status, hypothermia, bradycardia, hypoventilation, and even cardiovascular collapse (Table 207-5). These findings are not only secondary to a decline in metabolic function but also due to neurovascular and cardiovascular adaptations. Some of these adaptations are similar to those that occur in euthyroid patients exposed to a cold environment (decline in oxygen consumption and heat generation, and redistribution of blood flow centrally). In addition, there is a change in end-organ responsiveness to catecholamines and a decline in cardiac performance. This is due to an absolute diminution in b-adrenergic receptors (decreased inotrope and chronotrope activity). There is also relatively increased a-adrenergic responsiveness resulting in mild diastolic hypertension. [8] Increased CO_2 retention occurs because of decreased respiratory muscle strength and diminished ventilatory drive in response to hypercapnia. There is also decreased free-water clearance resulting in a dilutional hyponatremia, impaired gluconeogenesis, and decreased drug clearance that predisposes patients to drug toxicity from medication. [9]

| Infection |

| Hypothermia |
| Bradycardia |
| Hypoventilation |
| Periorbital edema |
| Nonpitting edema |
| Delayed deep tendon reflexes |
| Hypoglycemia |
| Hyponatremia |

TABLE 207-5   Clinical Presentation of Myxedema Coma

Diagnosis of myxedema coma requires high clinical suspicion. A patient suspected of presenting with myxedema coma commonly has a prior history of primary hypothyroidism or previous thyroid surgery. Medication noncompliance or coexisting stressors such as cold exposure, severe infection, or the addition of new medications may precipitate the onset of myxedema coma. The decline in function is usually gradual and insidious in onset. The physical examination may confirm a history of long-standing hypothyroidism. In addition, there may be clinical findings of hypothermia, hypoventilation, hypotension, bradycardia, and alteration or deterioration of the patient's mental status.

Laboratory evaluation of patients with suspected myxedema coma may reveal anemia; hyponatremia; hypoglycemia; elevated transaminases, creatine phosphokinase, and lactate dehydrogenase levels; hypercholesterolemia; and arterial blood-gas abnormalities (decreased P o_2 and increased P_{CO_2}). The electrocardiogram may demonstrate sinus bradycardia, prolongation of the QT interval, and low voltage with flattening or inversion of T waves. A chest radiograph may demonstrate an enlarged cardiac contour caused by a pericardial effusion. [9,10]

Treatment

There are no prospective studies on the optimum therapy for patients in myxedema coma; therefore, treatment recommendations are not uniform. However, initial therapy is directed toward stabilization. Patients may require endotracheal intubation and mechanical ventilation for airway protection and correction of hypoventilation, hypercapnia, and hypoxia. Indications for airway intervention are the same as for other conditions (see Chap. 15, "Tracheal Intubation and Mechanical Ventilation"). Correction of hypothermia is directed toward decreasing further heat loss. Cautious use of gentle passive external rewarming should be initiated but care should be taken to avoid hypotension from reversal of a patient's hypothermic vasoconstriction.

Specific therapy includes intravenous levothyroxine, which is recommended by most authors. [11] An initial intravenous bolus of levothyroxine (Table 207-6) is administered, followed by a reduced daily dose until the patient can take oral medication. This has the advantage of repleting the T_4 pool and allowing the hormone to enter tissues slowly. Other authors suggest that there may be decreased T_4 to T_3 conversion and subsequently recommend T_3 as the initial replacement hormone.

| Recognition |
| Supportive measures, including ventilatory support |
| Thyroid replacement |
| Levothyroxine (300 to 500 μg slow IV initial dose and then 50 to 100 μg IV per day) |
| T_3 (25 μg IV or PO q8h) |
| Combination of T_4 plus T_3 |
| Glucocorticoid |
| Hydrocortisone (100 mg IV q8h) |
| Hypothermia |
| Prevent additional loss |
| Passive external rewarming |
| Electrolyte correction |
| Gentle fluid restriction for dilutional hyponatremia |
| Hypertonic saline for severe hyponatremia |
| Hypoglycemia |
| Dextrose containing IV solution |
| Monitoring |
| Aggressive treatment of precipitating cause |
| Admit patients to a monitored setting |
| *Abbreviations:* T_3, triiodothyronine; T_4, thyroxine. |

TABLE 207-6   Treatment of Myxedema Coma

Routine administration of glucocorticoid is recommended to avoid the potential of precipitating adrenal crisis in patients with unrecognized adrenal insufficiency or

hypothyroidism secondary to hypopituitarism. If possible, a baseline cortisol level should be drawn prior to initiating therapy. Correction of hyponatremia is by means of fluid restriction. Severe hyponatremia has been successfully treated with hypertonic saline administration (see Chap. 23, "Fluids and Electrolyte Problems").

A search for a precipitating etiology must be initiated and aggressively treated. Infection is a common precipitant of myxedema coma. If possible, appropriate cultures should be obtained prior to initiating empiric antibiotic therapy.

All patients with a suspected diagnosis of myxedema coma should be admitted to an appropriately monitored inpatient bed for further evaluation and treatment.

208 ADRENAL INSUFFICIENCY AND ADRENAL CRISIS

Gene Ragland

Adrenal insufficiency consists of decreased levels or absence of hormones produced by the adrenal glands and results from structural or functional lesions of the adrenal cortex, the anterior pituitary gland, or the hypothalamus. Deficit of adrenal hormones may manifest clinically as a chronic, insidious disorder, or as an acute, life-threatening emergency. Therapy of adrenal insufficiency is specific and includes replacement of the deficient hormones.

Chronic adrenal insufficiency is due to a variety of causes. It may be primary (Addison's disease), due to failure of the adrenal glands. It also may occur secondarily because of failure of the pituitary gland (hypopituitarism) or as a tertiary insufficiency due to hypothalamic dysfunction. Iatrogenic adrenal suppression from chronic steroid use is termed iatrogenic tertiary adrenal insufficiency. Acute adrenal insufficiency (adrenal crisis) may result from certain acute events, or when a person with chronic adrenal insufficiency is subjected to stress and exhausts reserve adrenal hormones, or when replacement hormone medication is discontinued.

PATHOPHYSIOLOGY OF THE ADRENAL GLANDS

The adrenal glands are divisible into the cortex and medulla. The adrenal cortex is essential for life and produces glucocorticoid, mineralocorticoid, and androgenic steroid hormones. The medulla secretes the catecholamines epinephrine and norepinephrine, largely under neural control. No definite clinical condition has been ascribed to hypofunction of the adrenal medulla. Most of the manifestations of adrenal insufficiency occur when the physiologic requirement for glucocorticoid and mineralocorticoid hormones exceeds the capacity of the adrenal glands to produce them.

Cortisol

The major glucocorticoid is cortisol, which is secreted in response to direct stimulation by adrenocorticotropic hormone (ACTH) from the anterior pituitary gland. Secretion of ACTH is governed by the hormone corticotropin-releasing factor (CRF) from the hypothalamus. This normally occurs with a diurnal rhythm, with the highest levels in the morning and the lowest levels in the late evening. On stimulation by ACTH, the adrenal glands respond in minutes to secrete cortisol in direct proportion to the ACTH concentration. Cortisol is normally secreted at the rate of 20 to 25 mg/day. Through negative feedback inhibition, the plasma cortisol level acts to suppress ACTH release.

By an undefined mechanism, stress factors such as anoxia, trauma, infections, and hypoglycemia also can trigger CRF and ACTH release and produce cortisol levels several times normal. The release of CRF in response to stress is resistant to suppression through negative feedback inhibition.

Cortisol is a potent hormone and affects the metabolism of most body tissues. In general, cortisol acts to maintain blood glucose levels by decreasing glucose uptake at extrahepatic sites and by providing precursors for gluconeogenesis via protein and fat breakdown. Cortisol governs the distribution of water between extracellular and intracellular compartments and possesses a minor sodium-retaining effect. It also acts to enhance the pressor effects of catecholamines on heart muscle and arterioles. In supraphysiologic amounts, cortisol inhibits inflammatory and allergic reactions. Finally, through negative feedback inhibition, cortisol suppresses the secretion of ACTH and melanocyte-stimulating hormone (MSH) from the anterior pituitary gland.

Aldosterone

The major mineralocorticoid is aldosterone. The renin-angiotensin system and plasma potassium concentration regulate aldosterone through negative feedback loops. These mechanisms are probably of equal importance and far more important than the minor aldosterone-stimulating effect of ACTH.

Aldosterone acts to increase sodium reabsorption and potassium excretion, primarily in the distal tubules of the kidneys. Other tissue effects of aldosterone are minor in comparison with its regulation of sodium and potassium levels.

Androgens

Androgenic hormone production by the adrenal glands is regulated by ACTH and is trivial in men in comparison with the production of these hormones by the gonads. In women, however, androgens from the adrenal glands *do* contribute a significant proportion to androgen metabolism.

PRIMARY ADRENAL INSUFFICIENCY

Idiopathic

Primary adrenal insufficiency, or Addison's disease, is due to disease or destruction of the adrenal cortex and has a wide variety of causes (Table 208-1). Approximately 90 percent of the adrenal cortex must be involved before clinical manifestations of adrenal failure result. Idiopathic atrophy of the adrenal glands is the leading cause of chronic adrenal insufficiency. Idiopathic adrenal insufficiency has been further divided into autoimmune (70–75 percent) and truly idiopathic (25–30 percent).

TABLE 208-1   Pathogenesis of Primary Adrenal Insufficiency

There is an overwhelming association between idiopathic adrenal insufficiency and other autoimmune diseases. Associated diseases include diabetes mellitus, Hashimoto's thyroiditis, pernicious anemia, and primary ovarian failure. Other investigators have reported frequent association with hypoparathyroidism, chronic active hepatitis, malabsorption, chronic mucocutaneous candidiasis, alopecia, and vitiligo.

Infiltrative or Infectious

Adrenal tuberculosis has declined in frequency as a cause of Addison's disease but is still reported to be a cause in 17 to 21 percent of the cases. Fungal infections and other infiltrative processes are infrequent causes of adrenal insufficiency during active, disseminated disease. Adrenal insufficiency as a complication of the acquired immunodeficiency syndrome (AIDS) has been reported. Infectious infiltration of the adrenal glands with *Mycobacterium avium* or *M. intracellular* or with cytomegalovirus may have caused the adrenal failure. Metastatic carcinoma in the adrenal glands is a relatively frequent finding at autopsy in patients with certain carcinomas, but it rarely causes adrenal insufficiency.

Bilateral Adrenal Hemorrhage

Bilateral adrenal gland hemorrhage is rare. In general, patients with a serious underlying condition whose adrenal glands are stressed are at risk for this complication. Stress-stimulated adrenal glands are hemorrhage prone. The association between adrenal hemorrhage and anticoagulant therapy with heparin and dicumarol is well established. Adrenal hemorrhage in this setting is most likely to occur between the third and eighteenth day of anticoagulation. Sudden deterioration with hypotension and pain in the flank, costovertebral angle, or epigastrium should suggest this disastrous event. Associated findings may include fever, nausea, vomiting, and disturbed sensorium. Computed tomography (CT) and ultrasound can assist in establishing this diagnosis. Other stressful events that have been associated with adrenal hemorrhage include surgery, trauma, burns, convulsions, pregnancy, and adrenal vein thrombosis.

Adrenal crisis as a consequence of adrenal hemorrhage also occurs with overwhelming septicemia and in the newborn. Fulminant septicemia with meningococcus, pneumococcus, staphylococcus, streptococcus, *Haemophilus influenzae,* and gram-negative organisms has been reported to cause adrenal hemorrhage. The Waterhouse-Friderichsen syndrome is a life-threatening disorder resulting from overwhelming septicemia due to meningococcemia. The patient is acutely ill and has shaking chills, severe headache, and a petechial rash that may progress to extensive purpura. Bilateral adrenal gland hemorrhage frequently occurs with this disorder. Vascular collapse and death may result unless the patient is promptly treated.

Miscellaneous

Another cause of primary adrenal failure is bilateral adrenalectomy for metastatic breast or prostate cancer or for Cushing's syndrome. Following such a procedure, the patient is totally dependent upon replacement corticosteroids for life. Chemotherapeutic agents such as mitotane (*o,p*'-DDD) used in treatment of Cushing's disease can produce adrenal failure. Other drugs such as methadone, rifampin, and ketoconazole have been reported to cause adrenal insufficiency. Finally, rare congenital and inherited disorders can cause adrenal insufficiency.

In children, adrenal insufficiency is due to rare congenital causes or to acquired lesions of the hypothalamus, pituitary or adrenal cortex. By far, the most common cause of acquired chronic adrenal insufficiency is autoimmune destruction of the adrenal glands. Type I autoimmune polyendocrinopathy manifests with chronic mucocutaneous candidiasis, hypoparathyroidism and Addison's disease. Type II autoimmune disease presents with adrenal failure in association with thyroid disorder or insulin dependent diabetes mellitus.

Infections account for approximately 20 percent of the cases of pediatric adrenal insufficiency. Among those are infiltrative destruction of the gland by fungal infections and tuberculosis. Hemorrhage into the adrenal glands may occur in the neonatal period as a consequence of a complicated labor or asphyxia. Another cause of adrenal gland hemorrhage is the Waterhouse-Friderichsen syndrome resulting from meningococcemia and producing shock. Finally, about one-third of patients with adrenoleukodystrophy will develop adrenal insufficiency, usually after 4 years of age.

Clinical Features

The clinical manifestations of chronic adrenal insufficiency develop gradually with subtle signs and symptoms that provide a diagnostic challenge. The clinical presentation of Addison's disease can be explained on the basis of a deficiency of cortisol and aldosterone and a lack of feedback suppression of ACTH and MSH.

Cortisol deficiency manifests clinically with anorexia, nausea, vomiting, lethargy, hypoglycemia with fasting, and inability to withstand even minor stresses without shock. The ability to excrete a free water load is also impaired and can lead to water intoxication. Lack of aldosterone results in impaired ability to conserve sodium and excrete potassium. The patient with aldosterone deficiency presents with sodium depletion, dehydration, hypotension, postural syncope, and decreased cardiac size and output. Renal blood flow is decreased, and azotemia may develop. Hyperkalemia is commonly seen but rarely is severe. Lack of suppression of ACTH and MSH secretion occurs because of deficient cortisol levels and results in increased pigmentation.

The overall clinical picture of a patient with Addison's disease is that of one who is weak and lethargic, with loss of vigor, and fatigue on exertion. The patient may have a feeble tachycardic pulse. Postural hypotension and syncope are common. In spite of hypotension, the extremities usually remain warm. Heart sounds may be soft or almost inaudible on auscultation.

Gastrointestinal symptoms are a prominent feature of chronic adrenal insufficiency and include anorexia, nausea, vomiting, weight loss, abdominal pain, and sometimes diarrhea.

Cutaneous manifestations of Addison's disease include increased brownish pigmentation over exposed body areas such as the face, neck, arms, and dorsum of the hands, and over friction or pressure points such as the elbows, knees, fingers, toes, and nipples. Pigmentation of mucous membranes, darkening of nevi and hair, and longitudinal pigmented bands in the nails may be seen. Vitiligo, mucocutaneous candidiasis, and alopecia may occur with Addison's disease that has an autoimmune cause. Women with Addison's disease may exhibit decreased growth of axillary and pubic hair because of adrenal androgen deficiency. This is not seen in men because of adequate testicular androgen.

Mentally these patients vary from alert to confused. Unconsciousness is rare unless the condition is preterminal. The sensory modalities of taste, olfaction, and hearing may be increased. Hyperkalemic paralysis is a rare, emergent complication of adrenal insufficiency; the patient presents with a rapidly ascending muscular weakness which leads to flaccid quadriplegia. Treatment of this complication consists of the intravenous administration of glucose and insulin or bicarbonate.

LABORATORY   The usual laboratory findings in patients with primary adrenal insufficiency include hyponatremia, hyperkalemia, hypoglycemia, and azotemia. Hyponatremia is usually mild to moderate, and severe hyponatremia (<120 mEq/L) is rare. Hyperkalemia is usually mild, and the potassium level rarely exceeds 7 mEq/L. Initial potassium levels may be normal or low if protracted vomiting has occurred. Rarely, hyperkalemia may be severe and cause cardiac dysrhythmia or

paralysis.

Hypoglycemia is infrequent in adults with chronic adrenal insufficiency in the absence of infection, fever or alcohol ingestion. Moderate elevation of the blood urea nitrogen (BUN) level may occur because of dehydration secondary to aldosterone deficiency. Azotemia is usually reversible with rehydration.

Electrocardiographic changes include flat or inverted T waves, a prolonged QT interval, low voltage, a prolonged PR or QRS interval, and a depressed ST segment. The ECG changes reflective of hyperkalemia may also be present. The chest x-ray film may show a small, narrow cardiac silhouette due to decreased intravascular volume. A flat plate film of the abdomen may show adrenal calcification, which is most commonly due to tuberculosis but may occur with infection or hemorrhage.

SECONDARY AND TERTIARY ADRENAL INSUFFICIENCY

Secondary adrenal insufficiency may be due to disease or destruction of the pituitary gland, and tertiary insufficiency due to hypothalamic dysfunction, resulting in impaired capacity of the pituitary to secrete ACTH. Those disorders responsible for secondary or tertiary adrenal failure are listed in   Table 208-2 .

Secondary
   Pituitary tumor (chromophobe adenoma, craniopharyngioma, hamartoma,
      meningioma, glioma)
   Pituitary hemorrhage or vascular accident
   Postpartum pituitary infarction (Sheehan's syndrome)
   Infiltrative and granulomatous disease
      Sarcoidosis
      Hemochromatosis
      Histiocytosis X
   Internal carotid artery aneurysm
   Head trauma (basilar skull fracture)
   Infection (meningitis, cavernous sinus thrombosis)
   Hypophysectomy
   Pituitary gland irradiation
   Isolated ACTH deficiency
Tertiary
   Iatrogenic HPA suppression due to steroid therapy
   Discontinuation of replacement steroids

TABLE 208-2   Pathogenesis of Secondary or Tertiary Adrenal Insufficiency

The most common cause of tertiary adrenal insufficiency and adrenal crisis is iatrogenic adrenal suppression from prolonged steroid use. Rapid withdrawal of steroids from patients with adrenal atrophy secondary to chronic steroid use may result in collapse and death, especially under circumstances of increased stress. Exogenous administration of glucocorticoids may cause hypothalamic-pituitary-adrenal (HPA) suppression and subsequent adrenal atrophy. This complication has been reported to occur not only with oral steroids but also with those given by the intrathecal, topical, and inhalant routes.

The mechanism of continued adrenal atrophy following discontinuation of exogenous steroids may be a failure of normal diurnal release of CRF. Stress-induced release of ACTH may remain intact, but the atrophic adrenal glands are unable to secrete sufficient cortisol to meet the physiologic requirements in response to stress. The shortest time interval or the smallest dose at which HPA suppression occurs is unknown. As a general rule, there is no suppression regardless of the dose if its duration of use is less than three weeks. In addition, there is no suppression if the dose is <10 mg of prednisone regardless of the duration unless it is given on an h.s. timetable. Any patient who is on more than 20 mg of prednisone for greater than three weeks is suppressed and should have the necessary precautions taken.

Following prolonged supraphysiologic dosages of steroids, it may take up to 6 to 12 months for recovery of HPA function when steroids are withdrawn completely. Until complete recovery has occurred, it is wise to assume the patient will need basal steroid therapy and supplementary therapy during intercurrent illness or stress. Adrenal suppression must be suspected based upon the history of prior steroid use. When in doubt about the HPA status of a seriously ill or deteriorating patient, steroids should be given.

Clinical Features

Significant clinical and laboratory differences exist between patients with primary and those with secondary adrenal insufficiency. With secondary adrenal failure, the capacity of the pituitary to secrete ACTH is impaired. The level of aldosterone is largely unaffected because of its regulation by the renin-angiotensin system and the plasma potassium concentration. The clinical manifestations of secondary adrenal failure are due to insufficiency of cortisol and adrenal androgens. In addition, insufficiency of other anterior pituitary hormones such as growth hormone, thyroid hormone, and gonadotropic hormone may cause clinical abnormalities.

Patients with secondary adrenal insufficiency are better able to tolerate sodium deprivation without developing shock. This is true because of intact aldosterone secretion. Hyponatremia, hyperkalemia, and azotemia are not prominent features of secondary failure. Hypoglycemia, however, may be more common in patients with hypopituitarism because of concomitant growth hormone deficiency. Hyperpigmentation does not occur with secondary failure because ACTH and MSH are eliminated at their source, the pituitary gland. Finally, with secondary failure, men as well as women may exhibit signs of androgen deficiency because of insufficient gonadotopic hormone from the pituitary.

DIAGNOSIS

Primary adrenal insufficiency is diagnosed by demonstrating a low baseline plasma cortisol level and failure to increase this level in response to exogenous administration of ACTH. Any patient who has cortisol level of >20 μg/dL does not have adrenal insufficiency of any type. Failure to respond to ACTH stimulation occurs because the adrenal cortex is damaged or destroyed and has no functional capacity to respond. Secondary adrenal insufficiency is diagnosed by demonstrating low plasma cortisol and urinary metabolite levels that increase in a stepwise fashion with repetitive ACTH stimulation over a period of days. A variety of tests to assess the integrity of the HPA axis are available.

A rapid screening test can reliably distinguish patients with normal adrenal function from those with adrenal insufficiency. This test is based on the fact that adrenal response to a single injection of ACTH is maximal within 1 h. Plasma for measurement of baseline cortisol level is drawn, and then 25 units of corticotropin (synthetic ACTH) is administered subcutaneously, intramuscularly, or intravenously. Another plasma cortisol level is obtained 30 to 60 min later. Normal persons should respond with a doubling of the baseline cortisol level, unless the patient has an already existing high basal level due to stress or some other factor. In this instance, the cortisol level would not double but the patient could still have normal physiology. Patients with primary adrenal insufficiency show no increase in plasma cortisol levels, whereas those with secondary adrenal failure may show no, or a slight, response to corticotropin. A normal response is defined by a peak cortisol value of greater than or equal to 20 μg/dL. However, both falsely normal and abnormal rapid ACTH test results have been reported. This test should be used as a screening test, or to assess adrenal reserve in patients previously receiving steroids, but not as a diagnostic test for adrenocortical failure. A more prolonged period of ACTH stimulation is necessary to confirm adrenal failure and to reliably distinguish primary from secondary adrenal insufficiency. However, measurement of ACTH will also help clarify this differential and will be less labor-intensive.

TREATMENT

Glucocorticoid

Therapy of primary adrenal insufficiency consists of replacement of cortisol and aldosterone, and, on occasion, supplemental androgen therapy in the female patient. The usual maintenance dosage for glucocorticoid replacement varies from 20 to 37.5 mg of cortisol per day. Various preparations may be used (see   Table 208-3 for steroid equivalents). A generally accepted dosage schedule is 5 mg of prednisone in the morning followed by 2.5 mg of prednisone in the afternoon. This simulates the normal diurnal variation of cortisol secretion. A few patients, especially large active men, may require a total daily dose of 10 mg of prednisone for optimum response.

Drug	Equivalent Dose, mg	Na⁺ Retention
Short-acting		
Cortisone	25	2+
Hydrocortisone (cortisol)	20	2+
Prednisone	5	1+
Prednisolone	5	1+
Methylprednisolone	4	0
Intermediate-acting		
Triamcinolone	4	0
Long-acting		
Dexamethasone	0.75	0
Betamethasone	0.6	0

TABLE 208-3   Steroid Equivalents

Another treatment alternative is 5 mg of prednisone h.s. or 15 to 20 mg of hydrocortisone on awakening and 5 to 10 mg in the early afternoon. Finally, once a day dosing for prednisone is sufficient.

Mineralocorticoid

Mineralocorticoid replacement in patients with primary adrenal insufficiency can be achieved by administration of the synthetic mineralocorticoid fludrocortisone acetate (Florinef), 0.05 to 0.2 mg/day orally. This dosage should be appropriately reduced in patients in whom hypertension develops. It is also important for the patient with Addison's disease to maintain an adequate dietary salt intake.

Androgen

The woman with primary adrenal insufficiency may show signs of androgen deficiency such as decreased growth of axillary and pubic hair. Supplemental androgen therapy can be achieved with 2 to 5 mg of fluoxymesterone (Halotestin) orally per day.

Secondary Insufficiency

Treatment of secondary adrenal insufficiency differs from that of primary adrenal insufficiency with regard to mineralocorticoid and androgen replacement. Patients with secondary adrenal failure usually do not require mineralocorticoid therapy and can maintain salt and fluid balance with a diet generous in sodium chloride. In the presence of hypotension, however, supplementary fludrocortisone acetate, 0.05 to 0.1 mg/day, is indicated. Evidence of androgen insufficiency may occur with male and female patients with hypopituitarism. Sufficient androgen in the female patient can be achieved with 2 to 5 mg of fluoxymesterone orally per day. Larger dosages of this preparation or long-acting testosterone (Depo-Testosterone) can be used in the male patient. Patients with secondary insufficiency will also require thyroid hormone replacement.

ADRENAL CRISIS

Adrenal crisis is an acute, life-threatening emergency that must be suspected and treated based upon clinical impression. It is due primarily to cortisol insufficiency and to a lesser extent, aldosterone insufficiency, and occurs when the physiologic demand for these hormones exceeds the capacity of the adrenal glands to produce them.

Adrenal reserve may be exhausted in patients with chronic adrenal insufficiency when they are subjected to intercurrent illness or stress. These patients should be taught to respond to minor febrile illness or stress by increasing their glucocorticoid dose by 2 to 3 times the usual dose for a few days during the illness. Mineralocorticoid dose does not need to be changed. During an emergency from severe trauma or stress, dexamethasone 4 mg IM can be self-administered. A variety of conditions may precipitate crisis; these include major or minor infections, trauma, surgery, burns, pregnancy, hypermetabolic states such as hyperthyroidism, and drugs, especially hypnotics or general anesthetics. Adrenal crisis may also occur in patients with chronic adrenal failure if the patient fails to or is unable to take replacement steroid medication. The most common cause of adrenal crisis is abrupt withdrawal of steroids from a patient with iatrogenic adrenal suppression due to prolonged steroid use. Finally, bilateral adrenal gland hemorrhage from fulminant septicemia or other causes can produce adrenal crisis.

Clinical Features

The clinical manifestations of adrenal crisis are due primarily to insufficiency of cortisol and, to a lesser extent, insufficiency of aldosterone. Patients appear acutely ill. They are profoundly weak and may be confused. Hypotension, especially postural hypotension, is usual. Circulatory collapse may be profound. The pulse is feeble and rapid, and heart sounds may be soft. Temperature elevation is common but may be due to underlying infection. Anorexia, nausea, vomiting, and abdominal pain are almost universal. The abdominal pain may be severe, simulating an acute abdomen. Patients in crisis may exhibit increased motor activity which can progress to delirium or seizures.

Laboratory findings vary. The serum sodium level is usually moderately decreased but may be normal. Potassium levels may be normal or slightly increased. Rarely the potassium concentration may be markedly increased, and this can cause cardiac dysrhythmias or hyperkalemic paralysis. Hypoglycemia is characteristic and can be severe.

Treatment

Treatment must be instituted promptly based on clinical impression and should not be delayed for confirmatory testing of adrenal function. Therapeutic measures in treatment of adrenal crisis include replacement of fluids and sodium, administration of glucocorticoid, correction of hypotension and hypoglycemia, reduction of hyperkalemia, and identification and treatment of a precipitating cause of the crisis.

Fluids

A rapid infusion of 5% dextrose and isotonic saline should be started immediately. This acts to correct dehydration, hypotension, hyponatremia, and hypoglycemia. The extracellular volume deficit in the average adult in adrenal crisis is approximately 20 percent, or 3 L. The first liter should be given over 1 h, and 2 or 3 L may be required during the first 8 h of therapy. The functional capacity of the cardiovascular system is reduced with adrenal insufficiency, and the usual precautions with the rapid administration of saline should be observed.

Steroids

A water-soluble glucocorticoid should be administered promptly. As soon as the diagnosis of adrenal crisis is entertained, 100 mg of hydrocortisone sodium succinate (Solu-Cortef) or phosphate should be given in an intravenous bolus. In addition, 100 mg of hydrocortisone should be added to the intravenous solution. Usually, 200 mg of hydrocortisone is given every 6 h during the first 24 h of therapy. Glucocorticoid therapy acts to correct hypotension, hyponatremia, hyperkalemia, and hypoglycemia.

Mineralcorticoid therapy is not required during initial treatment of adrenal crisis. High dosages of hydrocortisone provide sufficient mineralocorticoid effect. As the total dosage of glucocorticoid is reduced below 100 mg/24 h, many patients need supplementary mineralocorticoid, which can be provided as desoxycorticosterone acetate (Percorten), 2.5 to 5.0 mg intramuscularly one or twice daily. If hypotension persists despite adequate volume and corticosteroid replacement, additional corticosteroid can be given and other causes of hypotension should be investigated. Vasopressors may be needed to correct hypotension. Adrenal hemorrhage should be

considered, especially if the patient is receiving anticoagulants.

Simultaneous Treatment and Testing

It is possible to treat adrenal crisis and to perform simultaneous, confirmatory diagnostic testing for adrenal insufficiency. Physiologic saline is administered, but instead of hydrocortisone, 4 mg of dexamethasone is added to the infusion. Additionally, 25 units of corticotropin is added to the solution, and this liter is infused in the first hour. Blood for plasma cortisol assay is obtained before and at the completion of the infusion. A 24-h urine collection for measurement of 17-hydroxycorticosteroid (17-OHCS) is collected. Additional corticotropin is added to subsequent intravenous solutions so that at least 3 units is infused each hour for 8 h. A third blood specimen for cortisol assay is obtained between the sixth and eighth hours of intravenous therapy.

If the patient has primary adrenal insufficiency, all plasma cortisol levels are low (<15 µg/dL), and the urinary 17-OHCS is also low, confirming the inability of the adrenals to respond to ACTH stimulation. An adequate rise in the plasma cortisol level excludes the diagnosis of adrenal insufficiency. A response indicative of partially intact adrenocortical reserve excludes the diagnosis of primary adrenal failure in favor of secondary adrenal insufficiency, but further testing is required to confirm this diagnosis. Other methods for simultaneous diagnosis and treatment have been described.

The adrenal crisis should begin to resolve favorably within a few hours after initiation of appropriate therapy. Intensive treatment and monitoring should continue for 24 to 48 h. Once the patient's condition has stabilized, the transition to an oral maintenance program can begin. Usually, 7 to 10 days are required for this transition.

The main causes of death during adrenal crisis are circulatory collapse and hyperkalemia-induced dysrhythmias. Hypoglycemia may contribute to demise in some cases. With prompt recognition and appropriate treatment, most patients in adrenal crisis should do well.

209 DIABETES MELLITUS

Micheal D. Rush
Sonia Winslett
Kimberley Dawn Wisdom

Diabetes mellitus is a group of metabolic diseases characterized by deficiency of insulin production, deficiency of insulin action, or a combination of the two deficiencies resulting in hyperglycemia. Chronic hyperglycemia is a final common pathway leading to long-term complications involving the eye, the nervous system, the kidneys, and the immune system that collectively can be grouped as microvascular complications. These complications are leading causes of blindness, chronic renal failure, and lower extremity amputation. Diabetes mellitus also predisposes individuals to accelerated atherogenesis, and the resultant hypertension leads to macrovascular complications of atherosclerotic cardiovascular, cerebrovascular, and peripheral vascular disease. Emergency physicians are frequently called on to evaluate and treat the complications of diabetes, and may in some cases make the initial diagnosis of diabetes. Early diagnosis and treatment are essential in preventing long-term complications of the disease.

This chapter focuses on the classification, epidemiology, pathophysiology, clinical features, and diagnosis of diabetes; management of acute hyperglycemia; and indications for hospital admission. This chapter also presents overviews on therapy for chronic hyperglycemia and the diagnosis and management of the microvascular complications of diabetes. Chapters on common diabetic emergencies, such as diabetic ketoacidosis (DKA), hyperosmolar nonketotic coma [newer terminology: hyperglycemic, hyperosmolar, nonketotic syndrome (HHNS)], and hypoglycemia, as well as individual chapters on stroke, myocardial ischemia and infarction, and peripheral vascular disease, common macrovascular complications of diabetes, are presented elsewhere in this text.

CLASSIFICATION

Diabetes can be grouped into four major categories (Table 209-1).[1] *Type 1 diabetes* [older terminology: insulin-dependent diabetes mellitus (IDDM) or juvenile-onset diabetes mellitus (JODM)] is characterized by an absolute deficiency of insulin secretion. The disease is believed to be primarily autoimmune in nature with a genetic predisposition and a possible link with viral infections or other environmental factors (such as absence of breast-feeding, diet, and factors related to low socioeconomic status) as possible triggers. Individuals with type 1 diabetes require insulin therapy to sustain life and are prone to DKA.

TABLE 209-1   Etiologic Classification of Diabetes Mellitus

Type 2 diabetes [older terminology: non-insulin-dependent diabetes mellitus (NIDDM) or adult-onset diabetes mellitus (AODM)] represents a combination of resistance to the action of insulin by the target organs and tissues with a relative inadequacy of compensatory insulin secretion. Type 2 diabetes is also believed to have a strong genetic predisposition, although it is clear that lifestyle issues such as diet and exercise can impact the development and severity of the disease. Patients with type 2 diabetes can have a variety of initial presentations ranging from life-threatening HHNS, or complications related to hyperglycemia alone, for years prior to having clinical symptoms of diabetes. Type 2 diabetics often require insulin at some point in their course for adequate glycemic control. The likelihood of insulin requirement increases with duration of disease, with 22 percent needing insulin in the first 4 years to about 60 percent after 20 years.

The third group represents *secondary* causes for diabetes. Collectively, patients with secondary diabetes represent only about 1 percent of all diabetes cases. The fourth group, *gestational diabetes mellitus* (GDM), is present only during pregnancy, and complicates about 4 percent of pregnancies in the United States annually (or about 135,000 cases). Excellent glycemic control is essential in preventing fetal cardiac and central nervous system abnormalities, as well as fetal macrosomia. [1]

EPIDEMIOLOGY

It is estimated that 100 million people worldwide have diabetes, with 85 percent of cases being type 2. It is projected that by the year 2010 this number will increase to 215 million. In most developed countries, diabetes is one of the five leading causes of death. [2]

From 1990 to 1992 data, according to the National Health Information Survey (NHIS), approximately 7.8 million Americans, or 3.1 percent of the total US population, had been diagnosed with diabetes mellitus, with the majority, more than 90 percent of cases, classified as type 2 (NIDDM). The prevalence of diabetes in the United States is increasing over time—from 0.37 percent in 1935 to 0.91 percent in 1960 to 3.1 percent in 1993. Approximately 625,000 new cases of diabetes of all types were diagnosed each year in the United States from 1990 to 1992, or 2.42 cases per thousand of population, with more than 90 percent of cases diagnosed as type 2 diabetes. This incidence rate has been stable over the last 20 years. The increased prevalence is accounted for by an increase in the population older than age 65, the group with highest diabetes prevalence. [3]

Incidence rates for type 1 diabetes worldwide range from less than 1 per thousand population in Shanghai, China, Mexico City, Mexico, and the Republic of Korea to a high of 35 per thousand population in Finland. Scandinavian countries tend to have much higher incidence rates for type 1 diabetes, whereas Asian countries tend to have much lower incidence rates. The incidence for type 1 diabetes is about 30,000 new cases diagnosed each year. It is reasonable to assume that Americans with ancestry in these ethnic groups would exhibit a similar epidemiologic trend. [4]

For type 1 diabetes in the United States, the prevalence is slightly higher among men than women, whereas the prevalence among type 2 diabetes is roughly equal between men and women. For type 1 diabetes, non-Hispanic whites are most commonly affected, followed by African Americans and Hispanic Americans. Type 2 diabetes is more common among African Americans, Mexican Americans, Japanese Americans, and Native Americans than among non-Hispanic whites.

In 1986, type 2 diabetes was estimated to account for 17.2 percent of all deaths in the United States, ranging from 1 percent in the 25 to 44-year age bracket to 13.7 percent among those aged 75 years or older. Among the total diabetic population aged 25 years or older, diabetes accounted for 5.4 percent of all deaths. Approximately 40 percent of deaths are due to ischemic cardiovascular disease. Generally, a middle-aged person with type 2 diabetes can expect 5 to 10 years of decreased life expectancy because of the disease. African Americans, Hispanics, and Native Americans are more likely to die of diabetes than are non-Hispanic whites. Individuals with type 1 diabetes are twice as likely to have diabetes listed as their underlying cause of death than are type 2 diabetics. Among type 1 diabetics, 15 percent will die before age 40, which is 20 times as likely as a person of similar age in the general population. DKA and coma are the most common causes of death in the early years of type 1 diabetes. Renal disease becomes the most common up to age 30, and cardiovascular disease is the most common after age 30. Although diabetes is listed relatively infrequently as the primary cause of death, diabetes ranks seventh in the leading underlying causes of death in the United States.[5,6]

RISK FACTORS

Type 1 Diabetes

Genetic and immunologic risk factors for type 1 diabetes include having a parent with type 1 disease, especially the father (three times more likely than if the mother has type 1). Certain HLA antigens (HLA-DR3 and HLA-DR4) located on chromosome 6 are present in 95 percent of type 1 diabetics. Type 1 diabetics also have a higher prevalence of islet cell cytoplasmic antibodies (ICAs), antibodies to insulin, and antibodies to the enzyme glutamic acid decarboxylase (GAD). Since concordance of type 1 diabetes occurs in only about 36 percent of monozygous twins, environmental factors must also play a role in the development of type 1 disease.

Dietary factors—such as breast-feeding for less than 3 months or not breast-feeding at all; exposure to cow's milk proteins, casein, and bovine serum albumin at age younger than 3 months; and exposure to food additives such as nitrates and nitrosamines—have also been associated with increased risk for development of type 1 diabetes.

Viral infections, especially Coxsackie B group, are strongly associated with type 1 disease, because these viruses are routinely isolated from the sera of patients newly diagnosed with type 1 disease. Other viral infections with possible epidemiologic associations with type 1 diabetes include congenital rubella, cytomegalovirus (CMV), and mumps.

Older maternal age, birth order, and lower socioeconomic status may also contribute to development of type 1 diabetes, but the results of studies are conflicting.

Type 2 Diabetes

Twin studies in type 2 diabetes establish a strong genetic link to development of the disease, with concordance rates of 34 to 100 percent for monozygous twins. Several candidate genes and defects in these genes are being studied as being associated with the development of type 2 disease. As previously noted, either background is associated with type 2 disease. Persons having a history of impaired fasting glucose (IFG) or impaired glucose tolerance (IGT) constitute a high-risk group for developing diabetes. Women with a history of gestational diabetes are much more likely to develop type 2 diabetes. Hypertension and hypertriglyceridemia are also risk factors for the development of diabetes.

Environmental risk factors for type 2 diabetes include a high-fat diet, increased alcohol intake, sedentary lifestyle, and obesity; particularly, increased abdominal girth, low birth weight, and lower socioeconomic status.[7,8]

PATHOPHYSIOLOGY

Type 1 diabetes results from destruction of insulin producing pancreatic b cells and absolute insulin deficiency. Type 2 diabetes begins with insulin resistance and increased insulin production.

The organs and tissues that are most affected by diabetes—the retina, the kidney, and the nerves—all readily take up glucose, leading to its intracellular accumulation and subsequent metabolic end products. Two major mechanisms leading to microvascular complications from hyperglycemia are the increased formation and accumulation of sorbitol and other polyols via the aldose reductase pathway and the formation of advanced glycosylation end products (AGEs) due to reactions of excess glucose with various cellular proteins.

Sorbitol formed from glucose through the aldose reductase pathway competitively inhibits *myo*-inositol formation, which causes a decrease in uptake of phosphoinositides into cell membranes, which subsequently decreases Na^+K^+-ATPase activity, with the ultimate clinical effect being slowed nerve conduction. This decrease in the synthesis of *myo*-inositol may be the common metabolic link to membrane damage in neuropathy, retinopathy, and nephropathy. Clinical trials with aldose reductase inhibitors in the prevention and treatment of microvascular complications of diabetes are ongoing.

Glycosylation and the subsequent formation of AGEs is another major explanation for diabetic microvascular pathology. Chemical crosslinks form between excess glucose and various cellular proteins, altering their structure and function; most notable of these is glycosylated hemoglobin (HgbA$_{1c}$), which forms proportional to glucose concentrations in the blood over time and is now used as a measure of glucose control in diabetes therapy. AGEs are thought to play a role in diabetic microvascular complications via effects on the structure and function of extracellular matrix and its interaction with the cell. An example of this is AGE formation on collagen, which, by trapping low-density lipoproteins, may be the etiology of accelerated atherogenesis seen in diabetes clinically. [9] A second potential mechanism for the pathogenesis of AGE formation from hyperglycemia is via action on AGE-specific receptors, which alters levels of various hormones and cytokines, such as nitric oxide, ultimately leading to vascular proliferation and decreased elasticity in existing vessels. Intracellularly, AGE formation on DNA molecules leads to subsequent mutations and other harmful effects on gene expression in mammalian cell cultures in vitro. Ongoing clinical trials using aminoguanidine, an inhibitor of AGE formation, show promise in the prevention and treatment of microvascular complications of diabetes.

Accelerated atherogenesis in diabetes is multifactorial and is related to microalbuminuria, insulin resistance, formation of AGE, modification/oxidation of lipoproteins, and endothelial injury (Table 209-2).

Type	Findings	Location
Nonspecific	Atherosclerosis	Large vessels of extremities, heart, and brain
Specific	Microangiopathic or endothelial proliferative changes of arterioles	Basement membranes of small vessels, i.e., retina, renal glomeruli, brain, and myocardium

TABLE 209-2 Classification of Diabetic Vascular Disease

CLINICAL FEATURES

Type 1 diabetes nearly always presents as DKA, often associated with an acute infection or other significant physiologic stress, in adolescents or in young adults. Type 2 diabetes can be present for years prior to the onset of clinical symptoms. It may present suddenly with HHNS. Frequently, type 2 diabetes is only diagnosed concurrently with the initial presentation of a macrovascular or microvascular complication of the disease.

Classic diabetes signs and symptoms include polyuria, polydipsia, fatigue, polyphagia, unexplained weight loss, poor wound healing, blurred vision, and a higher prevalence of certain infections, especially candidal vaginitis and balanitis, recurrent skin and skin structure infections, and malignant otitis externa. The presence of any of these symptoms or infections should lead an emergency clinician to check the patient's blood glucose level.

Documentation of the medical history of diabetic patients in the emergency department should be complaint directed but generally should also include questions on access to and frequency of home blood glucose monitoring, frequency and causes, if known, of recent hyperglycemia or hypoglycemia, recent glycosylated hemoglobin ($HgbA_{1c}$) values, presence of and therapy for microvascular and macrovascular complications of diabetes, recent adjustments by the patient or the patient's physician in their glycemic control regimen, any problems with adherence to therapy, and symptomatology suggestive of complications. Symptoms suggestive of potential complications or poor glucose control include visual changes, neurologic symptoms (especially numbness, dizziness, and weakness), chest pain, gastrointestinal symptoms, and genitourinary symptoms (especially overflow incontinence, changes in amount of urine, and sexual dysfunction). A thorough history of any recent or concurrent chronic medical illness, injury, or infection should be obtained. Current medications, diet and exercise history, and social history are also important components of the evaluation of diabetic patients. Medications such as diuretics or b blockers may affect glycemic control. Socioeconomic issues may be present, such as living conditions or the inability to afford home blood glucose monitoring or medications. Symptoms of depression and social history factors, including alcohol, tobacco, or illicit drug use, should be considered. Finally, diabetic patients should be fed according to schedule and they should receive their diabetic medication while being evaluated in the emergency department.

The physical examination of diabetics should be tailored to the patient's chief complaint. However, it should generally include blood pressure measurement, funduscopy (to look for hemorrhage or proliferative retinopathy), cardiovascular exam (including ausculation of the carotids and abdomen for bruits and assessment of peripheral pulses), extremity exam (especially the feet, for signs of skin breakdown and vascular disease), skin exam (including intertriginous areas, to assess for irritations and infections, especially around peripheral insulin injection sites and in the hands, assessing lancet puncture sites), and a neurologic exam (to screen for neuropathy). In children, measurements of height, weight, and sexual maturity should be obtained and compared with normals for age. [10]

DIAGNOSIS

The diagnostic criteria for diabetes have recently been revised, lowering the serum glucose values at which the diagnosis can be made, and include an intermediate category for patients whose glucose levels do not meet criteria for diagnosis of diabetes but are significantly abnormal. These changes reflect advances in knowledge of what levels constitute abnormality significant enough to produce the complications of diabetes. Replacing the old term of "borderline" diabetes are IFG (³110 to <126 mg/dL) and IGT, which constitute a group of patients who are generally euglycemic in everyday life but manifest hyperglycemia on oral glucose tolerance tests (>126 but <200 mg/dL) 2 h after an oral 75-g glucose load. In nonpregnant patients, these categories are not diagnostic entities in themselves but represent a group of patients at high risk of developing diabetes. An additional 12 million to 14 million Americans are thought to be glucose intolerant.

Diabetes can be diagnosed in three ways. Two of these may be feasible for emergency department physicians (Table 209-3). The criteria are based on symptoms of diabetes and a random or nonfasting plasma glucose level of 200 mg/dL or more, fasting plasma glucose level (no caloric intake for at least 8 h) of 126 mg/dL or more, or a 2-h post-75-g oral glucose challenge plasma glucose level of 200 mg/dL or more. Unless a patient is showing unequivocal hyperglycemia (300 mg/dL or more in the setting of acute metabolic decompensation such as DKA or HHNS), these values should be reproducible on at least one separate occasion to confirm the diagnosis.[1]

Symptoms of diabetes plus casual plasma glucose concentration ≥ 200 mg/dL (11.1 mmol/L). Casual is defined as any time of day without regard to time since last meal. The classic symptoms of diabetes include polyuria, polydipsia, and unexplained weight loss.

or

FPG ≥ 126 mg/dL (7.0 mmol/L). Fasting is defined as no caloric intake for at least 8 h.

or

2hPG ≥ 200 mg/dL during an OGTT. The test should be performed as described by the World Health Organization, using a glucose load containing the equivalent of 75-g anhydrous glucose dissolved in water.

In the absence of unequivocal hyperglycemia with acute metabolic decompensation, these criteria should be confirmed by repeat testing on a different day. The third measure (OGTT) is not recommended for routine clinical use.

Abbreviations: FPG, fasting plasma glucose level; 2hPG, 2 hr plasma glucose level; OGTT, oral glucose tolerance test.

TABLE 209-3 Criteria for the Diagnosis of Diabetes Mellitus

THERAPY

Therapy for diabetes can best be divided into acute therapy of severe hyperglycemia and life-threatening metabolic decompensation and the day-to-day prevention of hyperglycemia through insulin or oral hypoglycemic agent therapy.

DKA and HHNS are the acute life-threatening entities involving metabolic decompensation, with primarily type 1 diabetics in the case of DKA and type 2 diabetics with HHNS. Some overlap of DKA and HHNS can be seen in either type of diabetes. Acute hyperglycemia and chronic hyperglycemia represent intermediates between good glycemic control and the development of life-threatening metabolic decompensation as well as macrovascular and microvascular complications of diabetes. DKA and HHNS are discussed elsewhere in this book (Chap. 203 and Chap. 205, respectively).

ACUTE HYPERGLYCEMIA

Acute hyperglycemia, defined as a blood glucose level of greater than 300 mg/dL, can represent impending metabolic decompensation. High glucose levels, if present chronically, represent high risk for development of both macrovascular and microvascular complications of diabetes. Acute hyperglycemia should be treated aggressively in terms of seeking out and treating precipitating causes as well as correcting the glucose and other associated electrolyte abnormalities.

Clinical Features

Noncompliance with insulin or oral hypoglycemic therapeutic regimen should be a diagnosis of exclusion in patients with known diabetes. The history and physical examination should focus on finding an underlying cause for the hyperglycemia and include a thorough medication history to ascertain the potential contributions of glucose-altering medications, most commonly corticosteroids, sympathomimetics, diuretics, anticonvulsants, salicylates, and b-adrenergic receptor agonists or antagonists. A thorough evaluation for infections is indicated, with pneumonia, urinary tract, and foot/skin structure infections being most commonly associated with acute disturbances in glucose metabolism. Acute coronary or central nervous system ischemia is also a common cause of acute hyperglycemia. Finally, changes in or

noncompliance with insulin or oral hypoglycemic therapy may be the etiology for the hyperglycemia.

Symptomatically, younger adults may have only polyuria and/or polydipsia as symptoms, whereas elderly diabetics may be severely volume depleted, with acute mental status changes, hypovolemic shock, and acute renal insufficiency or failure.

Determination of serum electrolyte, blood urea nitrogen, and serum creatinine levels is indicated in the clinical assessment of acute hyperglycemia. Clinicians experienced in acid-base interpretation should be able to diagnose abnormalities based on venous electrolyte levels only, using respiratory rate and pulse oximetry to guide the rare need for ABG determination. Capillary blood glucose measurement is indicated every 1 to 2 h during therapy, with the caveat that capillary blood glucose (glucometer) determination may be inaccurate at low (less than 30 mg/dL) or high (more than 400 mg/dL) levels and may even be incorrect within this range. Coefficients of analytic variation within glucometer systems have been found to range from 4 to 33 percent. Ideally, analytic and user error would be no more than 10 percent.[11] Serum osmolality can be estimated from readily available blood chemistries by using the formula

$$ OSM = 2 \times [Na^+] + \frac{glu}{18} + \frac{BUN}{2.8} $$

Diagnosis of Underlying Causes

New-onset diabetes should be a diagnosis of exclusion as a cause of acute hyperglycemia. In the presence of a previously established diagnosis of diabetes, poor compliance may be a factor, particularly among youth but, again, it should be reserved as an etiology of exclusion for the adult presentation. A thorough history documentation and physical examination should guide the evaluation and, based on history or clinical findings, might include electrocardiogram and determination of the levels of cardiac enzymes, such as CK-MB and troponin I or T, to rule out ischemic heart disease or myocardial infarction; complete neurologic exam and computed axial tomography (CAT) of the head to exclude cerebral vascular accident; chest radiograph to assess for pneumonia; and urinalysis to rule out infection or rhabdomyolysis. Cellular and skin abscess should be sought. In sexually active females, the pelvis should be examined to rule out cervicitis or pelvic inflammatory disease as an occult precipitating factor.

Therapy

Therapy for simple acute hyperglycemia is similar to that for DKA and HHNS and includes volume repletion, intravenous (IV) regular insulin therapy, correction of electrolyte imbalance, and specific therapies directed toward any identified underlying cause of hyperglycemia.

The cornerstone of therapy for acute hyperglycemia is restoration of intravascular volume and reperfusion of vital organs, especially the kidneys. Infusion of normal saline (NS) 0.9% NaCl solution at a rate of 500 to 1000 mL/h should be initiated as soon as possible unless specific entities such as myocardial infarction with cardiogenic shock, acute renal failure, or stroke with cerebral edema contraindicate aggressive volume resuscitation. The use of two IV lines, 18 gauge or larger, are advisable to facilitate fluid resuscitation and correction of electrolyte imbalance. Aggressive volume resuscitation should be geared to the end point of lowering the serum glucose, restoring organ perfusion, and replacing extracellular volume depletion. Use caution with aggressive volume resuscitation in patients with a history of congestive heart failure or chronic renal insufficiency and reassess for further therapy frequently (approximately every hour or every 500 mL of IV fluid). Once improvement is noted in vital signs, hyperglycemia (200 mg/dL or less), and adequate urine output ensured, IV fluids may be reduced to maintenance levels or discontinued if the patient is taking oral fluids well.

Depending on the assessment of the degree of extracellular volume depletion, insulin therapy should generally be accomplished with regular human insulin intravenously since absorption of subcutaneous insulin in a volume-depleted patient can be erratic and unpredictable. Typically, an initial bolus of 0.1 U/kg IV regular human insulin is given, which may be repeated in 1 to 2 h. While the addition of a bolus priming dose of insulin may speed the onset of ketone body metabolism, no advantage in the outcome of patients with DKA has been demonstrated. Thus, a patient may simply be started on a regular insulin infusion of 0.1 U/kg ideal body weight per hour, with hourly capillary blood glucose monitoring to assess therapy. The blood glucose level will generally decrease much more rapidly in patients with type 2 diabetes than in those with type 1. If a patient is judged not to have clinical evidence of extracellular volume depletion, subcutaneous insulin administration at a 0.1 U regular insulin per kilogram dose is also acceptable. Once the capillary blood glucose level reaches 250 mg/dL or less, with resolution of symptoms and effective treatment of any underlying cause for hyperglycemia, patients are at low risk for acute metabolic decompensation.

The most prominent and generally most clinically significant electrolyte disorder in acute hyperglycemia is hypokalemia. There is frequently a total body deficit of potassium secondary to severe extracellular volume loss. A mild metabolic acidosis and hyperosmolar state may lead to nearly normal serum potassium levels initially. However, potassium replacement should remain a priority as soon as the potassium level is at or below 5.5 meq/L if renal function is assured. Potassium levels of less than 3.0 meq/L represent severe deficit and mandate emergent supplementation to prevent lethal dysrhythmias. This can be accomplished by adding 20 to 40 meq potassium chloride (KCl) per liter to the IV infusion. Potassium can also be replaced orally with multiple doses of 20 meq KCl. Phosphate therapy is not without complications and there is no indication for routine phosphate supplementation in the treatment of acute hyperglycemia, DKA, or HHNS. Patients with hyperglycemia refractory to therapy, severe electrolyte disturbance, significant prerenal azotemia or increase in baseline blood urea nitrogen and creatinine, or with serious underlying cause, should be admitted to the hospital for further workup and therapy. [12]

CHRONIC THERAPY FOR HYPERGLYCEMIA

The general guiding principal of diabetes therapy is to lower glucose levels on a consistent basis to normal or near normal. Keeping glucose levels at or near normal in type 1 diabetics (HgbA$_{1c}$ £ 7.0 percent; normal, 4.0 to 6.0 percent) through intensive insulin therapy as practiced in the Diabetes Control and Complications Trial (DCCT) dramatically reduces the risk of developing both the microvascular and the macrovascular complications of diabetes. [13]

Several preliminary studies affirm the association of good glycemic control with fewer complications in type 2 diabetes. However, more study is needed to define the population of type 2 patients that will receive the most benefit, given the increased risk of hypoglycemia involved with intensive insulin therapy. [14]

Intensive insulin therapy (2 h postprandial and an occasional middle of the night check) is indicated for well-motivated patients who administer multiple daily injections, and who can adjust doses and caloric intake appropriately. Target glucose values for therapy should be tailored to the individual. However, generally the goal is to keep blood glucose at 140 mg/dL or less in intensive-therapy candidates and 180 to 200 mg/dL or less in diabetics who do not meet criteria for intensive therapy. Target HgbA$_{1c}$ of 7.0 percent or less in intensive-therapy patients and 8.0 percent or less in non-intensive-therapy patients is a reasonable goal to prevent, delay the onset of, and delay progression of complications. Intensive therapy is generally not indicated for patients with autonomic insufficiency, adrenal or pituitary insufficiency, atherosclerotic coronary or cerebrovascular disease; for patients taking b-blocker medication; for patients with counterregulatory hormone deficiency; for the elderly or small children; for patients with psychiatric disorders; and for unreliable, chronically noncompliant patients.

Euglycemia reduces the chance of developing DKA or HHNS. Lowering blood glucose reduces the clinical signs and symptoms of diabetes, such as polyuria, polydipsia, blurred vision, weight loss, and poor wound healing. Consistently near-normal glucose values reduce the risk of microvascular complications of diabetes (specifically, neuropathy, retinopathy, and nephropathy). Excellent glycemic control is also associated with a more favorable and less atherogenic lipid profile, leading to fewer macrovascular complications.

Glycemic control in type 1 diabetes is accomplished primarily with multiple daily insulin injections, whereas glycemic control in type 2 patients is staged. Stage 1 is diet modification and weight reduction. Stage 2 includes oral hypoglycemics. Stage 3 represents insulin requirement, alone or in addition to oral hypoglycemic agents. Table 209-4 presents the various forms of insulin commonly prescribed, time to onset of action, time to peak effect, and their durations of action when given subcutaneously.[15] Insulin preparations available today are extremely pure and represent genetically engineered forms of human insulin produced by bacteria or yeast. Immunogenicity is rare. Table 209-5 presents frequently prescribed oral hypoglycemic agents with their usual dose, half-life, and duration of activity. Caution should be used in prescribing these agents to the elderly or to patients with impaired renal or hepatic function due to serious complications of hypoglycemia. Once the symptoms of acute hyperglycemia are controlled, and underlying causes or exacerbating factors are sought out and treated, initiation of oral hypoglycemic and/or insulin therapy in new-onset type 2 diabetics can usually be left to the primary care provider at 24 to 48-h follow-up if admission was not warranted. Finding new-onset type 1 diabetes in the absence of serious precipitating illness or metabolic disorder is rare. An excellent review on initiating insulin and/or oral hypoglycemic therapy is

Insulin	Onset (h)	Peak (h)	Duration (h)
Lispro	¼-½	½-1½	2-4
Regular	½-1	2-4	5-7
NPH	1-2	6-14	24+
Lente	1-3	6-14	24+
Ultralente	6	18-24	36+

TABLE 209-4 Pharmacology of Commonly Available Insulin Preparations

TABLE 209-5 Pharmacology of Commonly Available Oral Hypoglycemic Agents

Insulin can also be administered as a continuous subcutaneous insulin infusion (CSII), by means of a small pump that delivers insulin subcutaneously into the abdominal wall through a butterfly needle. Insulin is usually infused at a continuous basal rate with preprogrammed boluses just before meals. Both hypoglycemia and ketoacidosis are more frequent in patients with CSII. For emergency department patients with CSII who develop hypoglycemia, marked hyperglycemia, or DKA, it is best to shut off the pump in the emergency department while standard glucose or insulin therapy is administered.

A working knowledge of the pharmacology, including time to peak effect and duration of action of the various insulin and oral hypoglycemic preparations, should enable the emergency physician to make adjustments in a patient's usual insulin or oral hypoglycemic regimen, especially if the patient arrives with a home blood glucose diary. It is a good general rule not to change the total number of units of insulin by more than a 10 percent increase or decrease in a single day. Adjustment of oral agent dosage can generally be left to the primary care provider because it requires careful and close monitoring. If that option is not readily available, oral hypoglycemic agent dosing should generally not exceed a 20 percent increase or decrease. If the patient is not doing regular home glucose monitoring, be sure that he or she has the equipment and the knowledge to test regularly during the adjustment period to avoid severe hypoglycemia or hyperglycemia. When the availability of a primary physician is in question, some emergency departments are able to send a home health nurse to the patient's home for teaching and assessment.

A good home blood glucose-testing regimen is to take measurements prior to meals and at bedtime. Less than four home-monitored glucose values per day has been associated with poor glycemic control.[11] The "intensive therapy" was described earlier.

An alternate rotating testing regimen of taking measurements (before breakfast, 3 days; before lunch, 3 days; before the evening meal, 3 days; and before bedtime, 3 days) decreases the number of fingersticks per day. It is less useful, however, when adjusting insulin or oral agent dosages, but may increase compliance. If a patient is unwilling or unable to test his or her blood glucose regularly during an adjustment and is not at high risk for metabolic decompensation, any adjustment of regimen and further education should be left to a primary care provider or endocrinologist.

COMPLICATIONS OF DIABETES MELLITUS

Cardiovascular Complications

The heart is a major target organ for insulin, and marked changes in cardiac function occur in patients with diabetes mellitus.[16] Whether type 1 or type 2, coronary artery disease accounts for more than half of deaths in diabetics.[16] Factors contributing to the diabetic cardiac dysfunction are increased incidence of atherosclerosis of the coronary arteries, autonomic neuropathy, and microvascular disease (associated with hypertension and renal disease). Diabetics are prone to "silent" myocardial infarction, or infarction associated with atypical symptoms, such as weakness. Even in the absence of vascular disease and hypertension, some diabetics develop cardiomegaly, with systolic and diastolic ventricular dysfunction that may evolve into congestive heart failure.[17] Diabetic cardiomyopathy may be a direct effect of insulin deficiency or resistance on myocardial cell function. The detrimental effects of diabetes mellitus on the heart are more prominent in young diabetics and women.[17] Women usually have a lower risk of coronary artery disease but diabetes renders them more vulnerable to reinfarction and death after myocardial infarction and congestive heart failure. Vascular disease in diabetics may be either nonspecific (atherosclerosis of large vessels) or specific (microangiopathic disease in small vessels) for diabetes.

Most standard emergency department treatments for hypertension and cardiac disease can be utilized in diabetics with appropriate precautions. Moderate to severely elevated glucose levels should be decreased by utilizing small intravenous doses of regular insulin, but the glucose level should not be tightly controlled; the patient is undergoing a stressful event and the added stress and consequences of hypoglycemia should be avoided. There is a risk for intraocular bleed from thrombolytic administration to a diabetic with proliferative retinopathy. Even though the risk of intraocular bleed is low, *proliferative retinopathy is an absolute contraindication to thrombolytic therapy*. The challenge to the emergency physician is expedient evaluation for proliferative retinopathy while simultaneously evaluating the need for thrombolytics.

Retinopathy

Diabetic retinopathy is the leading cause in new cases of blindness in patients aged 25 to 74 in the United States. Patients with this complication are 29 times more likely to become blind than those without retinopathy. Glaucoma and cataracts, also more common in diabetics, can contribute to new cases of blindness in diabetic patients. Blindness due to diabetes is estimated to account for more than 500 million dollars in lost income and public expense annually. An estimated 97 percent of diabetics taking insulin (types 1 and 2), and 80 percent of diabetics who do not take insulin (type 2 only) who have had their diabetes for 15 years or longer have some diabetic retinopathy. Among those with this complication, 40 percent of insulin-using and 5 percent of non-insulin-using diabetics have the most severe form—proliferative retinopathy—that frequently leads to blindness.[18] In the DCCT, type 1 patients who had no retinopathy at baseline had their risk of developing sustained retinopathy lowered by 76 percent over patients who did not practice intensive glucose control. In those patients with mild retinopathy at the start of the study, intensive therapy reduced their risk for sustained retinopathy by 54 percent, the progression to proliferative retinopathy by 47 percent, and the need for laser photocoagulation treatment by 56 percent.[13]

Obtain a history of any visual changes from diabetic patients. On examination, low visual acuity and the presence of visual field defects should arouse suspicion for

retinopathy. Dilated funduscopy is often not practical in the emergency department, but a nondilated retinal exam can frequently reveal "cotton wool" exudates, microaneurysms, and vascular proliferation consistent with diabetic retinopathy (Table 209-6). A red and/or painful eye in association with headache or simply unexplained headache in diabetics should prompt measurement of intracocular pressures to rule out acute glaucoma. The presence of these findings should prompt a referral to an ophthalmologist for further examination and therapy.

Background (Simple)	Proliferative
Increased capillary permeability	New vessels
Capillary closure and dilation	Scars (retinitis proliferans)
Microaneurysms	Vitreal hemorrhage
Arteriovenous shunts	Retinal detachment
Dilated veins	
Hemorrhages	
Cotton-wool spots	
Hard exudates	

TABLE 209-6   Changes in the Diabetic Retina

Laser photocoagulation of proliferative retinopathy has been proven to be efficacious in preventing blindness from proliferative retinopathy, particularly in patients with macular edema. Vitrectomy may be necessary to preserve vision in cases of severe proliferative retinopathy with vision loss secondary to retinal hemorrhage and detachment or vitreous hemorrhage.[19] Experimental trials involving aldose reductase inhibitors and aminoguanidine in the treatment of diabetic retinopathy are ongoing.

Nephropathy

Diabetic nephropathy is one of the leading causes of end-stage renal disease. Approximately one-third of new cases of renal failure each year are due to diabetic nephropathy. Incidence approaches 40 percent lifetime in type 1 diabetes and 4 to 20 percent in type 2 diabetes. Since the overwhelming majority of diabetics are type 2, most patients with nephropathy will have this form of the disease. Hyperglycemia leads to glomerular hypertension and hyperfiltration, which in turn lead to deposition of protein in the mesangium. These protein deposits ultimately lead to sclerosis of the glomerulus and to renal failure. Intensive insulin therapy as practiced in the DCCT reduced by 60 percent the frequency of microalbuminuria, the clinical herald of diabetic nephropathy. In addition to being a marker for nephropathy, albuminuria has also been shown to correlate with high risk for coronary ischemic events. Angiotensin-converting enzyme (ACE) inhibitors have been shown to delay both the onset and progression of diabetic nephropathy. The effect of ACE inhibitors appears to be independent of their effect on controlling blood pressure. Overall prevention of nephropathy involves a combination of glycemic control, effective treatment of hypertension, restriction of dietary protein, and avoidance of nephrotoxic drugs or dyes.

The most useful clinical marker for nephropathy is the presence and degree of microalbuminuria. Patients with albumin excretion rates of as little as 30 mg/day are at high risk for developing diabetic nephropathy and subsequent renal failure. Unfortunately, standard urine dipsticks do not give positive results until the urinary excretion of albumin is greater than 360 mg/day. The 24-h albumin excretion can be estimated from quantitative analysis of single-voided, early-morning urine specimens, but the gold standard is measurement of albumin in a 24-h urine collection. Albumin excretion can vary and should not be measured during urinary infections, DKA, HHNS, or after exercise.

Blood pressure control, ideally 130/85 mmHg or lower, is crucial to slowing the progression of nephropathy. Calcium-channel blockers and ACE inhibitors are the best agents to begin therapy with in diabetic patients. Thiazide diuretics have side effects such as hyperglycemia, hypokalemia, and hyperlipidemia that make them unattractive. Patients with nephropathy should also be encouraged to eat a lower-protein diet (0.8 g/kg ideal body weight per day; consult a dietician) and avoid nephrotoxic drugs such as the nonsteroidal anti-inflammatory drugs (NSAIDs).

Neuropathy

Neuropathy can be divided into peripheral neuropathy and autonomic neuropathy. The degree of functional and structural abnormalities in nerves can be correlated directly with the degree and duration of hyperglycemia.

Symptomatic peripheral neuropathy results from loss of both myelinated and unmyelinated nerve fibers and blunted nerve fiber reproduction, resulting in abnormal firing of sensory neurons. Usually bilateral, it often consists of symmetrical stocking–glove loss in the distal extremities. Symptoms run a spectrum from numbness to paresthesias to constant burning pain. Physical examination may also demonstrate loss of vibratory sense and deep tendon reflexes. Intensive glycemic control as practiced in the DCCT reduced the incidence of clinical neuropathy by 60 percent. Drugs that have been proven effective in treating the pain associated with diabetic neuropathy include tricyclic antidepressants, especially amitriptyline, topical capsaicin, phenytoin, and carbamazepine. Narcotic analgesics have a high abuse potential in this setting, so their use should be avoided. The use of NSAIDs should also be avoided secondary to potential nephrotoxicity. Sensory nylon monofilament testing (Semmes-Weinstein) is a useful screening tool for early neuropathy.[20] Diabetic patients with depressed or absent Achilles' reflex or loss of vibratory sensation in the foot are at high risk for developing foot ulcers. Pain often subsides with time as neurons become destroyed.

Diabetic mononeuropathy usually affects a large peripheral nerve (femoral, obturator, sciatic, median, or ulnar) or an isolated cranial nerve (usually the third, fourth, or sixth). Patients present with sudden onset of symptoms related to the involved nerve. Mononeuritis multiplex, a rare form of mononeuropathy, involves several isolated nerves simultaneously. The symptoms of mononeuropathy usually resolve spontaneously after a few days to weeks. It may be difficult in the emergency department to differentiate the signs and symptoms of diabetic mononeuropathy from a transient ischemic attack or cerebrovascular accident.

Autonomic neuropathy represents the clinical entities of gastroesophageal reflux disease (GERD), gastroparesis, neurogenic bladder, impotence and sexual dysfunction, autonomic diarrhea (nocturnal, often with incontinence), and orthostatic hypotension. Symptoms of GERD include dysphagia, chest pain, and heartburn. Distinction from myocardial ischemia in the emergency department is often impossible, unless GERD has been previously diagnosed. Gastroparesis is the nonprogressive and nonrhythmic contraction of the gastric antrum, often with pylorospasm. Symptoms include epigastric pain, bloating, anorexia, nausea, early satiety, or vomiting.[21] Gastroparesis has been shown to respond to erythromycin, cisapride, and metoclopramide, all of which decrease gastric emptying time. Severe cases may not respond to medication.

Theories on the etiology of diarrhea in diabetics include (1) generalized autonomic neuropathy in poorly controlled type 1 diabetes; (2) small bowel dysmotility and abnormal intraluminal pressures; and (3) dysfunction of the a_2-adrenergic receptors of the small and large intestine that are responsible for stimulating sodium absorption and bicarbonate secretion. Infection, inflammatory bowel disease, irritable bowel syndrome, bacterial overgrowth due to small bowel stasis, or pancreatic exocrine deficiency can mimic the diarrhea associated with diabetes. Chronic diarrhea of diabetes is defined as increased frequency or liquidity of bowel movements of greater than three weeks duration. Incompetence of the internal anal sphincter may also mimic diabetic diarrhea and asymptomatic sensorimotor deficit commonly exists in the anal canal of diabetic patients. Rectal examination is always necessary to exclude fecal impaction as a cause of diarrhea.

Constipation is probably the most common gastrointestinal symptom in diabetics and is associated with autonomic neuropathy. The diet should include 30 mg of dietary fiber per day. Digital examination and sigmoidoscopy should exclude other anal and rectal diseases. Treatment with bethanechol may cause constipation. Autonomic diarrhea may respond to tetracycline therapy 1 to 2 doses orally (250 to 500 mg) early in the attack.[22] Clonidine has also been used successfully in treating diabetic diarrhea. The diarrhea usually will also respond to traditional antidiarrheal medicines. Neurogenic bladder may respond to bethanechol therapy. Erectile dysfunction may be successfully treated with the new oral agent, sildenafil, but this drug is contraindicated in patients using any form of organic nitrate therapy and should be used with caution in patients with known coronary artery disease. Symptomatic orthostasis can be treated by judicious increases of salt intake (in the absense of hypertension) or by using elastic stockings (which should be fitted by a specialist), or the symptoms may respond to fludrocortisone, which

increases arterial tone and expands intravascular volume. [22]

Infections

Diabetics who achieve and maintain excellent glycemic control (HgbA$_{1c}$ < 7 percent) are probably not at any greater risk from infection than the general population. A variety of factors, both those related to associated defects in immunity and disease-related effects, may account for the increased prevalence of certain infections in the diabetic population and poor wound healing in general.

There are possible epidemiologic associations between diabetes and urinary tract infections, candidal vulvovaginits, cystitis, and balanitis, pneumonia, influenza, chronic bronchitis, bacteremia, primary and reactivation tuberculosis, mucormycosis, malignant otitis externa, lower extremity skin and soft tissue structure infections, surgical wound infections, and Fournier gangrene. [23] However, only a few of these conditions have been shown to be more frequent in diabetics than in a nondiabetic control group in controlled studies.

There are several impairments seen in polymorphonuclear leukocytes in diabetic patients, including impaired migration, phagocytosis, intracellular killing, and chemotaxis that lead to an intrinsic decrease in immunity and in the ability to heal wounds properly. Disease-specific factors such as neuropathy, impairments in bladder emptying, and poor local circulation may further impair the immune response. Urostasis and increased glucosuria facilitate bacterial colonization in the urinary tracts of diabetics. Poor sensation may lead patients to ignore a minor wound on the lower extremities that subsequently becomes a serious infection. Atherosclerotic vascular disease may limit local circulation that is essential to proper wound healing. Even though there are few controlled outcome studies comparing diabetics with nondiabetics, it is probably prudent based on the known defects in the immune response to have a low threshold for hospitalization of diabetic patients with upper urinary tract, lower respiratory tract, or skin/skin structure infections for initial intravenous antibiotic therapy. However, the availability of home intravenous infusion therapy, and the development of oral antibiotics with excellent antimicrobial coverage, provide outpatient alternatives for the management of mild to moderate infectious complications.

There is little in the literature to guide the emergency physician when confronted with a febrile diabetic patient without an obvious source of infection. Given the potential for problems with host defects in immunity in patients with poor glycemic control, and given that many infections associated with diabetes can be catastrophic, fever without a clear source is a good reason to admit the patient. Some serious diabetic infectious complications are discussed below.

RHINOCEREBRAL MUCORMYCOSIS   Rhinocerebral mucormycosis is an invasive fungal infection of the nasal and paranasal sinuses, cometimes involving the palate and adjacent tissues. An estimated 70 percent of these infections occur in diabetic patients with ketoacidosis; the other 30 percent usually present in immunocompromised nondiabetic patients. The onset is sudden and rapidly progressive; patients present with periorbital or perinasal pain; blood-tinged nasal discharge; unilateral headache; increased tearing; swelling of eyelids and conjunctiva; and decreased vision. Physical signs can include black eschar on the nasal mucosa or hard palate due to ischemia, proptosis, and if the infection progresses, cranial nerve involvement or seizures. The organism has a propensity for vascular occlusion, therefore cavernous sinus thrombosis, as well as brain abscesses, can occur. [23]

Untreated patients usually die within a week, therefore prompt diagnosis and immediate, aggressive therapy must be initiated. Acidosis must be corrected and a surgeon consulted for extensive debridement of necrotic tissue and drainage of sinuses or abscesses. Computed tomography and/or magnetic resonance imaging should be obtained to both determine the extent of the infection and rule out an intracranial process. Amphotericin B is the drug of choice. Even with aggressive therapy, only 50 to 85 percent of patients are cured.

MALIGNANT OTITIS EXTERNA   This infection almost exclusively occurs in elderly diabetic patients without ketoacidosis. Unlike other serious infections in patients with diabetes mellitus, well-controlled glucose levels are present in up to half and systemic toxicity is often absent. Microangiopathies in the external auditory canal of diabetics is thought to be a predisposing factor for this infection. Patients present with unilateral otalgia, purulent discharge, and sometimes fever. Examination finds a tender, inflamed external auditory canal, and almost all have a mass of granular-appearing tissue. Neuropathies, usually of the seventh, ninth, tenth, or eleventh cranial nerves, occur in about one-half of patients and signals a poor prognosis; 50 percent of patients with cranial nerve paralysis die and the rest have some persistent paralysis.[24] The infection can progress to osteomyelitis of the mastoid, temporal bone, or base of skull, and meningitis, venous sinus thrombosis, or subdural emphysema. Magnetic resonance imaging or computed tomography can define the extent of anatomic involvement.

Infection is almost always due to *Pseudomonas aeruginosa* but staphylococci, fungi, and other gram-negative organisms have been isolated. Hence, recommended therapy parenteral antibiotics is imipenem, meropenem, ciprofloxacin, or the combination of a third-generation cephalosporin (ceftazidime) plus an antipseudomonal penicillin (ticarcillin) for four to six weeks. [24] Early surgical debridement and frequent cleansing are critically important.

CHOLECYSTITIS   Diabetics have a predisposition to cholelithiasis and acute cholecystitis has a higher morbidity and mortality rates, higher incidence of perforation, and greater chance (up to 25 percent) of developing emphysematous cholecystitis. Diabetics with unexplained fever, with or without abdominal pain, should be evaluated with ultrasound for cholecystitis. Emphysematous cholecystitis is a rare gas-producing infection that occurs more frequently in male diabetic patients, is associated with higher incidence of gangrenous gallbladders, and is more likely to perforate. Patients present with symptoms similar to acute cholecystitis and abdominal radiographs can reveal gas in the gallbladder and biliary tree. The causative agents are most frequently a clostridium species in addition to streptococci, *Escherichia coli,* and pseudomonas. Despite prompt treatment and surgery, the mortality rate (15 percent) is 3 to 10 times higher than ordinary cholecystitis.

PYELONEPHRITIS, PERINEPHRIC ABSCESS, AND PAPILLARY NECROSIS   Diabetics are at increased risk for two serious renal infections: emphysematous pyelonephritis and perinephric abscess. Emphysematous pyelonephritis is a rare, life-threatening infection with gas production in and around the kidney. Over 70 percent of these patients are diabetic. Patients with emphysematous pyelonephritis are ill with fever, flank pain, and sometimes a palpable mass. Bacteremia is often present. Aggressive treatment with parenteral antibiotics and nephrectomy is required. Even then, the mortality rate is still about 40 percent. Diabetics account for 35 percent of patients with perinephric abscess. Patients usually do not respond completely to parenteral antibiotics and surgical drainage is usually required. Even with surgical drainage, mortality is about 20 percent.

About 50 percent of patients who develop renal papillary necrosis have diabetes. Patients may be asymptomatic and not notice the sloughed papillary tissue excreted in their urine, or they may present with symptoms similar to acute pyelonephritis. Renal infection with ureteral obstruction may develop into sepsis and septic shock in these diabetic patients. Necrotic tissue fragments, red and white blood cells, and bacteria may be seen in the urine. Ureteral obstruction can be detected with ultrasound, computed tomography, and retrograde pyelography. Intravenous pyelogram should be avoided, especially if preexisting renal disease exists. Patients presumed to have pyelonephritis, but who appear to fail to respond to parenteral antibiotics, should be evaluated for renal papillary necrosis and perinephric abscess. Likewise, symptoms of flank pain suggesting renal colic should always be evaluated fully to exclude infection or papillary necrosis. Treatment still consists of aggressive intravenous antibiotics, urinary drainage, and, if severe, surgery to remove necrotic tissue.

Diabetic Foot Ulcers

Foot and lower extremity ulcers and associated infections are a major source of morbidity in the diabetic population, affecting some 15 percent of diabetics during their lifetime and accounting for 20 percent of diabetic admissions and nearly 50 percent of all lower extremity amputations in the United States. Direct costs each year for diabetic lower extremity ulcers and their complications exceed 500 million dollars annually. A pathologic triad of neuropathy, premature atherosclerotic vascular disease, and impaired immunity combine to make diabetic foot ulcers a multidisciplinary treatment challenge.

Peripheral neuropathy predisposes diabetic feet to ulceration, infection, and joint degeneration (Charcot joints) through the mechanisms of lack of sensation, diminished or absent proprioception, anhidrosis, and poor circulatory and thermal regulation. Risk factors for foot and lower extremity ulcers include high HgbA$_{1c}$ levels, older age, longer duration of diabetes, foot deformities, smoking, retinopathy, peripheral neuropathy, albuminuria, and low diastolic blood pressure. Preventing foot ulcers involves education on foot care and proper fitting of footwear, combined with good glycemic control to limit development of neuropathy and premature vascular disease.

A thorough clinical examination of the diabetic patient's feet should be performed during all emergency department visits even for unrelated complaints. Hair and nail growth, calluses, corns, deformities, erythema, swelling, sensation, and vascular function should be assessed. Any ulcerations found should be unroofed surgically and probed using a blunt-ended rigid probe to determine the depth and possible bone, joint, or tendon involvement. The ability to probe to bone through the ulcer

suggests the strong possibility of osteomyelitis and deep space soft tissue infection.

Based on the initial patient evaluation and foot examination, foot ulcers can be classified into non-limb-threatening, limb-threatening, and life-threatening infections. *Non-limb-threatening infection* is defined as small (under 2 cm of cellulitis or inflammation), does not involve deep structures or bone, and is the result of recent injury to a well-perfused limb. *Limb-threatening infection* (more than 2 cm of cellulitis or inflammation) with associated ascending lymphangitis, deep ulceration or abscess, large area of necrotic tissue, involvement of deep structures or bone, gangrene, or critical lower extremity ischemia defined by absence of palpable pulses. *Life-threatening infection* has clinical signs of sepsis, including fever, leukocytosis, hypotension, tachycardia, tachypnea, altered mental status, and metabolic abnormalities ranging from hypoglycemia to DKA and HHNS.

Generally, it is suggested that the debridement of foot and leg ulcers be just sufficient to judge the depth and extent of the ulcer and to rule out deep abscess. Management of foot ulcers that do not appear infected and do not expand to the deep structures or bone on exploration should include topical antibiotics and nonadherent padded dressings. Follow-up referral with a specialist in diabetic foot care should occur within a few days. Constrictive dressings, such as Unna paste boot (alkaline methylene blue), and tight-fitting shoes should be avoided. Avoidance of weight bearing on the affected limb is critical to avoid progression to infection and for proper healing.

Radiographs of the foot are indicated to exclude subcutaneous gas, foreign bodies, osteomyelitis, and Charcot joints. Swab cultures of foot ulcers may provide misleading results. Culture of tissue excised from the base of the ulcer provides the most accurate identification of the bacteria involved. Commonly isolated organisms include *Bacteroides* species, *Staphylococcus aureus, Staphylococcus epidermidis, Enterococcus, Escherichia coli, Proteus mirabilis,* and *Pseudomonas aeruginosa.* Empiric antibiotic therapy should be directed against these organisms.

In choosing antibiotic therapy for these infections, severity should be taken into account (Table 209-7). The use of aminoglycosides should generally be avoided because of their associated nephrotoxicity. For limb-threatening and life-threatening infections, immediate surgical consultation is indicated for incision and debridement, possible revascularization, or amputation.

TABLE 209-7   Empiric Antibiotic Therapy for Diabetic Lower Extremity Infections

Skin and Soft Tissue Complications

Several cutaneous disorders and infections are more common in diabetics (Table 209-8). Serious infections usually develop due to the combination of poorly controlled serum glucose, vascular insufficiency, and tissue hypoxia. These infections may spread rapidly with dramatic skin changes. The most common sites are lower extremities, but such infections may occur on the peritoneum, scrotum, and abdominal wall (especially at sites of penetrating trauma or surgery). They all require emergent, aggressive medical and surgical treatment. Hemodynamic support and correction of ketoacidosis and/or hyperglycemia is often required.

TABLE 209-8   Cutaneous Disorders and Infections Associated with Diabetes Mellitus

DISPOSITION AND INDICATIONS FOR HOSPITAL ADMISSION

Guidelines for admission considerations are listed in Table 209-9. These guidelines may result in admissions for diabetic patients for conditions that may be treated on an outpatient basis in the nondiabetic population. [26]

TABLE 209-9   Disposition/Guidelines for Hospital Admission

Patients who present with new-onset type 2 diabetes, type 1 diabetes without evidence of metabolic decompensation, acute hypoglycemia or hyperglycemia, and do not meet the aforementioned criteria for admission should see their primary care provider within 24 to 48 h as a general rule to arrange for general education and dietary evaluation and to initiate appropriate therapy for glycemic control. General discharge instructions for all diabetics, new or established, are detailed in   Table

* Follow a healthy diet.
* Self-monitor blood glucose regularly.
* Take insulin or oral hypoglycemics as directed.
* Reduce weight where appropriate.
* Cease smoking where appropriate.
* Exercise regularly in the absence of contraindications, such as foot ulcers.
* Practice good general foot care (check regularly for minor trauma and hot spots, keep nails trimmed properly, and wear well-fitted shoes).
* Wearing a Medic-alert bracelet or necklace.
* Be able to recognize symptoms of high blood sugar, such as frequent urination, thirst, dizziness, headache, nausea or vomiting, abdominal pain, lethargy, or blurry vision.
* Be able to recognize symptoms of low blood sugar, including fatigue, headache, drowsiness, agitation, pale or moist, visual changes, or loss of consciousness.
* Know how to help yourself or others with low blood sugar by self-administering or giving an awake person (who can swallow without gagging or choking) candy, fruit juice, or sugar or by calling an emergency phone number (e.g., 911) if the affected person is not able to respond.

EVALUATION OF THE PATIENT WITH ANEMIA

Emergency physicians encounter patients with anemia on a daily basis. Some of these patients have an acute anemia as a result of blood loss from trauma, gastrointestinal bleeding, or other acute hemorrhage. Many emergency department (ED) patients have chronic anemia that may or may not be related to the complaint that brought them to the ED.

Pathophysiology

Anemia is defined as a reduced concentration of red blood cells (RBCs). In healthy persons, normal erythropoiesis (RBC production) ensures that the number of RBCs present is adequate to meet the body's demand for oxygen and that RBC destruction equals production in order to maintain a stable RBC concentration. Anemia results when RBC production cannot keep up with RBC loss resulting from blood loss, hemolysis, or normal RBC senescence. Quantification of the RBC concentration is reflected in the RBC count per μL, hemoglobin concentration, or hematocrit (percentage of RBC mass to blood volume). Normal RBC values for adults are slightly different for males and females (Table 210-1). Based on pathophysiologic mechanisms, there are three categories of anemia (Table 210-2).

	Male	Female
RBC count (million/μL)	4.5–6.0	4.0–5.5
Hemoglobin (g/dL)	14–17	12–15
Hematocrit (%)	42.0–49.0	38.5–46.0

TABLE 210-1 Normal RBC Values for Adults

TABLE 210-2 Pathophysiologic Classification of Anemia

Clinical Features

Regardless of the cause of anemia, the clinical manifestations are the same. The severity of symptoms and signs related to anemia depend on several factors: the rate of development of anemia, the extent of anemia that is present, and the adequacy of cardiopulmonary adaptation. The symptoms of anemia are reflective of the cardiovascular compensation that occurs in an attempt to maintain tissue oxygenation in the face of decreased oxygen-carrying capacity in the blood. These compensatory mechanisms are increased cardiac output and the centralization of blood flow to provide oxygen to the most sensitive tissues. Symptoms such as palpitations, dizziness, feeling of postural faintness, exertional intolerance, and tinnitus are reflective of increased cardiac output. Clinical signs of increased cardiac output are tachycardia, a hyperdynamic precordium, and systolic murmurs. Pallor of the conjunctivae, skin, and nail beds reflects centralization of blood flow. Tachypnea at rest and hypotension are late signs and are ominous. Decreased tissue perfusion occurs long before hypotension. Coronary artery blood flow usually is not limited until the hemoglobin is 50 percent or less of normal, although it can occur at lesser levels of anemia in patients with restriction of coronary blood flow. In an otherwise healthy patient, the symptoms and signs of anemia resulting from increased cardiac output may not occur at rest until the hemoglobin concentration is below about 7g/dL, although tissue perfusion may be impaired. The emergency physician must keep in mind that the hemodynamic response to anemia may be altered by the use of ethanol, prescription drugs, or recreational drugs.

Diagnosis

The diagnosis of anemia is established by the finding of a decreased RBC count, hemoglobin, and hematocrit on the routine complete blood count (CBC). Other than in patients who are acutely hemorrhaging, it is often not essential that a specific cause of anemia be established in the ED. Further workup can be initiated in the ED and should be started before the transfusion of packed red blood cells (PRBCs).

The basic evaluation of a patient newly diagnosed with anemia includes the following: Hemocult (Smith-Kline Diagnostics, Inc.) examination if not already performed, review of the RBC indices provided with the CBC, reticulocyte count, and review of the peripheral blood smear (Table 210-3). The mean cellular volume (MCV) is the most useful guide to the possible etiology of an anemia. The reticulocyte count reflects activity in the bone marrow and, along with the MCV, can help classify an anemia quickly and provides a differential diagnosis and further course of action (Table 210-4).

TABLE 210-3   Initial Laboratory Evaluation of Anemia

TABLE 210-4   An Approach to the Patient with Anemia

Treatment

The treatment of anemia depends on the etiology of the anemia and the symptoms and clinical status of the patient. In the ED setting, one is faced most commonly with the management of anemia resulting from acute blood loss. All patients who have ongoing blood loss and anemia should have blood typed and crossmatched so that it is available for transfusion if needed. The decision to transfuse PRBCs has to be individualized for each patient with consideration of clinical symptoms, objective signs, age of the patient, presence of comorbid disease, and the likelihood of further blood loss. In general, patients who are symptomatic and hemodynamically unstable and have evidence of tissue hypoxia and/or limited cardiopulmonary reserve should have PRBCs transfused. In most settings, patients with anemia resulting from acute blood loss are transfused at hemoglobin levels of 7g/dL, if not at higher levels, as dictated by patient considerations discussed earlier.

ED patients with chronic anemia or a newly diagnosed anemia of uncertain etiology not caused by acute blood loss may not require immediate transfusion unless they are hemodynamically unstable, hypoxic, or have acidosis or ongoing cardiac ischemia. In a patient with newly diagnosed anemia of uncertain etiology, it is important that laboratory studies that may be required for hematologic evaluation are obtained prior to transfusion. Consultation with a hematologist may be beneficial to guide this evaluation. The condition of some patients with chronic anemias or anemias of uncertain etiology can be made worse by transfusion, so transfusion should not be undertaken unless specifically indicated.

Disposition

Any patient with anemia from ongoing blood loss should be admitted to the hospital for further evaluation and treatment. Patients with isolated anemia that is chronic or newly diagnosed and not related to blood loss do not necessarily require admission if they are asymptomatic, hemodynamically stable, have minimal comorbid disease, and close follow-up can be arranged. Patients newly diagnosed with anemia who also have abnormalities in the white blood cell or platelet count should have immediate hematologic consultation and probable admission.

THE BLEEDING PATIENT

Most bleeding that is seen in the ED is normal—the result of local wounds, lacerations, or other structural lesions. The majority occurs in patients with normal hemostasis. With careful attention to the history and physical findings, patients with pathologic bleeding often can be readily identified. Generally speaking, patients who manifest spontaneous bleeding from multiple sites, bleeding from untraumatized sites, delayed bleeding several hours after trauma, and bleeding into deep tissues or joints should be considered to possibly have a bleeding disorder.

Important historical data for the presence of a congenital bleeding disorder include the presence or absence of unusual or abnormal bleeding in the patient and other family members and the possible occurrence of excessive bleeding after dental extractions, surgical procedures, or trauma. Many patients with abnormal bleeding have an acquired disorder. Questioning about liver disease and drug use (particularly ethanol, aspirin, nonsteroidal anti-inflammatory drugs, warfarin, antibiotics, and other aspirin-containing products) may be helpful.

The site(s) of bleeding may provide an indication of the hemostatic abnormality. Mucocutaneous bleeding, including petechiae, ecchymoses, epistaxis, gastrointestinal, genitourinary, or heavy menstrual bleeding is characteristic of qualitative or quantitative platelet disorders. Purpura often are associated with thrombocytopenia and commonly indicate systemic illness. Bleeding into joints and potential spaces, such as between fascial planes and into the retroperitoneum, as well as delayed bleeding, is most commonly associated with coagulation factor deficiencies. Patients who demonstrate both mucocutaneous bleeding and bleeding in deep spaces often have disorders such as disseminated intravascular coagulation, where both platelet abnormalities and coagulation factor abnormalities are present.

Review of Normal Coagulation

The normal hemostatic system consists of a complex process that limits blood loss by the formation of a platelet plug (primary hemostasis) and the production of cross-linked fibrin (secondary hemostasis), which strengthens the platelet plug. These reactions are counterregulated by the fibrinolytic system, which limits the size of fibrin clot that is formed, thereby preventing excessive clot formation. Congenital and acquired abnormalities occur in all these systems. The affected patients may have excessive hemorrhage, excessive thrombus formation, or both.

PRIMARY HEMOSTASIS   *Primary hemostasis* is the platelet interaction with the vascular subendothelium that results in the formation of a platelet plug at the site of injury. Required components for this to occur are normal vascular subendothelium (collagen), functional platelets, normal von Willebrand factor (connects the platelet to the endothelium via glycoprotein Ib), and normal fibrinogen (connects the platelets to each other via glycoprotein II B-IIIA). Figure 210-1 depicts primary hemostasis.
FIG. 210-1. Primary hemostasis. See text for details. vWF, von Willebrand factor; plt, platelet.

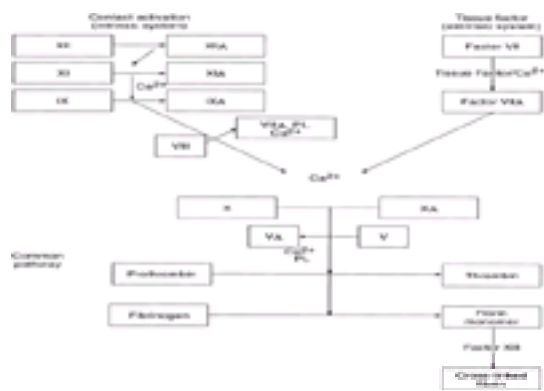
SECONDARY HEMOSTASIS   *Secondary hemostasis* describes the reactions of the plasma coagulation proteins by a tightly regulated mechanism. The final product is cross-linked fibrin, which is insoluble and strengthens the platelet plug formed in primary hemostasis. Figure 210-2 diagrams the reactions of secondary hemostasis.


FIG. 210-2. Secondary hemostasis, also known as the coagulation cascade. The unactivated coagulation proteins (factors) are indicated by roman numerals; after the reaction occurs, the factor is activated and designated by subscript A. There are two independent activation pathways. The contact system is known as the *intrinsic pathway,* and the tissue factor system is known as the *extrinsic pathway.* The pathways merge at the point of activation of factor X. This begins the common pathway that generates the final product, cross-linked fibrin. Ca^{2+}, calcium; fibrinogen is factor I; PL, phospholipid surface (often platelets); prothrombin is factor II.

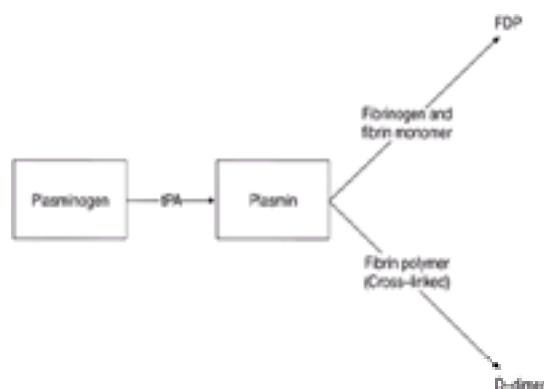
THE FIBRINOLYTIC SYSTEM   This complex system regulates the hemostatic mechanism by limiting the size of fibrin clots that are formed. A simplified schema is depicted in Fig. 210-3. The principal physiologic activator is tissue plasminogen activator (tPA), which is released from endothelial cells. tPA converts plasminogen, which is synthesized in the liver and adsorbed in the fibrin clot, to plasmin. Plasmin degrades fibrinogen and fibrin monomer into low-molecular-weight fragments known as *fibrin degradation products* (FDPs) and cross-linked fibrin into D-dimers.


FIG. 210-3. The fibrinolytic pathway. See text for details. FDP, fibrin degradation product; tPA, tissue plasminogen activator.

Other physiologic inhibitors of hemostasis with prevalent clinical applicability include antithrombin III and the protein C–protein S system. Antithrombin III is a protein that forms complexes with all the serine protease coagulation factors (factors XII_a, XI_a, IX_a, and thrombin), thereby inhibiting their function. Heparin potentiates this interaction, and this is the basis for its use as an anticoagulant. Protein C, which requires the presence of protein S for activation, is capable of inactivating the two plasma cofactors, factors V and VIII, and inhibiting their participation in the coagulation cascade.

Tests of Hemostasis

Table 210-5 outlines the screening tests of primary and secondary hemostasis as well as other commonly used coagulation tests. Table 210-6 lists many commonly used drugs that are associated with thrombocytopenia.

TABLE 210-5   Tests of Hemostasis

	Relative Incidence		Relative Incidence
Heparin	4+	Thiazides	2+
Gold salts	4+	Furosemide	2+
Sulfa-containing antibiotics	4+	Procainamide	2+
Quinine/quinidine	4+	Digoxin/digitoxin	2+
Amrinone	3+	Cimetidine/ranitidine	2+
Ethanol (chronic use)	3+	Phenytoin	1+
Aspirin	3+	Penicillins/cephalosporins	1+
Indomethacin	3+	Estrogens	1+
Valproic acid	3+	Protamine sulfate	1+
Heroin	3+	Interferon-α	1+

Note: Relative incidence based on number of case reports: 4+ equivalent to at least 50–100 reports; 3+ is 20 or more reports; 2+ is 10–20 reports; 1+ is 10 or less case reports.

TABLE 210-6   Drugs Associated with Thrombocytopenia

LABORATORY INVESTIGATION   The basic laboratory parameters that should be obtained in a patient with a suspected bleeding disorder are a complete blood count and platelet count, prothrombin time, and activated partial thromboplastin time. The results of these tests coupled with clinical evaluation should enable one to formulate a differential diagnosis. Further hematologic evaluation, using the tables provided in the chapter, can then follow. Hematologic consulation should be sought if the differential diagnosis or the laboratory approach is unclear.

211 ACQUIRED BLEEDING DISORDERS

Mary E. Eberst

PLATELET ABNORMALITIES

Acquired platelet abnormalities include both quantitative and qualitative defects. Quantitative problems are usually associated with bleeding complications at a platelet level of less than 50,000/μL with spontaneous bleeding, including central nervous system (CNS) hemorrhage, likely at a level below 10,000/μL. Table 211-1 depicts the causes of acquired thrombocytopenia; Table 210-6 displays the drugs most commonly associated with thrombocytopenia. Platelet counts above 400,000/μL are encountered most commonly in inflammatory reactions, patients with malignancy, splenectomized patients, and those with polycythemia vera. Thrombocytosis can be associated with bleeding or thrombosis and is considered an emergency when platelet levels exceed 1 million/μL or are associated with evidence of CNS dysfunction or acute thrombosis or hemorrhage.

Mechanism	Associated Clinical Conditions
Decreased platelet production	Marrow infiltration (tumor or infection)
	Aplastic anemia
	Viral infections (measles)
	Drugs (thiazides, estrogens, ethanol, interferon-α, chemotherapeutic agents)
	Radiation
	Vitamin B₁₂ and/or folate deficiency
Increased platelet destruction	Idiopathic thrombocytopenic purpura
	Thrombotic thrombocytopenic purpura
	Hemolytic uremic syndrome
	Disseminated intravascular coagulation
	Viral infections (HIV, mumps, varicella, EBV)
	Drugs (heparin, protamine)
Splenic sequestration	Hypersplenism
	Hypothermia
Platelet loss	Excessive hemorrhage
	Hemodialysis
	Extracorporeal circulation
Pseudothrombocytopenia	Not a disease state, laboratory phenomenon

Note: EBV, Epstein-Barr virus; HIV, human immunodeficiency virus.

TABLE 211-1   Pathophysiologic Mechanisms of Acquired Thrombocytopenia

Acquired qualitative platelet abnormalities, characterized by abnormal platelet function, occur in many disease states (Table 211-2). When present, functional abnormalities can be associated with excessive bleeding regardless of the platelet count. Table 211-3 outlines some commonly used drugs that can cause platelet dysfunction.

Uremia
Liver disease
Disseminated intravascular coagulation
Drugs (see Table 211-3)
Antiplatelet antibodies (ITP, SLE)
Cardiopulmonary bypass
Myeloproliferative disorders (PCV, CML)
Dysproteinemias (multiple myeloma, Waldenström's macroglobulinemia)
Preleukemias, AML, ALL
von Willebrand disease (congenital or acquired)

Note: ALL, acute lymphocytic leukemia; AML, acute myelogenous leukemia; CML, chronic myelogenous leukemia; ITP, idiopathic thrombocytopenic purpura; PCV, polycythemia vera; SLE, systemic lupus erythematosus.

TABLE 211-2   Clinical Conditions Associated with Qualitative Platelet Abnormalities

Aspirin, NSAIDs	Calcium channel blockers
Heparin and thrombolytics	Propranolol
Penicillins and cephalosporins	Nitroprusside
Nitrofurantoin	Nitroglycerin
Prostaglandins	Tricyclic antidepressants
Dextran	Phenothiazines
Chemotherapeutics	Antihistamines

Note: NSAIDs, nonsteroidal anti-inflammatory drugs.

TABLE 211-3   Commonly Used Drugs Associated with Platelet Dysfunction

The emergency management of patients with thrombocytopenia is based on the control of acute hemorrhage and maintenance of an adequate intravascular volume to maintain normal hemodynamics. Most patients with active bleeding and platelet counts less than 50,000/μL should receive platelet transfusion. Each unit of platelets infused should raise the platelet count by 10,000/μL. Patients with platelet antibodies, such as those with idiopathic thrombocytopenic purpura (ITP) or hypersplenism, are unlikely to respond to platelet transfusions. Some disease states, such as disseminated intravascular coagulation (DIC) and thrombotic thrombocytopenic purpura (TTP), actually may be exacerbated by platelet transfusion; hematologic consultation should be obtained. All patients with platelet counts less than 10,000/μL should receive immediate platelet transfusion, regardless of the underlying etiology, because of the high risk of spontaneous hemorrhage. Nonemergency therapies for thrombocytopenia with which the emergency physician should be familiar include antithymocyte globulin (ATG) for aplastic anemia; prednisone, intravenous gamma globulin, and splenectomy for ITP; prednisone, aspirin (ASA), plasma infusion, and plasma exchange for TTP and hemolytic uremic syndrome (HUS); as well as other

immunosuppressive and chemotherapeutic agents with direct effect on the bone marrow or peripheral antibody production.

The long-term management of qualitative platelet abnormalities that result from underlying disease is directed at treatment of the underlying problem. Acute hemorrhage in these patients sometimes can be controlled with platelet transfusion, but often this is only a temporary solution because the transfused platelets soon acquire the same functional defect. Other management options in patients with the more common acquired types of platelet dysfunction, such as liver disease, uremia, and DIC, are discussed below.

WARFARIN AND VITAMIN K DEFICIENCY

Prothrombin (factor II) is a vitamin K–dependent coagulation factor, as are factors VII, IX, and X, protein C, and protein S. In the liver, reduced vitamin K is required as a cofactor for the carboxylation of glutamic acid residues in the precursors of these coagulation proteins. Deficiency of vitamin K or inhibition of this process by an antagonist such as warfarin results in decreased levels of these factors in the plasma. In the United States, all hospital-born infants are prophylactically treated with intramuscular vitamin K_1. Nutritional deficiency of vitamin K is rare in adults; however, it does occur as a result of poor nutrition and malabsorption in patients with liver disease.

Sodium warfarin, a vitamin K antagonist, is widely used as an oral anticoagulant. Even in those who are closely monitored, as many as 25 percent of patients taking warfarin develop hemorrhagic complications due to severe coagulation factor deficiencies. Routinely monitored by the prothrombin time (PT), large doses of warfarin also can cause prolongation of the activated partial thromboplastin time (aPTT). The treatment of overdosage of warfarin depends on the severity of clinical manifestations, not the degree of prolongation of the PT. If there is no evidence of bleeding, temporary discontinuation of the warfarin may be all that is needed. Warfarin has a half-life of 2.5 days in patients with normal hepatic function. Patients who manifest bleeding complications can be treated with fresh frozen plasma (FFP) or vitamin K_1 (intravenous, intramuscular, or subcutaneous)—each has advantages and disadvantages. Infusion of FFP can result in the rapid repletion of coagulation factors and control of hemorrhage. FFP, however, carries some risk of viral transmission and the risk of volume overload. Parenteral administration of vitamin K_1 will reverse the warfarin effect in 12 to 24 h. Some do not advise intravenous administration of vitamin K_1 because of the risk of hypersensitive anaphylactic reactions, although usually 1 mg can be given intravenously safely. Intramuscular or subcutaneous vitamin K_1 is typically given in doses of 5 to 10 mg daily in states of coagulation factor deficiency. The use of oral vitamin K_1 for the treatment of acute bleeding is not recommended. Its absorption is erratic and the effect may not be observed for several days to weeks. In addition to the risk of intravenous administration of vitamin K_1, the major disadvantage to its use is that its effect may last up to 2 weeks, making it difficult or impossible to anticoagulate the patient using warfarin during that time.

Drug-induced deficiency of the vitamin K–dependent factors also can be seen in patients receiving some antibiotics, particularly the third-generation cephalosporins that contain the N-methylthiotetrazole side chain (moxalactam, cefamandole, cefotaxime, cefoperazone).

Warfarin has long been used as a rodenticide; however, resistance has developed in the animals, and new products known as *superwarfarins* are now used. Brodifacoum is the most widely available of these agents. Many case reports now in the literature describe intentional and accidental ingestion of these products. Such patients present with a severe coagulopathy; major mucosal bleeding and internal bleeding are common and can be fatal. Treatment with high doses of vitamin K_1, up to 50 to 100 mg/day for several weeks, is often required to correct this coagulopathy because of the long half-life of these products.

LIVER DISEASE

Acute and chronic diseases of the liver can be associated with many hemostatic abnormalities of clinical significance. Parenchymal diseases such as cirrhosis and hepatitis, and infiltrative diseases, such as metastatic neoplasms, cause a variety of coagulation problems (Table 211-4).

Coagulation factor deficiency due to decreased protein synthesis

Vitamin K deficiency

Thrombocytopenia

Increased fibrinolysis

Anemia

TABLE 211-4   Hemostatic Abnormalities in Patients with Liver Disease

Decreased Protein Synthesis   The hepatocytes are the site of synthesis of all the coagulation factors except factor VIII. Diseases affecting the hepatic parenchyma result in decreased synthesis of coagulation factors.

Vitamin K Deficiency   The synthesis of factors II (prothrombin), VII, IX, and X depends on vitamin K carboxylation. Vitamin K deficiency in patients with liver disease results from nutritional deficiency, malabsorption, and cholestasis, which prevents the absorption of this fat-soluble vitamin.

Thrombocytopenia   This is most often due to portal hypertension, which leads to hypersplenism and splenic sequestration. Ethanol causes direct bone marrow suppression and reduced production of all hematopoietic cells including platelets.

Increased Fibrinolysis   Several findings indicate that patients with significant liver disease have increased fibrinolysis and, according to some, a compensated, low-grade DIC. Fibrinogen levels are often low, and abnormal fibrinogen molecules are synthesized (dysfibrinogenemia). Fibrin and fibrinogen degradation products (FDPs and D-dimers) are often elevated due to poor hepatic clearance. The inactivator of plasmin, a_2-plasmin inhibitor, is synthesized in the liver. Decreased synthetic capability reduces the amount of this enzyme that is present and can lead to unregulated plasmin activity and increased fibrinolysis.

Anemia   Although not directly a result of the liver disease, anemia is common in patients with liver disease, particularly those whose hepatic dysfunction results from the use of ethanol. Ethanol causes direct bone marrow suppression and is commonly associated with folate and iron deficiency.

Patients with mild or moderate hepatic dysfunction most often have subclinical hemostatic abnormalities. Those with severe liver disease may have life-threatening bleeding. Laboratory studies that should be obtained include hemoglobin/hematocrit, PT, aPTT, thrombin clotting time (TCT), and platelet count. Fibrinogen levels and measurement of FDPs or D-dimers may not be readily available. In general, prolongation of the PT is a poor prognostic sign in patients with liver disease.

The management of patients with liver disease and a coagulopathy depends on the presence or absence of active bleeding and the need to do invasive procedures (Table 211-5). If there is no evidence of bleeding and no need for invasive procedures, treatment is not mandatory. When treatment is indicated, the following should be used. *Packed red blood cells* should be transfused if there is significant bleeding or blood loss to maintain hemodynamic stability. Vitamin K_1 should be given to all patients with liver disease and bleeding. A trial dose of 10 to 15 mg given subcutaneously or intramuscularly may take up to 24 h to have an effect. In most patients with significant liver disease, vitamin K_1 alone will not totally correct the prolonged PT. *FFP* can be given to temporarily replace coagulation factors. Its use is limited by the potential for volume overload; often the patient cannot tolerate the volume that would be required to completely replete the coagulation factors. Each unit is 200 to 250 mL and contains 200 to 250 units of each coagulation factor. *Platelet transfusions* may be used in severe bleeding situations, but in general, this will have a transient effect before the transfused platelets are sequestered in the spleen. *Desmopressin (DDAVP),* a synthetic analog of vasopressin, shortens the prolonged bleeding time in some patients with liver disease. There are no controlled trials to support its use, but generally its side effects are mild and there are few adverse

effects from a trial administration. The dose is 0.3 µg/kg subcutaneously or intravenously every 12 h up to three doses.

Packed red blood cells to maintain hemodynamic stability

Fresh frozen plasma

Platelet transfusions

Desmopressin (DDAVP)

TABLE 211-5   Treatment Options for Patients with Liver Disease and Bleeding

RENAL DISEASE

Hemostatic abnormalities are encountered commonly in patients with renal disease. Bleeding can be a complication of acute or chronic renal failure. Spontaneous bleeding commonly occurs involving the skin (purpura), mucous membranes (epistaxis and menorrhagia), and gastrointestinal and urinary systems. Less common is bleeding involving the central nervous system, retroperitoneum, pericardium, and other internal bleeding. Surgery or trauma can lead to fatal hemorrhage, even with aggressive management.

The bleeding tendency in patients with renal disease is related to the degree and duration of uremia. The bleeding time is the clinical test most often prolonged in uremia, although it cannot be used directly to predict hemorrhage. In patients with uremia, a number of factors contribute to the bleeding diathesis: uremic retention products, chronic anemia, platelet dysfunction, deficiency of coagulation factors, and thrombocytopenia. Anemia contributes to the bleeding by making it difficult for the platelets to adhere to the subendothelium at sites of damage. Platelet function is optimized when the hematocrit is maintained between 26 and 30 percent. Acquired deficiencies of clotting factors are common in patients with the nephrotic syndrome. Mild thrombocytopenia is common in patients with renal failure; the etiology is multifactorial, but the platelet count is generally above 100,000/µL.

Management of these hemostatic defects is both preventive and directed at acute bleeding episodes (Table 211-6). *Dialysis* improves platelet function transiently, lasting for 1 to 2 days. Optimally, patients are well dialyzed three times per week. *Partial correction of the anemia* of chronic renal disease also improves platelet function. This can be accomplished by the use of recombinant human erythropoietin on a chronic basis or transfusion of packed red blood cells in the acute setting. Desmopressin is a synthetic analog of vasopressin. In uremic patients with prolonged bleeding times, 50 to 75 percent will have shortening or normalization of the bleeding time when treated with desmopressin. The usual dose is 0.3 µg/kg body weight given subcutaneously or intravenously. This dose is given every 12 h up to three or four doses before transient tachyphylaxis develops. Intranasal desmopressin may also be effective in this setting. Side effects associated with desmopressin are generally mild and include headache, flushing, minor hypotension, tachycardia, nausea, abdominal cramps, and local site reaction. Severe complications—hyponatremia and thrombosis—rarely occur. Although the mechanism is unknown, *conjugated estrogens* also improve the bleeding time and clinical bleeding in more than 80 percent of uremic patients treated. *Cryoprecipitate infusion* is one of the older treatments for bleeding associated with renal failure. Its use has largely been replaced by the use of desmopressin, which has no risk of viral transmission because it is not a blood product. *Platelet transfusions* are not routinely used in this setting and are not effective because the infused platelets quickly acquire the uremic defect. Infusions of cryoprecipitate and platelets are only indicated for life-threatening bleeding used in combination with packed red blood cells, desmopressin, and conjugated estrogens.

Dialysis

Optimize hematocrit (recombinant human erythropoietin or transfusion of PRBCs)

Desmopressin (DDAVP)

Conjugated estrogens

Cryoprecipitate infusion*

Platelet transfusion*

Note: PRBCs, packed red blood cells.
*Only in life-threatening bleeding situation.

TABLE 211-6   Treatment Options for Patients with Uremia and Excessive Bleeding

DISSEMINATED INTRAVASCULAR COAGULATION

Disseminated intravascular coagulation (DIC) is a loosely defined syndrome that is reflective of serious underlying disease. Patients who have severe DIC have a mortality rate of up to 85 percent. DIC can be triggered by a wide variety of disorders (Table 211-7) and can be acute and life-threatening or chronic and compensated. The most common trigger of DIC is the liberation of tissue factor. Tissue factor is usually confined within the extravascular space; when it is released, the coagulation system is activated (Fig. 211-1). Small fibrin clots are formed and deposited as thrombi or emboli in the microcirculation. Fibrinolysis then occurs and can be massive. FDPs are released and further inhibit hemostasis. The usually tightly regulated system of coagulation and fibrinolysis becomes unbalanced. Because of clot formation, coagulation factors and platelets are consumed. Microthrombi in the circulation can lead to tissue hypoxia, and the red blood cells are damaged trying to pass through the microcirculation. The severity of DIC that develops depends on the synthetic function of the liver, the integrity of the vascular endothelium, and the capacity of the bone marrow to replace platelets. Chronic, compensated DIC occurs when the rate of consumption of clotting factors and platelets does not exceed their rate of production.

**TABLE 211-7   Common Causes of Disseminated Intravascular Coagulation**

FIG. 211-1. Pathophysiology of disseminated intravascular coagulation. Refer to text for details. FDPs, fibrin/fibrinogen degradation products.

Table 211-7 lists the more common causes of DIC, particularly as encountered in the emergency setting. The reader is referred to a standard text for a complete list of causes. DIC occurs in its most extreme form in *Neisseria meningitidis* sepsis and acute myelogenous leukemia, promyelocytic (M3) type.

The clinical complications of DIC are bleeding, thrombosis, and purpura fulminans. Although hemorrhage and thrombosis may occur simultaneously, in an individual patient, one may predominate. Bleeding occurs in up to 75 percent of patients with DIC. Bleeding from the skin and mucous membranes is most common; usually there is bleeding from several sites, including venipuncture sites, surgical wounds, epistaxis, petechiae, and ecchymoses. Hematuria and gastrointestinal bleeding are seen; intracerebral bleeding carries a very poor prognosis. Thromboses (usually microthrombi) predominate in some patients. Clinical signs of this include mental status changes, focal ischemia or gangrene, oliguria, renal cortical necrosis, and adult respiratory distress syndrome (ARDS). Purpura fulminans occurs when there are widespread arterial and venous thromboses. Gangrene develops in the digits or extremities and there is hemorrhagic infarction of the skin. Purpura fulminans is most commonly seen with high-grade bacteremia (*Streptococcus pneumoniae* or *N. meningitidis*).

The diagnosis of DIC is based on the clinical setting and characteristic laboratory abnormalities. The typical laboratory results in DIC are outlined in Table 211-8. Patients with chronic DIC have laboratory evidence of the disorder but no clinical evidence of hemorrhage or thrombosis.

TABLE 211-8   Laboratory Abnormalities Characteristic of Disseminated Intravascular Coagulation

The management of acute DIC is based on the symptoms demonstrated by the patient and the underlying disease state. Many patients with DIC require no specific therapy if there is no evidence of bleeding or thrombosis and laboratory studies are not deteriorating. The first principle of management is to stabilize the patient hemodynamically, providing oxygen, fluids, and life support as needed. If possible, the primary cause of the DIC needs to be treated. The high mortality rate in severe DIC is primarily due to the underlying disorder. Antibiotics can be given and the fetus or retained uterine products removed; however, in many circumstances, little can be done rapidly. Further management depends on the predominant symptoms of the patient—bleeding or thrombosis.

Bleeding requires replacement therapy based on the amount of bleeding, risk of bleeding (i.e., postoperative), and the extent of depletion of coagulation factors and platelets. The PT is the best indicator of clotting factor depletion. If the PT is prolonged by more than 2 to 3 s and there is bleeding, replacement is indicated. Factor levels also can be used to guide therapy if they are readily available. The fibrinogen level should be maintained above 100 to 150 mg/dL and the other factor levels at or above 50 percent of normal. FFP is used to replace clotting factors; each unit contains 200 to 250 units of each factor. Usually given 2 units at a time, there are 200 to 250 mL of fluid per unit, making volume overload a potential problem. Cryoprecipitate is used to replace fibrinogen. There are 100 to 250 mg fibrinogen per bag of cryoprecipitate; 10 bags are typically given at one time. Platelet replacement is indicated if the count is less than 50,000/μL and there is bleeding or if it is less than 20,000/μL regardless of bleeding. Each unit of platelets transfused should raise the platelet count 10,000/μL; typically, 6 units of random donor platelets (or one apheresis unit) are given at a time. As with the use of any blood products, there is a small risk of viral transmission. Patients with DIC also should be given vitamin K$_1$ and folate.

The treatment of microthromboses in DIC with systemic heparinization is controversial. Its use has not been conclusively shown to improve survival and may make the overall clinical situation worse. Heparin should be considered and may be beneficial for some patients with DIC if the underlying condition is carcinoma, acute promyelocytic leukemia, or retained uterine products. Patients with purpura fulminans may also benefit from anticoagulation. In this setting, the continuous infusion of low-dose heparin (5–10 units/kg/h) is recommended. Patients with large thromboses, such as seen with Trousseau's syndrome, should receive full-dose heparinization. Antifibrinolytic agents such as a e-aminocaproic acid (EACA) and tranexamic acid are used in DIC with great caution. Although these drugs may reduce bleeding and fibrinogen consumption, they may convert a bleeding disorder into a thrombotic disorder. When used, these antifibrinolytic agents usually are given in conjunction with low-dose heparin infusion to minimize the potential for thrombosis. They are occasionally used in DIC patients with acute promyelocytic leukemia or prostate cancer.

HEPARIN AND THROMBOLYTIC THERAPY

Heparin

Heparin is an anticoagulant widely used for the treatment and prevention of venous thrombotic and thromboembolic disease. Administered intravenously or subcutaneously, heparin prevents thrombus formation and the extension and propagation of the preformed thrombus. Heparin reduces the ability of blood to clot by enhancing the ability of antithrombin III to form complexes with the activated serene protease coagulation factors (XII$_a$, XI$_a$, IX$_a$, and thrombin), thereby inhibiting their activity in the coagulation cascade. Heparin also may have an anti-inflammatory effect. Because it does not cross the placenta, heparin is the drug of choice when anticoagulation is needed during pregnancy. The dosing of heparin depends on the clinical setting (see Chapter 216). Heparin therapy is generally monitored by the aPTT, with variable goals depending on the clinical setting and laboratory standards. As with any drug, there are risks when heparin is used; these risks need to be weighed against the risk of not using heparin. The fatality rate is up to 15 percent for untreated venous thromboses.

Bleeding is the major complication of heparin therapy, occurring in up to 33 percent of all treated patients, with 1 to 7 percent of these episodes considered serious or life-threatening (requiring transfusion of blood). Some patients are at higher risk of developing bleeding complications, particularly those with a history of renal failure, gastrointestinal bleeding, head injury, heavy alcohol use, malignancy, recent surgery or trauma, or hemorrhagic disorders. Concomitant use of medications such as aspirin, warfarin, steroids, or nonsteroidal anti-inflammatory drugs (NSAIDs) also places patients at higher risk of bleeding complications. If significant bleeding complications develop, the heparin should be immediately stopped. The half-life of heparin is 60 to 90 min but can be longer if high levels are present. Protamine

sulfate can be used to neutralize heparin; 1 mg protamine sulfate neutralizes 100 units of standard molecular weight heparin.

Thrombocytopenia is the other major complication of heparin therapy. Two types of thrombocytopenia can occur. The more common type of thrombocytopenia develops in up to 25 percent of patients treated with heparin. This is a benign, transient decrease in platelets; the platelet count usually remains greater than 100,000/μL and is thought to be due to platelet aggregation and sequestration in the spleen. Heparin therapy generally does not have to be discontinued, and the platelet count rises spontaneously. The second type of thrombocytopenia, known as *heparin-induced thrombocytopenia,* occurs in 1 to 5 percent of patients treated with heparin and can be life-threatening. Heparin-induced thrombocytopenia occurs when antibodies are formed against the platelets. This can occur immediately in patients who have received heparin previously, but it takes 6 to 10 days for the antibodies to form in previously untreated patients. Severe thrombocytopenia results; platelet counts less than 50,000/μL and arterial thromboses can occur. In this setting, the heparin must be completely eliminated, and other anticoagulants can be used if necessary (warfarin, dextran). Lepirudin (recombinant hirudin) is a new anticoagulant recently approved for use in patients with heparin-induced thrombocytopenia who require anticoagulation. The platelet count usually will return to normal 4 to 6 days after the heparin is stopped. It is controversial whether these patients should ever be treated with heparin again. Long-term use of heparin, for greater than 1 month, is associated with accelerated osteoporosis.

Low-molecular-weight heparins (LMWHs) were introduced into clinical practice in the early and middle 1990s. These compounds are made by chemical or enzymatic hydrolysis of unfractionated heparin and have about one-third the molecular weight of unfractionated heparin. The mechanism of anticoagulant activity of the LMWHs is not completely understood. Like unfractionated heparin, they have inhibitory effect against factor X_a, but other mechanisms are also postulated.

The indications for use of LMWHs are currently being evaluated in clinical trials. At this time, LMWHs are frequently used for the prophylaxis of deep venous thrombosis (DVT) after orthopedic surgery and treatment of patients with acute DVT. In patients with acute, proximal DVT, there is sufficient evidence that LMWHs are an effective and safe alternative to treatment with intravenous unfractionated heparin. Other clinical settings where LMWHs have been used are currently being further studied: treatment of malignancy-associated thromboembolic disorders, acute pulmonary embolus, unstable angina, thrombotic and ischemic stroke, after interventional cardiac procedures, for maintenance of the patency of arterial grafts, and for prevention of DVT during pregnancy and the postpartum period.

The advantages of LMWHs compared with unfractionated heparin are the following: increased bioavailability, longer half-life that allows for once- or twice-daily subcutaneous administration, a more predictable anticoagulant response; they are generally safe and effective for home treatment, and there are fewer complications with bleeding and heparin-induced thrombocytopenia. Reported side effects of LMWHs include bleeding, heparin-induced thrombocytopenia, local skin reaction, pruritus, and rare skin necrosis.

Enoxaparin, dalteparin, and ardeparin are the most widely available of the LMWH products. Compared with unfractionated heparin, LMWHs have a lower anticoagulant potency but a more predictable anticoagulant effect. Because of their weaker anticoagulant effect, the LMWHs usually do not prolong the aPTT, so their effect is not monitored by the aPTT. In general, treatment with LMWH is not monitored by laboratory testing. If needed, monitoring could be done by anti-factor X_a assay. With long-term therapy, platelet counts should be monitored periodically. It is important to note that the different LMWHs are given according to a dose specific for that preparation.

Thrombolytics

Thrombolytic agents are able to dissolve preformed arterial and venous thrombi and emboli and restore blood flow to anoxic tissue. Currently available thrombolytics are listed in Table 211-9. These products work by inducing a systemic fibrinolytic state. This fibrinolytic state is not limited to the thrombus; it occurs throughout the circulation. This results in the potential for major hemorrhagic complications, which occur in about 9 percent of patients treated with thrombolytics compared with an average of 4 percent significant bleeding complications in patients treated with heparin. Because of this risk, the diagnosis of thrombus or embolus should be firmly established before treatment begins. Although theoretically more thrombus specific, major and minor bleeding complications are as common with recombinant tissue plasminogen activator (r-tPA) as with streptokinase.

Agent	Abbreviation
Streptokinase	SK
Urokinase	UK or uPA
Alteplase (recombinant tissue plasminogen activator)	tPA
Anistreplase (anisoylated plasminogen streptokinase activator complex)	APSAC
Reteplase (recombinant deletion mutation of tissue plasminogen activator)	rPA

TABLE 211-9   Currently Available Thrombolytic Agents

Clinical indications for consideration of the use of thrombolytic therapy are as follows:

Deep venous thrombosis—Thrombolytics have been used for the treatment of acute, large DVTs; thrombolytics produce complete or near-complete lysis of clots, superior to that seen when heparin is used alone. There is a decreased incidence of postphlebitic syndrome and lower extremity ulcers. Some studies show an increased risk of hemorrhagic complications up to three times that seen with heparin alone, so patients must be selected carefully.

Acute myocardial infarction—Vascular reperfusion is the major determinant of improved clinical outcome and mortality reduction. The best results are found in patients with recent onset of chest pain (less than 6 h). Thrombolytics are administered systemically or by intracoronary injection.

Pulmonary embolism—The role of thrombolytic therapy in patients with pulmonary embolism is not clearly defined; however, it should be considered in patients with acute onset of symptoms (<48 h), evidence of hemodynamic compromise, presence of massive emboli, or the presence of submassive emboli superimposed on chronic cardiopulmonary disease. Patients with pulmonary embolism who receive thrombolytic therapy have greater reperfusion, earlier normalization of the perfusion scan, and decreased pulmonary artery pressures, although no clinical trial has confirmed improved survival.

Peripheral arterial occlusion—Acute peripheral arterial occlusions as well as those in some central sites are commonly treated with systemic or intra-arterial infusion of thrombolytic agents. In this setting, urokinase may be superior to streptokinase.

Acute ischemic stroke—Until recently, no clinically effective therapy for acute ischemic stroke has been available. Several multicenter randomized clinical trials have studied the use of r-tPA for the treatment of acute ischemic stroke in progress. The best outcome occurs when treatment is initiated within 3 h of the onset of symptoms in carefully selected patients. Patients treated with r-tPA have an improved neurologic outcome at 3 months, although there is an increased risk (three to nine times compared with placebo) of intracranial hemorrhage.

Specific recommendations for the use of thrombolytic agents in various clinical settings are available in Chapter 216. Many institutions have protocols for the use of thrombolytic agents. Contraindications to use the thrombolytic therapy are outlined in Table 211-10.

TABLE 211-10   Contraindications to Thrombolytic Therapy

Bleeding is the major complication of thrombolytic therapy. Less common complications include fever, embolization of thrombi, and allergic reactions. Bleeding complications are primarily due to the dissolution of hemostatic plugs at sites of recent vascular injury. Superficial bleeding is usually not a major problem and can be controlled with local measures. Thrombolytic agents are discontinued at the first indication of major bleeding. Although the half-life of the thrombolytics is short, the systemic fibrinolytic state remains for 12 to 36 h after the infusion is stopped because it takes that long for fibrinogen to replenish itself. Cryoprecipitate can be given to replete fibrinogen and reverse the lytic state. EACA can also be given to inhibit the fibrinolytic state.

INFECTION WITH HUMAN IMMUNODEFICIENCY VIRUS

The current use of combination therapy, including the use of protease inhibitors, for the treatment of HIV-1 infection has improved the morbidity and mortality associated with HIV-1 infection significantly. These therapies, however, have not yet had a significant impact on the hemostatic abnormalities commonly seen in patients infected with HIV-1. The most common hemostatic abnormalities observed in patients infected with HIV-1 are thrombocytopenia and acquired circulating anticoagulants—lupus-type anticoagulants and anticardiolipin antibodies.

Thrombocytopenia is one of the earliest findings in asymptomatic HIV-1-infected individuals. Three to 60 percent of all HIV-1-infected patients will have thrombocytopenia at some time during the course of their illness. Both increased peripheral platelet destruction and decreased platelet production occur. Patients infected with HIV-1 have an increased incidence of immune platelet destruction, such as ITP. HIV-1 also can directly infect bone marrow megakaryocytes, resulting in decreased thrombopoiesis. The use of zidovudine (AZT) may result in improved platelet counts and rarely causes thrombocytopenia.

After thrombocytopenia, the most common hemostatic abnormality in HIV-1-infected patients is prolongation of the aPTT. This is usually due to the presence of a lupus-type anticoagulant. Often a transient defect, the lupus-type anticoagulant may appear with an acute opportunistic infection and disappear when the infection is treated. Anticardiolipin antibodies, which are detected by enzyme-linked immunosorbent assay (ELISA) and do not affect the basic hemostatic screening tests, are also more common in HIV-1-infected patients. One or both of these antibodies occur in 22 to 82 percent of patients with HIV-1 infection. These antibodies themselves do not predispose to clinical bleeding, but they result in an increased risk of thrombosis. However, concomitant hemostatic abnormalities such as platelet dysfunction or hypoprothrombinemia (associated with lupus-type anticoagulant) may lead to bleeding manifestations.

Another hemostatic complication of HIV-1-infection is anemia, which occurs in the majority of patients at some time in the course of their disease. Etiologies include ineffective erythropoiesis, the effect of HIV-1 and opportunistic infections on the bone marrow, and the use of AZT, which causes significant anemia in at least one third of patients. TTP is an uncommon but well-described complication of HIV-1 infection. TTP may be the initial manifestation of the infection and is characterized by the pentad of fever, thrombocytopenia, neurologic symptoms, renal insufficiency, and microangiopathic hemolytic anemia (see Chap. 214). Many patients infected with HIV-1 are also infected with the hepatitis viruses and have significant liver disease with resultant coagulation abnormalities.

USE OF ASPIRIN AND NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Table 211-3 depicts many of the commonly used drugs that can affect platelet function. Of these, the most commonly used are aspirin and the NSAIDs, which will be discussed in more detail.

Aspirin inhibits platelet function by acetylating and irreversibly inactivating platelet cyclooxygenase. Normally, platelet cyclooxygenase allows the formation of endoperoxides and thromboxanes, which stimulate platelet aggregation. This effect can be seen with as little as 80 mg aspirin per day and can continue for as long as 7 to 10 days after the aspirin is stopped, until the affected platelets are replaced by new platelets. The clinical significance of aspirin ingestion and bleeding is usually minimal except in some surgeries, cardiothoracic, plastic, and neurosurgery, where small amounts of blood loss are crucial, and in patients with underlying bleeding disorders (congenital or acquired) such as von Willebrand's disease, hemophilia, liver disease, uremia, or heavy ethanol ingestion. Chronic aspirin ingestion can lead to gastrointestinal blood loss; however, this is primarily from the direct effect of aspirin on the gastric mucosa. Platelet transfusion is the only acute treatment to overcome the platelet dysfunction induced by aspirin but this is rarely required.

The NSAIDs such as ibuprofen, indomethacin, and naproxen reversibly inhibit platelet cyclooxygenase. Inhibition of platelet cyclooxygenase occurs only as long as there is active drug in the circulation. The transient defect in platelet aggregation usually lasts less than 24 h. An exception is the drug piroxicam, which has a 2-day half-life; the resultant platelet dysfunction may be present for days. NSAIDs can be safely used in patients with hemophilia.

CIRCULATING ANTICOAGULANTS

Acquired inhibitors of blood coagulation, also known as *circulating anticoagulants,* can have serious clinical consequences or only be laboratory phenomena that have little clinical impact. These inhibitors are antibodies directed against one or more of the coagulation factors. Although inhibitors have been described against most of the coagulation factors, the two most common are discussed here. Factor VIII inhibitors are a type of "specific" inhibitor, directed only against factor VIII. The lupus anticoagulant is a "nonspecific" inhibitor that is directed against several of the coagulation factors.

Factor VIII Inhibitors

Factor VIII inhibitors most commonly occur in patients with congenital factor VIII deficiency, hemophilia A (see Chap. 212). Factor VIII inhibitors also can develop in patients with previously normal hemostasis; the incidence is estimated at 0.2 to 1.0 per million persons per year. Although uncommon, this is an important clinical entity to recognize because the mortality rate approaches 50 percent. About one-half the affected patients are otherwise healthy individuals, usually older than age 65. The other patients have underlying associated conditions such as autoimmune disorders [systemic lupus erythematosus (SLE), rheumatoid arthritis, ulcerative colitis], lymphoproliferative disorders (multiple myeloma, Waldenström's macroglobulinemia, benign monoclonal gammopathy of uncertain significance), women in pregnancy and the postpartum period, and patients with allergic drug reactions (penicillins, sulfonamides, phenytoin). Clinically, these patients without a prior bleeding history present with massive spontaneous bruises, ecchymoses, and hematomas. Laboratory studies classically show a normal PT, normal TCT, and greatly prolonged aPTT that does not correct with "mixing." A factor VIII–specific assay will show that the factor VIII activity is very low or absent. The other specific factor assays should be normal or only slightly decreased. Quantitative measurement of the inhibitor by the Bethesda inhibitor assay is important for the emergency management of bleeding episodes. Long-term management is directed at the suppression of antibody production by steroids, intravenous gamma globulin, or cytotoxic agents. The management of acute, often life-threatening bleeding episodes should be directed by a hematologist or coagulation specialist. Treatment options include high doses of factor VIII concentrates, the use of unactivated or activated prothrombin complex concentrates, porcine factor VIII, and potentially recombinant factor VII$_a$.

Lupus Anticoagulant

The lupus anticoagulant is an antiphospholipid antibody that interferes in vitro with many of the coagulation reactions. Its name is a misnomer because the majority of

affected patients do not have lupus and very few have a clinical bleeding disorder. The lupus anticoagulant is identified in 5 to 15 percent of patients with SLE. Associated conditions include other autoimmune disorders, drug reactions (procainamide and phenothiazines), malignancies, and patients with HIV-1 infection in the setting of acute opportunistic infections. Many affected patients have no underlying disease state. Clinically, many patients are asymptomatic, with the abnormality discovered on routine coagulation screening tests. Arterial or venous thromboses occur in 23 to 58 percent of patients. Recurrent fetal loss, thought to be due to thrombosis of placental vessels and placental infarction, is also common. Some patients have thrombocytopenia, but they also may have ITP. Bleeding abnormalities are uncommon in patients with the lupus anticoagulant unless they have associated hypoprothrombinemia (usually patients with SLE), significant thrombocytopenia, or other underlying abnormality predisposing them to hemorrhage, such as uremia.

Laboratory studies of patients with the lupus anticoagulant typically show a normal or slightly prolonged PT, mild to moderate prolongation of the aPTT (not usually more than 10–15 s prolonged), and a normal TCT. The prolonged aPTT will not correct with "mixing." If the PT is prolonged by more than 3 s, the patient should be evaluated for concomitant hypoprothrombinemia (factor II). Factor-specific assays done in this setting will show a decrease in all the factor levels, although none are extremely low. Various tests can be done to verify the presence of the lupus anticoagulant. These are the dilute Russell viper venom time, kaolin clot time, platelet neutralization procedure, and tissue thromboplastin inhibition test. Asymptomatic patients found to have the lupus anticoagulant require no treatment. If there is an associated underlying disorder, it should be treated, and with resolution, the lupus anticoagulant may disappear. Patients who suffer thrombotic events are managed with long-term anticoagulation (those with venous thrombosis) or low-dose aspirin (those with arterial thrombosis). Patients with the lupus anticoagulant can often be managed through a successful pregnancy when treated with prednisone and ASA.

212 HEMOPHILIAS AND VON WILLEBRAND'S DISEASE

Mary E. Eberst

Hemophilias are hereditary bleeding disorders due to deficiency of factor VIII (hemophilia A, classic hemophilia) or factor IX (hemophilia B, Christmas disease). Von Willebrand's disease is a related hereditary deficiency of a portion of the factor VIII complex. These disorders are discussed below.

HEMOPHILIA

Patients with hemophilia A, factor VIII deficiency, account for 85 percent of patients with hemophilia. This X-linked, recessive disorder occurs in 1 in 10,000 live male births. Hemophilia B, factor IX deficiency, is also an X-linked recessive disorder and occurs in 1 in 25,000 to 30,000 live male births. Thirty percent of affected patients have no family history of hemophilia; spontaneous mutations are believed to be responsible. Females are generally carriers of hemophilia A or B, have 50 percent of normal factor VIII or factor IX activity, and are asymptomatic. On occasion, due to extreme lyonization, a female carrier can have lower factor VIII or factor IX levels and have clinical manifestations of the disease.

Classification

The clinical classification of the hemophilias is based on the severity of deficiency. Patients classified as mildly deficient have 6 to 60 percent of normal factor VIII or factor IX activity; moderate disease is 1 to 5 percent of normal; severe hemophilia describes patients with less than 1 percent of normal factor activity and accounts for 60 percent of all patients. The most common bleeding manifestations are outlined in Table 212-1. Unless there is other underlying disease, patients with hemophilia do not have problems with minor cuts and abrasions. Bleeding in hemophiliacs is characterized by deep hematomas and hemathroses that occur spontaneously or with minimal trauma; the bleeding is often delayed several hours after minor injury.

Site	Comments
Hemarthroses	Leads to joint destruction and chronic arthropathy if not treated aggressively
Hematomas	Bleeding into soft tissues or muscle; this bleeding can dissect along fascial planes; most dangerous near in the neck (airway compromise), limbs (compartment syndromes) and retroperitoneum (massive blood loss)
Mucocutaneous bleeding	Bleeding in the oropharynx, gastrointestinal tract, epistaxis, hemoptysis, bleeding after dental extractions
Central nervous system	Intracranial bleeding is the most common cause of bleeding death in hemophiliacs, has a 34% mortality; subdural hematomas—occur spontaneously or with minimal trauma
Hematuria	Common, usually not serious, and the source is rarely found
Pseudotumor	Bone cysts that result from unresolved hematomas; usually have to be removed surgically

TABLE 212-1 Common Bleeding Manifestations in Patients with Hemophilia

Unfortunately, bleeding is not the only problem facing patients with hemophilia. Many hemophiliacs also have chronic hepatitis and are infected with the human immunodeficiency virus type 1 (HIV-1) as a result of their exposure to blood products. In hemophilic patients who received plasma products prior to the mid-1980s, 90 percent have serologic evidence of hepatitis B, 85 to 100 percent have hepatitis C antibodies, and 60 to 90 percent have HIV-1 infection. Those most likely to be infected with HIV-1 are patients with severe hemophilia A without an inhibitor. Hemophilia B patients are less likely to be infected with HIV-1 as a result of the products they receive for treatment—about 50 percent are infected. Since 1985, acquired immunodeficiency syndrome (AIDS) has become the leading cause of death in patients with hemophilia. Hemophilic patients with AIDS account for 1 percent of the total U.S. AIDS population. Since 1986, as a result of new viral inactivation procedures, there have been few seroconversions resulting from the use of currently available factor replacement products.

Patients with hemophilia are usually identified in childhood or adolescence; however, those with a mild deficiency may go undetected until there is a major hemostatic challenge. Occasionally, an emergency physician will encounter a patient with acute bleeding who may have an undiagnosed coagulopathy. Table 212-2 lists some historical and clinical findings that might be indicative of the presence of a bleeding disorder. Hematologic consultation should be obtained for these patients.

History of easy bruising, epistaxis, menorrhagia, or gastrointestinal bleeding

History of the development of hematomas following minor trauma

History of excessive bleeding after dental extractions or minor surgery

Family history of any of the preceding

Apparent excessive bleeding from minor wounds in the absence of aspirin or nonsteroidal anti-inflammatory therapy

Abnormal coagulation studies not previously known to be abnormal

TABLE 212-2 Historical and Clinical Findings Suggestive of an Underlying Coagulopathy

Testing

Coagulation screening tests in patients with hemophilia typically show a normal prothrombin time (PT), normal thrombin clot time (TCT), and prolonged activated partial thromboplastin time (aPTT), reflective of the abnormality in the intrinsic pathway. However, if the factor VIII level in hemophilia A or factor IX level in hemophilia

B is greater than 30 percent of normal activity (mild hemophilia), the aPTT can be normal. The only way to distinguish hemophilia A and hemophilia B is by specific factor assays of factors VIII and IX. Inhibitors are circulating antibodies, usually IgG, that are directed against factor VIII or factor IX, whichever factor the patient is lacking. Inhibitors occur in 10 to 15 percent of patients with severe hemophilia A and in about 10 percent of patients with severe hemophilia B. Inhibitors develop in response to exposure to the "missing factor" through replacement therapy. Most of these develop early in life. An inhibitor is diagnosed in the laboratory when the plasma of a patient with hemophilia with a prolonged aPTT is "mixed" 50-50 with the plasma of a "normal" control. If the aPTT corrects to normal with this "mix," no inhibitor is present, just a factor deficiency. If, however, the mix does not correct, an inhibitor is present. Further testing can be done to determine which coagulation factor the inhibitor is directed against, although in patients with known hemophilia, it is against the missing factor. The quantity of inhibitor that is present is measured most commonly by the Bethesda inhibitor assay (BIA) and is reported in BIA units. This quantitation is important in determining what type of factor replacement therapy the patient will require.

Bleeding Complications

The emergency physician needs to be aware of major bleeding emergencies that can develop in patients with hemophilia. These patients require emergent factor replacement therapy and management by hemophilia specialists. Air transport to specialized centers should be considered for intracranial, intrathoracic, or intraabdominal bleeding, even if the patient appears "stable." Bleeding into the *central nervous system* (CNS) can occur spontaneously as well as with trauma. Any patient with hemophilia who complains of a new headache or any neurologic symptoms requires immediate factor replacement therapy followed by immediate computed tomographic (CT) scanning of the head. Spontaneous or traumatic bleeding into *the neck, retropharynx, or pharynx* has a high potential for airway compromise. Such bleeding can be spontaneous or precipitated by successful or unsuccessful placement of external jugular lines or other trauma. These patients require immediate factor replacement and immediate CT scanning to define the bleeding area. Airway management, including oral intubation, takes priority. If not preceded by factor replacement therapy, intubation must be followed immediately by factor replacement. Hemophilic patients with complaints of back, thigh, groin, or abdominal pain may have bleeding into the *retroperitoneum*. Bleeding into this potential space can be life-threatening because of the large potential area and the ability of the bleeding to dissect along fascial planes. Immediate factor replacement and CT scanning are indicated. *Compartment syndromes* result from muscle bleeds within the fascial compartments of the extremities. Complaints of pain and paresthesias and the findings of sensory, motor, or vascular deficits raise this possibility. After factor replacement therapy is initiated, the compartment pressure can be measured. Surgical fasciotomy may be required and needs to be done within 8 h after the onset of symptoms for best chance of full neurovascular recovery. The most common manifestation of hemophilia that will be encountered is the hemarthrosis. There may or may not be clinical evidence of an acute problem with the joint, but the patient can reliably report when bleeding is occurring. Prompt treatment of hemarthroses can prevent or reduce the long-term sequelae of hemophilic arthropathy. Patients with hemophilia should never receive intramuscular injections unless factor replacement is given and maintained for several days. Central lines, including femoral lines and external jugular lines, should not be placed in patients with hemophilia prior to factor replacement therapy; life-threatening bleeding can result. Arterial blood gases or lumbar puncture should not be performed on patients with hemophilia without coverage of factor replacement therapy. A compartment syndrome can result in the extremity, or epidural bleeding in the spinal canal.

The management of hemophilic bleeding depends on the type of hemophilia that is present, the severity of deficiency, the presence or absence of an inhibitor, and the location of bleeding. Each of these will be discussed separately.

Management of Factor VIII Deficiency (Hemophilia A) without an Inhibitor

Patients with mild or moderate hemophilia A may respond to treatment with desmopressin (1-desamino-8-D-arginine vasopressin, desmopressin). It is helpful to know if the patient has been treated previously with desmopressin successfully. In patients who respond, desmopressin can raise the factor VIII activity level up to threefold. Its mechanism of action is not entirely understood, but desmopressin is believed to cause release of von Willebrand factor (vWF) from storage sites in the endothelial cells; the increased amount of vWF is then capable of carrying additional amounts of factor VIII in the plasma. The usual dose of desmopressin is 0.3 μg/kg of body weight administered intravenously or subcutaneously every 12 h. Some authors suggest 30 μg as a maximum dose. A concentrated form of desmopressin can be administered intranasally. The dose is 150 μg (one metered dose) for patients weighing less than 50 kg and 300 μg for patients weighing 50 kg or more. A response in the factor VIII level should be seen in 1 h. This dose can be repeated three or four times before temporary tachyphylaxis develops. The advantages of desmopressin are that it is not a blood product and therefore carries no risk of viral transmission, and it is easily administered in the hospital or home setting. Serious side effects are uncommon. Common reactions include facial flushing and headache, and mild hyponatremia can develop, especially in pediatric patients.

Patients with moderate or severe hemophilia A and significant bleeding will require treatment with factor VIII concentrates. In settings where virally safe factor VIII concentrates are not available and life-threatening bleeding requires treatment, cryoprecipitate or fresh-frozen plasma (FFP) can be used temporarily; however, these products carry a risk of viral transmission, so they should be administered for this purpose only in true emergencies. Each bag of cryoprecipitate contains about 100 units of factor VIII. FFP contains 1 unit of factor VIII per milliliter of FFP. Most patients with hemophilia A without an inhibitor are treated with factor VIII products made by recombinant DNA technology. Table 212-3 outlines the currently available factor VIII concentrates. Other products of lesser purity, which carry some small risk of hepatitis transmission (but not HIV-1), may still be available and used electively by some patients who are already infected, because of their lower price. These products should not be given to patients with negative or uncertain infection status unless it is a true emergency. Factor VIII concentrates are dosed by units; 1 unit is the amount of factor VIII activity in 1 mL of normal plasma. One unit of factor VIII per kilogram should raise the circulating factor VIII level by 2 percent. The amount of factor VIII needed to raise a patient with hemophilia to a desired circulating level of factor VIII can be calculated by

$$\text{Factor VIII (units)} = \text{weight in kg}/2 \times (\% \text{ activity desired} - \% \text{ intrinsic activity})$$

Recombinant products:	Monoclonal antibody purified:
Recombinate	Koate
Kogenate	Monoclate-P
Bioclate	Hemofil-M
Helixate	Monarc-M

Typical dose: One unit of factor VIII per kilogram should raise the circulating factor VIII level by 2%; products are typically dosed every 8–12 h for moderate or life-threatening bleeding events and every 12–24 h for minor bleeding events; dosing depends on patient response and postinfusion factor VIII levels.

TABLE 212-3 Currently Available Factor VIII Concentrates

Table 212-4 outlines specific treatment recommendations for factor VIII replacement therapy in patients with hemophilia A. After the loading dose, subsequent doses of factor VIII should be adjusted based on factor VIII level assays.

TABLE 212-4   Factor VIII Replacement Therapy for Patients with Hemophilia A (No Inhibitor)

Ancillary therapies in the management of bleeding episodes include rest, potential immobilization, analgesia, and the use of antifibrinolytic agents, which are most commonly used in patients undergoing dental or oral surgery. e-Aminocaproic acid (EACA) and tranexamic acid are examples. These can be used alone in some cases or in conjunction with factor VIII concentrates. These agents are contraindicated in patients with hematuria.

Management of Factor VIII Deficiency (Hemophilia A) with Inhibitor Present

The use of factor replacement therapy in hemophilic patients with inhibitors is guided by the inhibitor titer (number of BIA units) and the type of response the patient has to factor VIII concentrates. This anamnestic response is usually either a rapid increase in the inhibitor titer within 2 to 3 days (high responders) or a low response where the inhibitor increases little or none (low responders). Table 212-5 outlines the treatment options available for treatment of hemophilia A patients with inhibitors.

TABLE 212-5   Replacement Therapy for Hemophilia A Patients with Inhibitors

Management of Factor IX Deficiency (Hemophilia B) without an Inhibitor

Table 212-6 outlines the goals of replacement therapy for patients with hemophilia B. The products that are available for replacement therapy are listed in Table 212-7. The highly purified factor IX concentrates are the treatment of choice if available. One unit of factor IX per kilogram should raise the circulating factor IX level by 1 percent. This amount can be calculated by

TABLE 212-6   Factor IX Replacement Therapy for Patients with Hemophilia B

TABLE 212-7   Products Used for Replacement Therapy in Patients with Hemophilia B

$$\text{Factor IX (units)} = \text{kg} \times (\%\ \text{activity desired} - \%\ \text{intrinsic activity})$$

If it is necessary to raise the factor IX level to 75 to 100 percent (e.g., life-threatening situations), this should be done with the highly purified concentrates because they carry essentially no risk of thrombogenicity. In settings where factor IX concentrates are not available, FFP can be used to raise the factor IX level. The use of FFP in this setting should be limited to emergency treatment because of the small risk of viral transmission and the inability to raise the factor IX levels adequately because of volume constraints. One unit of FFP will raise the factor IX level by 3 percent in an average-sized person.

Management of Factor IX Deficiency (Hemophilia B) with Inhibitor Present

The products available for the treatment of hemophilia B patients with inhibitors are outlined in Table 212-8 along with treatment guidelines. The treatment of each patient must be individualized based on the clinical response.

Type of Product	Used for	Initial Dose
Highly purified factor IX concentrates	Bethesda inhibitor titer <10 units	Variable
Prothrombin complex concentrates (PCCs)	Bethesda inhibitor titer <10 units	75 units/kg
Activated prothrombin complex concentrates (aPCCs)	Bethesda inhibitor titers >10 units or unresponsive to the above	Variable, about 75 units/kg
Recombinant factor VII,	Not yet commercially available	Variable

TABLE 212-8 Products Used for Replacement Therapy in Patients with Hemophilia B with Inhibitors

Indications for Hospital Admission

Hemophilic patients with bleeding episodes will require hospital admission in these situations:

- The patient has potentially life-threatening bleeding involving the CNS, neck, pharynx, retropharynx or retroperitoneum, or potential compartment syndrome.
- The patient is not capable of administering factor replacement therapy at home.
- The patient requires treatment for several days.
- The patient needs close monitoring.
- The patient requires parenteral pain control.

VON WILLEBRAND'S DISEASE

Von Willebrand's disease, which is caused by a deficiency or abnormality of vWF, is the most common inherited bleeding disorder. The vWF is a glycoprotein that is synthesized, stored, and secreted by vascular endothelial cells; it is also found in plasma and platelets. vWF has two functions: (1) in primary hemostasis, vWF allows platelets to adhere to the damaged endothelium; and (2) vWF carries factor VIII in the plasma.

It is estimated that 1 in 100 persons has a gene defective for vWF, which is inherited in an autosomal dominant pattern. However, only 1 in 10,000 manifests a clinically significant bleeding disorder. The most severe type of von Willebrand disease (vWD), known as type III, is very rare, occurring in 1 in 1 million persons; it results from an autosomal recessive defect.

Testing

Test	Typical Result in vWD	Comments
Bleeding time	Prolonged	Measures platelet and vessel wall interaction (primary hemostasis); this test has high variability—if prolonged, it is important data; if normal, does not rule out vWD
vWF antigen	Low or normal	Is an acute phase reactant, increased in stress and pregnancy
vWF activity	Low	Evaluates the function of vWF by measuring the ability of vWF to agglutinate platelets in the presence of the antibiotic ristocetin
Factor VIII activity	Low or normal	May be normal or slightly decreased in vWD, except very low or absent in type III vWD
Multimeric analysis	Variable	Separates the vWF molecule into its subunits (multimers) based on molecular weight; needed to distinguish types of vWD

Note: vWF, von Willebrand's factor; vWD, von Willebrand's disease.

TABLE 212-9 Laboratory Evaluation of Patients with von Willebrand's Disease*

A variety of tests are used to establish the diagnosis of vWD. Coagulation screening tests will show a normal PT, normal TCT, and usually normal aPTT, although it may be prolonged in moderate or severe vWD due to the decreased factor VIII activity. The other tests used in the evaluation of vWD are outlined in Table 212-9. The diagnosis of vWD can be difficult to establish because of variability in test results. Oftentimes, patients have to be tested repeatedly when there is a high index of suspicion in order to establish the diagnosis. The tests can be affected by estrogens, progesterones, oral contraceptive agents, thyroid disease, infections, and exercise.

Based on the results of testing, patients with vWD can be classified into three main types, outlined in Table 212-10. There are many subtypes that are clinically unimportant.

Type	Occurrence	Defect
I	70–80% of patients with vWD	All multimeric forms are present but their quantity is diminished
II	10–15%	The vWF molecule is abnormal, missing some of the multimers
III	<10%	Essentially no vWF is present

Note: vWD, von Willebrand's disease; vWF, von Willebrand's factor.

TABLE 212-10 Classification of von Willebrand's Disease

Von Willebrand disease can be difficult to distinguish from mild hemophilia A. The bleeding time should be normal in hemophilia, although it is also often normal in patients with vWD. The von Willebrand antigen and activity should be normal or elevated in patients with hemophilia. The factor VIII activity level will be low in patients with hemophilia and may be normal or slightly low in patients with vWD. In some cases, it is nearly impossible to distinguish type I vWD and mild hemophilia A.

Bleeding Complications

The hemorrhagic tendency in patients with vWD is highly variable among patients with the same type of vWD, even among patients from the same family who have an identical genetic defect. Most characteristics are mild bleeding symptoms from mucocutaneous surfaces (such as epistaxis), easy bruising, bleeding after dental

extractions, menorrhagia, and gastrointestinal bleeding. Patients with type III vWD have a severe bleeding diathesis with spontaneous hematomas and hemarthroses similar to patients with severe hemophilia.

Treatment

The treatment of vWD depends on the type of disease that is present and the severity of bleeding. Table 212-11 shows the recommended therapy for patients with vWD. Desmopressin is the mainstay of therapy for patients with type I vWD; plasma products that contain vWF are used for types II and III. Desmopressin can be administered subcutaneously or intravenously at a dose of 0.3 µg/kg of body weight. This dose is given every 12 h to a total of three or four doses before temporary tachyphylaxis develops. A concentrated form of desmopressin can be administered intranasally. The dose is 150 µg (one metered dose) for patients weighing less than 50 kg and 300 µg for patients weighing 50 kg, more. In a setting where treatment is essential and desmopressin or the specifically recommended factor VIII concentrates are not available, cryoprecipitate can be used to replace the vWF that is needed for hemostasis. Each bag of cryoprecipitate contains about 100 units of vWF activity. Cryoprecipitate should only be used in emergencies because there is a small risk of viral transmission. Women with vWD are often treated with hormonal agents (estrogens and/or progesterones), which cause an increase in the vWF activity. Bleeding associated with dental procedures can often be managed with fibrinolytic inhibitor agents such as EACA and tranexamic acid.

Type I	Desmopressin (DDAVP)
Type II	Factor VIII concentrates (Humate-P or Koate-HS) or cryoprecipitate
Type III	Factor VIII concentrates (Humate-P or Koate-HS) or cryoprecipitate

This chapter discusses the most common inherited hemolytic anemias including the hemoglobinopathies, sickle cell anemia and its variants, glucose-6-phosphate dehydrogenase deficiency (which is a red blood cell enzymatic defect) and hereditary spherocytosis (a defect in the red blood cell membrane).

SICKLE CELL ANEMIA

Pathophysiology

A hemoglobinopathy is an inherited disease resulting from the presence of one or more abnormal hemoglobins. More than 400 hemoglobin variants have been described. Normal human hemoglobin consists of four polypeptide chains and four heme groups. The four polypeptide chains consist of two alpha chains and two nonalpha chains, which are most commonly beta. The majority of hemoglobin in a normal adult consists of two alpha chains and two beta chains and is called *hemoglobin A* (HbA, a_2b_2). Other normal nonalpha chains are gamma (hemoglobin F) and delta (hemoglobin A$_2$) (Table 213-1).

Phenotype	Types of Hemoglobin Present	Percent	Genotype
Normal adult	HbA	96–98	2 alpha 2 beta
	HbF	0.5–0.8	2 alpha 2 gamma
	HbA$_2$	1.5–3.2	2 alpha 2 delta
Sickle cell trait (heterozygous)	HbAS	A 60–65	2 alpha 1 beta 1 sickle
		S 35–40	
Sickle cell disease (homozygous)	HbSS	S 80–90	2 alpha 2 sickle
	HbF	F 2–20	2 alpha 2 gamma
	HbA$_2$	A$_2$ 2–4	2 alpha 2 delta

TABLE 213-1   Composition of Normal Human Hemoglobin and the Sickle Hemoglobin Variants

The most common hemoglobin variant, known as *hemoglobin S* (HbS), results from a single point mutation on the beta chain: Valine is substituted for glutamic acid in the sixth position. Hemoglobin S is little problem when it is carrying oxygen (oxyhemoglobin form), but when it is deoxygenated, HbS polymerizes within the red blood cell causing the sickle shape. Sickled red blood cells increase the viscosity of the blood, leading to sludging or obstruction in the microcirculation. Eventually, the cells may become irreversibly sickled. Conditions that increase the amount of sickling include acidosis and increased 2,3-diphosphoglycerate (both cause the oxygen dissociation curve to shift to the right, which favors the formation of the deoxyhemoglobin form), vascular stasis, dehydration, the presence of higher levels of HbS in the cells, and low oxygen tension. The presence of hemoglobin F (HbF) has a protective role; higher HbF levels are associated with less sickling phenomena. Sickled red blood cells are rapidly hemolyzed resulting in a red blood cell survival of 10 to 20 days, compared with the normal red blood cell lifespan of 120 days.

In the US African-American population, about 8 percent carry the sickle cell gene; these persons have HbAS (a $_2$bS, sickle cell trait). Inherited in an autosomal codominant pattern, sickle cell disease (SCD) results when the patient inherits the sickle gene from both parents. This is hemoglobin SS (a $_2$S$_2$) and occurs in 0.14 to 0.20 percent of the US African-American population, resulting in about 50,000 patients with SCD. When the sickle cell gene is inherited from one parent and another abnormal beta-chain gene is inherited from the other parent, heterozygous hemoglobinopathies result, such as hemoglobin SC disease and sickle–b thalassemia (see below).

Clinical Features

The clinical manifestations of SCD are variable between patients, but all are related to chronic hemolytic anemia, and virtually every organ system can be affected by recurrent vasoocclusive events. First, we will review the common clinical findings in patients with SCD; then we will discuss the problems that are likely to bring the patient to the emergency department (Table 213-2).

Vasoocclusive Crises	Hematologic Crises	Infectious Crises
Musculoskeletal pain	Splenic sequestration	Pneumonia
Abdominal pain	Aplastic crisis	Meningitis
Pulmonary crisis		Osteomyelitis
Central nervous system crisis		Urinary tract infection
Priapism		Sepsis
Hand and foot syndrome		
Renal crisis		

TABLE 213-2   Clinical Emergencies in Patients with Sickle Cell Anemia

Patients with SCD have a chronic hemolytic anemia with a baseline hemoglobin of 6 to 9 g/dL and a reticulocyte count of 5 to 15 percent. These patients commonly have cardiopulmonary disease, including decreased pulmonary function and reserve, decreased resting arterial oxygen tension, systolic and diastolic flow murmurs, congestive heart failure, cardiomegaly, and cor pulmonale. Myocardial infarction is rare in patients with SCD. Icterus is the rule as a result of chronic hemolysis.

Bilirubin gallstones are found in up to 75 percent of patients with SCD. Hepatomegaly and liver function test abnormalities are common. Splenomegaly is seen in children with SCD; however, by adulthood, the spleen is usually small as a result of recurrent infarction. Renal abnormalities including isosthenuria (inability to concentrate urine) and papillary necrosis occur commonly because of sickling phenomena in the hypertonic, acidic renal medulla. Bony abnormalities, resulting from expansion of the marrow space, and bony infarcts are typical. Radiographs of the bones show thinning of the cortices and sparseness of the trabecular pattern; the biconcave "fishmouth" changes in the vertebrae are pathognomonic of SCD. Skin ulcerations occur over the distal lower extremities. Ophthalmologic problems primarily involving the retinae are common. Chronic disabilities resulting from central nervous system vasoocclusive events are seen.

Since the mid-1990s, many patients with SCD have been treated with hydroxyurea. Hydroxyurea can significantly decrease the clinical manifestations of SCD in many patients. Hydroxyurea is believed to work by increasing the concentration of HbF and results in decreased sickling phenomena.

Table 213-2 outlines the types of crises that occur in patients with SCD. Frequently, a patient will have more than one type of crisis at a time.

VASOOCCLUSIVE CRISES   Painful vasoocclusive crises are the most common reason for visits to the emergency department (ED) by patients with SCD. These crises account for the greatest morbidity and mortality among these patients. The average adult sickle cell patient has four severe attacks per year; however, some patients experience crises daily. Vasoocclusive events are more common in adult patients with higher hemoglobin levels and lower amounts of HbF. The underlying pathophysiology is sludging of sickled red blood cells in the microcirculation with infarction. This event can be precipitated by infection, exposure to cold, dehydration, and high altitude. In children, up to 80 percent of the vasoocclusive events are infection-related. In adults, up to one-third of vasoocclusive crises are related to bacterial or viral infections, but the majority of crises are unexplained. Patients can have "typical" crises with pain in the same location recurrently, but the pain can be anywhere.

Musculoskeletal Pain   Vasoocclusive crisis with pain involving the bones, joints, and muscles is the most prominent manifestation of SCD. This pain can be anywhere but most often involves the humerus, tibia, femur, and low back area. Examination may reveal local tenderness, but often there are no physical findings. The differential diagnosis includes osteomyelitis and acute arthritides such as gout and rheumatoid arthritis. Pain in the hip with difficulty walking raises the possibility of avascular necrosis (AVN) of the femoral head. If there is local tenderness or an effusion, an aspirate should be obtained for culture or the joint fluid evaluated for signs of infection. Plain radiographs may show changes of osteomyelitis or AVN but are of little value in detecting bony infarction. Magnetic resonance imaging (MRI) can be used to document infarction. Bone scans and gallium scans can differentiate infarction from osteomyelitis and may show osteomyelitis in the early stages before plain radiographs will show abnormalities.

Abdominal Pain   This is the second most common type of vasoocclusive crisis experienced by patients with SCD. Abdominal pain due to vasoocclusive crisis typically is of relatively acute onset, diffuse, poorly localized, and often recurrent. These patients have diffuse pain without peritoneal signs; bowel sounds should be present. Pain in the right upper quadrant (RUQ) raises the possibility of cholecystitis and the RUQ syndrome. At least 75 percent of patients with SCD have bilirubin gallstones; however, only 10 percent are ever symptomatic. The RUQ syndrome involves the sudden onset of RUQ pain, progressive hepatomegaly, and extreme hyperbilirubinemia (>50 mg/dL). Resulting from intrahepatic cholestasis, the outcome of the RUQ syndrome is usually benign in pediatric patients, but some adult patients progress to liver failure. The remainder of the differential diagnosis of sickle cell patients with abdominal pain suspected of having vasoocclusive crisis includes pancreatitis, mesenteric infarction, hepatitis, hepatic infarction, appendicitis, perforated viscus, and pelvic inflammatory disease. Ultrasound examination and computed tomographic (CT) scanning of the abdomen and pelvis may be helpful. Surgical consultation is indicated if the diagnosis remains uncertain.

Pulmonary Crisis   This problem occurs in up to 30 percent of patients with SCD and accounts for 15 percent of adult deaths. The presentation of pleuritic chest pain, fever, leukocytosis, and possible pulmonary infiltrate raises the differential diagnosis of pulmonary infarction, acute chest syndrome, bacterial or viral pneumonia, and pulmonary thromboembolus. The acute chest syndrome occurs when a pulmonary infarct becomes secondarily infected. This is a major cause of death in patients with SCD above age 10. Such patients often have a precipitous decrease in pulmonary function and severe hypoxia. The chest radiograph may not show an infiltrate for up to 2 days. Arterial blood gas analysis, complete blood count (CBC), and the presence of sputum may be helpful. Ventilation-perfusion ($\dot{V}/\dot{Q}$) scan of the lung may be helpful, especially if a baseline study for comparison is available. Pulmonary angiography should be avoided, if possible, because the contrast material can induce more pulmonary sickling. Sickle cell patients with significant pulmonary signs or symptoms should be admitted to the hospital. Empiric antibiotics are often given until the diagnosis becomes clear.

Central Nervous System Crisis   This is the only type of vasoocclusive crisis that is painless. Overall, neurologic complications occur in 15 to 25 percent of patients with SCD. The most common problems are cerebral infarction in children and cerebral hemorrhage in adults. Other complications of central nervous system (CNS) vasoocclusive events are transient ischemic attacks, seizures, headache, dizziness, cranial nerve palsies, unexplained coma, paresthesia, meningitis, vestibular dysfunction, and sensory hearing loss. There is an increased incidence of subarachnoid hemorrhage (SAH) in patients with SCD. Evaluation of patients with CNS complaints should include a CT scan of the head and a lumbar puncture to rule out SAH and meningitis. MRI is better than CT scanning for demonstrating the CNS effects of vasoocclusive phenomena.

Priapism   This complication occurs in up to 30 percent of males with SCD. The persistent, painful erection results from the sickling of cells in the corpus cavernosum, which prevents the emptying of blood from the penis. Surgical decompression may be required, and permanent impotence may result.

Hand and Foot Syndrome (Dactylitis)   This complication of SCD usually occurs in the first 2 years of life and may be the first sign that a child has SCD. The patient presents with swelling of the hands and/or feet (one to four extremities involved) that is the result of vasoocclusion of the nutrient arteries to the metacarpals and/or metatarsals. Avascular necrosis of the bone marrow in the involved bones occurs.

Renal Crisis   Vasoocclusive events involving the kidneys are very common but often asymptomatic. Infarction in the renal medulla may cause flank pain, renal colic-type pain, and costovertebral angle tenderness. Patients may have gross or microscopic hematuria and may pass tissue resulting from papillary necrosis. Pyelonephritis and urinary tract infection must be excluded, and adequate/stable renal function should be documented.

HEMATOLOGIC CRISES   Heralded by an acute drop in the hemoglobin level, patients with hematologic crisis will present with weakness, shortness of breath, fatigue, worsening of congestive heart failure, or shock. There are two types of hematologic crisis.

Acute Splenic Sequestration   This occurs primarily in children and is the second most common cause of death in children with SCD under the age of 5. Often preceded by viral infections, sickled cells block the splenic outflow, causing pooling of peripheral blood and sickled cells in the spleen. Such patients present in hypovolemic shock with an enlarged spleen. These crises are divided into major and minor. In a major sequestration crisis, the spleen enlarges rapidly and the hemoglobin drops to <6 g/dL or >3 g/dL from baseline. A minor sequestration crisis is specified by an enlarging spleen and a hemoglobin >6 g/dL. These patients will have a higher than usual reticulocyte count reflective of normal compensatory bone marrow activity. Such patients are managed with transfusion of red blood cells and exchange transfusions; splenectomy may be considered.

Aplastic Crisis   This life-threatening complication of SCD occurs when bone marrow erythropoiesis is slowed or stopped. The hematocrit falls to as low as 10 percent, and the reticulocyte count falls to as low as 0.5 percent. The white blood cell count and platelet counts usually remain stable. Aplastic crises can be precipitated by viral infections (particularly parvovirus B $_{19}$), folic acid deficiency, or the ingestion of bone marrow toxins such as phenylbutazone. This is usually a self-limited problem, but red blood cell transfusions may be required for severe anemia or cardiopulmonary compromise.

INFECTIOUS CRISES   Infection is a common contributor to death in patients of all ages with SCD, especially children under the age of 5. Functionally asplenic after early childhood and with impaired phagocyte functioning, patients with SCD are and should be treated as immunocompromised hosts. Sickle cell patients who present with an unexplained fever of 38°C (101°F) or higher require evaluation for a source of bacterial infection and consideration for early treatment with broad-spectrum antibiotics. Sickle cell patients can be rapidly overwhelmed by bacterial sepsis, particularly with encapsulated organisms, such as *Hemophilus influenzae* and *Streptococcus pneumoniae.* Other common diseases are pneumonia caused by these organisms as well as *Mycoplasma pneumoniae,* meningitis, and osteomyelitis due to *Salmonella typhimurium, Staphylococcus aureus,* and *Escherichia coli.* Patients with iron overload from frequent transfusions who are treated with the chelating agent deferoxamine are at risk for infection with *Yersinia enterocolitica.*

Diagnosis

The diagnosis of SCD is usually established in early life based on the family history, ideally before the child begins to develop complications. The diagnosis is made by documenting the presence of sickle hemoglobin. Sickled red blood cells should be seen on the peripheral smear. Quick tests to determine the presence of sickle

hemoglobin are the metabisulfite test and the Sickledex (Ortho-Clinical Diagnostics) test. Hemoglobin electrophoresis is required to distinguish homozygous SS disease from sickle cell trait and the other heterozygous sickle syndromes.

LABORATORY STUDIES   The laboratory evaluation required for an individual patient who presents to the ED can be tailored to the symptoms of the patient and the physical findings. Commonly obtained studies include the following evaluations.

Complete Blood Count   A complete blood count (CBC) should be obtained in most sickle cell patients with severe crisis. The "normal" white blood cell count in patients with SCD ranges from 12,000/μL to 18,000/μL but usually has a normal differential. Elevations higher than the patient's baseline or the presence of a left shift are notable. The baseline hemoglobin in sickle cell patients is typically 6 to 9 g/dL. A fall in the hemoglobin by 2 g/dL or a fall in the hematocrit by 4 to 6 percent may reflect hematologic crisis or blood loss. The platelet count is often elevated at baseline. The peripheral smear should show sickled cells and Howell-Jolly bodies, which indicate the loss of splenic function.

Reticulocyte Count   A reticulocyte count should be obtained if the hemoglobin has fallen by 2 g/dL or more. The baseline reticulocyte count is typically 5 to 15 percent; lower values may reflect aplastic crisis.

Electrolytes   Electrolytes should be obtained in any patient who appears significantly dehydrated, because imbalances occur readily due to isosthenuria.

Liver Function Tests   Liver function tests should be obtained in sickle cell patients who present with abdominal pain. These patients often have baseline abnormalities and a chronically elevated indirect bilirubin due to chronic hemolysis.

Erythrocyte Sedimentation Rate   The erythrocyte sedimentation rate (ESR) is not a reliable indicator of inflammation or infection in patients with SCD because sickled cells cannot form rouleaux, which is the basis for the test. The ESR is helpful only if it is elevated, since a normal value does not rule out infection or inflammation.

Arterial Blood Gas   An arterial blood gas should be obtained in any patient with SCD who presents with respiratory complaints. It is very helpful to know a baseline value because adults may have chronic mild to moderate hypoxia. A Pa_{O_2} of less than 60 mmHg in adults or less than 70 mmHg in children usually indicates an acute problem.

Urinalysis   A urinalysis should be obtained in any sickle cell patient with urinary symptoms or fever.

RADIOLOGIC STUDIES   **Chest X-ray**   A chest x-ray should be obtained in any patient with pulmonary signs or symptoms. In the acute chest syndrome, the chest x-ray may be normal for 2 days, so a normal radiograph does not exclude a problem.

Bone Films   Bone films should be considered for the patient who presents with localized bone tenderness. Plain radiographs will not show infarction and will only show osteomyelitis after about 10 days. A bone scan or MRI can show changes of osteomyelitis within 24 h.

Abdominal Ultrasound or CT Scan   An abdominal ultrasound or CT scan may be helpful in patients with abdominal pain. The presence of vasoocclusive crisis will not alter these studies; however, they may show changes of cholecystitis, pancreatitis, bowel infarction, abscesses, or appendicitis.

Computed Tomography of Head or MRI Scan   Computed tomography of the head (head CT) or an MRI scan should be obtained in any sickle cell patient who presents with neurologic symptoms or signs. MRI is a more sensitive study in this setting.

General Management

General recommendations will be reviewed here as well as some specific guidelines for the initial treatment of complications. Additional suggestions are included above under the types of crises and laboratory and radiologic evaluation.

The general management of patients with sickle cell disease who present to the ED is primarily supportive. Patients with unstable vital signs or neurologic compromise need emergency care. The basic care of patients who present with "crisis" include the following:

Hydration. Any type of crisis may be precipitated or exacerbated by dehydration. Oral rehydration can be attempted if the patient can tolerate fluids and the episode is relatively mild. Intravenous rehydration will be needed for patients who are orthostatic or in severe pain. Fluid overload needs to be avoided in light of potential underlying cardiopulmonary disease. One-half normal saline at a rate of one to one and a half times maintenance dose is a reasonable fluid choice.

Analgesia. Sickle cell patients need prompt pain relief with adequate analgesia. The presence of narcotic addiction or the potential for its development should not alter what is prescribed in the ED. Sickle cell patients who frequently seek help in the ED will benefit from a protocol treatment plan so they know what to expect and manipulative behavior is minimized. The emergency staff should have a consistent approach to the use of narcotics in these patients. It is reasonable to administer up to two doses of narcotics in the ED over a 4- to 6-h period; if patients still have significant pain, they should be admitted to the hospital. Nonnarcotic analgesics such as acetaminophen or ibuprofen can be used for mild pain, although most sickle cell patients do not come to the ED for mild pain. Although ketorolac will not manage the pain of a severe crisis, some have found it helpful as an adjunctive treatment. Oral narcotics such as acetaminophen-codeine or oxycodone may be adequate for moderate pain. Parenteral narcotics are necessary for severe pain. A combination of meperidine and promethazine is commonly used. A typical dose would be 100 mg of meperidine and 25 mg of promethazine intravenously or intramuscularly. Some patients will have developed tolerance to narcotics and require larger doses. Intravenous morphine, sometimes via patient-controlled analgesia is useful in selected patients.

Supplemental oxygen. Supplemental oxygen is only beneficial if the patient is hypoxemic.

Cardiac monitoring. Cardiac monitoring should be considered if the patient has a history of cardiopulmonary compromise or any acute complaints referable to those systems.

Specific Recommendations for Complications

INFECTIONS   Sickle cell patients with infectious symptoms or a temperature greater than 38.3°C (101°F) should be presumed to have a bacterial infection. Basic laboratory studies should be obtained as well as cultures of blood, sputum, and urine as indicated. Radiographs should be obtained. There should be a low threshold for lumbar puncture. In most patients, parenteral antibiotics should be administered for 48 h or until the cultures are finalized. Intravenous cephalosporins such as cefuroxime or ceftriaxone are generally used. Suggested oral or outpatient regimens would be cefprozil or amoxicillin/clavulanate.

Sickle cell patients need to be vaccinated in childhood against *S. pneumoniae, H. influenzae,* and hepatitis B. Children with SCD generally receive prophylactic daily oral penicillin up to age 6; this practice is not known to be helpful in adults.

PULMONARY CRISIS   Sickle cell patients with pulmonary crisis need aggressive management including hospitalization until the diagnosis becomes apparent. Since the differential diagnosis includes pneumonia, empirical antibiotics such as cefuroxime and erythromycin are often given. Oxygen is administered for hypoxemia, and close monitoring is needed for possible decompensation. Pulmonary thromboembolism is also in this differential diagnosis. If significant $\dot{V}/\dot{Q}$ mismatch is demonstrated on $\dot{V}/\dot{Q}$ scan or large vessel occlusion on pulmonary angiography, heparinization is indicated. Patients with significant cardiopulmonary decompensation may be treated with exchange transfusion.

CNS CRISIS   Sickle cell patients with signs or symptoms of neurologic compromise need emergent care and close monitoring. After the patient is stabilized, a head CT or MRI should be obtained. If there is no contraindication, a lumbar puncture should be performed to rule out SAH and meningitis. Seizures and cerebral edema are managed conventionally. These patients require admission to an intensive care unit. When there is an acute CNS event, exchange transfusion is used to lower

the HbS concentration to less than 30 percent.

LOCALIZED BONE PAIN This finding, especially when accompanied by fever and leukocytosis, raises the possibility of osteomyelitis. Radiographs, bone scan, or MRI may not be immediately helpful or available. The site should be directly aspirated for culture, and the patient started on parenteral antibiotics to cover *S. aureus* and *S. typhimurium,* such as fluoroquinolone or third-generation cephalosporin.

PRIAPISM When a patient with sickle cell disease presents with priapism, urologic consultation should be obtained. The patient should receive analgesia and hydration, and the bladder should be emptied by catheterization, if possible. Exchange transfusions may be instituted, but if not successful, surgical intervention will be necessary.

Disposition

After evaluation in the ED (including physical examination and laboratory and radiographic studies as indicated), conservative supportive therapy, and observation, a diagnosis usually can be established that will dictate the disposition of the patient.

The following are some guidelines for hospital admission for sickle cell patients:

1. Patients with pulmonary, neurologic, or infectious crisis
2. Patients with splenic sequestration or aplastic crisis
3. Patients with other types of vasoocclusive crises who do not have adequate pain control after analgesics in the ED, the determination to be made after 4 to 6 h and no more than 2 doses of narcotic analgesics.
4. Patients who are unable to maintain adequate hydration
5. Patients in whom the diagnosis is uncertain

Patients with SCD who are discharged from the ED need to have the following:

1. The ability to maintain adequate oral hydration
2. A 2- or 3-day supply of oral analgesics that provide adequate pain relief
3. Instructions to return to the ED for increased pain, fever greater than 38°C (100.4°F), or a change in their symptoms
4. Follow-up, preferably with their primary care physician, in 12 to 24 h for children or 24 to 48 h for adults.

VARIANTS OF SICKLE CELL DISEASE

Sickle Cell Trait

This carrier state for SCD is the most frequently encountered sickle hemoglobin variant; it is *not* a mild form of sickle cell disease. Approximately 8 percent of the US African-American population, or 2.5 million people, carry the gene for sickle hemoglobin. This heterozygous state is a result of autosomal dominant inheritance and results in HbAS. Each red blood cell contains both normal HbA (60 percent) and HbS (40 percent). The abundance of normal HbA prevents sickling under most physiologic circumstances. Hematologically, these patients are normal. Their red blood cells have a normal life span, so they are not anemic. Sickled red blood cells should not be seen on peripheral blood smear except under extreme hypoxia; if seen under normal circumstances, the diagnosis is incorrect.

Clinically, patients with sickle cell trait have minimal complications. The kidney is the most frequently affected organ. Microinfarcts occur in the medulla, leading to papillary necrosis and impaired concentrating ability. Hematuria can be found in 1 percent of patients with sickle cell trait. Exposure to high altitude has been associated with splenic infarction and cerebrovascular complications. Women with sickle cell trait have an increased incidence of urinary tract infections and hematuria during pregnancy. Persons with sickle cell trait have an increased incidence of sudden death during physical training, presumably due to increased sickling with extreme exertion. However, the majority of patients with sickle cell trait are asymptomatic, lead normal lives, and overall have a normal life expectancy.

Sickle Cell–Hemoglobin C Disease (HbSC Disease)

This heterozygous sickle cell variant results when the gene for HbS is inherited from one parent and the gene for HbC is inherited from the other parent. Hemoglobin C results from a single point mutation in the beta-chain gene; lysine is substituted for glutamic acid at the sixth position. About 2.4 percent of US African-Americans carry the gene for HbC. This gene frequency is one-fourth that for HbS, but the prevalence among adults of SC and SS disease is almost the same because those with HbC have a near-normal life expectancy. The red blood cells of these patients contain 50 percent HbS and 50 percent HbC. Because HbC does not polymerize as readily as HbS, the disease generally has less severe clinical consequences. These patients have a mild to moderate hemolytic anemia and mild reticulocytosis. The peripheral smear shows abundant target cells and a few sickle cells, and HbC may be seen precipitated as a rhomboid crystal in the red blood cells. Splenomegaly is a feature of HbSC disease and persists into adulthood in 60 percent of patients. Overall, patients with HbSC disease have few clinical complications, although some have profound medical problems as complex as those seen in patients with SCD. Patients with HbSC disease can have painful crises and organ infarcts. They are at higher-than-normal risk for bacterial infections. Ocular complications and visual loss occur, as well as infarcts in the renal medulla and avascular necrosis of the femoral heads. Women with HbSC disease have an increased incidence of complications in pregnancy.

Sickle Cell–Beta (b) Thalassemia Disease

This heterozygous sickle cell variant occurs when the gene for sickle hemoglobin is inherited from one parent and the gene for b thalassemia is inherited from the other parent. In US African-Americans, the gene frequency for b thalassemia is 0.8 to 1.0 percent. The frequency of sickle cell–b-thalassemia disease is 2 per 3200 births. The severity of the disease that results, including the degree of anemia and frequency of clinical complications, depends on the type of b-thalassemia gene that is inherited. Between 80 and 90 percent of affected individuals have a b-thalassemia gene that results in the production of some normal beta chains; thus some normal HbA is made. These patients have a mild hemolytic anemia with near-normal hemoglobin levels, few crises, and minimal organ damage. Those 10 to 20 percent of patients who inherit a b-thalassemia gene that produces no beta chains, and therefore no normal hemoglobin, have severe hemolytic anemia and vasoocclusive symptoms comparable with patients with SCD. Splenomegaly is found in 70 percent of patients with sickle cell–b thalassemia disease.

DEFICIENCY OF GLUCOSE-6-PHOSPHATE DEHYDROGENASE

Deficiency of the red blood cell (RBC) enzyme glucose-6-phosphate dehydrogenase (G-6-PD) is the most common human enzyme defect, affecting nearly one-tenth of the world's population. In this inherited abnormality, the activity of this enzyme is markedly diminished. As a result, the RBC is unable to protect itself against oxidant stress. Normally, reduced glutathione is generated to protect the sulfhydryl groups of hemoglobin and the red cell membrane from oxidation. When the enzyme is deficient, the hemoglobin sulfhydryl groups become oxidized and the hemoglobin precipitates within the RBC, forming Heinz bodies that are readily removed from the circulation.

Clinically, the resulting hemolytic anemia varies greatly in severity. It is an X-linked disorder, and clinical manifestations are seen in male heterozygotes and female homozygotes. In the United States, 15 percent of African-American males have a mild form of this deficiency. Acute hemolytic crises occur that are incited by bacterial and viral infections, exposure to oxidant drugs, metabolic acidosis (such as diabetic ketoacidosis), and ingestion of fava beans in some patients. Within 1 to 3 days following oxidant stress, the patient can develop hemoglobinuria and the potential for vascular collapse. These hemolytic crises are generally well tolerated and self-limited because only the older RBCs will hemolyze. In more severe but less common variants of this disease, the patient can have severe chronic hemolytic anemia. The diagnosis of G-6-PD deficiency can be established by the demonstration of decreased enzyme activity through quantitative assay. There is no specific treatment for this disease. Prevention of hemolytic episodes is crucial, with prompt treatment of infections and the avoidance of oxidant drugs. The drugs most commonly associated with oxidant stress are sulfa drugs, antimalarials, pyridium, and nitrofurantoin. HIV-positive patients are commonly screened for this defect because of the common use of the sulfa drugs for the treatment and prophylaxis of *Pneumocystis carini,* pneumonia.

HEREDITARY SPHEROCYTOSIS

Hereditary spherocytosis (HS) is the most prevalent hereditary hemolytic anemia among people of northern European descent. An estmated 1 in 4500 persons is affected. The disease is typically inherited in an autosomal dominant pattern, but in up to 20 percent of patients it is the result of an apparent spontaneous mutation. The abnormal shape of the RBCs results from molecular abnormalities in the cytoskeleton of the RBC membrane, most commonly with the proteins spectrin and ankyrin. Because of their abnormal shape, the RBCs are caught in the spleen and destroyed. As a result of the typically mild symptoms, the diagnosis may not be established until adulthood. Clinically, HS is characterized by a hemolytic anemia that is usually mild (a small minority of patients have severe anemia), splenomegaly, and intermittent jaundice from indirect bilirubin (due to hemolysis). Pigment gallstones are common.

Patients with HS have a mild anemia, and the peripheral blood smear shows spherocytes with a normal mean corpuscular volume and increased mean corpuscular hemoglobin concentration (>36 percent). The diagnosis of HS is established by the osmotic fragility test. Splenectomy is the treatment for patients with HS. This cures the anemia, although the spherocytes are still present.

214 ACQUIRED HEMOLYTIC ANEMIAS

Mary E. Eberst

This chapter reviews some of the anemias that result from hemolysis that is precipitated by an acquired or extrinsic abnormality. Table 214-1 outlines these conditions, which include antibody-mediated (immune) hemolytic anemias; fragmentation hemolysis, either microvascular or macrovascular; anemias resulting from direct toxic effects; anemias resulting from mechanical injury; and anemia that is the result of abnormal splenic function (hypersplenism).

TABLE 214-1   Classification of Acquired Hemolytic Anemias

The general laboratory evaluation of patients with suspected hemolysis is reviewed here; the characteristic results for each type of anemia will be discussed below. Patients newly diagnosed with or suspected of having any of these hemolytic anemias should have immediate hematologic consultation and be admitted to the hospital.

LABORATORY EVALUATION OF HEMOLYTIC ANEMIA

1. *Complete blood count* (CBC). The anemia that occurs may be mild or severe; verify normal/abnormal white blood cell count and platelet count.
2. *Reticulocyte count.* This is the single most useful test in ascertaining the presence of hemolysis and a normal bone marrow response; this should be elevated and can be as high as 30 to 40 percent.
3. *Review of the peripheral blood smear.* Most hemolytic disorders are associated with changes in the morphology of the red blood cells (RBCs); typical changes may include
   a. *Spherocytes.* These are the most common morphologic abnormality in hemolytic diseases; they will be most abundant in patients with warm antibody immune hemolysis and those with hereditary spherocytosis (Chap. 213).
   b. *Schistocytes.* These are fragmented RBCs that result from direct trauma within the vasculature, most often in the microvasculature (known as *microangiopathic hemolytic anemia,* MAHA), but also can occur in the macrovasculature; schistocytes are markers of nonimmune hemolysis.
4. *Unconjugated (indirect) bilirubin.* This should be elevated in the presence of hemolysis as a result of heme catabolism; the direct (conjugated) bilirubin should be normal unless there is concomitant hepatic or biliary dysfunction.
5. *Haptoglobin.* This binds to the protein globin that is released when hemoglobin is catabolized, so this should be low or absent in the presence of significant hemolysis. Haptoglobin is an acute-phase reactant that may be increased in conditions such as severe infection, tissue destruction, myocardial infarction, and burns and in some cancer patients; in these settings, the haptoglobin level may be increased, despite the presence of hemolytic anemia.
6. *Plasma free hemoglobin.* This should be elevated in hemolysis.
7. *Lactic dehydrogenase* (LDH). This should be elevated in hemolysis; it can be a relatively sensitive marker used to follow the course of a hemolytic disease.

AUTOIMMUNE HEMOLYTIC ANEMIAS

There are three types of antibody-mediated, so-called immune, hemolytic anemias:

1. Warm antibody hemolytic anemia. These antibodies are reactive at body temperature.
2. Cold antibody hemolytic anemia. These antibodies react with the patient's RBCs at temperatures below normal body temperature.
3. Drug-induced immune hemolytic anemia. Certain drugs can cause an immune reaction in some patients that results in destruction of their RBCs.

Immune hemolytic anemias are characterized in the laboratory by the Coombs antiglobulin test, also known as the *direct Coombs' test* or *direct antiglobulin test* (DAT). This test demonstrates the presence of immunoglobulin (IgG) or complement (C3) on the surface of the RBC. It is only positive in immune-mediated hemolytic anemias. The indirect Coombs' test is used primarily for pretransfusion screening for antibodies; it demonstrates the presence of free antibodies in the patient's serum. Immune hemolysis is typified by abundant spherocytes on the peripheral blood smear.

Warm Antibody Hemolytic Anemia

This disease is characterized by the presence of antibodies directed against IgG and/or C3 that are deposited on the surface of the RBC. It comprises 70 percent of all cases of immune hemolytic anemia. These antibodies react with the RBCs at 37°C. After the antibody-RBC interaction, the RBCs are trapped and destroyed in the spleen.

Patients of any age may be affected, but warm antibody hemolytic anemia is most likely to occur in older adults, women more often than men. Most often it is idiopathic; however, up to 25 percent of affected patients have an underlying disease that affects the immune system such as chronic lymphocytic leukemia, Hodgkin's or non-Hodgkin's lymphoma, or systemic lupus erythematosus (SLE). In adults, the disease is typically relapsing. In young children, it often follows an acute infection or immunizations and is unlikely to recur.

The clinical presentation and course of disease are highly variable depending on the severity of the anemia and how rapidly it develops. Many patients will have a

mild anemia with splenomegaly. In this setting, the Coombs' test will be positive for IgG but not C3, and the indirect Coombs' test will be negative. Life-threatening anemia also can occur with hemoglobin levels less than 7 g/dL and a reticulocyte count greater than 30 percent. These patients may have marked splenomegaly, pulmonary edema, and mental status changes. Venous thrombosis also can occur. Patients with severe hemolysis generally have a Coombs' test that is positive for both IgG and C3, and the indirect Coombs' test is also often positive. Rare patients have Evans's syndrome, where there is coexistent immune destruction both of RBCs and platelets by different antibodies.

The treatment of warm antibody hemolytic anemia depends on the degree of anemia that develops and the ability of the patient to hemodynamically tolerate anemia. When there is only mild anemia, no treatment is necessary. When significant hemolysis is present, the first-line treatment is prednisone, 1.0 mg/kg per day. About 75 percent of patients will respond to steroid therapy, but up to one-half of these will relapse after the steroids are tapered. Transfusion of red blood cells is difficult in these patients because they will be impossible to crossmatch. Transfusion is indicated for symptoms of angina, congestive heart failure, mental status changes, orthostasis, or hypoxia. In this setting, the patient is slowly transfused with the best match available; acute transfusion reactions can occur. Splenectomy is the second-choice treatment for patients who fail or cannot tolerate steroids. Immunosuppressive drugs such as azathioprine and cyclophosphamide are used occasionally. Treatment of any underlying immunologic disease also may help control the hemolytic anemia. Death in these patients results from severe anemia that cannot be corrected, immunosuppression, venous thrombosis, or underlying immunologic disease.

Cold Antibody Hemolytic Anemia

Cold-reactive antibodies, those which react maximally at temperatures between 4 and 20°C and not usually above 32°C, account for 10 to 20 percent of patients with immune hemolytic anemia. There are two types of diseases where this occurs: cold agglutinin disease and paroxysmal cold hemoglobinuria. These antibodies react with the RBCs in the superficial microcirculation where it is cool, then the hemolysis occurs when the red blood cells reenter the central circulation and are warmed.

COLD AGGLUTININ DISEASE   This can be an acute, transient disease mostly seen in younger people or a chronic disease primarily in older patients. It is typically caused by an IgM antibody, and the Coombs' test will only be positive for C3, because the IgM will not be attached to the RBCs at warmer temperature. The acute form of this disease is mostly seen in patients with *Mycoplasma* pneumonia or infectious mononucleosis; the IgM antibodies are directed against the I antigen or i antigen on the RBC surface, respectively. Only rare patients develop significant hemolysis, but severe anemia and renal failure can occur. The acute form of this disease is self-limited. Chronic cold agglutinin disease is more common than the acute form and primarily occurs in patients with underlying lymphoid neoplasms. These patients typically have a mild to moderate anemia that results from hemolysis occurring in portions of the body exposed to lower temperatures (acrocyanosis). These patients should be kept in a warm environment, and treatment is directed against the underlying disease. Some of the hemolysis may respond to treatment with prednisone.

PAROXYSMAL COLD HEMOGLOBINEMIA   This disease is characterized by acute episodes of hemolysis following exposure to cold. Two groups of patients can be affected by this disease: (1) those with congenital or tertiary syphilis that is untreated and (2) patients with viral illnesses such as mumps or measles. In this disease, the immune hemolysis is caused by an IgG antibody called the *Donath-Landsteiner antibody,* which is directed against the P-antigen complex on the RBC surface. Clinically, after exposure to cold, affected patients will have hemoglobinuria, chills, fever, and pain involving the back, legs, and abdomen. The direct Coombs test is only positive during an acute attack. When associated with syphilis, this disease goes away after appropriate antibiotic therapy. Now most commonly seen in patients with viral infections, the hemolysis is self-limited but can cause transient severe anemia.

Drug-Induced Hemolytic Anemia

Many drugs have been directly linked to immune hemolytic anemia. There are three types of reactions that can occur and result in hemolysis.

AUTOANTIBODY INDUCTION   a-Methyldopa is the prototype drug of this reaction, and 10 to 20 percent of patients taking moderate-to-high doses will develop a positive direct Coombs' test. In this drug reaction, the RBCs become coated with an IgG that is directed against the Rh complex. Other drugs that can cause this are L-dopa, procainamide, ibuprofen, diclofenac, and thioridazine. Generally, it takes an extended period of drug exposure to develop the positive Coombs' test, and only a small number of those patients will develop severe hemolysis. The hemolysis ceases after the drug is stopped, but the Coombs' test may remain positive for a year or more.

HAPTEN-INDUCED IMMUNE HEMOLYSIS   Penicillin is the classic drug associated with this reaction. Immune hemolysis can develop in patients receiving large intravenous doses of penicillin or penicillin-type antibiotics and usually starts 1 to 2 weeks after the therapy begins. The patient forms an antibody against the offending drug; then the antibody combines with the drug-RBC complex and causes hemolysis. Other drugs that can cause hemolysis by this mechanism include oxacillin, ampicillin, carbenicillin, and some cephalosporins. The hemolysis stops when the drug is discontinued.

INNOCENT BYSTANDER IMMUNE HEMOLYSIS   Quinidine is the prototype drug for this reaction. Antibodies (IgG or IgM) are formed against the drug; then the drug-antibody complex binds to the RBC and hemolyzes it. Other drugs linked to this mechanism include quinine, isoniazid, sulfonamides, hydrochlorothiazide, antihistamines, insulin, chlorpromazine, tetracycline, acetaminophen, hydralazine, cephalosporins, fenoprofen, and sulindac. Even a small dose of the drug can cause hemolysis; however, these drugs are very commonly prescribed and the associated hemolysis is very rare.

FRAGMENTATION HEMOLYSIS

Microangiopathic Hemolytic Anemia (MAHA)

This type of hemolytic anemia is associated with a variety of disorders; however, the mechanism leading to hemolysis is consistent. The fragmentation of RBCs results from their passage through abnormal arterioles: usually there is damage to the vessel wall or endothelial surface or fibrin has been deposited in the arteriole. Schistocytes are characteristically found on the peripheral blood smear.

THROMBOTIC THROMBOCYTOPENIC PURPURA (TTP) AND HEMOLYTIC UREMIC SYNDROME (HUS)   These diseases will be discussed separately; however, TTP and HUS may well represent variant clinical presentations of a single disease. In selected patients, the specific diagnosis may be impossible to establish.

Thrombotic Thrombocytopenic Purpura   TTP is a heterogeneous clinical syndrome characterized by this pentad of symptoms and signs:

1. Microangiopathic hemolytic anemia (MAHA) with characteristic schistocytes on the peripheral blood smear and a reticulocytosis
2. Thrombocytopenia with platelet counts ranging from 5000 to 100,000/µL
3. Renal abnormalities including renal insufficiency, azotemia, proteinuria, or hematuria
4. Fever
5. Neurologic abnormalities including headache, confusion, cranial nerve palsies, seizures, or coma

TTP has been diagnosed in patients of all ages but occurs most commonly between the ages 10 and 60. Women are affected more commonly than men. The course of the disease is typically acute and fulminant, lasting days to months, but it can be chronic and relapsing in 10 percent of patients. The overall survival rate is 80 percent, but the course is rapidly fatal in some patients. The majority of patients diagnosed with TTP have no apparent predisposing condition. In a small number of patients, TTP has been linked to genetic predisposition, pregnancy, immunologic diseases (SLE, rheumatoid arthritis, Sjögren's syndrome), or infections (viral, *Mycoplasma* pneumonia, subacute bacterial endocarditis, human immunodeficiency virus).

The pathogenesis of TTP is uncertain, but the presence of one or more platelet aggregating agents is likely responsible. Several abnormalities of the vascular endothelium and endothelial cell function have been implicated, including the release and presence of large von Willebrand multimers, decreased production of prostacyclin, inadequate fibrinolysis as a result of deficient tissue plasminogen activator (tPA) production, the presence of a platelet agglutinating protein, and deficient production of IgG molecules. Whatever the etiology, the result is the deposition of hyaline material within the lumina of capillaries and arterioles. These microthrombi are made of platelets and a small amount of fibrinlike material. These deposits may be found in any tissue but occur most frequently in the heart, brain, kidneys, pancreas, and adrenal glands.

The diagnosis of TTP is established clinically by the presence of the signs and symptoms listed above. Treatment should begin immediately based on these clinical and laboratory features. Biopsies are sometimes done of the gingiva, kidney, or bone marrow but are not essential to establish the diagnosis and should not delay

therapy.

Clinically, the neurologic abnormalities are the most common presenting complaint, but hemorrhagic signs and symptoms and those referable to anemia are also common presentations. Laboratory studies will reflect the presence of MAHA with an anemia of variable degree (the hemoglobin will be less than 6 g/dL in one out of three patients), reticulocytosis, elevated indirect bilirubin, elevated LDH, negative Coombs' test, and the presence of schistocytes on the peripheral smear (the diagnosis of TTP is doubtful without schistocytes). Thrombocytopenia, reflective of the intravascular microthrombi, is often severe with the count less than 20,000/µL in 50 percent of patients. A mild leukocytosis with a left shift is common. The blood urea nitrogen (BUN) and creatinine are typically elevated to a mild to moderate degree. Urinalysis usually shows some degree of proteinuria and may show microscopic hematuria. Coagulation screening tests should be normal.

The salient features in the differential diagnosis of TTP are outlined in Table 214-2.

	Evans Syndrome	TTP	HUS	DIC	HELLP
Autoimmune hemolytic anemia	Present	No	No	No	No
Microangiopathic hemolytic anemia (MAHA)	No	Persistent	Prominent	Often present	Present
Coombs test	Positive	Negative	Negative	Negative	Negative
Thrombocytopenia	Present	Persistent	Present	Present	Present
Renal abnormalities	No	Mild	Prominent	No	No
Neurologic abnormalities	No	Persistent	Rare or mild	No	No
Hepatic dysfunction	No	May have	May have	May have	Persistent
Fever	No	Present	Present	May have	No
Coagulation studies	Normal	Normal	Normal	Abnormal	Normal
Pregnancy-associated	No	Can be	Can be	Can be	Always

Key: TTP, thrombotic thrombocytopenic purpura; HUS, hemolytic uremic syndrome; DIC, disseminated intravascular coagulation; HELLP, hemolysis, elevated liver function, low platelets.
*Disease descriptions here are based on presence of isolated disease without complications; individual patients often have other problems that make syndrome less readily identified.

TABLE 214-2   Characteristics of Acquired Hemolytic Anemias*

The diagnosis of TTP represents a medical emergency. Patients should be treated by experienced hematologists. Rapid transport to a tertiary care center is indicated. Some centers have a policy of initially admitting all TTP patients to an intensive care unit. When the diagnosis of TTP is established or suspected, fresh-frozen plasma should be infused immediately. The foundation of therapy for TTP is plasma exchange transfusion (PLEX). Some patients will respond favorably to plasma infusions alone, and these can be given until the exchanges can be initiated. The plasma exchange uses fresh-frozen plasma (FFP) or fresh unfrozen plasma (FUP). The plasma is thought to provide a substance that the patient is lacking or remove an unknown toxic substance. These exchanges may be required daily for a period of several months. TTP patients are also treated with prednisone (or methylprednisolone), 1 mg/kg per day, and antiplatelet therapy consisting of aspirin or dipyridamole. Refractory patients may receive immunosuppressive therapy such as vincristine, azathioprine, or cyclophosphamide. Splenectomy is sometimes done but has little correlation with clinical improvement. Supportive care includes the transfusion of packed red blood cells as needed and hemodialysis if indicated. Platelet transfusions should be avoided, unless there is uncontrolled hemorrhage, because they can aggravate the thrombotic process. Clinical and hematologic progress in patients with TTP is assessed by improvement in neurologic and renal function, decrease in the reticulocyte count, decrease in the LDH, and increase in the platelet count.

Hemolytic Uremic Syndrome   HUS is a disease mainly of infancy and early childhood, with a peak incidence between 6 months and 4 years of age. An adult form also exists (see below). The overall mortality rate is 5 to 15 percent, and the prognosis is worse in older children and adults. HUS is one of the most common causes of acute renal failure in childhood. HUS is characterized by acute renal failure, microangiopathic hemolytic anemia, fever, and thrombocytopenia.

In children, the development of HUS often follows a prodromal infectious disease, usually diarrhea or an upper respiratory infection. Diarrhea, particularly that associated with *Escherichia coli* serotype 0157:H7, as well as with *Shigella, Yersinia, Campylobacter,* and *Salmonella,* may be antecedent. Other implicated bacteria and viruses include *Streptococcus pneumoniae,* varicella, echovirus, and coxsackie A and B. Some cases of HUS are familial, with a genetic or HLA-type predisposition.

As noted earlier, HUS and TTP actually may be clinical variations of the same disease. Like TTP, HUS is pathologically identified by microthrombi, consisting of platelet aggregates, that occlude the arterioles and capillaries. In HUS, the microthrombi are confined mostly to the kidneys; in TTP, they occur throughout the microcirculation. The platelet-fibrin hyaline material is found in the afferent arterioles and glomerular capillaries. A defect in the vascular endothelium is thought to cause these platelet aggregates. It is not precisely known how the endothelial damage occurs, but the toxins released from bacteria or viruses have been implicated. The damaged endothelial cells are then thought to release large and ultralarge vonWillebrand factor multimers that lead to platelet aggregation.

Like TTP, HUS is primarily a clinical and laboratory diagnosis. The signs and symptoms of acute renal failure predominate. Although neurologic dysfunction is not a key feature of HUS, it does occur in up to one-third of HUS patients at some point in the course of their disease. Laboratory studies reflect the presence of MAHA. Thrombocytopenia is present but generally not to the degree seen in TTP. The BUN and creatinine will be markedly elevated, and urine, if present, will contain protein and red blood cells. Coagulation studies are usually normal.

The treatment of HUS primarily consists of early dialysis for management of renal failure and general supportive care. Up to 90 percent of HUS patients with acute renal failure will eventually regain normal renal function. Plasma exchange or infusion is not usually used in the treatment of childhood HUS. HUS is rarely a recurrent disease, but it has been known to recur in patients who have undergone renal transplantation.

Adult HUS   When HUS occurs in adult patients, it can be difficult or impossible to differentiate between HUS and TTP. HUS is diagnosed when there is prominent renal failure and minimal neurologic dysfunction. Of adults diagnosed with HUS, two-thirds are women. Associated factors are the use of oral contraceptive agents, preeclampsia, eclampsia, other obstetric complications, and the postpartum period. HUS also rarely occurs in association with the chemotherapeutic drug mitomycin C and in other cancer patients who may or may not have received chemotherapy. The renal failure in adults with HUS may be reversible, even after as long as 1 year.

PREGNANCY-ASSOCIATED HEMOLYSIS   Microangiopathic hemolytic anemia (MAHA) can occur in pregnancy as a complication of preeclampsia, eclampsia, or placental abruption. The presence of preeclampsia, hemolysis, elevated liver enzymes, and low platelet counts is known as the *HELLP syndrome.* The HELLP syndrome can occur with minimal signs or symptoms of preeclampsia. The pathogenesis is not entirely known, but preeclampsia can be associated with microvesicular fatty infiltration of the liver and with localized or systemic endothelial damage that can lead to MAHA. Untreated, HELLP can result in hepatic failure or rupture, disseminated intravascular coagulation (DIC), or congestive heart failure. Treatment begins with prompt delivery of the infant followed by supportive care.

DISSEMINATED INTRAVASCULAR COAGULATION   DIC is discussed in Chap. 211. MAHA occurs in about 25 percent of patients with DIC. The degree of hemolysis that occurs in DIC is much less than that seen in TTP or HUS. The basic pathology in DIC is the deposition of fibrin in the microvasculature. Fragmentation and hemolysis of the RBCs occur as they pass through the microcirculation. Schistocytes, reflective of MAHA, are often found on the peripheral smear of patients with DIC, but their absence does not rule out DIC. Along with the factor replacement therapy required in DIC, patients with significant hemolysis and anemia will require transfusion of packed red blood cells to maintain adequate circulation and oxygenation.

MALIGNANCY-ASSOCIATED HEMOLYSIS   MAHA can be seen in patients with widely disseminated cancer. Gastric adenocarcinoma is the malignancy most frequently associated with MAHA, although it also occurs with adenocarcinomas of the lung, breast, and of unknown primary. The pathogenesis is uncertain, but hypotheses include the following: vessels that supply malignant tumors may be structurally abnormal; circulating tumor cells may damage the endothelial surface; or tumor cells may give off factors that promote platelet aggregation and microvascular changes. Patients with MAHA due to widespread malignancy have a very poor prognosis.

HEMOLYSIS IN VASCULITIS   MAHA can be seen in vascular diseases such as SLE, polyarteritis nodosa, Wegener's granulomatosis, and scleroderma. In this setting, damage to the endothelial surface is thought to result from deposition of immune complexes and fibrin in the microcirculation.

HEMOLYSIS IN MALIGNANT HYPERTENSION   Patients with malignant or accelerated hypertension can develop MAHA as a result of narrowing and hardening of

the afferent arterioles and swelling of the endothelial cells. This hemolysis subsides after normalization of the blood pressure.

Macrovascular Hemolysis

Traumatic hemolysis can occur in patients with artificial heart valves or severe calcific aortic stenosis. Some degree of hemolysis occurs in up to 10 percent of patients with aortic prostheses; mechanical valves are more likely to cause hemolysis than porcine valves. Mitral valve replacements cause less hemolysis because of the lower pressure gradient. Hemolysis also can occur in patients with prosthetic patches in the heart and, rarely, in patients who have undergone aortofemoral bypass. The hemolysis that occurs in this setting is generally mild and well tolerated. These patients should receive supplemental iron and folate. If the hemolysis is severe, the defective valve may have to be replaced.

DIRECT TOXIC EFFECTS CAUSING HEMOLYSIS

Infections

Destruction of RBCs occurs commonly in the course of many infectious diseases. Those diseases with the most profound effect on RBCs will be reviewed here.

Transmitted by mosquitoes, malaria is the world's most common cause of hemolytic anemia. RBC hemolysis results from direct parasitization of the RBCs. Hemolysis also results from direct parasitization of RBCs in babesiosis, which is transmitted by ticks or blood transfusions. Infection with *Bartonella* is also associated with direct parasitization of RBCs and resultant hemolysis.

Hemophilus influenzae type B infection can produce hemolysis by altering the RBC surface. The capsular polysaccharide of the bacterium binds to the RBC surface and then antibodies destroy the bacterium as well as the RBC. Those with *H. influenzae* meningitis have the greatest potential to develop severe hemolysis.

Clostridium perfringens (welchii) infection can result in severe hemolysis by direct lysis of red blood cells. The organism releases enzymes that acutely degrade the phospholipids of the RBC membrane bilayer and the proteins in the structural membrane. This infection is seen most commonly in patients with acute cholecystitis, after surgery involving the biliary tree, after abortions, and in uterine infections. Clinically, the patient may have acute hemodynamic collapse and profound intravascular hemolysis. *Clostridium* septicemia has a mortality rate over 50 percent.

Mycoplasma pneumoniae and infectious mononucleosis are associated with cold agglutin disease, as described earlier.

Many viral infections can be accompanied by hemolytic anemia, including measles, cytomegalovirus, varicella, herpes simplex, coxsackie, and human immunodeficiency virus.

Other Toxins that Cause Hemolysis

Insect, Spider, and Snake Bites   Acute intravascular hemolysis can occur following bites/stings of bees, wasps, the southern black widow spider, and the brown recluse spider. The bites of American snakes, pit vipers and coral snakes, are known to cause coagulation abnormalities but rarely cause hemolysis. The bite of the cobra snake does cause intravascular hemolysis.

Copper   Copper has a direct hemolytic effect on red blood cells. Copper sulfate contamination from copper pipes can taint hemodialysis fluid, and copper sulfate is sometimes used in suicide attempts. Patients with Wilson's disease experience transient episodes of hemolysis as a result of their elevated copper levels.

Drug-Induced Oxidative Hemolysis

Oxidative hemolysis of RBCs can result from exposure to a number of drugs that cause the formation of methemoglobin. These drugs oxidize ferrous hemoglobin (+2) to ferric hemoglobin (+3), which is methemoglobin. Methemoglobin cannot bind oxygen, so the oxygen-carrying capacity of the blood is decreased. A large number of commonly used drugs can cause methemoglobinemia, but not at therapeutic doses (Table 214-3). Toxic methemoglobinemia occurs when more than 10 percent of the hemoglobin has been oxidized to the ferric form. Clinically, methemoglobinemia should be suspected in patients who are cyanotic without cardiopulmonary disease. This cyanosis is not relieved by oxygen. The venous blood appears chocolate brown. The arterial blood gas will reflect a normal Pa $_{O_2}$, but decreased measured oxygen saturation. Table 214-4 shows the clinical effects of acute methemoglobinemia. Levels of methemoglobin greater than 20 to 30 percent of the total hemoglobin should be treated. Methylene blue is given intravenously at a dose of 1 to 2 mg/kg in a 1% solution over 5 min. Methylene blue reduces methemoglobin back to oxygen-carrying hemoglobin through a series of reactions.

Benzocaine, lidocaine
Nitrates, nitrites
Sulfonamides
Phenacetin
Azulfidine
Pyridium
Dapsone and other antimalarials

TABLE 214-3   Drugs That Cause Oxidative Hemolysis

Percent of Total Hemoglobin that Is Methemoglobin	Clinical Effects
10–15	Peripheral cyanosis
30–35	Headache, weakness, breathlessness
55	Dyspnea, bradycardia, seizures, arrhythmias
60–70	Vascular collapse, coma
80 or more	Incompatible with life

TABLE 214-4   Clinical Effect of Acute Methemoglobinemia

MECHANICAL DAMAGE CAUSING HEMOLYSIS

Heat Denaturation   Temperatures above 47°C cause direct damage to erythrocytes by denaturation of the cytoskeletal protein, spectrin. This can occur in patients with extensive burns. Within 24 h of the burns, acute hemolytic anemia can develop with gross hemoglobinuria and spherocytes and schistocytes on the peripheral

blood smear.

March Hemoglobinuria   This type of hemolysis can occur in soldiers and joggers and in karate and conga-drumming enthusiasts. Red blood cell destruction is the result of direct trauma to the cells in the vessels of the feet or hands. These patients rarely become anemic but do have hemoglobinuria after strenuous exercise or activity.

Cardiopulmonary Bypass   Patients who have been on cardiopulmonary bypass can develop a *postperfusion syndrome* that consists of acute intravascular hemolysis, leukopenia, and fever. This hemolysis is thought to result from the activation of complement as blood passes through the oxygenator.

ANEMIA DUE TO ABNORMAL SPLENIC FUNCTION

There are many disease states that result in splenic enlargement (Table 214-5). The main function of the normal spleen is to filter defective red blood cells and foreign particles and to participate in antigen processing and antibody synthesis. When the spleen is enlarged, its activity is increased, a condition known as hypersplenism. Hypersplenism results in the sequestration of red blood cells as well as platelets and white blood cells. Unlike the platelets and white blood cells, which can survive within the spleen and be released back into the circulation, the sequestered red blood cells are not metabolically self-sufficient and are prematurely destroyed within the spleen. Hemolysis within the spleen is greatest when the splenomegaly is caused by inflammatory states or splenic congestion due to elevated portal pressure.

Cause of Splenic Enlargement	Disease Example[s]
Splenic congestion due to elevated portal pressure	Cirrhosis, portal vein thrombosis, splenic vein obstruction, congestive heart failure, Budd-Chiari syndrome
Infiltrative disease	Leukemia, lymphoma, amyloidosis, polycythemia vera
Inflammatory states	Rheumatoid arthritis, SLE, sarcoidosis
Infections	Bacterial endocarditis, infectious mononucleosis, miliary tuberculosis, malaria, schistosomiasis
Hereditary hemolytic anemias	Sickle cell anemia
Acquired hemolytic anemias	Autoimmune hemolytic anemia

Note: SLE, systemic lupus erythematosus.

215 BLOOD TRANSFUSIONS AND COMPONENT THERAPY

Mary E. Eberst

Since the time of the first blood transfusions in the late 1600s and recognition of the ABO blood grouping system by Landsteiner in 1900, transfusion medicine has become a complex medical specialty. It is not important that all practitioners be familiar with the intricacies of blood banking, but any physician who is responsible for the transfusion of blood products to patients needs to have a basic understanding of what products are available, what product is appropriate in a given clinical situation, and what are the potential complications of the transfusion.

This chapter reviews the different types of blood products that are available, with an emphasis on component therapy. The potential complications of transfusions, immediate and delayed, are reviewed. Two topics of particular importance in emergency medicine, emergency transfusion and massive transfusion, are briefly discussed.

AVAILABLE BLOOD PRODUCTS

Whole Blood

Modern transfusion medicine recommends that it is preferable to give patients only the specific portions of blood they require. This is achieved by the use of component therapy. Therefore, whole blood is rarely used in current practice, except for exchange transfusions for neonates. A unit of whole blood contains 435 to 500 mL of blood plus a preservative-anticoagulant solution. CPDA-1 (citrate phosphate dextrose adenine) is the additive in current use. With proper collection and storage of the blood at 2° to 6°C, in the presence of this additive, whole blood has a shelf life of 35 days. The *shelf life* is defined as viability of at least 70 percent of the red blood cells 24 h after infusion. Whole blood is not entirely "whole" at the time of administration because during storage, beginning 24 h after collection, there is a loss of platelets and some coagulation factors. By 72 h after collection, there are virtually no viable platelets and negligible factor VIII activity in "whole" blood. Experts suggest that fewer than 10 percent of all patients requiring transfusions actually require all the components of whole blood. Whole blood has the advantage of simultaneously providing volume and oxygen-carrying capacity. This is also accomplished by the use of packed red blood cells and crystalloid solution, and this is the preferred procedure. Disadvantages to the use of whole blood transfusion are that it is rarely available in the United States; clotting factors are present in low levels; whole blood often contains elevated levels of potassium, hydrogen ion, and ammonia; the patient is exposed to a large number of antigens; and volume overload can occur before the needed components are replenished.

Component Therapy

A unit of donated blood contains about 450 mL of whole blood. In current practice, shortly after collection this blood is separated into its components: red blood cells, platelets, plasma, and cryoprecipitate. This method allows for the widest usage of available blood and optimal storage for each component.

Packed Red Blood Cells

Packed red blood cells (PRBCs) are prepared from whole blood by centrifugation followed by the removal of 80 to 90 percent of the plasma. A preservative solution, such as Adsol (dextrose, adenine, and mannitol), is added, resulting in a storage time of up to 42 days. PRBCs are stored at 4°C. Each unit of PRBCs transfused should raise the hemoglobin by 1 g/dL or the hematocrit by 3 percent. The advantages to the use of PRBCs compared with whole blood include reduced risk of volume overload; decreased infusion of citrate, ammonia, and organic acids; and the decreased risk of alloimmunization because the patient is exposed to fewer antigens. PRBCs provide rapid restoration of oxygen-carrying capacity in patients with acute or chronic blood loss.

It is impossible to set specific criteria for the transfusion of PRBCs, although general guidelines can be used and adapted to each clinical setting. The decision to transfuse must be individualized for each patient. The impact of blood loss is variable among patients, depending on the underlying cause, the rate of blood loss, the patient's underlying health status, the cardiopulmonary reserve, and the activity level of the patient. There are three common settings where the transfusion of PRBCs should be considered:

1. *Acute hemorrhage.* Acute hemorrhage, as seen in patients with trauma, bleeding from the gastrointestional (GI) tract, or from a ruptured aortic aneurysm, often requires emergency transfusion of PRBCs. In otherwise healthy patients, the loss of up to about 1500 mL of blood (about 25 to 30 percent of the blood volume in a 70-kg person) can be replaced entirely with crystalloid solutions. Blood losses greater than this usually require the transfusion of PRBCs to replace oxygen-carrying capacity and crystalloid solution to replace volume.
2. *Surgical blood loss.* Otherwise healthy surgical patients usually do not require preoperative transfusion of PRBCs unless the hemoglobin is less than 7 g/dL or large amounts of blood loss are expected. Intraoperative blood loss of 1500 to 2000 mL can often be replaced with just crystalloid if the patient initially had a normal hemogram. Most patients will require transfusion of PRBCs and crystalloid when blood loss exceeds 2 L.
3. *Chronic anemia.* Patients with chronic stable anemia probably only require transfusion of PRBCs if the hemoglobin falls to less than 7 g/dL or if they are symptomatic or have underlying cardiopulmonary disease.

Some general guidelines for patients in the emergency department (ED) whose blood should be typed and crossmatched for potential transfusion include those with (1) evidence of shock from whatever cause, since early on it may not be clear what the etiology is; (2) known blood loss of more than 1000 mL; (3) ongoing gross bleeding; (4) those with a hemoglobin less than 10 g/dL or hematocrit less than 30 percent; or (5) patients who are potentially going for surgery where blood may be lost (laparotomy after trauma or for ectopic pregnancy).

Other patients who may need blood products but do not meet these criteria should have blood sent to the blood bank for typing and antibody screening. Many institutions have criteria for the number of units to be crossmatched in a particular clinical setting. Many clinicians believe that it is not worth the risks of transfusion to transfuse just one unit of PRBCs; i.e., do not transfuse until the patient requires 2 or more units to be transfused.

In addition to PRBCs, red blood cells are available as leukocyte-poor, frozen, or washed, when required for certain patients. *Leukocyte-poor RBCs* have 70 to 85 percent of the leukocytes removed by centrifugation, filters, or ultraviolet irradiation. This preparation is indicated for patients who are transplant recipients or transplant candidates (bone marrow or solid organ) in order to prevent immunization against leukocytes and in patients who have a history of previous febrile nonhemolytic transfusion reactions. *Frozen RBCs* are prepared by adding a cryoprotective agent and then storing the cells for as long as several years at below

freezing temperatures. The freezing process destroys the other blood constituents except for a small number of immunocompetent lymphocytes. Prior to transfusion, the cells are thawed and washed with a solution that removes 99.9 percent of the plasma and cellular debris. This process is expensive but can provide a supply of rare blood types, provides metabolically superior RBCs, and results in reduced antigen exposure for transplant candidates. *Washed RBCs* are prepared from whole blood or PRBCs. Isotonic saline is used to wash the RBCs, resulting in the removal of plasma proteins, some leukocytes, and some platelets. Washed RBCs must be infused within 24 h because of the risk of bacterial contamination during processing. Washed RBCs are used for patients who have hypersensitive reactions to plasma (usually IgA-deficient patients), neonatal transfusions, and in patients with paroxysmal nocturnal hemoglobinuria in order to avoid the precipitation of hemolytic episodes.

Platelets

Platelets for transfusion are obtained through whole blood donations or by plateletpheresis of a single donor. Platelets can be stored for up to 5 days at 20° to 24°C with agitation, although platelet recovery and survival is sometimes better with shorter storage periods. Generally, random donor units are given six at a time (6-pack), or the patient is given one plateletpheresis pack. Each of these totals 250 to 350 mL and contains about 4×10^{11} platelets. Six random donor packs or one plateletpheresis pack should raise the platelet count by 50,000 to 60,000/µL in an average-size adult. The posttransfusion platelet count should be checked 1 and 24 h after platelet infusion. Transfused platelets should survive 3 to 5 days unless there is platelet consumption or refractoriness. Patients with fever, certain infections, disseminated intravascular coagulation (DIC), excessive bleeding, splenomegaly, or antibodies against the transfused platelets may be refractory to platelet transfusion. It is preferable to use ABO-compatible platelets whenever possible to avoid the passive administration of ABO-incompatible plasma. This is particularly true in patients weighing less than 40 kg and patients who receive numerous transfusions. A small amount of RBCs contaminate the platelets, so Rh-negative women of childbearing age should receive Rh-negative platelets.

The clinical indications for the transfusion of platelets depend on the underlying etiology of the thrombocytopenia, the presence or absence of active bleeding, the presence of other disease states that may cause platelet dysfunction, and the need for surgical or invasive procedures. When the patient has thrombocytopenia due to the presence of antiplatelet antibodies, platelet transfusion is generally futile. General guidelines for platelet transfusion in adults include the following:

1. When the platelet count is above 50,000/µL, excessive bleeding due to thrombocytopenia is unlikely unless there is platelet dysfunction present.
2. The platelet count should be maintained at 50,000/µL or greater in patients undergoing major surgery or in those with ongoing significant bleeding.
3. When the platelet count is between 10,000 and 50,000/µL, there is an increased risk of bleeding with trauma or invasive procedures; bleeding that develops spontaneously or as a result of invasion should be treated with platelet transfusions; patients with concurrent disease (renal or liver) causing platelet dysfunction can bleed spontaneously with these counts.
4. When the platelet count is below 10,000/µL, there is a high risk of spontaneous hemorrhage and platelets should be transfused prophylactically, although in patients with immune thrombocytopenia, there may be little or no effect to platelet transfusion.

Special platelet preparations are indicated for some patients. Those who become refractory after multiple transfusions may need HLA-matched platelets. Immunosuppressed patients should receive irradiated platelets to prevent the alloimmunization that can occur as a result of leukocyte contamination.

Fresh-Frozen Plasma

Fresh-frozen plasma (FFP) is plasma that is obtained after the separation of whole blood donations into its plasma and cellular (RBCs and platelets) components. Frozen within 6 h of the collection, FFP is stored at –18°C for up to 1 year. Each bag of FFP contains 200 to 250 mL and, by definition, contains 1 unit of each coagulation factor per milliliter of FFP and 1 to 2 mg of fibrinogen per milliliter of FFP. Transfused FFP should be ABO-compatible. The desired dose to be transfused can be estimated from the plasma volume and the desired incremental increase in factor activity. A typical starting dose is 8 to 10 mL/kg, or approximately two to four bags of FFP. After infusion, the patient should be reevaluated for clinical bleeding and posttransfusion coagulation studies obtained.

The indications for transfusion of FFP are as follows:

1. The presence of a coagulopathy due to acquired factor(s) deficiency with active bleeding or prior to invasive procedures; the patient should have significant (1.5×) prolongation of the prothrombin time (PT) and/or activated partial thromboplastin time (aPTT), or a specific coagulation factor assay less than 25 percent of normal; patients in this category include those with liver disease, DIC, and those taking warfarin.
2. Patients with congenital isolated factor deficiencies when specific virally safe replacement products are not available (see below); those with isolated deficiencies of fibrinogen, factor VIII, or factor XIII are probably better treated with cryoprecipitate.
3. Patients with thrombotic thrombocytopenic purpura (TTP) in the process of plasma exchange (see Chap. 214).
4. Some patients who receive massive transfusion and have evidence of a coagulopathy and active bleeding (see below).
5. Patients with antithrombin III deficiency when antithrombin III concentrates are not available.

FFP is *not* indicated for patients who require volume expansion.

Cryoprecipitate

Cryoprecipitate is the cold precipitable protein fraction derived from FFP thawed at 1° to 6°C; it can be stored frozen for up to 1 year. The contents of a bag of cryoprecipitate are outlined in Table 215-1. The typical dose of cryoprecipitate given is two to four bags per 10 kg—usually 10 to 20 bags at a time. When given in large volumes, it is preferable to use ABO-compatible cryoprecipitate.

Factor VIIIC	80–120 units
von Willebrand Factor	80 units
Fibrinogen	200–300 mg
Factor XIII	40–60 units
Fibronectin	Variable

TABLE 215-1   The Contents of Cryoprecipitate (per Bag)

The indications for transfusion of cryoprecipitate are as follows. Keep in mind that it should not be used to treat hemophilia unless virally safe (recombinant or monoclonal-antibody purified) factors are not available and the patient has an immediately life-threatening bleed (see Chap. 212).

1. For patients with hypofibrinogenemia. In patients with congenital deficiency of fibrinogen or those with consumptive coagulopathy such as DIC, transfusion is indicated when the fibrinogen level is less than 100 mg/dL.
2. For patients with von Willebrand disease and active bleeding, cryoprecipitate should only be used when desmopressin (DDAVP) is not available or does not work and factor VIII concentrates containing von Willebrand factor are not available.
3. For patients with hemophilia A, only when virally inactivated factor VIII concentrates are not available.
4. For use as fibrin glue surgical adhesives.
5. For fibronectin replacement, which may be beneficial to promote healing in patients with trauma, severe burns, or sepsis.

Albumin

Albumin accounts for about 50 percent of the circulating protein and 75 percent of the plasma oncotic pressure. Albumin replacement products are available as 5% or 25% solutions in saline. Plasma protein fraction (PPF) is a similar product; it is a 5% solution containing 88 percent albumin and 12 percent globulins. These products undergo heat inactivation for 10 h at 60°C and are not known to transmit viral diseases.

The clinical indications for albumin infusion are controversial but may include the following:

1. As colloid replacement to replace or maintain oncotic pressure. Most clinical experimental studies suggest that there is no advantage to colloid solutions over crystalloid in the acute management of hemorrhagic shock. Infused albumin solutions rapidly distribute to the extravascular space and are expensive.
2. In conjunction with large volume paracentesis in patients with refractory ascites.
3. In patients with severe burns. Most centers are moving away from this practice.

Immunoglobulins

Intravenous immunoglobulins, commonly referred to as *IVIg,* are being increasingly used for a variety of medical conditions. There are six preparations currently available in the United States. Several incidences of transmission of the hepatitis C virus have been documented with use of these products. The current indications for use are as follows:

1. Primary and secondary immunodeficiency, such as in patients with congenital immunodeficiency or chronic lymphocytic leukemia, bone marrow transplant patients, pediatric patients infected with the human immunodeficiency virus (HIV-1), and for the prevention of sepsis in premature infants and of infection in patients in intensive care settings.
2. Patients with immune or inflammatory disorders such as immune thrombocytopenic purpura or Kawasaki syndrome.

Two notable and interesting complications that may occur with the infusion of immunoglobulins are (1) anaphylaxis, which can occur in patients with IgA deficiency; these patients need to be given the IgA-depleted product; and (2) development of transient positive serologies in some patients due to the passive transfer of antibodies against hepatitis C and cytomegalovirus (CMV)

Antithrombin III (ATIII)

Antithrombin III is a serum protein that has inhibitory effects on coagulation factors, activated factor II (thrombin), as well as activated factors IX, X, XI, and XII. Deficiency of ATIII can be congenital or acquired. Replacement ATIII is available in two preparations obtained by heparin-affinity chromatography. The products undergo viral inactivation for 10 h at 60°C, which inactivates HIV-1. There are ever-expanding uses for ATIII replacement, but currently its main use is for patients with hereditary deficiency of ATIII with acute thromboembolism or the prophylaxis of thrombosis in these patients. It is also being used experimentally for the prevention of thrombosis in surgical patients, for obstetric emergencies, and for shock and DIC.

Specific Factor Replacement Therapy

The most common congenital factor deficiencies, hemophilia A, hemophilia B, and von Willebrand disease, are discussed in Chap. 212 . Other congenital factor deficiencies are rare and unlikely to be encountered, but the emergency physician needs to be aware of their existence and have a basic knowledge of what products are used for the management of acute bleeding episodes. Table 215-2 outlines the recommended therapy for congenital factor deficiencies.

TABLE 215-2   Replacement Therapy for Congenital Factor Deficiencies

COMPLICATIONS OF TRANSFUSIONS

Up to 20 percent of all transfusions may lead to some type of adverse reaction. Fortunately, most of these reactions are mild and not of long-term consequence to the patient. Transfusion reactions can occur while the transfusion is in process (immediate reactions) or the adverse result may not become apparent for hours to years (delayed reactions). Table 215-3 outlines the types of acute transfusion reactions and their management and evaluation.

TABLE 215-3   Acute Transfusion Reactions: Recognition, Management, Evaluation

Immediate Transfusion Reactions

ACUTE HEMOLYTIC TRANSFUSION REACTION   This is a medical emergency that occurs when incompatible RBCs are transfused. Most often this is an intravascular event resulting from incompatibility in the ABO blood group system. Table 215-4 reviews compatibility in the ABO blood group system. An acute hemolytic reaction occurs when the incompatible transfused cells are immediately destroyed by antibodies. The overall incidence of acute hemolytic transfusion reactions is estimated at 1 in 21,000 to 1 in 250,000 units transfused, but the outcome is fatal in 1 in 100,000 transfusions.

Phenotype	Antigens on RBCs	Antibodies in Serum	Can Receive RBCs of Type
A	A	anti-B	A, O
B	B	anti-A	B, O
AB	A and B	None	A, B, O
O	None	anti-A; anti-B	O

TABLE 215-4   ABO Blood Group System Compatibility

Clinically, a transfusion reaction should be suspected when the patient complains of fever, chills, low back pain, breathlessness, or a burning sensation at the site of infusion. If the reaction progresses, the patient may develop hypotension, bleeding, respiratory failure, and acute tubular necrosis. More severe reactions occur in anesthetized or unconscious patients because of their inability to alert the staff that something is amiss. The management of a patient with a possible transfusion reaction begins with the immediate discontinuation of the transfusion. While the transfusion workup is in progress, the patient should be aggressively hydrated in order to maintain a brisk diuresis (at least 100 mL/h) for at least 24 h. Furosemide may be required to maintain the diuresis. Cardiorespiratory support may be needed. The laboratory evaluation of a possible hemolytic transfusion reaction includes the finding of hemoglobinemia (elevated plasma free hemoglobin) and hemoglobinuria. Other tests for hemolysis should be performed including haptoglobin and bilirubin. Direct and indirect Coombs test should be performed on pre- and posttransfusion blood samples. A complete blood count, creatinine, and coagulation tests will also be helpful.

A less common and less serious type of acute hemolytic transfusion reaction is extravascular hemolysis (in the spleen), usually caused by transfusion of incomplete Rh cells. These patients may be asymptomatic and only rarely have hemoglobinemia and hemoglobinuria. Laboratory studies in this situation will show a positive Coombs test, elevated level of indirect bilirubin, and a poor response to the transfusion—the hemoglobin and hematocrit do not rise as expected. This type of hemolytic reaction usually does not require any treatment.

FEBRILE NONHEMOLYTIC TRANSFUSION REACTION   This reaction is estimated to occur once for every 200 units transfused. During the transfusion or within a few hours after its completion, the patient has a temperature elevation of at least 1°C and usually has chills. The usual cause of this febrile reaction is an antigen-antibody reaction involving the plasma, platelets, or white blood cells that are passively transfused to the recipient along with the RBCs. Such a reaction occurs most commonly in patients who have been multiply transfused or in multiparous women. Febrile reactions not involving hemolysis are usually mild but can be life threatening in patients with tenuous cardiopulmonary status or in those who are already critically ill. As in the acute hemolytic transfusion reaction, the first step in management is to stop the transfusion. Clinically, it is impossible to distinguish initially between a febrile nonhemolytic reaction and the more serious acute hemolytic transfusion reaction. The hemolytic transfusion must be ruled out by repeat crossmatching of the blood and repeat Coombs testing. Infections that could potentially be responsible for the fever and chills should be considered. Patients with a known history of febrile reactions to transfusions can be pretreated with acetaminophen or aspirin and meperidine can be given to treat the chills, or the patient can be given leukocyte-depleted blood components.

ALLERGIC TRANSFUSION REACTION   Allergic reactions to the transfused products occur in about 1 percent of all transfusions. The reaction is thought to be due to exposure to plasma proteins. Such reactions most commonly occur in IgA-deficient patients. Typical allergic symptoms such as skin erythema, urticaria, pruritus, bronchospasm, vasomotor instability, and, rarely, anaphylaxis occur. True anaphylaxis occurs only once in 20,000 transfusions. Such reactions are rarely serious. The severity of the reaction is not dose-related—the transfusion often can be completed. When an apparent allergic transfusion reaction occurs, the infusion should be discontinued while the patient is evaluated and treated with diphenhydramine. If the patient improves with this therapy, the transfusion can be restarted. Some clinicians routinely premedicate patients who have a history of allergic transfusion reactions.

Delayed Reactions

INFECTIONS   Since HIV-1 was identified in the U.S. blood supply in the mid-1980s, several screening methods have been instituted to ensure the safety of the blood products in current use. The majority of blood products available in the United States today are collected from volunteer donors who reliably provide a safer product than that obtained from paid donors. There are two levels of screening of the donors and blood: (1) donor prescreening by a questionnaire that excludes persons with a high risk of viral exposure and (2) serologic testing of the donor blood. The tests typically performed on donor blood are outlined in   Table 215-5. Some component products, factor replacement products in particular, undergo further treatment to ensure viral inactivation. The risks of transmission of various infections by transfused blood products are listed in Table 215-6. These risks are averages; the actual risk may be higher or lower depending on the incidence of infection in the area the blood is collected. Rarely, blood products become contaminated with bacteria during preparation or bacterial infection can come from an infected donor. This should be considered when a patient develops fever during or shortly after the transfusion of blood products.

ABO, Rh determination	Hepatitis B surface antigen
Antibody to HIV-1	Hepatitis B core antibody
Antigen to HIV-1 p24	Antibody to hepatitis C
Antibody to HIV-2	ALT
Antibody to HTLV-I/II	Serology for syphilis

Note: HIV, human immunodeficiency virus; HTLV, human T-cell leukemia virus; ALT, alanine transaminase.

TABLE 215-5   Tests Performed on Donated Blood

TABLE 215-6   Estimated Risk of Infection Transmission via Blood Products, 1998

DELAYED HEMOLYTIC REACTION   This reaction occurs 7 to 10 days after transfusion as a result of an antigen-antibody reaction that develops after the transfusion. Laboratory studies reflect a slowly falling hemoglobin, and a previously negative Coombs test becomes positive. The patient is generally asymptomatic. Further blood bank workup is needed to detect the causative antibody.

HYPERVOLEMIA   The transfusion of PRBCs or plasma results in the rapid expansion of intravascular volume. Such expansion may not be well tolerated by patients with limited cardiovascular reserve, particularly infants and elderly patients. Patients may complain of headaches and shortness of breath; on examination, they will have signs of congestive heart failure. Treatment consists of slowing the rate of infusion and diuresis of the patient. As a general guide, infusions in adults are at a rate of 2 to 4 mL/kg/h. This can be slowed to 1 mL/kg/h in patients at risk of fluid overload.

HYPOTHERMIA   Hypothermia may develop in patients who receive rapid infusion of large quantities of refrigerated blood. This is generally only a problem if three or more units are given rapidly. PRBCs are stored at 4°C, platelets at 20° to 24°C, and FFP at −18°C. Rapid infusers/warmers may be used but should not raise the temperature to more than 40°C, or hemolysis can occur. The easiest method for warming blood is to infuse it along with warmed (39° to 43°C) normal saline, which will warm and dilute the blood.

NONCARDIOGENIC PULMONARY EDEMA   Noncardiogenic pulmonary edema occurs in approximately 1 in 5000 transfusions. Believed to be due to incompatibility of passively transferred leukocyte antibodies, the problem usually develops within 4 h of the transfusion. Clinically, the patient has respiratory distress, fever, chills, and tachycardia, and a chest radiograph shows diffuse patchy infiltrates without cardiomegaly. There is no evidence of fluid overload or congestive heart failure. In the majority of cases, the pulmonary infiltrates resolve over a few days and only supportive care is needed. This reaction can, however, be fatal in patients who are already critically ill.

ELECTROLYTE IMBALANCE   Citrate is a component of the preservative solution used in blood storage; it functions as an anticoagulant by chelating calcium. Significant hypocalcemia rarely occurs as a result of transfusion-related citrate exposure because patients with normal hepatic function readily metabolize citrate to bicarbonate. Even with massive transfusion, calcium replacement is rarely needed.

Hypokalemia can be a problem when large amounts of blood are transfused. When the citrate is metabolized to bicarbonate, the blood becomes alkalotic and potassium is driven to the intracellular compartment.

Hyperkalemia rarely is a problem after blood transfusions even though the potassium content increases in stored blood. This may be a problem for patients with renal failure or neonates.

GRAFT-VERSUS-HOST DISEASE   This unfortunate reaction, which is fatal in more than 90 percent of cases, can occur after the transfusion of nonirradiated cellular blood components into an immunocompromised host. Graft-versus-host disease occurs when immunologically competent lymphocytes are passively transferred to an immunoincompetent host who is unable to destroy the donor lymphocytes. The donor lymphocytes engraft, recognize the host as foreign, then attack the host tissues. Bone marrow aplasia commonly results.

EMERGENCY TRANSFUSIONS

In the ED, the administration of type O blood or type-specific incompletely crossmatched blood may be lifesaving; however, it carries the risk of severe, life-threatening transfusion reactions. Massive, uncontrolled hemorrhage from any cause may necessitate transfusion with uncrossmatched type O blood. Its use is limited to the early resuscitative phase of patients with shock from exsanguinating hemorrhage and insufficient response to infused crystalloid solutions. Patients with trauma, massive GI bleeding, ruptured aortic aneurysm, or unexpected intraoperative hemorrhage may be candidates to receive emergency transfusions. Before any transfusions are given, baseline laboratory studies should be done, including blood for typing and crossmatching. Current practice limits the use of uncrossmatched type O blood to the initial resuscitation of patients with massive hemorrhage. Type-specific blood often can be obtained from the blood bank in 10 to 15 min after the sample is received and will avoid the majority of transfusion reactions. Fully crossmatched blood typically can be obtained in 30 to 60 min. Most hospitals use Rh-negative blood when it has not been fully crossmatched. PRBCs are the only blood product that can be given for emergency transfusion. Plasma products contain too many antibodies and should not have a role in the early phase of treatment of massive hemorrhage. As soon as type-specific crossmatched PRBCs are available, they should be given. Subsequent crossmatching will become more difficult as increasing amounts of uncrossmatched blood are transfused.

MASSIVE TRANSFUSION

Massive transfusion is defined as the replacement of a volume equivalent to the patient's normal blood volume within a 24-h period. Potential complications of this procedure are bleeding, citrate toxicity, and hypothermia. Bleeding is the most frequent complication and is related to platelet and factor deficiencies. Actual thrombocytopenia does not regularly occur in this setting because even after the replacement of one blood volume, most patients still have about 35 to 40 percent of their original platelet count, about 100,000/μL. Bleeding is the result of mild thrombocytopenia combined with platelet dysfunction from renal or liver disease or DIC, and coagulation factor deficiencies. Coagulation factor deficiencies can develop in the setting of massive transfusion because stored blood has low levels of coagulation factors, especially factors V and VIII. The coagulopathy may be worsened by hypothermia, shock, sepsis, underlying liver disease, or DIC. In current practice, the routine use of platelet transfusions and FFP in massive transfusion is unwarranted, costly, and dangerous. Platelet transfusions should be given only if there is thrombocytopenia with oozing or excess bleeding. FFP should be given only when there is a documented coagulopathy and bleeding.

In modern blood banking, citrate toxicity is rarely a problem unless whole blood is being transfused. Patients receiving more than five units of whole blood, neonates, or patients with liver disease are at risk of hypocalcemia. An ionized calcium level should be obtained. The QT interval is not a reliable indicator of hypocalcemia in this setting. If calcium needs to be repleted, 5 to 10 mL of calcium gluconate given slowly IV is recommended.

Hypothermia is a potential risk when the patient receives three or more units of blood rapidly. When giving large quantities of blood rapidly, the blood itself needs to be warmed or it can be administered with warm saline (see above) in order to prevent iatrogenic hypothermia.

BLOOD ADMINISTRATION

The administration of blood products begins with the absolute identification of the patient and the unit to be transfused. Blood products are generally infused through large bore intravenous tubing (16 gauge or greater) to prevent hemolysis and permit rapid infusion if needed. Normal saline is the only crystalloid fluid compatible with PRBCs. Saline is usually given with the blood to dilute it and facilitate infusion. If multiple units of blood are to be given or are being given rapidly, warmed saline can be given concurrently (warmed to 39° to 43°C) or the blood itself can be warmed in an electric blood warmer. Blood will hemolyze if warmed to more than 40°C. Except in emergency settings, the infusion of blood is started slowly over the first 30 min, when reactions are most likely to occur. Patients without cardiovascular disease can be given a unit of PRBCs over 1 to 2 h. Those with a risk of hypervolemia should receive each unit over 3 to 4 h. Micropore filters should be used when giving any blood product in order to filter microaggregates of platelets, fibrin, and leukocytes. Rapid infusion of blood in the emergency setting may be facilitated by the use of pressure infusion devices that apply pneumatic pressure (up to 300 mmHg) to the blood unit.

216 EXOGENOUS ANTICOAGULANTS AND ANTIPLATELET AGENTS

Stephen D. Emond
John R. Cooke
J. Stephan Stapczynski

Antithrombotic therapy is standard for numerous arterial and venous thromboembolic conditions, including acute myocardial infarction (AMI), unstable angina pectoris, deep venous thrombosis (DVT), pulmonary embolism (PE), and stroke or cerebrovascular accident (CVA). Moreover, antithrombotic agents help prevent occlusive vascular disease in patients at risk for thrombosis. These agents, however, also have the potential to cause life-threatening complications, primarily uncontrolled hemorrhage. This chapter provides an overview of antithrombotic agents, including mechanisms, indications, contraindications, and therapies, as well as evaluation and management of acute bleeding complications. Detailed management of thromboembolic disorders is discussed in their respective chapters.

PATHOPHYSIOLOGY OF THROMBOSIS

The clotting cascade is discussed in detail in Chap. 210. Arterial thrombi, composed primarily of platelets bound by thin fibrin strands, develop under high-flow conditions, especially at sites of ruptured atherosclerotic plaques. Both anticoagulants and platelet-inhibiting drugs effectively prevent and treat arterial thrombosis. In contrast, venous thrombi form in areas of sluggish blood flow, and are composed mainly of red blood cells and large fibrin strands. Anticoagulant drugs are effective in preventing and treating venous thromboembolism, while platelet-suppressing agents are less important. [1]

AGENTS

Both arterial and venous thrombi may result in local vascular obstruction or distant embolization. Antithrombotic agents interfere with these processes by (1) preventing formation of the platelet-fibrin net (blocking thrombin activation or platelet function) or (2) accelerating clot breakdown (fibrinolysis). Antithrombotic agents are grouped by mechanism of action.[2] Anticoagulants block synthesis and activation of clotting factors. Antiplatelet agents interfere with platelet activation or aggregation. Fibrinolytics (inaccurately referred to as thrombolytics) dissolve the fibrin component of thrombi.

Oral Anticoagulants

Oral anticoagulants are used for prophylaxis of thromboembolic CVAs (in patients with atrial fibrillation, left ventricular thrombus, or cardiac valvular abnormalities or prostheses), DVT, and PE, as well as for certain peripheral arterial diseases (Table 216-1).

TABLE 216-1   Antithrombotic Therapy Guidelines

Sodium warfarin, a hydroxycoumarin compound, is the most widely used oral anticoagulant in North America. Readily absorbed from the gut, it reaches peak blood concentrations in 90 min and has a circulating half-life of 36 to 42 h. Warfarin blocks activation of vitamin K and thereby interferes with hepatic carboxylation of coagulation factors II, VII, IX, and X (Fig. 216-1). Without these vitamin K–dependent cofactors, the extrinsic pathway of thrombus formation is blocked. Warfarin also blocks the synthesis of proteins C and S, which work together to inhibit the function of factors V and VII in the coagulation cascade. Warfarin dosing is guided by the international normalized ratio (INR), a standardized measurement of prothrombin time (PT), with a desired therapeutic range of 2.0 to 2.5 in most cases. [3] Drugs and food that interfere with warfarin absorption or hepatic metabolism can have a profound effect on warfarin activity (Table 216-2).[4]

FIG. 216-1. Clotting factors and tests of coagulation.

Consideration	Prothrombin Time (PT)*
MAJOR	
Vitamin K malabsorption or dietary deficiency	↑
Excess vitamin K	↓
Reduced gut bacteria (antibiotics)	↑
Decreased warfarin absorption	↓
Altered warfarin metabolism (cytochrome P-450)	↑ or ↓
Drug effects	↑ or ↓
OTHER	
Decreased clotting factor production (liver disease)	↑
Increased metabolism of clotting factors (fever)	↑
Confounding technical or laboratory factors (e.g., phlebotomy, handling in transport, thromboplastin reagents)	↑ or ↓

* ↑ = PT prolonged; ↓ = PT decreased.

TABLE 216-2   Warfarin Interactions

The pharmacologic effect of warfarin is to inhibit the synthesis of the four coagulation factors and protein C and S, resulting in a decrease in their plasma levels according to their half-life. Protein C has the shortest half-life (8 h), and its plasma level falls the most quickly. Factor VII has the shortest half-life of the coagulation factors, about 7 h, and plasma levels fall thereafter. Factor II has the longest half-life, about 60 h, and its plasma levels fall the most slowly after the start of warfarin therapy. The phase delay between the fall in protein C (an antithrombotic protein) and the fall in the affected four coagulation factors (thrombotic proteins) results in a transient state of increased thrombogenesis that lasts for about 24 to 36 h. This potential hypercoagulable state is reduced but not eliminated by initiating warfarin therapy with 5-mg/d doses.[5] For patients in whom sudden intravascular thrombosis can be fatal (e.g., those with a prosthetic heart valve), anticogulation should be ensured with heparin [or perhaps a low-molecular-weight (LMW) product] before starting oral warfarin. Thus, a noncompliant patient with a prosthetic heart valve who has stopped oral anticoagulants should not simply be discharged with instructions to restart warfarin.

There also appears to be rebound during warfarin withdrawal. During the first 4 days, factors VII and IX increase more rapidly than proteins C and S, resulting in an imbalance between provokers and inhibitors of coagulation.[6] This potential hypercoagulable condition appears to exist biochemically for about 4 days during warfarin withdrawal. However, prospective studies have shown no increased incidence of clinical episodes of thrombosis with sudden termination of warfarin therapy compared to gradual tapering. The thromboembolic events that occur in patients after warfarin discontinuation are related more to the underlying condition than to the method of termination.

The two major complications of warfarin therapy are major bleeding episodes and skin necrosis. Bleeding is usually related to the degree of anticoagulation and can be prevented by laboratory monitoring with dose adjustments. Reversal with vitamin K_1 or factor replacement may be necessary for major hemorrhage. Skin necrosis occurs primarily in patients with protein C deficiency. This complication usually develops 3 to 8 days after starting treatment and is due to thrombosis of small cutaneous vessels. Warfarin in contraindicated in pregnancy because it is teratogenic and causes fetal hemorrhage.

Parenteral Anticoagulants

UNFRACTIONATED HEPARIN   A mixture of glycosaminoglycan chains of varying lengths, unfractionated heparin contains a unique subunit that binds antithrombin III (AT-III). The heparin–AT-III complex binds to and inhibits coagulation factors IX$_a$ and X$_a$, of the intrinsic pathway, and, most important, thrombin. Heparin is not an anticogulant by itself, and AT-III deficiency is a rare but important cause of heparin resistance. Unfractionated heparin must be given parenterally (intravenously or subcutaneously). Its half-life (30 to 150 min) depends on the dose and route. Weight-based intravenous heparin dosing protocols are the most reliable approach for rapidly achieving a therapeutic response and preventing further thrombosis during acute thromboembolic events. The subcutaneous method is less reliable for the treatment of acute thromboembolic disease because the bioavailability of subcutaneous unfractionated heparin ranges from 10 to 90 percent, depending on the dose. However, the subcutaneous route may be acceptable for prophylaxis, as opposed to treatment of thrombosis. One disadvantage of unfractionated heparin is that it interferes with most laboratory investigations for hypercoagulable states. However, functional assays for protein C and S can be performed if heparin is removed from the plasma by an absorbent column or by heparinase.[7] Both unfractionated heparin and the newer LMW derivatives do not cross the placenta and are safe to use in pregnancy.

The two major complications of unfractioned heparin are major bleeding episodes and heparin-induced thrombocytopenia. Bleeding is related to the degree of anticoagulation and can be prevented by laboratory monitoring with dose adjustment. In the event of major hemorrhage, the infusion can be stopped, and the anticoagulant effect will be greatly diminished in a few hours. Heparin-induced thrombocytopenia (HIT) is due to an antibody, usually IgG, that attaches to and stimulates platelets. This platelet activation produces both thrombocytopenia and a tendency for thrombosis. The incidence of HIT is between 1 and 3 percent in patients treated with unfractionated heparin but significantly less in patients treated with LMW products. The onset of HIT is usually 5 to 12 days after heparin treatment is started but may be sooner for patients who developed the antibody from a previous exposure. The platelet count nadir is often modest, typically 20,000 to 150,000 per μL. Thrombosis may involve the skin (similar to warfarin-induced cutaneous necrosis), the arteries (e.g., femoral artery thrombosis), or the veins (e.g., recurrent DVT or PE).

The anticoagulant effect of heparin has been traditionally monitored with the activated partial thromboplastin time (aPTT), which is widely available from clinical laboratories (Table 216-1).[2,8] However, the reagents used in the aPTT vary significantly in their sensitivity to unfractionated heparin, and the therapeutic range must be defined for each brand of aPTT reagent. In addition, there is not a linear relationship between heparin concentration, the anticoagulant activity of heparin (as measured by its anti-factor X$_a$ activity), and the aPTT. For most purposes, a therapeutic range for heparin can be either an aPTT of 1.5 to 2.5 the "normal" value, or a heparin level of 0.2 to 0.4 U/mL when assayed by protamine titration or 0.3 to 0.7 U/mL when assayed for anti-X$_a$ activity.[8] Unfractionated heparin can increase the PT and INR by a variable amount, depending on the heparin concentration and the thromboplastin reagent used in the assay. Typically, therapeutic concentrations of heparin increase the PT by approximately 1 to 5 s.

LOW-MOLECULAR-WEIGHT HEPARIN FRACTIONS   Enoxaparin, dalteparin, and ardeparin are prepared from unfractionated heparin and contain almost solely short (<18 saccharide units) chains. LMW heparin binds to AT-III, but the short saccharide chains of LMW are not adequate for binding to thrombin. However, the LMW/AT-III complex can bind to and inhibit factor X$_a$, accounting for the anticoagulant effect.[9] Compared to unfractionated heparin, LMW heparin is highly bioavailable (90 percent) and has a longer circulating half-life (3 to 4 h), allowing once- or twice-daily subcutaneous dosing. LMW heparin is used primarily for DVT prophylaxis, and enoxaparin can be used in unstable angina and non-Q wave AMI.[10] Compared to unfractionated heparin, the dose-response curve of LMW heparin is much more predictable, and laboratory monitoring is not routinely used in clinically stable patients, particularly those receiving prophylactic treatment for venous thrombosis or higher doses for treatment of venous thromboembolism.[11] LMW heparin is cleared by the kidneys, and, in patients with significant renal impairment, therapy may be monitored by anti-X$_a$ activity.[9,11] The therapeutic level is not precisely known. An anti-X$_a$ activity of 0.6 to 1.0 IU/mL obtained 4 h after a twice-daily subcutaneous treatment of venous thromboembolism appears to be a conservative therapeutic range. The LMW heparins produce small, dose-related elevations in the PT, INR, and aPTT. Compared to unfractionated heparin, LMW heparin has the advantage that therapy does not affect the laboratory investigation of potential hypercoagulable states.

DANAPAROID   Danaparoid is a mixture of LMW glycosaminoglycans that produces predominately anti-X$_a$ activity. The bioavailability of danaparoid is nearly 100 percent, and it has an antithrombotic half-life of about 8 h. Danaparoid is currently recommended only for DVT prophylaxis at doses of 750 U (1250 U for patients >90 kg) twice daily by subcutaneous injection. Laboratory monitoring is not routinely required for this prophylactic regimen.[11] Like other LMW heparins, danaparoid produces minimal elevation in PT, INR, or aPTT. Intravenous danaparoid can also be used for systemic anticoagulation, but this approach is not currently approved by the US Food and Drug Administration (FDA).

HIRUDIN   Derived from the medicinal leech, hirudin exerts its anticoagulant activity by binding tightly to thrombin, blocking both the active and the substrate binding sites.[11] Hirudin produces its anticoagulant activity independently of AT-III and, unlike heparin, is not affected by plasma and platelet proteins. Hirudin is prepared by recombinant technology and differs slightly from the natural substance. Recombinant hirudin has been modified into a number of available analogues such as lepirudin and bivalirudin. Hirudin and its analogues are currently FDA-approved for anticoagulation in patients with heparin-associated thrombocytopenia. Administered intravenously, hirudin has a half-life of 50 min. Administered subcutaneously, the bioavailability is 90 percent, and the half-life is 2 to 3 h. Intravenous

hirudin is monitored using the aPTT, generally maintaining a target range of 1.5 to 2.5 times the "normal" value. In theory, hirudin should both prevent new clot formation and dissolve existing thrombus. However, clinical trials of hirudin versus heparin in AMI or unstable angina demonstrated excess bleeding complications with no long-lasting benefits.[12] While a recent study showed benefit when hirudin was administered after reperfusion with streptokinase, hirudin is not currently approved for this indication.[13]

Blockers of Platelet Activation

Aspirin irreversibly blocks cyclooxygenase, an enzyme that in the platelet stimulates arachidonic acid conversion to thromboxane A$_2$ and in the blood vessel wall promotes prostacyclin synthesis. The net effect of aspirin in ischemic arterial beds depends on the balance between thromboxane A$_2$, a potent vasoconstrictor and platelet-aggregation agent, and prostacyclin, a vasodilator and platelet-aggregation inhibitor. Since prostacyclin synthesis is stimulated at lower aspirin levels than is thromboxane A$_2$ conversion, treatment plans often use low-dose strategies (e.g., 81 mg/day). For more rapid antiplatelet effect, a medium or higher dose (e.g., 162 mg) is indicated (Table 216-1).[14]

Aspirin is quickly absorbed in the upper gastrointestinal tract, reaches peak blood concentrations in 15 to 20 min, and circulates with a half-life of 30 to 60 min. However, its inhibitory effect is irreversible and lasts for the life span of the platelet (about 10 days). The bleeding time (BT) has been sometimes used to detect the antiplatelet activity of aspirin, but virtually all recognize that BT has poor reproducibility, sensitivity, and specificity when used to measure platelet-aggregation abnormalities.

Side effects are mainly gastrointestinal and dose related, and may be reduced with concomitant use of antacids, enteric coating, and buffering agents. Aspirin should be avoided in patients with known hypersensitivity and used cautiously in those with bleeding disorders or severe hepatic disease. Active gastrointestinal hemorrhage (e.g., bleeding peptic ulcer) is a contraindication to aspirin use. However, in AMI and unstable angina with occult gastrointestinal bleeding (e.g., guaiac-positive stool), most experts favor aspirin use with careful monitoring.[14] Aspirin therapy is also associated with a slightly increased risk of hemorrhagic stroke (12 per 10,000 over 3 years), but this risk is more than counterbalanced by a tenfold reduction in the risk of myocardial infarction and a threefold reduction in the risk of ischemic stroke.[15]

Blockers of Platelet Aggregation

During platelet aggregation, fibrinogen forms a bridge between adjacent platelets by binding to the platelet-surface receptor, glycoprotein IIb-IIIa. A variety of agents that interfere with the platelet membrane and the glycoprotein IIb-IIIa receptor have been introduced into clinical practice during the past few years.

PLATELET MEMBRANE ALTERING AGENTS   Ticlopidine and clopidogrel deform the region of the platelet membrane next to its fibrinogen receptor and render it ineffective. Both of these agents have little utility in the acute setting. Ticlopidine (250 mg twice daily) improves outcomes in unstable angina but has a 24- to 28-h delay in its onset of action and is associated with reversible neutropenia. Ticlopidine is currently approved for use in patients with cerebrovascular diseases for whom aspirin therapy fails or who are aspirin-intolerant or allergic.[16] Clopidogrel (75 mg per day), a similar agent, has been approved for secondary prevention of AMI and CVA and in established peripheral artery disease. Its side effects include gastrointestinal upset and possible interactions with other medications.[17]

GLYCOPROTEIN IIB-IIIA RECEPTOR INHIBITORS   Abciximab, eptifibatide, and tirofiban, glycoprotein IIb-IIIa receptor inhibitors, have been studied in AMI, unstable angina, and high-risk patients undergoing percutaneous angioplasty (PCTA).[18] Benefit has been consistently found when these agents are used in combination with other antithrombotic (aspirin, ticlodipine, or heparin) and reperfusion (fibrinolytics or PCTA) therapy.[18,19] Patients receiving glycoprotein IIb-IIIa inhibitors are more likely to have bleeding complications (particularly if heparin is also used and usually related to catheterization or coronary artery bypass surgery) but have no increased risk of intracranial hemorrhage. However, there is no clear evidence that glycoprotein IIb-IIIa inhibitors need to be started in the emergency department, as opposed to waiting until the patient reaches the catheterization laboratory or coronary care unit.[20]

Fibrinolytic Agents

Although mechanisms vary, each fibrinolytic agent eventually activates plasminogen to plasmin, which then dissolves the fibrin component of thrombi. Fibrinolytics currently approved in the United States include streptokinase (SK); anisoylated plasminogen-streptokinase activator complex (APSAC), or anistreplase; recombinant tissue plasminogen activator (tPA), or alteplase; reteplase; and urokinase.

STREPTOKINASE AND ANISTREPLASE   SK, derived from b-hemolytic streptococci, binds to and activates plasminogen, producing plasmin, which in turn catalyzes fibrin lysis and thrombus dissolution. Circulating fibrinogen also undergoes plasmin-induced lysis, producing a state of "systemic fibrinolysis." SK is administered as a slow infusion (usually 1.0 to 1.5 million U intravenously over 60 min) and has a serum half-life of about 23 min, but in most patients systemic effects persist for up to 24 h. Because of the prolonged fibrinolytic state and increased risk of hemorrhage, anticoagulation with heparin is usually delayed following treatment with SK. SK is the least expensive fibrinolytic; typical wholesale costs approximate $300 per dose. Anistreplase, a modified active plasminogen-streptokinase complex, has an effect similar to that of SK, but its chief advantage is that it can be administered as a slow bolus (usually 30 mg intravenously over 5 min) and has a serum half-life of about 90 min. Anistreplase is costly ($1700 per dose) and has produced no improvement in outcome when compared to SK. Both SK and anistreplase are antigenic. In the Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries (GUSTO) trial, allergic reactions occurred in about 6 percent of patients treated with SK and subcutaneous heparin.[21] Antibodies to SK develop approximately 5 days after treatment and persist for 6 months; retreatment with SK or anistreplase is not advised during this interval. In addition, SK or anistreplase should not be administered within 12 months of a streptococcal infection.

TISSUE PLASMINOGEN ACTIVATOR AND RETEPLASE   tPA is a naturally occurring enzyme in vascular endothelial cells that directly cleaves a specific peptide bond in plasminogen, converting it to active plasmin, with subsequent fibrinolysis. tPA has binding sites for fibrin, which would suggest specificity for activity in the thrombus and less systemic fibrinolysis. Despite the in vitro clot specificity of tPA, its clinical side-effect profile is comparable to that of other fibrinolytics. The serum half-life of tPA is less than 5 min, and it produces a shorter fibrinolytic state that does SK. Heparin is commonly administered shortly after the completion of tPA infusion. Unlike SK and anistreplase, tPA is not antigenic. In the GUSTO trial utilizing front-loaded tPA and intravenous heparin, the rate of allergic reactions was under 2 percent.[21] Currently, tPA is commonly used for AMI, for which it is administered in a front-loaded format: 15-mg bolus, then 0.75 mg/kg over 30 min (maximum 50 mg), and then 0.50 mg/kg over 60 min (maximum 35 mg; Table 216-1). Reteplase, a derivative of tPA, is dosed as a double bolus (10-U bolus followed by a second dose at 30 minutes).[22] Both tPA and reteplase are expensive, approximately $3000 per treatment.

UROKINASE   Urokinase has become nearly obsolete in acute management of thromboembolic disease, except for dissolution of indwelling-catheter-associated fibrin sheath and thrombosis, for which it is given as a local infusion starting at 500 U/kg/h (without a bolus) delivered directly into the catheter or into the affected vessel.[23] Systemic and other bleeding complications are infrequent with low-dose local therapy.

INDICATIONS FOR ANTITHROMBOTIC THERAPY

Acute Myocardial Infarction

The National Heart Lung and Blood Institute has established the principle that routine AMI patients should receive emergency reperfusion therapy, either fibrinolytic therapy initiated within 30 min or angioplasty within 60 min after arrival in the emergency department. There are four general criteria for emergent fibrinolytic therapy in AMI: (1) clinical presentation consistent with AMI within 12 h of symptom onset, (2) an electrocardiogram showing ST-segment elevation in two or more contiguous leads or new-onset left bundle branch block, (3) absence of contraindications (Table 216-3), and (4) absence of cardiogenic shock. Angioplasty, if available within 60 min of presentation, are preferred over peripheral fibrinolytic therapy for AMI with cardiogenic shock. Important additional considerations, however, include patient age, location of the infarct, relative contraindications to fibrinolysis, and duration of symptoms within the 12-hour criterion.

TABLE 216-3 Contraindications to Fibrinolytic Therapy

The decision to administer a fibrinolytic agent for a routine AMI should be made by the emergency physician. Specialty consultation may only delay treatment under such circumstances and is not necessary before initiating fibrinolysis. Patients who do *not* meet all four eligibility criteria (e.g., because symptoms have been present for >12 h or relative contraindications to fibrinolytic therapy are present) may still derive benefit from fibrinolytic therapy provided that no absolute contraindications are present and the differential diagnosis does not include disorders in which fibrinolytic therapy is harmful (e.g., aortic dissection). Under such circumstances, consultation with the physician who will assume continued definitive care of the patient (e.g., a cardiologist or internist) is reasonable and appropriate before initiating fibrinolysis.

The rapid administration of fibrinolytic therapy is of greater importance than the specific agent used. After this general principle, there is great debate concerning the differential benefit, if any, of particular agents. For example, in the GUSTO trial, the 30-day overall mortality rate with front-loaded tPA and intravenous heparin was 6.3 percent compared to SK and subcutaneous heparin, with a 7.2 percent mortality rate, or SK and intravenous heparin, with a 7.4 percent mortality rate. [21] This approximately 1 percent difference in absolute mortality rates translates into the observation that approximately 100 patients need to be treated with tPA for one additional life to be saved compared to treatment with SK. Further subgroup analysis revealed that the benefits of tPA over SK were less or nonexistent for patients with inferior myocardial infarction, those over 75 years of age, or those in whom fibrinolysis was not initiated until more than 4 h after symptom onset. While SK can be used in most cases, tPA is the agent of choice for patients with any of the following: (1) known allergy to SK or anistreplase, (2) prior administration of SK in the previous 6 months or anistreplase in the previous 12 months, (3) prior streptococcal infection in the previous 12 months, or (4) hemodynamic instability. [14]

Trials of prehospital fibrinolysis for AMI using bolus therapy (anistreplase) suggests that paramedic-initiated fibrinolytic therapy might be delivered earlier than hospital-initiated fibrinolysis without increased complications. [24] However, no mortality rate difference has been demonstrated. Very early fibrinolytic therapy (i.e., within 70 min of symptom onset), whether paramedic- or hospital-initiated, resulted in markedly diminished in-hospital mortality rates and infarct size. The American College of Emergency Physicians has stated that prehospital fibrinolytic therapy for AMI is still investigational, but in rural and remote communities, such therapy seems medically reasonable when excessive delays (>30 min) until arrival at the hospital may occur. [25] Special paramedic training in the clinical evaluation and treatment of AMI must be done on a continuing basis.

Immediate administration of aspirin alone results in a 23 percent reduction in rates from AMI, an effect that is even more pronounced when aspirin is used in combination with a fibrinolytic agent. [14] Aspirin should be given at a dose of 160 to 325 mg (chewed). Intravenous heparin is generally given to patients who receive tPA and is continued for at least 72 h. Intravenous heparin is usually started simultaneously with tPA at a dose of 70 to 80 U/kg intravenous bolus, followed by a continuous infusion of 15 to 18 U/kg/h. As noted above, heparin therapy is usually monitored with the aPTT, which should be first checked 6 h after the bolus dose and every 6 h thereafter during the first 24 h of therapy. Heparin is of uncertain benefit with SK and anistreplase, since it may increase bleeding complications and thus is not recommended if these fibrinolytic agents are used. [14]

Deep Venous Thrombosis or Pulmonary Embolism

Treatment for acute DVT or PE can be accomplished with unfractionated heparin using a weight-based intravenous regimen with monitoring by the aPTT and subsequent adjustments guided by the results. Alternatively, acute PE or DVT can be treated with LMW heparin, either enoxaparin 1 mg/kg or dalteparin 100 IU/kg, administered subcutaneously twice a day. The advantages of LMW heparin are a more predictable anticoagulant effect, easier administration, no requirement for laboratory monitoring, and a decreased risk of complications (major bleeding and heparin-induced thrombocytopenia). LMW heparin appears to be as effective as unfractionated heparin in the treatment of acute DVT or PE and, with the abovementioned advantages, has much to recommend it. The major disincentive to using LMW heparin is greater cost than for unfractionated heparin.

Fibrinolytic therapy offers significant advantages over conventional anticoagulant therapy in DVT and may result in prompt resolution of symptoms, prevention of PE, restoration of normal venous circulation, preservation of venous valvular function, and prevention of the postphlebitic syndrome. [26] Fibrinolytic therapy does not prevent clot propagation, rethrombosis, or subsequent embolization. Heparin therapy and oral anticoagulant therapy must always follow a course of fibrinolysis.

Unfortunately, patients with DVT may have absolute contraindications to fibrinolytic therapy. Fibrinolytic therapy is also not effective once the thrombus is adherent and begins to organize. Venous thrombi in the legs are often large and associated with complete venous occlusion. Theoretically, fibrinolytics, which act on the surface of the clot, may not be able to penetrate and lyse the entire thrombus. In such cases, catheter-directed fibrinolytic therapy is useful. Nevertheless, in selected patients, fibrinolytic therapy is more effective than heparin in achieving vein patency and reduces by half the incidence of postphlebitic syndrome at 3 years.

The hemorrhagic complications of fibrinolytic therapy are formidable (about three times higher than with heparin), including the small, but potentially fatal, risk of intracerebral hemorrhage (Table 216-4). Currently, fibrinolytic therapy is not recommended in routine cases of DVT but may be considered for patients with massive iliofemoral vein thrombosis or young patients with acute onset of extensive DVT.

TABLE 216-4 Inclusion and Exclusion Criteria for Fibrinolytic Therapy in Acute Ischemic Stroke

Ischemic Stroke

Prompt restoration of cerebral blood flow in acute ischemic stroke leads to improvement or resolution of neurologic deficits, but at the risk of intracranial hemorrhage. Only tPA has been shown to benefit carefully selected patients with acute ischemic stroke if given within 3 h of the onset of stroke symptoms. [27]

At the time of publication, three large randomized, double-blind, placebo-controlled studies—the National Institute of Neurologic Disorders and Stroke (NINDS) tPA Stroke Trial, the European Cooperative Acute Stroke Study (ECASS I), and the Second European-Australasian Acute Stroke Study (ECASS II)—had evaluated the efficacy of tPA for ischemic CVA.[28],[29] and [30] Only the NINDS trial found statistical benefit in the primary end points for patients seen within 3 h of stroke symptom onset.[28] Eligibility criteria were strict: only 4 percent of the patients screened in NINDS were eligible for treatment. ECASS I patients were enrolled within 6 h of symptom onset and had no improvement in the primary end points but had some improvement in secondary functional measures and neurologic outcomes.[29] In ECASS II, patients again enrolled within 6 h after symptom onset had no statistical benefit with tPA in the primary end points, although post hoc analysis showed some benefit.[30] All three studies found that fibrinolytic treatment increased the incidence of intracranial hemorrhage from three to ten times, partially reducing the potential benefit of cerebral reperfusion.

In NINDS, patients in the tPA group were given 0.9 mg/kg, up to 90 mg total, over 1 h (10 percent of the total was given as an initial bolus). Antiplatelet and anticoagulation agents were withheld for the first 24 h following treatment. On the basis of these studies, tPA is contraindicated in patients with rapidly improving neurologic signs or minor symptoms, significant pretreatment hypertension (blood pressure > 185/110 mmHg or requiring aggressive therapy to control), seizure at onset, or symptoms suggestive of subarachnoid hemorrhage Table 216-4. Currently, tPA can be recommended only if the protocol used in the NINDS stroke trial is strictly followed. Physicians are advised to obtain informed consent from patients or their proxies in all cases. It is best to have an emergency department policy developed in cooperation with neurologists concerning the administration of tPA for acute CVA.

COMPLICATIONS OF ANTICOAGULATION AND ANTITHROMBOTIC THERAPY

The presentation and management of clinically important bleeding varies by agent. Effective management requires prompt identification of bleeding, supportive care, and agent-specific remedies (see Table 216-5). Major bleeding complications include intracranial hemorrhage or any bleeding requiring transfusion.

TABLE 216-5   Emergency Treatment of Bleeding Complications of Antithrombotic Therapy

Warfarin

Risk of warfarin-induced bleeding is related to the intensity of therapy. For most purposes, the target INR is 2.0 to 2.5, except with mechanical valves, which require more intense anticoagulation (Table 216-1). The INR should be checked regularly, and special care should be paid to patients of extreme age (>80), with low–vitamin K diets, or on antibiotics or other medications with warfarin interactions (Table 216-2).

While melena or unexplained hematomas may be obvious signs of warfarin complications, less obvious presentations should also prompt investigation. Subtle confusion in an elderly patient on warfarin may suggest a subdural hematoma, and tachycardia with back pain may occur with retroperitoneal bleeding. An episode of gastrointestinal bleeding or hematuria may be a marker for underlying pathology and mandates further investigation.

Warfarin excess is confirmed by measuring the PT (INR). In patients with a high PT (INR) *without* clinically evident bleeding, cessation of warfarin, careful observation, and periodic monitoring is the safest course. [31] With clinically significant bleeding, however, reversal may be required, but the speed and extent of reversal must be balanced against the risk of recurrent thromboembolism in patients who require therapeutic anticoagulation. For example, an overanticoagulated patient with a prosthetic mitral valve may develop fatal thrombosis if rapidly and fully reversed. Five methods are available for reversal of warfarin: oral vitamin K_1, subcutaneous vitamin K_1, intravenous vitamin K_1, fresh-frozen plasma (FFP), and coagulation factor concentrates.

One mg of oral vitamin K_1 reliably reverses warfarin overanticoagulation in patients with INRs between 4.5 and 9.5. [32],[33] Reversal is significant by 16 h, and the INR is within the therapeutic range by the second day. Subcutaneous vitamin K_1 (1 to 2 mg) reverses warfarin, with a measurable effect on the INR by 8 to 12 h. [34] Additional doses are often required up to a mean total dose of 4 to 5 mg to return the INR to 3 or less. Both oral and subcutaneous vitamin K_1 are given as warfarin doses are withheld, and both approaches require normal liver function to be effective. Low-dose oral and subcutaneous vitamin K_1 carry a small risk for patients who require therapeutic anticoagulation, and it is recommended that the emergency physician consult an appropriate specialist before using either approach.

Intravenous vitamin K_1 carries a rare but serious risk of anaphylaxis and should not be used for routine reversal of therapeutic overanticoagulation. For patients who require continued anticoagulation, intravenous administration carries the risk of overcorrection not associated with oral or subcutaneous use. [35] For patients with INRs between 6 and 12, the intravenous dose of vitamin K_1 should be 0.5 mg.[36] Intravenous vitamin K_1 should be used for patients poisoned by an ingestion of warfarin (suicidal overdose) or a rodenticide (superwarfarin). [37] Generally, such patients do not require therapeutic anticoagulation, and reversal does not carry the risk of recurrent thrombosis. Since the theapeutic half-life of vitamin K_1 is short (2 h) and that of warfarin is long (up to 4 days), significantly poisoned patients require continued doses until the therapeutic effect of warfarin is depleted.

From the standpoint of the risk of recurrent thrombosis, the safest method of reversing therapeutic overanticoagulation is with coagulation factor infusion using either FFP or factor concentrates. A dose of FFP 15 mL/kg (typically 3 U) will acutely restore coagulation factor levels to at least 30 percent of normal and control most bleeding without undue risk. Reversal of anticoagulation with FFP is usually safe for short periods, regardless of indication for anticoagulant therapy. [38] For patients with life-threatening hemorrhage and who require rapid, complete reversal, coagulation factor concentrates are more reliable and preferred. [39]

Heparin

Heparin-induced bleeding is treated according to the clinical severity and aPTT level. [40] Up to one-third of patients receiving heparin develop some form of bleeding complication, with a 2 to 6 percent risk for major bleeding. An increased risk (up to 20 percent) for major bleeding is associated with a number of comorbid conditions, including recent surgery or trauma, renal failure, alcoholism, malignancy, liver failure, and gastrointestinal bleeding as well as the concurrent use of warfarin, fibrinolytics, steroids, or antiplatelet drugs. Unfortunately, heparin-associated bleeding is not always reflected by a supratherapeutic aPTT. Other complications of brief heparin use include a benign transient thrombocytopenia (due to splenic sequestration and platelet aggregation), and allergic reactions.

A more serious problem is HIT. Heparin therapy must be stopped as soon as the condition is recognized. Protamine is not effective against this immune-mediated response. The platelet count generally returns to normal in 4 to 6 days. During the recovery phase, however, the risk of arterial or venous thrombosis is substantially elevated, and the potential complications include gangrene, stroke, and death. It is unclear whether such patients should ever be exposed to heparin again. LMW heparin preparations do not eliminate the risk of HIT, because of potential cross-reactivity.

If bleeding develops during heparin therapy, heparin administration should be stopped immediately. While heparin's half-life is dose dependent (30 to 150 min), its anticoagulation effect can last up to 3 h. Thus, observation may be appropriate in less severe cases, with serial aPTTs used to determine when therapy may be

resumed. While protamine can reverse the anticoagulant effect of heparin (a ratio of 1 mg intravenous protamine neutralizes 100 U of heparin administered in the prior 4 h), the adverse effects of protamine are significant. Protamine should be given slowly intravenously over 1 to 3 min and not exceed 50 mg in any 10-min period. However, because the half-life of protamine is short, a heparin rebound may occur, requiring a second treatment. Allergic reactions are possible, and about 0.2 percent of patients receiving protamine develop anaphylaxis (which has a 30 percent mortality rate). Thus, protamine should be reserved for major bleeding complications.

In general, LMW heparin preparations cause less bleeding than does unfractionated heparin. The effectiveness of protamine in reversing LMW heparin effects is compound specific; for example, protamine does not completely reverse the actions of enoxaparin.

Aspirin

Upper gastrointestinal irritation is the most common side effect of aspirin therapy, while life-threatening gastrointestinal bleeding is uncommon. [41] As noted above, intracranial hemorrhage, the most feared complication of anticoagulation and antithrombotic therapy, appears to occur rarely with aspirin alone. [15] Some patients are markedly sensitive to aspirin such that even low doses lead to markedly prolonged bleeding times and risk of severe clinical hemorrhage, particularly related to surgery or trauma. Uremic patients are especially sensitive to bleeding induced by aspirin. The combination of alcohol and aspirin can also prolong a patient's bleeding time.

Unfortunately, the BT is a poor test to confirm bleeding complications of aspirin. If aspirin-associated bleeding is suspected [e.g., persistent oozing after tooth extraction despite normal platelet count (>100,000/μL) and coagulation studies], further workup should include obtaining a careful history for ingestion (significant unintentional ingestion may occur, since some 300 over-the-counter medications contain aspirin), and a salicylate level. Management of acute aspirin-induced hemorrhage involves the transfusion of enough normal platelets to increase the platelet count by 50,000/μL (e.g., 6 U). Because of the irreversible effect of aspirin on platelets, the hemostatic compromise might last for 4 to 5 days after aspirin has been discontinued, and platelet transfusions may have to be repeated daily.

Fibrinolytics

The most significant complications of fibrinolytic therapy are hemorrhagic, and the most catastrophic complication is intracranial hemorrhage, seen in at least 1 to 3 percent of patients. [42] In the GUSTO trial, the incidence of "moderate or worse" bleeding was highest in the front-loaded tPA plus heparin arm. [21] Fibrinolytics should not be given to any patient with an absolute contraindication (Table 216-3 and Table 216-4). In patients with a relative contraindication, careful weighing of potential risks and benefits of fibrinolysis in consultation with the physician who will assume in-hospital care of the patient is indicated.

Allergic reactions and anaphylaxis from SK and anistreplase should be treated with 50 mg diphenhydramine and 125 mg methylprednisolone intravenously. Hypotension occurs in up to 10 percent of patients treated with either SK or tPA, and is treated by slowing the fibrinolytic infusion rate and administering intravenous crystalloid, paying close attention to the patient's volume status.

To minimize the bleeding risks associated with fibrinolytic therapy, the following precautions should be observed: (1) avoid all unnecessary needle sticks, (2) avoid any arterial punctures, (3) limit venous access to easily compressible sites (e.g., avoid central lines, especially the jugular or subclavian veins), and (4) avoid both nasogastric tubes and nasotracheal intubation.

Careful monitoring of the patient is crucial. The hematocrit should be checked every 4 to 6 h after fibrinolytic therapy is initiated. A fall in hematocrit of greater than 2 percent should prompt a search for the source of blood loss. Most bleeding episodes (more than 70 percent) occur at vascular puncture sites, but intracranial, intrathoracic, retroperitoneal, gastrointestinal, genitourinary, or soft-tissue extremity hemorrhage may occur.

External bleeding at any site should be controlled with prolonged manual pressure. Significant bleeding, especially from an internal site, mandates discontinuation of the fibrinolytic agent, aspirin, and heparin. Volume replacement using normal saline or lactated Ringer's solution should be provided as necessary and supplemented with red blood cell transfusions if clinically indicated. The thrombin time, aPTT, platelet count, and fibrinogen level should be checked. Heparin administered within 4 h of the onset of bleeding can be reversed with protamine (1 mg of protamine for every 100 U heparin).

Massive bleeding with hemodynamic compromise necessitates coagulation factor replacement in addition to the interventions recommended above. Ten units of cryoprecipitate (rich in fibrogen) should be administered and the fibrinogen level rechecked. If the fibrinogen level is less than 100 mg/dL, the dose of cryoprecipitate should be repeated. If bleeding continues after cryoprecipitate or if bleeding persists despite a fibrinogen level above 100 mg/dL, 2 U of FFP should be given. If bleeding persists after appropriate cryoprecipitate and FFP treatments, a BT should be checked. If it is less than 9 min, 10 U of platelets should be administered, followed by an antifibrinolytic agent (e.g., e-aminocaproic acid or tranexamic acid); if the BT time is less than 9 min, platelets are not necessary, but an antifibrinolytic agent should still be administered for continuing hemorrhage. The dose of e-aminocaproic acid is 5 g intravenously over 60 min, followed by a continuous infusion of 1.0 g/h for 8 h or until bleeding stops. The dose of tranexamic acid is 10 mg/kg intravenously every 6 to 8 h.

Fibrinolytic-associated intracranial hemorrhage requires an aggressive and rapid approach. Immediately discontinue the fibrinolytic agent, aspirin, and heparin. Administer protamine in the dose outlined above if the patient received heparin. The patient should also receive cryoprecipitate, FFP, platelet transfusion, and an antifibrinolytic agent (e.g., e-aminocaproic acid or tranexamic acid). A neurosurgeon should be consulted immediately.

217 EMERGENCY COMPLICATIONS OF MALIGNANCY

John J. Sverha
Marc Borenstein

The approach to patients with potential emergency complications of malignancy can be hindered by many factors. Patients may be uncomfortable or have insufficient knowledge to candidly discuss the extent of their malignancy in the emergency department (ED). The emergency physician may be unfamiliar with the large and frequently changing number of chemotherapeutic agents as well as the complex classification and staging of malignancies. Both patients and physicians may have the false impression that aggressive diagnostic and therapeutic interventions are futile in the presence of advanced malignancy.

Changing trends in the management of cancer-related emergencies include an increasing number of older patients receiving chemotherapy, more aggressive chemotherapy regimens, broader use of chemotherapy particularly with solid tumors (nonhematologic malignancies), and an increasing use of bone marrow transplantation. This, coupled with an increasing prevalence of malignant disease, longer patient survival, and increased complications of treatment, demands from emergency physicians the ability to recognize and treat a wide spectrum of oncologic emergencies.

Myelosuppression from chemotherapy and radiotherapy can result in coagulopathies and infection. Tumor growth can produce signs and symptoms of local compression on the spinal cord or airway, and certain tumors are associated with unique complications, such as hyperviscosity syndromes from tumor-related gammopathies. Table 217-1 lists the most important life-threatening oncologic emergencies. Table 217-2 lists common chemotherapeutic agents, their indications, and toxicities associated with their use.

Related to local tumor compression
   Acute spinal cord compression
   Upper airway obstruction
   Malignant pericardial effusion with tamponade
   Superior vena cava syndrome

Related to biochemical derangement and systemic collapse
   Hypercalcemia of malignancy
   Syndrome of inappropriate ADH (SIADH)
   Hyperviscosity syndrome
   Adrenocortical insufficiency with shock

Related to myelosuppression
   Granulocytopenia and sepsis
   Immunosuppression and opportunistic infections
   Thrombocytopenia and hemorrhage
   Anaphylaxis and transfusion reactions

TABLE 217-1   Emergency Complications of Malignancy

TABLE 217-2   Chemotherapeutic Agents: Toxicities and Therapeutic Uses

ACUTE SPINAL CORD COMPRESSION

Multiple myeloma
Non-Hodgkin's and Hodgkin's lymphomas
Lung carcinoma
Prostate carcinoma
Breast carcinoma

Spinal cord compression can result from bleeding, infection, or fracture. It may be the first sign of a neoplasm or can complicate pre-existing metastatic disease. The incidence is estimated at greater than 5 percent, and repeated occurrences in the same patient have been reported. Spinal cord compression occurs most commonly as a complication of breast or lung carcinoma and lymphoma. In at least 95 percent of patients, a long history of back pain, often several weeks to several months, elapses prior to diagnosis. The pain is progressive in severity and duration, typically continuous, and requires analgesics. It may be radicular, and when affecting the thoracic spine, radicular pain is characteristically bilateral. Symptoms and signs of myelopathy are late findings. Once neurologic deficits from spinal cord compression are present, the tempo of deterioration increases dramatically, with some patients progressing from weakness to complete paralysis in a matter of hours. Once ambulatory function is seriously impaired or lost, less than 10 percent of patients recover the ability to ambulate despite aggressive management.

The single most important approach to the diagnosis of spinal cord compression is for the emergency physician to recognize the significance of persistent, progressive unexplained back or neck pain in a patient with known malignancy. Symptoms suggestive of cord compression include decreased sensation, urinary retention, lower extremity weakness, and difficulty with walking. Pain of involved vertebrae may be localized and/or intensified with percussion during physical examination. The neurologic examination should assess reflexes, motor and sensory function, rectal sphincter tone, and gait. A major exception to the nearly routine presence of pain is in lymphoma; if lytic bony metastases are absent, the patient may have a diminished sensory level or flaccid paralysis with absent or minimal pain.

Plain radiographs should be obtained in any patient having a history of malignancy who presents with persistent, progressive back or neck pain. In the absence of

prior disk or degenerative disease associated with chronic back pain or acute trauma, this principle may be applied to all adult patients presenting with unexplained persistent, progressive back pain of 1 to 6 months' duration, particularly in patients over age 50. Discovery of bony metastases on radiographs *even in the absence of any neurologic deficits* requires either magnetic resonance imaging (MRI) or myelography. Although still the "gold standard" in many institutions, myelography is being supplanted by MRI.

If spinal cord compression is suspected, dexamethasone 100 mg/day IV in four divided doses should be initiated in the ED and typically is tapered over 4 to 5 days. The patient's overall status should be assessed with hematologic, electrolyte, and other laboratory studies. Further treatment decisions, including candidacy for emergency surgery, is assessed by a team approach using neurosurgery, oncology, radiology, and radiation oncology. Radiation therapy is the definitive treatment for most patients. Surgical laminectomy and decompression are indicated if there is architectural instability, tissue confirmation of cancer is required, maximal radiation therapy has been given previously, or the tumor is particularly radioresistant.

UPPER AIRWAY OBSTRUCTION

Laryngeal carcinoma
Thyroid carcinoma
Lymphoma
Metastatic lung carcinoma

Acute upper airway obstruction is generally associated with aspiration of foreign bodies or food, with epiglottitis, or with other oropharyngeal infections. Malignancy-related obstruction to airflow is more insidious and often attended by voice change. This is generally a late manifestation of tumors arising in the oropharynx, neck, and superior mediastinum. Acute compromise is uncommon unless infection, hemorrhage, or inspissated secretions supervene. Rapidly growing tumors such as Burkitt's lymphoma and anaplastic carcinoma of the thyroid are capable of compromising airflow within weeks and should be suspected in afebrile individuals with stridor and palpable anterior neck masses.

Fiberoptic laryngoscopy is usually necessary to evaluate airway lumen size, because local anatomy is generally greatly distorted. Lateral soft-tissue x-rays are of value in assessing laryngotracheal patency. Establishment of an effective airway is crucial, and surgical tracheostomy may be required prior to the intitiation of radiotherapy.

MALIGNANT PERICARDIAL EFFUSION WITH TAMPONADE

Malignant melanoma
Hodgkin's lymphoma
Lung carcinoma
Breast carcinoma
Ovarian carcinoma

Malignant melanoma has special predilection for the heart, but the most common cause of malignant pericardial effusion is carcinoma of the lung and breast. Pericardial disease also can result from mediastinal irradiation, infection, or drugs such as cyclophosphamide, granulocyte-macrophage colony-stimulating factor (GM-CSF), and cytarabine.

The hemodynamic consequences of malignant pericardial effusions are a function of the volume and speed of accumulation. Even collections greater than 500 mL may be well tolerated if development is slow. Sudden intrapericardial bleeding is associated with dyspnea, chest pain, and hypotension. If the myocardium is also involved with metastatic disease, cardiac dysfunction will result in a decrease in cardiac output as well.

The classic clinical features of cardiac tamponade are (1) hypotension and a narrowed pulse pressure, (2) jugular venous distention, (3) diminished heart sounds, (4) pulsus paradoxus greater than 10 mmHg, (5) low QRS voltage on electrocardiography, and (6) cardiomegaly without evidence of congestive heart failure on chest radiograph. Diagnosis is confirmed by echocardiography. Emergency percutaneous pericardiocentesis may be life-saving. It can be done blindly, if extreme haste is needed, or under fluoroscopic guidance.

The care of patients with malignant pericardial effusions who are not in extremis should be discussed with an oncologist. The patient's tumor type, symptom severity, and prognosis are all considered in determining a treatment plan that may include systemic chemotherapy, intrapericardial chemotherapy, elective pericardiocentesis, creation of a pleuropericardial window, or other surgical techniques.

CORONARY ARTERY DISEASE

Many cancer patients also have coronary artery disease. Anemia from bone marrow suppression or malignant infiltration can result in decreased myocardial oxygen supply. Interferon and interleukin 2 (IL-2) can increase cardiac output, resulting in an increased myocardial oxygen demand. Several chemotherapeutic agents have been associated with cardiac ischemia, including 5-fluorouracil, vinblastine, and IL-2. Sternal pain mimicking angina has been associated with GM-CSF.

Many agents have been associated with tachyarrhythmias, bradyarrhythmias, and atrioventricular conduction blocks. These include the anthracyclines, 5-fluorouracil, interferon, IL-2, GM-CSF, and paclitaxel. Myocarditis has been reported in association with anthracyclines and cyclophosphamide. Anthracyclines are directly toxic to myocardial cells, while cyclophosphamide toxicity appears to be vascular. Anthracycline-induced cardiomyopathy may occur months to years after cessation of treatment and is related to the total cumulative dose. It is irreversible. It is evaluated and managed in the same manner as any dilated, congestive cardiomyopathy.

SUPERIOR VENA CAVA SYNDROME

Small-cell (oat-cell) lung carcinoma
Squamous cell lung carcinoma
Lymphoma
Breast carcinoma

The superior vena cava syndrome is frequently a de novo diagnosis first established in the ED. A history of previously documented malignancy is often lacking, and patients may seek medical attention because of the insidious and progressive nature of their symptoms. Obstruction to blood flow in the superior vena cava elevates venous pressure in the arms, neck, face, and cerebrum. Patients with moderate obstruction complain of headache, edema of the face and arms, or a nondescript feeling of head congestion and fullness in the neck and face. As venous pressure rises, intracranial pressure also rises, and syncope may ensue. Critical intracranial pressure elevations associated with bilateral papilledema are rare but represent a true medical emergency.

On physical examination, neck vein and upper chest vein distention may be apparent. Facial plethora and telangiectasia often are prominent, but edema of the face and arms is generally subtle. Papilledema on funduscopic examination indicates critical intracranial pressure and justifies early diuretic therapy. A palpable supraclavicular mass due to direct tumor extension occasionally can be noted with tumors of the superior mediastinum. Chest radiography will demonstrate an enlarged mediastinum and possibly an isolated primary lesion in the lung parenchyma.

Prompt administration of diuretics and glucocorticoids may help reduce venous pressure. Furosemide 40 mg intravenously, methylprednisolone 120 mg intravenously, or dexamethazone 16 to 20 mg intravenously is frequently used.

Superior vena cava compression is generally not life-threatening. In most cases, it is very important to obtain tissue diagnosis prior to initiation of therapy because

treatment with chemotherapeutic agents may be used exclusively or combined with radiation therapy depending on specific tumor type. Tissue sampling can be done safely by a number of approaches, including fiberoptic bronchoscopy with transbronchial biopsy, lymph node biopsy, pleural fluid cytology, needle biopsy, or limited thoracotomy.

HYPERCALCEMIA OF MALIGNANCY

Renal cell carcinoma
Multiple myeloma
Squamous cell lung carcinoma
Breast carcinoma
Lymphoma

Mild elevations of serum calcium are well tolerated and produce little in the way of symptoms. However, when serum calcium levels rise rapidly or exceed ionic thresholds, cardiac, neural, and muscular electrophysiology may be greatly altered. A number of mechanisms have been identified that promote release of bony calcium into the circulation. Bony involvement with myeloma, carcinoma of the breast, or carcinoma of the lung will release calcium by local matrix destruction. Squamous cell carcinoma of the lung may produce a parathormone-like substance, and an osteoclast-activating factor has been associated with lymphoma.

Approximately 40 percent of patients with multiple myeloma will have hypercalcemia, often accompanying the clinical triad of back pain, anemia, and lethargy. Hypercalcemia from any cause may produce nausea, vomiting, anorexia, and constipation. Altered mental status, confusion, and coma are consistent with rapid and/or high levels of hypercalcemia. Elevated ionized calcium is responsible for neuromuscular dysfunction, and therefore, serum calcium levels should be interpreted in conjunction with serum phosphorus, albumin, and blood pH determinations. The QT interval of the electrocardiogram may shorten as the serum calcium rises.

The majority of patients with malignancy-induced hypercalcemia will improve with saline infusion and intravenous furosemide (1–2 L saline load and 80 mg of IV furosemide). This will promote renal calcium excretion but depends on adequate renal function and glomerular filtration. Because renal insufficiency is a common accompaniment in myeloma, assessment of blood urea nitrogen and creatinine levels is important to ensure both adequacy of response and avoidance of iatrogenic fluid overload. Hemoconcentration and dehydration additionally may aggravate hypercalcemia. For severe hypercalcemia, hemodialysis or peritoneal dialysis against a low- or no-calcium dialysate may be necessary.

Other measures are part of the overall management of hypercalcemia but have an onset of action that is too slow to be effective in the ED. The intravenous administration of inorganic phosphate is a rapid and effective method for decreasing blood calcium level but should not be used in most patients because it may produce metastatic tissue calcification leading to hypotension, renal failure, and death. Oral phosphate, given as 1 g of sodium acid phosphate daily, produces a maximal effect after several days. Glucocorticoids should not be given prior to oncology consultation because they may become part of the patient's chemotherapy regimen. The effect of glucocorticoids is greatest in the hematologic malignancies, lymphomas, and breast cancer but may take several days to develop. Mithromycin acts by inhibiting bone resorption. The dose is 25 µg/kg delivered as an IV infusion, and its effect is usually evident in 24 to 48 h.

SYNDROME OF INAPPROPRIATE ADH

Primary and metastatic malignancy of the brain
Small cell lung carcinoma
Pancreatic adenocarcinoma
Prostate carcinoma

Ectopic secretion of antidiuretic hormone (ADH) may come from a variety of malignancies. In addition, excessive endogenous secretion of ADH may be caused by chemotherapy (*Vinca* alkaloids, cyclophosphamide), narcotics, phenothiazines, antidepressants, and head trauma. Regardless of etiology, the syndrome of inappropriate ADH (SIADH) consists of serum hyponatremia, less than maximally dilute urine, excessive urine sodium excretion (U_{Na} > 30 meq/L), and decreased serum osmolarity, all in the presence of euvolemia, absence of diuretic therapy, and normal renal, adrenal, and thyroid function.

Symptoms of hyponatremia range from anorexia, nausea, vomiting, and weakness to confusion, decreased mental status, seizures, and coma. Patients with a serum sodium level above 125 mEq/L generally are asymptomatic or mildly symptomatic and usually can be controlled with water restriction of 500 mL/day along with close follow-up. Demeclocyline, a tetracycline derivative, can be given at a dose of 250 mg qid, and this raises the serum sodium by producing a nephrogenic diabetes insipidus. Patients with serum sodium concentrations below 115 mEq/L may present with severe, life-threatening manifestations requiring acute care monitoring, meticulous attention to intake and output measurements, and frequent electrolyte determinations. Furosemide 0.5 to 1.0 mg/kg is given with normal saline supplementation to maintain euvolemia and effect a net free water clearance. In addition, 3% hypertonic saline may be used, but the amount must be calculated carefully to avoid volume overload and congestive heart failure. Hemodynamic monitoring may be necessary for patients with associated cardiopulmonary disease. Seizures, when present, are typically tonic-clonic and may be recurrent. Treatment is with standard loading doses of phenytoin. Focal seizure or the development of neurologic deficits requires head computed tomographic (CT) imaging. To avoid the development of central pontine myelinolysis, the rate of rise in serum sodium should not exceed 1 mEq/L per hour.

HYPERVISCOSITY SYNDROME

Multiple myeloma
Waldenström's macroglobulinemia
Chronic myelocytic leukemia

Viscosity is the flow-resisting characteristic of fluids. Marked elevations in certain serum proteins will produce sludging and a reduction in microcirculatory perfusion. IgA myeloma components and IgG subtype 3 proteins have a tendency to polymerize, leading to symptomatic hyperviscosity. Macroglobulinemia is the most common cause for hyperviscosity by virtue of the high molecular weight and high intrinsic viscosity of IgM proteins. Serum viscosity relative to water is normally 1.4 to 1.8, and symptoms develop at viscosities greater than five times that of water.

Fatigue, headache, anorexia, and somnolence are early nonspecific symptoms. As blood flow slows, microthromboses may occur, with the advent of local symptoms such as deafness, visual disturbances, and jacksonian or generalized seizures. The diagnosis of hyperviscosity must be considered in the emergency department when patients with unexplained stupor or coma are found to have anemia, with rouleau formation on the peripheral blood smear. The most readily appreciated physical findings are in the ocular fundi and include "sausage-linked" retinal vessels, hemorrhages, and exudates. Laboratory evaluation should include coagulation, renal, and electrolyte profiles. Hypercalcemia can coincide, and when M-component protein concentrations are high, "factitious" hyponatremia may also be present. A clue to the presence of hyperviscosity may be the laboratory's inability to perform chemical tests because of the serum stasis in the analyzers, undoubtedly due to "too thick" blood. Serum viscosity and protein electrophoresis determinations are diagnostic.

The emergency physician's role is predominantly suspicion and recognition of the syndrome in patients with unexplained stupor and coma. Hyperviscosity is generally a presenting manifestation of certain plasma cell dyscrasias, and a history of previously documented disease is often lacking. Initial therapy is rehydration followed by hematology consultation and emergency plasmapheresis. When coma is present and the diagnosis rapidly established, a temporizing measure may be a two-unit phlebotomy with saline infusion and replacement of the patient's red cells.

ADRENAL INSUFFICIENCY AND SHOCK

Lung carcinoma
Breast carcinoma
Malignant melanoma
Retroperitoneal malignancies
Withdrawal of chronic steroid therapy

Adrenal insufficiency may be related to adrenal gland replacement by metastatic tumors or to adrenocortical suppression by therapeutic glucocorticoid administration. In either case, maximal adrenal function may be inadequate to support the individual when stressed by infection, dehydration, surgery, or trauma. Adrenal crisis and shock with vasomotor collapse may be sudden and fatal. The differential diagnosis of cancer patients with fever, dehydration, hypotension, and shock would more frequently include sepsis and hemorrhagic shock. Adrenal crisis is less common than bleeding and sepsis, but the steroid-dependent patient should be empirically given intravenous steroids with both glucocorticoid and mineralocorticoid effect.

Laboratory clues to the possible concomitant presence of adrenal insufficiency may be mild hypoglycemia, hyponatremia, hyperkalemia, and eosinophilia. Azotemia is, however, nonspecific and is often present in dehydration from any cause. In suspected cases, a serum cortisol should be drawn prior to steroid treatment.

Normal adrenal glands maximally produce approximately 300 mg per day of hydrocortisone when stressed. This has served as a guideline for replacement therapy. Adrenalectomized individuals are maintained on average doses of 35 to 40 mg of hydrocortisone per day, and this is increased during potential stress. Appropriate emergency doses of hydrocortisone hemisuccinate (Solucortef) would be 250 to 500 mg intravenously.

GRANULOCYTOPENIA, IMMUNOSUPPRESSION, AND INFECTION

Overwhelming infection is a common cause of death in the immunocompromised host. A variety of factors may contribute to increased susceptibility to infection in cancer patients. Important factors include

1. Malnutrition and cachexia
2. CNS dysfunction
3. Granulocytopenia
4. Impaired humoral immunity and antibody production, as in chronic lymphocytic leukemia or multiple myeloma
5. Altered cellular immunity, as in Hodgkin and other lymphomas
6. Postsplenectomy susceptibility to serious pneumococcal infections
7. Reactivation tuberculosis with concurrent glucocorticoid therapy
8. Polymicrobial enteric sepsis from bowel organism entry; carcinoma of colon or mucosal damage from chemotherapy
9. Nosocomial infections transmitted through blood transfusion and blood products
10. Immunosuppression and myelosuppression of chemotherapy
11. Indwelling catheters

Both the frequency of infection and the mortality rate increase significantly when the circulating granulocyte pool is below 1000 to 1500/µL. Cancer patients are at risk for a variety of bacterial, viral, and fungal infections. Frequently encountered infections include pneumococcal sepsis and pneumonia; *Staphylococcus aureus* infection; enteric gram-negative pneumonia or sepsis, including *Pseudomonas* infections; and localized or disseminated varicella-zoster viral and cytomegalovirus infections. Immunosuppression predisposes to invasion by organisms that are normally held at bay by host defenses and biocompetition from normal body flora. Such opportunistic infections include *Pneumocystis carini* pneumonia (protozoal), disseminated candidiasis, aspergillosis, cryptococcal meningitis, pulmonary nocardiosis, and histoplasmosis. Recent trends include a decreasing incidence of *Pseudomonas* and an increasing incidence of methicillin-resistant staphylococci and the emergence of gram-positive coryne-bacteria.

Patients with an absolute neutrophil count of 500 or less and a fever greater than 38.5°C on one occasion or greater than 38°C on two to three occasions constitute a true medical emergency. Although only 60 to 80 percent of neutropenic patients with fever are culture proven or clinically documented to have an infectious etiology (the others presumably have fever secondary to the malignant process itself or its treatment), the emergency physician must assume an infectious etiology and act accordingly, rapidly obtaining cultures and initiating appropriate antibiotics. Life-threatening sepsis, regardless of specific antimicrobial etiology, may progress rapidly, producing shock and irreversible end-organ damage. Restoration of euvolemia and the use of broad-spectrum bactericidal antibiotics are recommended. Attention to local institutional bacterial sensitivities is very important in making specific antibiotic choices. Frequently used combinations include an aminoglycoside (gentamicin or tobramicin) with an extended-spectrum penicillin (ticarcillin) or an aminoglycoside (gentamicin or tobramicin) with an third-generation cephalosporin (ceftazidime or ceftriaxone). Amikacin should be reserved for bacterial resistance documented on culture and not initiated as part of an initial regimen. Empirical use of vancomycin for methicillin-resistant staphlococci generally depends on the degree to which these organisms are encountered at one's institution. Aztreonam or the new fluoroquinolones may be substituted for an extended-spectrum penicillin or a third-generation cephalosporin if a patient is highly penicillin allergic with a history of serious systemic reaction or anaphylaxis. Anaerobic coverage may be obtained by the addition of clindamycin or metronidazole.

BONE MARROW TRANSPLANTS

Emergency physicians can expect to care for increasing numbers of bone marrow transplant patients due to the rising prevalence and survivability of this procedure. Bone marrow transplants are currently performed for malignant conditions such as leukemia, lymphoma, and selected solid tumors as well as for nonmalignant conditions such as aplastic anemia, thalassemia, and sickle cell anemia.

Bone marrow transplants can be categorized as either allogeneic or autologous. In an allogeneic transplant, bone marrow is first obtained from an HLA-matched donor, preferably a sibling. The patient then receives high-dose chemotherapy or radiotherapy to eliminate native bone marrow and destroy residual cancer cells. The donor marrow is then administered to the recipient intravenously. The recipient is profoundly myelosuppressed for a period of 1 to 3 weeks until the transplanted cells assume their place in the recipient's bone marrow by a process known as *engraftment*. Autologous transplantation is performed in a similar manner, although a sample of a patient's own marrow is taken before high-dose chemotherapy, and it is this sample that is used to reestablish hematopoetic cell function.

Emergency physicians are unlikely to encounter the acute complications of bone marrow transplantation because these patients often are kept in the hospital for several weeks following their transplant until engraftment occurs. However, emergency physicians should be aware of the long-term complications and consequences of bone marrow transplantation. Like solid-organ transplant recipients, bone marrow recipients are at increased risk of infection. This risk is not just confined to the period of granulocytopenia preceding engraftment. Even with a normal neutrophil count, bone marrow transplant patients have a residual cellular and humoral immunodeficiency that persists for 12 to 24 months after transplantation. Return of immune function generally is slower in allogeneic transplant recipients than in autologous transplant recipients. Bone marrow transplant patients are at particular risk of infection from encapsulated bacteria, *Pneumocystis carinii,* cytomegalovirus (CMV), varicella-zoster virus, *Candida,* and *Aspergillus.* CMV pneumonitis is the most common infectious cause of death after bone marrow transplantation and typically occurs 1 to 6 months following the transplant. To decrease the risk of opportunistic infection, bone marrow transplant patients are often prophylactically administered penicillin, trimethoprim-sulfamethoxazole, and ganciclovir for the first 3 to 6 months following their transplant. A fever or other sign of infection should be taken very seriously in a bone marrow transplant patient (even if the neutrophil count is normal), and a treatment plan should be developed in conjunction with the patient's hematologist.

A complication unique to bone marrow transplant patients is graft-versus-host disease. This disorder occurs only in allogeneic transplant patients. It is caused by immunologically competent donor cells attacking target antigens in the recipient. Patients develop rash, diarrhea, and an elevated serum bilirubin level. The diagnosis is confirmed histologically by appropriate biopsy. Without treatment, the condition is often fatal. Treatment with prednisone, cyclosporine, antithymocyte globulin, or thalidomide improves the long-term prognosis of these patients. Unfortunately, these drugs also delay immunologic recovery and increase the risk of opportunistic infection.

Another unusual complication of bone marrow transplantation is hepatic venoocclusive disease. This condition usually occurs within 30 days of transplantation and is caused by thrombotic obstruction of small intrahepatic venules with resulting damage to the surrounding centrilobular hepatocytes. The exact precipitant of this disease is unknown. The diagnosis should be considered in patients with jaundice, tender hepatomegaly, and ascites. Up to 20 percent of all bone marrow transplant recipients have some degree of hepatic venoocclusive disease. In severe cases, progressive hepatic and renal failure occur. Treatment is largely supportive, although

thrombolytic therapy has shown some promise.

HEMATOLOGIC SYNDROMES

Thromboembolism is not uncommon in cancer patients and is due to a number of factors such as a hypercoagulable state; decreased proteins C, S, and antithrombin III; and the effect of metastases on activation of the coagulation pathway. Cancer patients are at increased risk for both deep venous thrombosis and pulmonary embolism. However, anticoagulation may result in bleeding at sites of metastatic disease, so that treatment options are more complex and may include placement of a filter in the inferior vena cava.

Polycythemia is enhanced production of red cells due to increases in sensitivity of erythropoietin. Any organ system can be affected by resulting thrombosis, bleeding, or hyperviscosity, but CNS effects are the most devastating. Celiac or mesenteric vessel ischemia, or Budd-Chiari syndrome, is seen when gastrointestinal vessels are involved. If the hematocrit is greater than 60 percent and symptoms are present, emergency phlebotomy is necessary.

Either acute or chronic leukemias can result in white blood cell counts greater than 100,000/μL. A leukocrit of greater than 10 percent is often associated with clinically significant hyperviscosity, and CNS dysfunction and respiratory distress can occur from capillary leukostasis. Diuretics worsen symptoms because they will increase the leukocrit. Treatment is directed at the underlying malignancy, and allopurinol should also be administered in anticipation of massive tumor lysis, to prevent acute gouty arthropathy and renal failure.

GASTROINTESTINAL SYNDROMES

Acute gastrointestinal complications may or may not be related to the underlying malignancy. In patients with cancer, even gastric cancer, the major causes of gastrointestinal bleeding are still hemorrhagic gastritis and peptic ulcer disease. Intraarterial hepatic chemotherapy infusions have been associated with gastrointestinal bleeding, especially from the duodenum. Chemotherapy or radiotherapy can cause vomiting, resulting in Mallory-Weiss tears or reflux esophagitis.

Cancer patients with acute abdominal processes present with typical signs and symptoms unless they are receiving exogenous steroids. Acute appendicitis has been reported to occur in up to 4 percent of patients with leukemia.

RENAL AND UROLOGIC SYNDROMES

Renal insufficiency in the cancer patient often has multiple etiologies. Prerenal azotemia is common due to vomiting, anorexia, or diuretic use. Hepatic and peritoneal disease also may cause sequestration of fluid in the peritoneal cavity, leading to intravascular volume depletion. Multiple myeloma and lymphoma can cause rapidly progressive renal failure by intraglomerular amyloid deposition. In addition, several chemotherapeutic agents (i.e., carmustine, cisplatin, and mitomycin) are directly nephrotoxic.

Urologic emergencies in the cancer patient include urinary tract hemorrhage, urinary tract obstruction, and priapism. Gross hematuria is often the presenting symptom of urinary tract cancers but also can be caused by local invasion of the urinary tract by colonic or gynecologic tumors. Hemorrhagic cystitis occurs after cyclophosphamide administration in about 5 percent of patients. Hemorrhage can be life-threatening, with up to 20 percent requiring blood transfusion. Hemorrhagic cystitis also occurs after radiation therapy of gynecologic, genitourinary, and rectal cancers. Bleeding can occur months to years after radiation treatment, and while bleeding is usually minor, rarely serious bleeding can occur.

Ureteral obstruction in the cancer patient can be caused by direct tumor compression or uric acid nephropathy during chemotherapy or may be secondary to retroperitoneal fibrosis following radiation therapy. Acute ureteral obstruction presents with flank pain similar to urolithiasis. Chronic ureteral obstruction is often painless and, if unilateral, is often only detected incidentally. Chronic bilateral ureteral obstruction eventually will cause renal failure with patients presenting with symptoms of uremia. Urinary retention at the level of the bladder is also seen in cancer patients. It can be caused by mechanical bladder outlet obstruction, brain or spinal cord metastases, or as a side effect of medications.

Priapism in cancer patients may be caused by a primary hematologic malignancy (i.e., leukemia, myeloma), metastases to the corporal bodies of the penis, or secondary to disruption of venous outflow by pelvic tumor. Corporal shunting procedures used for idiopathic priapism usually are not effective in priapsim caused by malignancy.

218 THE NEUROLOGIC EXAMINATION IN THE EMERGENCY SETTING

Hubert S. Mickel

The *emergency* neurologic assessment is focused on obtaining the information that is needed to make rapid management decisions, establish the priorities in examination and management, and assist in making a decision regarding intervention, further examination, and disposition. Stated simplistically, the emergency physician's responsibility, once any immediate threat to life has been addressed, is primarily to determine *that* a neurologic problem potentially exists and *that* the critical conditions associated with that problem are identified or excluded; the neurologist or neurosurgeon often subsequently determines *what* the problem is. This chapter describes the elements of the basic *neurologic examination* appropriate to the emergency department.

ASSESSMENT OF THE NEUROLOGIC EXAMINATION

Overview

A quick assessment of the normal nervous system is provided by finding a normal gait with normal associated movements, a normal speech process and content, and a normal mental status. Conversely, many neurologic deficits can be quickly ascertained by simply looking at the patient. There may be a dense hemiparesis, or there may be neglect of one side. A conversation with the patient may demonstrate a significant mental status abnormality or speech deficit.

There is no universally accepted neurologic screening examination for the emergency setting. However, the brief neurologic screening examination should include as a minimum these components:

1. Mental Status   Orientation, affect, speech (content and process)
2. Cranial Nerves   Pupillary response, fundoscopy, extraocular movements, facial muscle strength, visual fields as appropriate
3. Motor System   Strength in basic muscle groups, resistance to passive movement (tone), pronator drift
4. Sensation   Light touch, proprioception, pain, as appropriate
5. Coordination   Gait, finger-to-nose or other cerebellar testing, Romberg
6. Reflexes   Deep tendon reflexes (biceps, triceps, knees, ankles), plantar reflexes

Mental Status Examination

The goal of the mental status examination is to determine if an abnormality of mental status exists and whether it points to a structural, metabolic, toxic, or infectious etiology.

An alteration of mental status requires a deficit in alertness or awareness or both. Alertness requires the normal functioning of the ascending reticular activating system (ARAS), which passes through the midline of the brainstem up through the thalamus, resulting in arousal of the cerebral hemispheres. Awareness, tested as orientation, requires alertness plus the normal functioning of the cerebral hemispheres. The obtunded patient responds to voices, but there is an abnormality in alertness. Because the ARAS passes through the pontine tegmentum in proximity to the medial longitudinal fasciculus, one needs to examine for focal brainstem deficits, especially pupillary or gaze abnormalities, in the obtunded patient. The drowsy patient may have a decreased level of alertness or awareness, so that one needs to examine for cortical and brainstem deficits. The alert patient may have deficits in awareness but no brainstem lesions that affect the ascending reticular activating system. Deficits in awareness point to abnormalities in cortical function. Questions to assess awareness center on orientation to time, place, person, and situation, as well as the ability to follow simple commands. Determining the digit span (normally seven numbers forward and five numbers backwards) can provide a quick assessment of the mental ability impaired in dementia. Confusion of right and left and the inability to calculate (subtracting 7 serially from 100 or 3 serially from 20) are abnormalities resulting from a dominant parietal lobe lesion. Having the patient recall three objects after a five-minute interval assesses recent memory.

Reversible causes of altered mental status such as hypoglycemia, narcotic overdose, hypoxia, or hypercarbia should be quickly investigated and treated. If a structural etiology of altered mental status is indicated by history or associated neurologic findings, a noncontrast head CT or possibly other neuroimaging study is needed emergently.

Delirium is a distinctly abnormal mental state characterized by disorientation, fear, irritability, misperception of sensory stimuli, and, often, visual hallucinations. Delirium accompanies diffuse metabolic and multifocal cerebral illness, and its presence implies a generalized impairment of brain functions or at least a bilateral involvement of limbic structure. In the elderly patient presenting with delirium from a nursing facility, a diagnosis of high frequency is urosepsis.

Psychiatric causes of altered mental status produce abnormalities of affect, behavior, and content of consciousness, but not of alertness and awareness. In psychosis, there is a defect in reality testing, so that hallucinations and delusions are accepted many times as real. Psychiatry uses *organic brain syndrome* to denote a dementia, which is an impairment of awareness due to various pathological lesions usually scattered throughout the cerebral hemispheres.

Speech

If a speech problem exists, a key question is whether *dysarthria,* a disorder of the motor mechanism of articulation, may result from either cerebellar dysfunction or from primary motor dysfunction. The character of the dysarthria is different, and dependent upon the cause. Cerebellar disease may produce an abnormality in cadence of speech, while motor dysfunction produces abnormalities in enunciation. Examples of words or phrases that when rapidly spoken demonstrate a subtle dysarthria are: "Seventy-Seven Register Street" and "Methodist Episcopal." Alert, aware, dysarthric patients may be able to tell you that their speech is different than usual.

Dysphasia is a disorder of the normal cerebral processing of speech by which meanings are comprehended and expressed. The defect may be in finding words or names, with or without difficulty in writing, but without defect in comprehension (expressive dysphasia); or a difficulty in understanding spoken or written speech (receptive dysphasia); or a more diffuse difficulty in the appreciation of word sounds and grammatical construction, with or without a defect in manipulating numbers, with or without a jumbling of spoken words (jargon speech). In expressive dysphasia, the abnormality lies in executing speech and may be obvious. Asking the patient to name several objects, or to tell the name of parts of a watch or articles of clothing, may elucidate a mild dysnomia. On the other hand, the receptive dysphasic patient does not understand speech and may not understand written language. Many dysphasic patients have abnormality in both executing (expressive dysphasia) and understanding speech (receptive dysphasia).

Cranial Nerves

Generally speaking, if cranial nerves II to VIII are intact, it is less likely that the lower cranial nerves are involved in isolation. Cranial nerve I abnormality can be found in isolation, but when it occurs is often related to injury or tumor (e.g., olfactory groove meningioma).

CRANIAL NERVE I There are occasions when testing olfactory perception is of value. In testing olfaction, the patient needs to be able to identify an odor or to distinguish between two odors, neither pungent (which may test cranial nerve (cranial nerve) V more than cranial nerve I). One cause for loss of olfactory perception is distraction of the olfactory nerves from the cribriform plate, as may occur with fracture through the cribriform plate or from falls onto the occiput.

CRANIAL NERVE II Examination of the visual fields by confrontation is important whenever a CNS hemispheral lesion is suspected or whenever the patient complains of a visual deficit. Visual field testing can be done at the bedside by comparing the patient's visual perception of moving fingers, or a moving small, white object, to your own perception in all four quadrants of the visual fields. Rapid screening of visual field deficit can be done with both eyes, but, customarily, the visual field of each eye should be tested alone.

The physiologic blind spot, increased in papilledema and inflammation of the optic nerve, can be measured using a small, white object and bisecting the distance between you and the patient. When the patient looks with one eye at your eye, find your own physiologic blind spot in the temporal field lateral to the point of fixation, by determining where the white object disappears. Measure the size of the patient's physiologic blind spot to yours, with the assumption that yours is normal.

Lesions posterior to the optic chiasm produce a homonymous visual field defect that may be complete, e.g., hemianopsia, or partial, e.g., quadrantanopsia. Lesions affecting the crossing fibers of the optic chiasm produce a bitemporal defect, which requires testing the visual field of each eye alone for recognition. Visual fields may constrict as a consequence of glaucoma, papilledema, or retinitis pigmentosa.

In nondominant parietal lobe dysfunction, bedside testing may also demonstrate visual inattention to double simultaneous stimulation. The patient perceives the visual stimulus when tested singly in the abnormal visual field but is inattentive to the stimulus when both visual fields are stimulated simultaneously. The consultant generally does more complex visual field testing.

Fundoscopic examination is an important part of the examination in conditions such as hypertensive urgencies, visual loss or visual complaints, ocular pathology, and suspected increased intracranial pressure (ICP).

The use of mydriatics for fundoscopic examination in altered mental status is problematic, because another examiner may mistake the pupillary dilatation for evidence of herniation. Furthermore, pupillary size as a finding of value in assessing clinical changes is lost.

Papilledema develops rapidly in the child (unless the fontanelles are still open), but it is not likely to be found in the adult within the first 24 h following an acute CNS lesion that results in ICP. Instead of papilledema, the early fundoscopic findings of increased ICP are:

1. The ratio of the diameter of retinal venules to arterioles increases from the normal 3:2 ratio to as high as 4:1;
2. Capillary engorgement occurs that makes the optic disc pinker;
3. The physiologic cup fills in from the bottom and all sides, obscuring the white lamina cribrosa at its depth;
4. Venous pulsations disappear, which, when seen in the upright patient, are normally at the edge of the physiologic cup. Venous pulsations are difficult for many examiners to identify; but, when seen, they may be abated by pressure on the globe. This phenomenon can be used to confirm that venous pulsations are indeed present;
5. The optic disc begins to elevate. Initially the elevation of the disc is nasal, superior, and inferior, and lastly, temporal. To determine if slight elevation of the optic disc exists, one focuses on a vessel that traverses the disc and then focuses on the same vessel on the retina. If the vessel is seen 1 diopter more positive on the disc, the disc is elevated.

Increased ICP occurring acutely many times results in an alteration of the sensorium due to involvement at a midbrain level. However, one cannot use this association to prove the presence or absence of increased ICP. Patients with pseudotumor cerebri may have increased ICP with papilledema but without demonstrable alteration of mental status.

CRANIAL NERVES III, IV, AND VI Extraocular muscle function and pupillary function are a basic part of the examination with all CNS complaints. First, one observes the pupils, their size, shape, and equality, then their reaction to light. Is there a consensual reaction to light? Is there a reaction to convergence? Table 218-1 describes common pupillary abnormalities.

TABLE 218-1   Common Pupillary Abnormalities

The extraocular muscle (EOM) function can be assessed by having the patient follow your finger through upward, downward, lateral, superolateral, and inferolateral gaze. The examiner looks for dysconjugate movements or for the patient's report of diplopia. An optimal way to examine EOM function is to use a red lens over one eye and test with a small flashlight. If diplopia exists, the patient perceives both a red and a white light, separated horizontally, vertically, or on an angle. Because diplopia is the result of weakness of movement of the affected eye, the visual image of light in that eye is further away from the macula, so that the image is perceived as further away in the direction the eye is tested; for example, further to the right on testing right lateral gaze. The eye with the visual image furthest from the center is the abnormal one.

Abnormality in EOM function result from lesions affecting cranial nerve nuclei III, IV, and VI within the brainstem; the medial longitudinal fasciculus that extends between the cranial nerve VI nucleus caudally to the opposite cranial nerve III nucleus rostrally, passing throughout the midline of the pontine tegmentum; as well as the cranial nerves themselves after exiting the pons. A lesion of the medial longitudinal fasciculus, most commonly from demyelination or ischemia, results in an internuclear ophthalmoplegia.

A lesion of the cranial nerve III or nucleus results in pupillary dilation as well as weakness to paralysis of ocular motion medially, inferiorly, and superiorly. A lesion of cranial nerve VI or nucleus results in impaired ability to move the eye laterally past the midline. Function of the cranial nerve IV nerve is seldom tested in the presence of normal cranial nerve III and cranial nerve VI function.

Normal functioning to look to the side starts with a signal to the abducens nerve (cranial nerve VI) from the parabducens nucleus. The signal is then sent upwards over the medial longitudinal fasciculus (MLF) to cranial nerve III. With an internuclear ophthalmoplegia, a lesion of the MLF prevents the signal from arriving. The result is that the ipsilateral eye looks lateral (abducts), but the contralateral one continues to look straight-ahead (failure to adduct).

Uncal herniation does not occur without altering the function of the ascending reticular activating system. Uncal herniation characteristically occurs when expanding lesions within the temporal lobe or within the temporal fossa shift the inner, basal edge of the uncus and hippocampal gyrus toward the midline so that they bulge over the incisural edge of the tentorium. The midbrain becomes flattened against the opposite incisural edge. If forceful enough, a notching of the cerebellar peduncle on the side contralateral to the lesion (Kernohan's notch) occurs with resulting hemiparesis contralateral to the herniating side. The ipsilateral third nerve, as well as the posterior cerebral artery, becomes compressed against the free edge of the tentorium, or cranial nerve III is caught between stretched branches of the posterior

cerebral artery, producing a scissors-like compression of cranial nerve III. The pupillomotor fibers that are carried on the outside of the nerve are first affected, producing dilation of the pupil, initially with a sluggish reaction to light. Later, fibers for extraocular movements are involved, producing the fixed, blown pupil. Decorticate posture is likely at this point. As the opposite pupil begins to dilate, the functioning level becomes still lower in the brainstem, so that decerebrate posturing may begin to become evident. As function progressively deteriorates, the clinical findings become identical to those of the lower stages of central transtentorial herniation.

Central transtentorial herniation results from both hemispheres herniating through the tentorium somewhat symmetrically, compressing the midbrain and diencephalon. In the early diencephalic stage of central transtentorial herniation, pupils show a small range of contraction to light, and patients make appropriate motor responses to orbital roof pressure, In the later diencephalic stage, the motor response to stimulation is stiffening of the legs and arms (decerebrate rigidity). In the midbrain-upper pons stage, the pupils are midposition and fixed, with the patient assuming a decerebrate posture. In the lower pons-upper midbrain stage, eyes are fixed, EOMs are motionless, and the patient is flaccid.

EOM testing alone may point to a diagnosis. In myasthenia gravis, diplopia or ptosis worsens on sustained effort. In acute Wernicke's encephalopathy, there is an inability to look laterally to either side as a result of involvement of periaqueductal gray matter in the upper brainstem. Upon the parenteral administration of thiamine, the abnormality may correct itself within several minutes.

CRANIAL NERVE V   The corneal reflex requires the first division of the trigeminal nerve for sensory input and the facial nerve (cranial nerve VII) for the motor response. The corneal reflex may be abnormal in cerebellopontine angle lesions, which may involve cranial nerve V, VII, and VII, making it important to perform the test in patients presenting with auditory, labyrinthine, or cerebellar complaints. The nasociliary reflex involves the same sensory input as the corneal reflex, but the motor response lies with cranial nerve III. Hence, the two reflexes do not test the same level of motor response, although they do involve similar testing of cranial nerve V's sensory input and provide alternatives for testing facial sensation in the unresponsive patient. The trigeminal nerve also provides innervation to the masseter muscles. Masseter muscle testing should also be performed when checking the trigeminal nerve.

CRANIAL NERVE VII   Check for facial asymmetry by looking at the palpebral fissure width as well as the depth of the nasolabial fold. If asymmetry is present, be certain that there is no bony asymmetry of the face, where the larger side looks flatter. If facial weakness is suspected, test willed movement such as showing the teeth, shutting the eyes, frowning, and smiling. Significant asymmetry of strength in wrinkling the forehead suggests a peripheral motor lesion, whereas maintenance of forehead movement and loss of the lower half of facial muscle strength suggest an upper motor neuron lesion. The tympanic membranes should always be examined in the presence of a facial palsy to look for vesicles associated with herpes zoster and Ramsey-Hunt syndrome, as well as to identify a purulent otitis media, which can affect the chorda tympani nerve. Testing taste is important in peripheral facial lesions. Sense of *taste* on the anterior two-thirds of the tongue may be lost from a lesion of the facial nerve proximal to the chorda tympani branch.

CRANIAL NERVE VIII   Auditory acuity can be assessed by rubbing fingers together or by whispered voice. If one uses a tuning fork, lateralization of the sound to one side, when the tuning fork is placed in the midline towards the vertex of the skull, is an abnormal finding (Weber test). Sound is lateralized to the side of a conduction-hearing deficit and away from the side of a neural- or sensory-hearing deficit. A conduction hearing loss is present if the sound perceived is louder or heard longer when the tuning fork is placed on the bone behind the external pinna as compared with in front of the ear (Rinne test). The tuning fork most frequently used for testing is 128 cps, or C. A higher-frequency tuning fork is more easily drowned out by background noise. Also, patients with high-frequency hearing loss may provide a different test result with tuning forks of high frequency. A lower-frequency tuning fork has the disadvantage of increased size. Given the loudness of background noise in most emergency departments, subtle differences are not likely to be detected.

Labyrinthine dysfunction is suspected in the presence of nystagmus or a history of vertigo. Formal testing of labyrinthine function should be reserved for the patient with vertigo. There is a note of caution, however. Maximal turning of the head to one side may compress the ipsilateral vertebral artery. Extension of the neck, as in looking at the ceiling, may compress both vertebral arteries. It is possible that the vertigo elicited by these maneuvers results from vertebrobasilar disease rather than from labyrinthine disturbance, especially in the elderly patient.

One may test for positional vertigo with the Barany maneuver. One should be hesitant to perform this test on the elderly vertiginous patient, given the possibility of vertebrobasilar disease. The patient should sit close enough to one end of the stretcher so that the head would be over the edge if the patient were lying down. The patient keeps the eyes open during the maneuver and reports any nausea or vertigo. The patient's head is turned 45° to one side. The examiner supports the head and shoulders and brings the patient quickly to a reclining position with the head still rotated and hanging over the edge of the stretcher. The position is maintained for 20 s. The examiner observes the eyes for nystagmus, noting the time of onset from the change in position, direction of eye movement, the nature of associated symptoms, whether the nystagmus disappears while maintaining the same head position, and whether the response fatigues on repeated testing. The head is turned to the other side and the same maneuver and observations are done. A peripheral lesion produces predominantly horizontal, sometimes rotatory nystagmus, with the fast component away from the side of the lesion, and the response can be suppressed by visual fixation. A central lesion within the brainstem or cerebellum produces nystagmus in any direction and is sometimes vertical. When horizontal, the fast component is towards the side of the lesion, and the response cannot be suppressed by visual fixation.

Ice water calorics are not customarily a high priority in the emergency department, but may be valuable in selected circumstances of significant brainstem dysfunction or suspected brain death. To attempt to elicit doll's eyes movement in the emergency department in a comatose patient who may have fallen is hazardous in view of possible cervical fracture. Further, neither maneuver is likely to alter the need for imaging studies.

CRANIAL NERVES IX AND X   The gag reflex should be assessed in any patient in which there is a question of handling secretions appropriately. Absence of or asymmetry in eliciting the gag reflex suggests a brainstem lesion. (Presence or abscence of the gag reflex should never be used to determine the necessity of airway intervention.)

CRANIAL NERVE XI   The trapezius and sternocleidomastoid muscles should be tested by elevating the shoulders against resistance and turning the head to each side against resistance when adjacent cranial nerves are affected and in patients with motor weakness.

CRANIAL NERVE XII   It is important to test tongue movements if lower cranial nerves are affected, or in the presence of generalized or lateralized weakness. The tongue may deviate to one side when protruded. Placing the tip of the tongue against the adjacent cheek tests for strength of the tongue muscles.

Finding atrophy indicates a chronic lower motor neuron lesion. Fasciculations of the tongue occur frequently in amyotrophic lateral sclerosis.

Motor System

POSTURE   *Decorticate posture* consists of abnormal flexor response in the arm at the elbow and wrist with extension of the leg. Fully developed, this pattern is referred to as decorticate rigidity. The arms are brought up over the chest with both the elbows and wrists flexed. *Decerebrate posture* consists of abnormal extensor response in the arm and the leg. Fully developed, this pattern is referred to as decerebrate rigidity and consists of opisthosthotonus with the teeth clenched, arms stiffly extended, adducted, and hyperpronated. The legs are stiffly extended and the feet are plantar flexed. Early in the development of an acute cerebral lesion, an abnormal posture may occur only in response to a noxious stimulus. Hemiparesis alone results in external rotation of the leg and foot on the affected side. The finding is not dissimilar to that seen with hip fracture, except that the leg is not foreshortened, and there is neither hip tenderness nor pain on hip movement. Seeing abnormalities in posture should be part of the initial observation of a patient. If a hemiparetic posture is suspected, one should look for evidence of facial flattening on the same side: wider palpebral fissure and flatter nasolabial fold, as well as an extensor plantar response or other indications of hemiparesis.

STRENGTH   Motor strength is usually tested when focal or generalized weakness is either the presenting complaint or suspected by history or examination. (Table 218-2). Strength should be assessed in all four extremities. The earliest upper motor neuron weakness occurs in the dorsiflexors of the wrist and ankle. An adequate screening motor examination includes abduction of the shoulder, extension and flexion of the elbow, extension of the wrist and fingers, grip (testing with two fingers), flexion of the hip, extension of the knee, and dorsiflexion of the foot.

TABLE 218-2   Segmental Innervation of Muscles

The following rating scale may be used for documentation:

0 = No movement
1 = Flicker
2 = Able to move when gravity eliminated
3 = Able to move against gravity
4 = Able to move against resistance
5 = Normal strength

Apart from determining the existence of a deficit, the initial examination is important to note further evolution or improvement.

The greatest concern in patients presenting with generalized weakness is whether the patient has the strength to breathe and ventilate adequately. Forced vital capacity and a peak negative inspiratory force should be obtained. Abnormal results can be followed to determine a trend, or, if markedly abnormal, can indicate the need for intubation.

RESISTANCE TO PASSIVE MOVEMENT   The early parkinsonian patient may present with *rigidity* or with a *cogwheel phenomenon.* Alteration in resistance to passive movement may occur in some demented patients where the amount of resistance is proportional to the amount of force applied (*gegenhalten*). The *spastic catch,* with a "clasp-knife" character from spasticity, is seldom present in an acutely developing lesion. *Flaccidity* results from denervation, which may be peripheral, as well as from deep coma.

ATROPHY   One should examine the bulk of the muscles and the relationship of atrophy to loss of power of contraction. This may give important information on how long the deficit may have been present. In amyotrophic lateral sclerosis, the area of the first dorsal interosseus, between the metacarpal bones of the thumb and index finger, is frequently atrophic. In the presence of atrophy, one should look for fasciculations and consider amyotrophic lateral sclerosis. The tongue is also a place where fasciculations are commonly found.

TREMOR AND INVOLUNTARY MOVEMENTS   Involuntary movements are usually seen when the limbs are at rest, such as the rhythmic tremor of parkinsonism, but may be more obvious during movement, as in chorea or the distal, rhythmic, sometimes rotatory, essential tremor (Table 218-3). Most involuntary movements represent slowly developing neurologic disorders and do not require emergent intervention. An exception is the abrupt, constant while awake, proximal, swinging movements of hemiballismus, a violent form of hemichorea, caused by a lesion (infarct, hemorrhage, metastasis) of the subthalamic nucleus.

TABLE 218-3   Features of Tremor Types

PRONATOR DRIFT   The *pronator drift* is tested by having the patient hold the arms outstretched with the palms upwards and the eyes closed. A positive finding results from turning or pronating the hand while the arm drift downwards. The pronator drift is a valuable screening tool for determining the presence of a subtle neurologic deficit and should be incorporated in the emergency examination of a conscious patient when any hemispheric lesion is suspected. A normal finding requires normal strength and motor functioning as well as normal proprioception mediated through the sensory fibers of the posterior columns.

GAIT AND STANCE   Gait testing is an essential part of every neurologic examination. If the patient cannot stand, try to determine whether it is the result of weakness or of unsteadiness. If the patient can stand but is unsteady, note whether the patient tends to consistently fall in one direction, and whether the unsteadiness is increased with the eyes closed (Romberg's test).

The characteristic disorders of gait are:

1. Hemiplegic gait—circumduction of the leg with a stiff knee, scraping the floor.
2. Spastic paraplegic gait—slow, stiff movements, tilting of the pelvis and delayed flexion of hips.
3. Steppage gait—flopping feet, lifted too high, as with a foot drop.
4. Sensory ataxia—wide base, uneven steps, stamping.
5. Cerebellar—wide base, with irregularity, deviation or reeling, staggering or turning.
6. Parkinsonism (festinating)—stooped, with short steps, may accelerate, chasing center of gravity, or may have some degree of retropulsion, finding it difficult to stop when stepping backwards.

Chronic gait abnormalities can be detected by examining the soles of shoes for asymmetrical wear. Spasticity from hemiparesis results in increased wear of the toe of the shoe on the affected side. Midline cerebellar disease produces a widened stance and a wide-based gait. For cerebellar hemispheric lesions, the initial subtle finding may only be a difficulty in turning rapidly, especially if asymmetrical. Walking heel-to-toe may accentuate a subtle abnormality in coordination. Standing with the eyes closed and the feet together (Romberg test) requires normal position sense functioning as well as adequate strength in both legs. If a patient can stand with the feet together with the eyes opened but cannot do so with the eyes closed, this suggests a difficulty in proprioception or position sense (posterior columns). If this is not accomplished with the eyes opened or there is tendency to veer to one side on walking, the lesion is likely cerebellar or labyrinthine. When walking successively forwards and backwards with the eyes closed, movement in a direction perpendicular to the line of walking occurs in cerebellar hemispheric lesions. A progressive turning clockwise or counterclockwise (compass gait) occurs in labyrinthine lesions.

COORDINATION   When possible, gait testing and performance of the Romberg test are important to assess complaints of incoordination. The finger-to-nose test, heel-to-shin test, and testing rapid alternating movements are valuable in assessing cerebellar function. In finger-nose and heel-to-shin testing, cerebellar lesions produce movements perpendicular to the line of movement. The rapid rhythmic cadence is disrupted in rapid alternating movements (Table 218-4).

EXAMINATION	CEREBELLAR	PROPRIOCEPTIVE
Influence of vision	Darkness or closing eyes does not affect symptoms or signs	Darkness or closing eyes markedly increases symptoms and signs
Sensory changes	Sensory problems not integral part but may be superimposed as in sensory neuropathy and alcoholic cerebellar degeneration	Impaired position and vibratory sense are integral to diagnosis
Finger-to-nose and heel-to-shin tests	Marked intention tremor with dysmetria may be present. Present with eyes open	Inaccuracy in tests, most marked in legs, aggravated by eye closure
Gait	Wide-based with asynchronous limb movements. Difficulty in executing turns while crossing streets	Wide-based, stepping high-stepping, foot-slapping gait (often foot first drop from motor neuropathy)
Romberg test	Patient equally unsteady with eyes open or closed	Patient may be stable with eyes open but becomes markedly unsteady with eyes closed (positive Romberg)

TABLE 218-4   Cerebellar and Proprioceptive Incoordination

Reflexes

DEEP TENDON REFLEXES   The deep tendon reflexes (DTRs) (Table 218-5) can be pathologic by being asymmetric, absent, or hyperactive. Hyperactivity is generally associated with upper motor neuron dysfunction and is manifested by clonus, i.e., repetitive jerking of the reflex, or by pathologic spread, i.e., muscles that are innervated by adjacent motor nerve roots contract. Examples of pathologic spread are adductor spread when eliciting a knee jerk or finding a positive Hoffmann reflex, with the thumb flexing on flicking the tip of the middle finger. Hypoactive reflexes in the lower extremities can be recruited by the Jendrassik maneuver: locking the finger tips together and pulling. This maneuver decreases the inhibition of the reflex arc by internuncial neurons within the spinal cord. The major value of the maneuver lies in assisting in determining whether a weak reflex is present or not. Finding abnormality in DTRs can help in the assessment of spinal cord lesions, radicular lesions, and peripheral nerve lesions.

SPINAL ROOTS	REFLEX
C5 to T1	Pectoralis
C5/C6	Biceps, brachioradialis
C6/C7	Pronator reflex
C7/C8	Triceps
T8/T9	Upper abdominal reflex*
T11/T12	Lower abdominal reflex*
L2 to L4	Quadriceps (knee jerk, patellar reflex)
L5	Achilles (ankle jerk)
S1/S2	Plantar reflex*
S3/S4	Superficial anal*

*Reflex arc receptors are in the skin rather than stretch receptors in muscle fibers.

TABLE 218-5   Common Motor Reflexes Tested in Neurologic Examination

PLANTAR REFLEX   This reflex, described by Babinski originally as an up-going large toe and fanning of the other toes, was elicited using a goose quill. After a 10-year dispute with Sherrington and the English neurophysiologists, Babinski settled for motion of the large toe alone but supposedly still carried the goose quill. Observing the movement of the other toes can occasionally prove helpful, however, when the response of the large toe is in doubt. Asymmetry of the plantar reflexes should be observed and recorded.

A strong or painful stimulus is not needed to elicit the plantar reflex. A gentle sensory stimulus from the heel towards the toes in the distribution of S1 in the lateral foot will suffice. If the plantar response is contaminated by withdrawal, externally rotating the leg, so that the lateral knee lies on the stretcher, does much toward minimizing the effects of withdrawal.

ABDOMINAL REFLEX   The abdominal reflex is obtained by gentle scratching as with a broken Q-tip stick in all four abdominal quadrants. The normal response is contraction of the abdominal musculature in that quadrant. The reflex is normally present in people with strong abdominal musculature, but may be absent in older persons or those with abdominal surgery or multiple pregnancies. The normal finding is similar in relevance to a normal plantar response. The chief value of the reflex is when there is asymmetry or loss below a certain level. Finding normal abdominal reflexes in the face of asymmetrical plantar reflexes decreases some concern over the asymmetrical plantar reflexes.

ANAL REFLEX   The superficial anal reflex results from a contraction of the levator ani and associated peroneal muscles when perianal skin is scratched on either side. It is lost with damage to S3-S4, segments of the spinal cord or their nerve roots. This reflex, as well as rectal sphincter tone, is important to assess following spinal cord trauma.

Sensory Examination

The sensory examination (Fig. 218-1) is the least reliable part of the neurologic examination. It is also very time-consuming to test systematically touch, pain, temperature, position, and vibratory sensations. Situations where a careful sensory examination is needed include:
FIG. 218-1. Nerve root origin of various reflexes. (From Haymaker W, Woodhall B: *Peripheral Nerve Injuries: Principles of Diagnosis*. Philadelphia: WB Saunders, 1945, p. 16. Used by permission.)

1. Pain syndrome, especially on the trunk, looking for a dermatomal pattern as in preeruptive herpes zoster, or in the leg, looking for discogenic radiculopathy.
2. Localized atrophy or weakness.
3. Numbness, pins and needles, tingling, coldness or pain in any part.
4. Trophic changes, especially painless ulcers, blisters, and joint lesions, should lead to careful testing for loss of pain sense.
5. Presence of ataxia should always lead to careful evaluation of position and vibratory sense.
6. Visual inattention suggesting a non-dominant parietal lobe lesion.
7. Recurrent paroxysms of pain, suggesting a thalamic syndrome.
8. Spinal cord trauma or other causes of a sensory level or dissociated sensory loss.
9. Perianal sensation in suspected spinal cord dysfunction.
10. Following trauma to an extremity with motor or sensory complaints.
11. Following stroke with finding of a hemiparesis or hemianopia.

If sensory abnormalities exist related to the median, ulnar, or peroneal nerves, examination for Tinel's sign should be performed, if feasible, over the carpal ligament, the ulnar groove, and distal to the head of the fibula, respectively.

Two-point discrimination has utility, particularly for peripheral nerve lesions. There is normal variation when regions are compared. In the tongue, normal two-point discrimination is 1 mm, while the finger tip is 2 to 6 mm, the forearm and chest are 40 mm, and the thigh and upper arm are 75 mm.

Patients will on occasion attempt to influence the examiner to make a diagnosis that does not exist. A few counter maneuvers may be helpful to determine if lesions are real (Table 218-6).

OCCURRENCE	PROCEDURE
Feigned weakness in leg	Patient is instructed to lift the weak leg up off the bed. Your hand under the heel of the opposite foot should experience downward pressure if a real attempt is made. Procedure is not of value with bilateral weakness.
Feigned weakness in arm or feigned unconsciousness	Lifting the hand above the face and dropping it should result in the hand striking the face in real weakness or unconsciousness. When feigned, the hand will slip to the side, not striking the face.
Feigned unconsciousness	Painful, noxious stimulus can be produced without much force by pressure on the supraorbital nerve above the pupil in the eyebrow.
Plantar reflex contaminated by withdrawal	External rotation of the leg with flexion of the knee decreases the amplitude of withdrawal.
Feigned continuous seizure	No lactic acidosis in serum chemistries. Prolactin is not elevated. Behavior is sometimes suggestible.
Feigned blindness	A cloth or wheel with stripes or repeating pattern is moved across the visual field from left to right and right to left. The presence of nystagmus demonstrates that there is visual perception (optico-kinetic nystagmus).

TABLE 218-6 **Methods to Overcome Voluntary Patient Movements and Feigned Deficits**

Michael Schull

HEADACHE

Headache represents up to 4 percent of all emergency department (ED) visits.[1] ED physicians are generally concerned with identifying those patients whose headaches are caused by life-threatening conditions. Most patients, however, have benign primary headache syndromes and are concerned with receiving rapid and effective treatment for their headaches. Both of these priorities need to be kept in mind.

Epidemiology

Migraine headaches have prevalence rates of approximately 17 percent in women and 5 percent in men.[2] Most ED patients have benign primary headache syndromes, but approximately 3.8 percent have serious or secondary pathology.[1]

Classification

Detailed headache classification criteria were published by the International Headache Society in 1988.[3] For practical purposes, headaches are generally divided into primary headache syndromes, including migraine, tension-type, and cluster headaches, and secondary causes. The most common secondary causes are listed in Table 219-1.

TABLE 219-1   Primary and Secondary Causes of Headache

Approach to Patients with Headache in the Emergency Department

The American College of Emergency Physicians (ACEP) clinical policy for adults with headache[4] groups all causes of headache into four broad categories (Table 219-2). Evaluation of the headache patient has four essential objectives:

Headache Category	Examples
I. Critical secondary causes requiring emergent identification and treatment	Subarachnoid hemorrhage, meningitis, brain tumor with raised ICP
II. Critical secondary causes not necessarily requiring emergent identification or treatment	Brain tumor without raised ICP
III. Generally benign and reversible secondary causes	Sinusitis, hypertension, post-lumbar puncture headache
IV. Primary headache syndromes	Migraine, tension type, or cluster

Abbreviation: ICP, intracranial pressure.

TABLE 219-2   ACEP Headache Categories

1. To appropriately select patients for emergency investigation and treatment of suspected critical secondary headache causes
2. To diagnose and effectively treat patients with generally benign and reversible secondary headache causes
3. To provide effective treatment for primary headache syndromes
4. To provide appropriate disposition and follow-up (including outpatient investigations and referral as necessary) for all discharged patients

The central role played by the history in the evaluation of the headache patient is emphasized in the guidelines published by ACEP and those of other groups.[2,4,5] Patients with an atypical history, a substantial change from the previous headache pattern, or certain high-risk features, as summarized below, need to be investigated in the ED.[2,4,5]

HISTORY **Headache Pattern** Atypical features include first severe headache or worst headache ever. Headaches that began days earlier and steadily worsen should be considered atypical. Patients with a long-standing history of headaches should be investigated emergently if their headache is significantly different from prior ones in terms of its duration, severity, or associated symptoms.[2,4]

Onset Sudden-onset headache, especially if is begins during exertion, is an independent predictor of intracranial pathology,[1] and up to 25 percent of such

headaches are caused by subarachnoid hemorrhages (SAHs).[6]

Headache Location   The location of the headache is nonspecific and should not be relied upon for diagnosis. Migraines are most commonly unilateral and tension-type headaches bilateral, but the reverse may also be true.[7] Occipito-nuchal location of headache among ED patients is an independent predictor of intracranial pathology, though, its positive predictive value is only 16 percent.[1] It is, however, the most common location for the headache of an acute SAH.[8]

Associated Symptoms   Other atypical features include a history of syncope, altered level of consciousness, confusion, neck pain or stiffness, persistent visual disturbance, fever, or seizures.[2,4] The history should also include a search for symptoms of nonneurologic conditions causing headache, such as visual change and eye pain from glaucoma or iritis; jaw claudication, suggestive of temporal arteritis; or congestion and facial pain, suggestive of sinusitis.[4]

Other History   Medications [e.g., nitroglycerin, chronic analgesic use, monoamine oxidase inhibitors (MAOIs), or anticoagulants], a remote history of trauma, or toxic exposures (e.g., carbon monoxide) may be important risk factors. Inquire also about prior headache history, the results of any previous neuroimaging, and comorbid conditions, such as malignancies, AIDS or HIV seroconversion, coagulopathy, and hypertension.[4]

Family History   Migraine headaches occur more commonly in patients with a family history of migraines or motion sickness.[9] Headache patients should be asked about relatives with SAH, since the risk of ruptured intracranial aneurysm in first- and second-degree relatives is up to four times higher than in the general population.[10]

PHYSICAL EXAMINATION   Vital sign abnormalities are warning signs of a possible serious cause. Fever suggests infection, such as meningitis or sinusitis, but can also occur in SAH. Marked hypertension should raise suspicion of a hypertensive urgency or emergency.

A focused examination looking for important nonneurologic causes of headache is then carried out. In the head and neck, the sinuses should be examined for evidence of sinusitis, the temporal arteries palpated for tenderness or reduced pulsation, suggestive of temporal arteritis, and the dentition and temporomandibular joints examined for tenderness.[4] An eye examination should be carried out to exclude acute glaucoma or iritis. Fundoscopy may reveal papilledema or the absence of venous pulsations, both signs of raised intracranial pressure (ICP), or subhyaloid hemorrhage (gravity-dependent venous hemorrhage between the retina and vitreous membrane, convex at the bottom and flat at the top when the patient is examined sitting), which is highly suggestive of SAH.

Finally, a careful neurologic examination is mandatory, focusing on the mental status, cranial nerves, motor and sensory exams, reflexes, gait, and cerebellar testing. The patient should also be examined for papilledema, visual field defects, or meningial signs. Abnormalities in the setting of headache require emergent investigation,[2,4,5] since focal or nonfocal neurologic findings in an ED headache patient have a 39 percent positive predictive value for intracranial pathology.[1]

SPECIAL CONSIDERATIONS   **Women**   Migraine headaches are more common in women and are influenced by hormonal factors. Menarche, menstruation, oral contraceptive use, pregnancy, and menopause may all affect migraine. Higher estrogen levels are generally associated with improved symptoms.[11]

Pregnancy   Preeclampsia should be ruled out in pregnant women. Pregnancy improves migraine symptoms in 60 to 70 percent of patients.[11]

Older Age   Headaches that begin in patients over 50 years of age are worrisome and may herald the presence of a secondary cause.[1] However, one study of new-onset headache in older patients still found primary headache syndromes to be the commonest diagnosis.[12]

Children   The basic approach to headaches in the pediatric population is the same as in adults but somewhat modified in recognition of different likelihoods among the causes (Fig. 219-1). Classification of pediatric headaches is shown in Table 219-3. Most children presenting to the ED have headache related to an underlying febrile illness, such as an upper respiratory or other viral infection, or trauma. Dental causes may be a common source. Migraines are possible but not frequent, and only rarely does the first headache result in ED presentation. There is usually a family history of migraines or motion sickness. Transient neurologic deficits may accompany migraines. Life-threatening causes of headache include meningitis or encephalitis, mass lesions and increased ICP, and hypertension. Absence of fever in particular should prompt accurate assessment of blood pressure. Inadvertent or intentional poisonings should also be considered. For example, headache may be the presenting (and only) complaint of carbon monoxide poisoning. Shunt malfunction in children with hydocephalus often presents with headache as a major component.

FIG. 219-1. Diagnostic approach to headache in the pediatric population. (From Charney E: Headache, in Ludwig S, Fleisher G (eds):   *Pediatric Emergency Medicine.* Baltimore, Williams & Wilkins, 1993, p 375, with permission.)

TABLE 219-3   Classification of Headaches in the Pediatric Population

Children with chronic headaches do not usually present to the ED with headache as their primary complaint, and, although vigilance is required, such headaches are usually due to nonacute causes, such as muscle tension, vision disturbance, or psychogenic causes.

If a thorough examination does not reveal a life-threatening condition, symptomatic treatment with simple analgesics and antipyretics is sufficient, and patients should be referred to their primary care physician for follow-up and further evaluation.

Using Clinical Data to Guide Decision-Making

With the clinical data compiled in the history and physical examination, patients may be classified according to the ACEP groupings (Table 219-2). Patients suspected of having critical secondary causes of headache should undergo emergent investigations, as outlined below, and have appropriate treatment initiated. Those suspected of benign and reversible secondary causes should undergo diagnostic tests if required and have treatment initiated, generally as outpatients. The largest group of ED headache patients have assessments that suggest a benign primary headache syndrome, and the objective for these patients is to provide effective therapy.

Appropriate follow-up should be ensured for all discharged patients. Outpatient investigation and referral may be required, especially in cases such as poorly controlled primary headache syndromes or occasionally a patient with a suspected critical secondary cause not needing emergent investigation (e.g., suspected brain tumor without raised ICP). In cases such as the latter, outpatient workup is appropriate only if the physician is confident that the patient will not be lost to follow-up.

Investigation of the ED Headache Patient

COMPUTED TOMOGRAPHY SCANNING   The ED patient whose headache requires emergent investigation usually begins with a noncontrast computed tomography (CT) scan.[4] The use of contrast material increases the time, expense, and risk of adverse effects (minor 10 percent, severe 0.1 percent),[5] and the noncontrast CT scan usually adequately excludes critical lesions or mass effects requiring emergent interventions. In particular, the noncontrast CT scan is the best neuro imaging test for diagnosing an acute SAH, but CT scan cannot rule it out. When there is strong suspicion of small lesions likely to be missed without contrast (e.g., in an AIDS patient suspected of cerebral toxoplasmosis or suspected small brain mass), then a CT with contrast material may be needed.[5]

LUMBAR PUNCTURE   Lumbar puncture (LP) is required in cases such as suspected meningitis, or suspected SAH with a normal CT scan. Contraindications to LP include the suspicion of raised ICP, which can be excluded by the absence of papilledema, normal level of consciousness, and normal findings on neurologic examination. Venous pulsations seen at the disc margins on fundoscopic examination with the patient upright effectively rule out ICP. Venous pulsations may be terminated temporarily with pressure on the globe. If these conditions are met, then a CT scan need not necessarily be carried out prior to LP, especially if the CT is likely to be delayed. In cases of suspected meningitis without evidence of raised ICP, LP may be done without prior CT in order to avoid any delay in starting antibiotics.[4]

MAGNETIC RESONANCE IMAGING   The cost and restricted availability of magnetic resonance imaging (MRI) limit its utility in the emergency investigation of headache. MRI is more sensitive than CT in evaluating brain injuries, such as diffuse axonal injuries, small parenchymal contusions, or isodense subdural hemorrhages, and most tumors.[5] In acute SAH, however, MRI is no more sensitive than CT in the first few days following a bleed. [13] CT scanning and LP are adequate for the large majority of ED headache patients requiring emergent investigation.

Primary Headache Syndromes

The term "primary headache" includes all forms of migraine, tension-type, and cluster headaches. There is considerable clinical overlap in primary headache syndromes, and it has been suggested that they share a pathophysiology and represent different ends of a clinical spectrum. [7]

MIGRAINE   **Epidemiology**   Migraine headaches are common, with onset usually in the early teens or even younger. Prevalence is estimated at approximately 5 percent for males and 15 to 17 percent for females.[2] Prevalence peaks in both sexes at around 40 years of age and then gradually declines.

Pathophysiology   Early theories postulated abnormal vasculature as the root cause of migraine headaches, with vasoconstriction being responsible for the aura and rebound vasodilatation the cause of the pounding headache. It now seems clear that migraines are a primary response of brain tissue to some trigger, while the disordered activity of blood vessels is secondary.

Auras are thought to be due to primary neuronal dysfunction. The neurologic symptoms of auras are believed to result from a slowly spreading wave of neuronal hypoactivity traveling across brain tissue. There is a corresponding decrease in local blood flow where neuronal activity is reduced. This reduction in blood flow does not follow vascular territories, which makes it unlikely to be vasospastic in origin. [9]

Pain-sensitive intracranial structures, such as blood vessels and the dural matter, are largely supplied by sensory axons of the trigeminal ganglion in the supratentorium, while the upper cervical roots innervate the posterior fossa. Animal models suggest that the headache of migraine is related to activation of these sensory axons, leading to the release of various peptides. This causes sterile neurogenic inflammation in pain-sensitive arteries, the dura, and meningial tissues, and promotes local vasodilatation. The release of these peptides and the resulting inflammation and plasma extravasation can be blocked by sumatriptan, a selective agonist of 5-HT$_{1D}$ (serotonin) receptors, as well as by ergots, indomethacin, and others. Sumatriptan also has direct vasoconstricting effects. Both mechanisms may explain its efficacy at revealing migraine headache. The neurophysiologic pathways linking auras and headaches are still poorly understood.

What actually triggers these complex mechanisms for migraines? Enhanced excitability of occipital cortex neurons in migraine patients has been proposed as a possible trigger, but no clear answer has yet emerged. [9]

Clinical Features   Migraine without aura accounts for about 80 percent of migraines. The headache generally is slow in onset and lasts from 4 to 72 h. It is typically unilateral and pulsating, and worsened by physical activity. Nausea, vomiting, and photo- or phonophobia frequently accompany the headache. [3] The scalp may or may not be tender. These features, however, are not entirely sensitive (migraines need not be unilateral or pulsating) or specific (the same features can be present in tension-type headaches).[7] Suspicion should be raised when a patient presents with a "migraine" that is significantly different from prior headaches. The headache in migraine with aura is similar but is preceded or accompanied by an aura that develops gradually over minutes, lasts no more than 60 min, and is fully reversible.

Visual auras are the commonest, usually consisting of scintillating scotomata (i.e., dark spots) or flashing lights, but virtually any neurologic symptom or sign can occur. Other "typical" auras include hemiparesthesia, hemiparesis, aphasia, or other speech difficulties. Rarer types of aura include those with brainstem symptoms (basilar migraine), those lasting longer than 60 min (migraine with prolonged aura), and aura without accompanying headache (migraine aura without headache). Auras should be distinguished from migraine prodromes, which occur many hours prior to the headache and can consist of lethargy, hyperactivity, yawning, depression, food craving, polyuria, or fluid retention. [9]

Other, less common forms of migraine include ophthalmoplegic migraine, in which headache overlaps with paresis of one or more cranial nerves III, IV, and VI, or retinal migraine, with sudden monocular scotoma or blindness associated with headache. Childhood periodic syndromes (previously known as migraine equivalents) are ill-defined childhood syndromes thought to be associated with migraine, in which symptoms such as abdominal pain or vomiting are prominent while headache may be absent.[3] Rarely, migrainous infarction may occur (previously called complicated migraine), characterized by an aura lasting more than 7 days or neuroimaging evidence of cerebral infarction. [3]

Clearly, in a patient who presents with a focal neurologic deficit and headache, migraine of any sort must be a diagnosis of exclusion unless the patient has a clear history of previous similar migraines, including the neurologic deficit, and normal results of prior investigations. Given that they rarely last more than 60 min, the aura and deficits would be expected to resolve in migraine patients prior to discharge from the ED.

Treatment   Advances in the understanding of the pathophysiology of migraine have been paralleled by much improved ED treatment options for severe migraine. Yet, while an impressive array of medications has been studied and virtually every route of administration has been tried, there remains a wide spectrum of clinical practice and no clear consensus on the best therapy. This reflects the fact that, to date, no migraine treatment has been shown to be superior in all respects. [14]

Physicians choosing a medication should consider several factors besides efficacy in relieving headache in the ED, including the ability to *abort* migraine (i.e., prevent recurrence after relief of symptoms), contraindications, relief of other symptoms, side effects, cost, ease of administration, and time to return to normal activities. Patients should also be asked about their previous experience with a drug and whether they are willing to accept the same treatment again. Unfortunately, many

migraine studies do not adequately assess these outcomes and suffer from other limitations.

At present, several effective options are available for the ED management of acute severe migraine headache, based on a review of ED randomized controlled trials (RCTs) and consensus guidelines prepared by the Canadian Headache Society. [2] Dihydroergotamine (DHE), a 5-HT$_{1D}$ (serotonin) receptor agonist, is highly effective in relieving headaches and is an appropriate first-line therapy for migraine. [2,15] However, DHE causes vomiting in a significant proportion of patients, probably due to its affinity for other serotonin and dopamine receptors. Patients should therefore be pretreated with an antiemetic, such as metoclopramide or prochlorperazine. [2] Sumatriptan, a more selective 5-HT$_{1D}$ agonist than DHE, is effective in relieving headache in the ED and causes less nausea and vomiting. [14,16] However, ED-based studies have shown that subcutaneous sumatriptan results in frequent but short-lived minor adverse effects (e.g., sensations of heat, tingling, chest discomfort, and injection site reactions), is more costly, and has a higher 24-h recurrence rate than DHE. [16] While sumatriptan may still be useful for migraines unresponsive to other medications, it should not be given within 24 h of the administration of DHE or other ergots, since both cause vasoconstriction. [2]

Other migraine drugs studied in ED-based RCTs and shown to be effective include metoclopramide, [17] chlorpromazine,[15,18] prochlorperazine,[17] and ketorolac.[18] Table 219-4 summarizes dosing, contraindications and precautions for each drug. Regardless of medication chosen, patients should be placed in a darkened, quiet area in order to lessen the associated phono- and photophobic symptoms. Given that patients may have been vomiting and had poor oral intake for hours or days prior to their arrival in the ED, intravenous rehydration is also frequently of benefit. [2]

TABLE 219-4   Emergency Department Treatment Options for Migraine Headache

Dexamethasone has been touted as effective in reducing the rate of recurrent migraine following standard treatment. [2] In one ED-based RCT, patients received either 20 mg intravenous dexamethasone or placebo after standard migraine therapy. A significant reduction in the rate of 48- to 72-h recurrent migraine was found in the dexamethasone group as compared to the placebo group.[19]

Special mention is reserved for the use of opioid analgesics in migraine. Meperidine is still used as an acute migraine treatment despite several studies that have shown it to be less effective than other agents.[20] The frequent use of opioids in chronic and recurrent headache conditions may lead to adverse effects, and may even exacerbate headaches.[20] While some patients may require opioid analgesics, the preferred treatment is one of the numerous, more effective alternatives to opioids. [2]

Pregnant Women   Migraines generally improve during pregnancy, especially after the first trimester. Nonpharmacologic therapy, such as rest and ice, should be tried first, but in patients with intractable headache or nausea and vomiting, medications may be used. [11] Acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs) are considered class B by the US Food and Drug Administration (i.e., no evidence of risk in pregnant women, but there are no controlled trials) and can be used. However, NSAIDs should be used very cautiously, if at all, in the third trimester, since they inhibit labor and decrease amniotic fluid volume. Metoclopramide, another class B drug, can be very useful, especially if there is significant nausea and vomiting. [11]

Prophylaxis   Patients with frequent recurrent migraines may benefit from prophylactic medications, such as b blockers without intrinsic sympathomimetic activity (atenolol, metoprolol, nadolol, propanolol), calcium–channel blockers, tricyclic antidepressants, or NSAIDs. However, obstetric or neurologic consultation should be obtained before starting these drugs in the ED. In patients already on prophylaxis and experiencing breakthrough migraines, drugs should be titrated up to maximally tolerated doses for several months before concluding that a given medication is ineffective. They also must be withdrawn slowly to prevent rebound headaches. [2]

TENSION-TYPE HEADACHES   Previously, extracranial muscle tension was thought to be a causative factor in tension-type headaches. However, this relationship has been questioned, given the problem of demonstrating muscle tension and the difficulty of determining whether it is a cause or merely an epiphenomenon. More recent theories suggest that tension-type headaches and migraines may share a common pathophysiology and that they represent different ends of a clinical spectrum.[7]

Tension-type headaches are defined in such a way as to distinguish them from migraines. Therefore, they are described as bilateral, nonpulsating, not worsened by exertion, and not associated with nausea or vomiting.[3] However, patients with severe tension-type headaches may indeed have nausea and vomiting, and mild migraine might easily fit the description of a tension-type headache. [7]

Treatment for mild headaches consists of simple analgesics or NSAIDs. For severe tension-type headaches, treatment is the same as for migraines, given the difficulty of distinguishing between the two entities.

CLUSTER HEADACHES   Cluster headaches are generally rare (prevalence rates of 0.4 percent of the general population), and they are very short-lived even without treatment. Unlike other primary headaches, they are more common in men, and onset is usually after 20 years of age.

Dysfunction of the trigeminal nerve is believed to cause cluster headaches, and the fact that they respond to 5-HT $_{1D}$ agonists suggests a common mechanism with migraines.[21]

Cluster headaches are characterized by very severe, unilateral orbital, supraorbital, or temporal pain lasting 15 to 180 min. The pain is such that patients can rarely lie still, and most are pacing and restless. The headaches are associated with at least one of the following signs on the ipsilateral side: conjunctival injection, lacrimation, nasal congestion, rhinorrhea, facial swelling, miosis, or ptosis. They tend to occur in "clusters," that is, daily on the same side of the face for several weeks, before remitting for anywhere from weeks to years.[3]

Given the short duration of cluster headaches, any medication used in their treatment must act very rapidly. Oxygen is effective in up to 70 percent of patients, and DHE and sumatriptan have also been shown to be rapidly effective. Oral agents are unlikely to be effective for acute attacks, given the long time for absorption and the short duration of cluster headaches, but NSAIDs may be useful in reducing the frequency and severity of future attacks. [21]

DISPOSITION OF PATIENTS WITH PRIMARY HEADACHE SYNDROMES   Regardless of the type of primary headache, poor response to treatment should heighten suspicion of a secondary cause and prompt emergent investigations. However, improvement of a presumed primary headache as a result of treatment does not rule out secondary causes.[4] Patients who respond well to ED management may usually be discharged with appropriate follow-up. Occasionally, a patient with intractable migraine may require admission for more aggressive pain control.

Secondary Causes of Headache

More complete discussions of most of these entities are found elsewhere in this text.

SUBARACHNOID HEMORRHAGE   **Epidemiology**   SAH has an annual incidence of approximately 1 per 10,000 in the United States [10] and represents 1 percent of all nontraumatic headaches seen in the ED.[1] However, SAH accounts for up to a quarter of all sudden severe headaches.[6] SAH occurs in young people, with a median age of 50 years. Mortality rates from SAH are high; 50 percent of patients die within 6 months, and only 58 percent of survivors regain their premorbid neurologic state.[22]

Clinical Features   At the time of presentation, almost half of patients with SAH have normal findings on neurologic examination, including normal vital signs, normal level of consciousness, and no neck stiffness.[22] The headache of SAH is most commonly severe and of sudden onset, but it may also be more subtle. The most common location for the headache is occipitonuchal.[6] Many presentations are atypical and may mislead the clinician. For example, sudden-onset intense neck pain may be mistakenly attributed to radiculopathy. Also, resolution of the pain even without treatment does not exclude the diagnosis. Beware of radiation of pain down along the spine, since this suggests tracking of subarachnoid blood down the spinal canal.

Diagnosis   Investigation of suspected SAH usually begins with a plain CT scan of the head. Retrospective studies suggest sensitivity of newer generation CT may be in excess of 93 percent for the detection of SAH when symptom presentation is within 24 h and may be even higher if performed within 12 h of symptom onset.[23] However, no study has convincingly shown that CT alone can rule-out SAH, even within 12 h.[24] CT sensitivity falls to slightly over 80 percent after 24 h and decays rapidly thereafter. Older generation CT scanners were less sensitive among patients who were alert compared to those with altered sensorium.[25] It remains unclear whether this finding holds with new generation scanners.[26]

Most authorities consider an LP to be mandatory following a negative CT. An alternate view suggests that LP may be unnecessary when the pretest probability is very low.[27] However, this view has itself been challenged on the basis that so-called low-probability patients (isolated severe headache and absence of neurologic findings) may still have up to a 12 percent chance of SAH and that CT may be less sensitive in these patients.[26] Thus, given the potential for catastrophic outcome, it remains prudent to perform an LP on all patients suspected of SAH in whom the CT scan was negative. In fact, restricting investigations to only an LP has been proposed for patients meeting "lone acute sudden headache" criteria (acute sudden headache without neck stiffness and normal neurologic examination, vital signs and level of consciousness). However, the utility of this protocol has not been proven in clinical studies. [28]

The gold standard for the diagnosis of SAH is the presence of xanthochromia in the cerebrospinal fluid supernatant. If LP is performed 12 h or longer after headache onset (sufficient time for xanthochromia to develop) and spectrophotometry is used for the cerebrospinal fluid analysis, xanthochromia is virtually 100 percent sensitive for up to 2 weeks following a bleed. Naked-eye detection of xanthochromia may lead to false-negative results in up to 50 percent of cases. [10]

MENINGITIS   All forms of meningitis can cause headache. In viral or bacterial meningitis, the headache may be severe and of rapid onset, and is usually accompanied by fever and meningismus. Opportunistic infections in immunocompromised patients, such as cryptococcal meningitis, may present with a more insidious onset of headache, and fever and neck stiffness may be absent. An LP is required if there is any suspicion of meningitis, and it need not be preceded by a CT scan in patients with normal findings on neurologic examination, a normal level of consciousness, and no papilledema. If the LP must be delayed for any reason and bacterial meningitis is suspected, antibiotics should be started immediately. [4]

INTRAPARENCHYMAL HEMORRHAGE AND CEREBRAL ISCHEMIA   About 55 percent of patients with intraparenchymal hemorrhage report headaches at the onset of their symptoms. Only 17 percent of ischemic stroke patients and 6 percent of patients with transient ischemic attacks (TIAs) complain of headache. Other neurologic signs and symptoms are present in most patients.

SUBDURAL HEMATOMA   A history of remote trauma in a patient with a headache should raise suspicion of a subacute or chronic subdural hematoma. A low threshold for initiating investigations is appropriate for high-risk patients, including patients on anticoagulants, chronic alcoholics, and the elderly, in whom there may be no clear history of trauma.[4]

BRAIN TUMOR   Up to 70 percent of patients with brain tumors complain of headache at the time of diagnosis, and only about 8 percent have normal findings on neurologic examination. [12] The headache may be unilateral or bilateral, intermittent or continuous. The classic headache of brain tumors (worse in the morning, associated with position and nausea and vomiting) occurs in only a few. If headache is suspected of being due to a tumor and 24-h follow-up can be ensured, a reliable patient with normal findings on neurologic examination, including no papilledema, can be investigated as an outpatient. [4,12]

TEMPORAL ARTERITIS   **Epidemiology**   Temporal arteritis (TA) occurs almost exclusively in patients over 50 years of age. In this age group, there is an annual incidence rate of 15 to 30 cases per 100,000 persons, and it occurs more commonly in women.[29]

Pathophysiology   TA is a systemic panarteritis that selectively involves arterial walls with significant amounts of elastin. [12]

Clinical Features   Headache is the most common symptom of TA, reported in 60 to 90 percent of patients. The headache is most often severe, throbbing, and usually located over the frontotemporal region. Other strongly suggestive features include jaw claudication or evidence of polymyalgia rheumatica, with which TA is strongly associated. The involved temporal artery may be nonpulsatile or tender, or have a diminished pulse. The most serious complication is loss of vision, usually due to ischemic optic neuritis. [12,29]

Diagnosis   The diagnosis is established by fulfilling three of the five following criteria: age over 50 years, new-onset localized headache, temporal artery tenderness or decreased pulse, erythrocyte sedimentation rate over 50 mm/h, and abnormal arterial biopsy findings. [29]

Treatment   In order to prevent loss of vision, treatment should begin immediately with 40 to 60 mg/day prednisone when TA is clinically suspected. Patients should be referred urgently for definitive diagnosis and follow-up. [29]

OPHTHALMIC DISORDERS   Acute glaucoma may present with headache, and in other eye disorders, such as iritis or optic neuritis, some patients may describe eye or supraciliary pain as headache. These conditions can usually be distinguished by a careful history and eye examination, including measurement of intraocular pressure when necessary.[4]

HYPERTENSION   Hypertension may cause headaches, with higher diastolic pressures generally associated with more severe headaches. Physicians should be cautious prior to making this diagnosis, however, since hypertension may also occur as a sign of other secondary headache conditions (e.g., stroke, pheochromocytoma, or preeclampsia) or may simply be secondary to the pain and anxiety associated with a primary headache syndrome.[4] When other secondary causes of headache, including hypertensive emergency (see Chap. 53), have been ruled out, reduction of the blood pressure should result in improvement or resolution of the headache. While some consider isolated headache associated with hypertension as evidence of possible end-organ involvement, most such patients can be discharged following complete resolution of symptoms and blood pressure reduction if follow-up in the next 24 to 48 h can be arranged.

SINUSITIS   Infection of the sinuses may result facial pain or headache. Maxillary sinusitis, by far the commonest type, causes pain over the anterior aspect of the face, rather than headache. Involvement of other sinuses can cause headache: frontal sinusitis over the forehead, ethmoid sinusitis behind and between the eyes, and sphenoid sinusitis a diffuse headache. The headache frequently varies with head position. Symptoms predictive of sinusitis include colored nasal discharge, maxillary toothache, and poor response to decongestants, while reliable signs include purulent nasal discharge and abnormal transillumination (not easy to do properly in the ED). Regardless of plain sinus x-ray findings, patients with four or more of the abovementioned features have a very high likelihood of sinusitis, while those with fewer than two features are very unlikely to have sinusitis.

DRUG-RELATED AND TOXIC OR METABOLIC HEADACHES   Various drugs, such as nitrates, MAOIs, or chronically used analgesics, may cause headache. Such metabolic conditions as hypoxia, hypercapnia, and hypoglycemia and such toxins as monosodium glutamate and carbon monoxide may cause headache as well. Withdrawal from alcohol may also result in headache. Such headaches can be identified either in the history or through appropriate laboratory testing. [4]

BENIGN INTRACRANIAL HYPERTENSION (PSEUDOTUMOUR CEREBRI)   A rare entity, benign intracranial hypertension (BIH) should be considered in a young, obese patient presenting with long-standing headaches. Nausea, vomiting, and visual disturbance may also be present. While its cause is unknown, BIH has been linked to the use of oral contraceptives, vitamin A, and tetracycline and to thyroid disorders. BIH is characterized by papilledema, a normal level of consciousness,

normal CT scan findings, and markedly elevated cerebrospinal fluid pressure on LP. The only serious adverse outcome is the potential for visual loss. Initial treatment is usually with acetazolamide or steroids. When these fail, repeated LPs to drain cerebrospinal fluid or surgery (cerebrospinal fluid shunts or optic nerve sheath fenestration) may be tried.

INTERNAL CAROTID AND VERTEBRAL ARTERY DISSECTION   While rare, dissection of the internal carotid or vertebral artery is frequently associated with headache. Dissection may be spontaneous or the result of trauma and generally occurs in younger patients (median age, 40 years). Internal carotid artery dissection may be suspected in a patient with unilateral anterior neck pain or headache, usually around the eye or frontal area. Most patients present with or eventually develop neurologic signs, such as TIA, stroke, Horner syndrome, transient monocular blindness, or cranial nerve palsies. Vertebral artery dissection typically presents with marked occipital or posterior neck pain associated with signs of a brainstem TIA or stroke. Diagnosis is usually made by angiography. Duplex scanning and MRI may also identify vessel abnormalities. SAH may be caused by dissection through the adventitia of the vessel, and this must be ruled out prior to initiating anticoagulant therapy.

POST–LUMBAR PUNCTURE HEADACHE   Between 10 and 36 percent of patients who undergo LP develop a headache within 24 to 48 h due to a persistent cerebrospinal fluid leak from the dura. The incidence of post-LP headaches can be minimized through the use of smaller-bore needles with noncutting tips in order to spread, rather than cut, dural fibers. [30] Patients who present to the ED with a post-LP headache may respond to simple analgesics, but, if this treatment fails, a blood patch may be required. This procedure involves an epidural injection of autologous blood at the level of the LP in order to "patch" the cerebrospinal leak. [31]

CRANIAL AND FACIAL PAIN DISORDERS

Temporomandibular Disorder

Temporomandibular disorder (TMD) refers to persistent discomfort due to dysfunction of the temporomandibular joint (TMJ), surrounding muscles, and ligaments. Symptoms include TMJ noise and pain on movement, limited jaw movements, locking of the jaw on opening, bruxism, and tongue, lip, or cheek biting. Headache may be associated with TMD as well, but in patients with headache and bruxism, it is often not clear which is cause and which is effect. Patients with TMD can usually locate their pain in the TMJ area. It is usually acute and associated with jaw movement. More diffuse symptoms may be the result of dysfunction of the muscles and ligaments used for mastication. Effective management of TMD often requires a multidisciplinary team, and improvement usually occurs with conservative measures. Simple radiographs of the TMJs are of little use in the ED, since the diagnosis of TMD frequently requires more sophisticated imaging techniques. Simple analgesics or NSAIDs can be tried as an initial treatment.

Trigeminal Neuralgia (Tic Douloureux)

Trigeminal neuralgia is characterized by paroxysms of severe unilateral pain in the trigeminal nerve distribution lasting only seconds, with normal findings on neurologic examination. There is no pain between paroxysms. Treatment can be medical or surgical. Carbamazepine is a very effective treatment. If it fails, the patient is unlikely to have trigeminal neuralgia. Patients with trigeminal neuralgia may present to the ED because symptoms are of recent onset or recurrent, and they should be started or restarted on carbamazepine. Pain control is rarely an issue, since the paroxysms are so brief. Patients with intractable symptoms despite medical therapy should be referred to a neurologist or neurosurgeon.

William G. Barsan

Stroke is the third leading cause of death and the leading cause of disability in the United States. Over 700,000 Americans are afflicted yearly; of these, almost 20 percent will die within the first year. Those who survive are often socially and financially devastated, losing their ability to walk, speak, or care for themselves. Stroke-related costs, including physician and nursing services, hospital and nursing-home care, and lost wages, currently exceed $30 billion a year. These figures are expected to increase with the aging US population, as the incidence of stroke doubles each decade after age 55. Research suggests that early accurate diagnosis and management of patients arriving with stroke at the emergency department may lessen the impact of this disease. [1]

The use of tissue plasminogen activator for select patients with ischemic stroke requires a high level of involvement by emergency physicians. The etiology of stroke is diverse, ranging from cardiac emboli to a rupture of a congenital berry aneurysm. Effective treatment for one stroke type may be disastrous when applied to another stroke type. The anatomic location of the lesion and the mechanism of the stroke must be determined before effective treatment can be administered.

STROKE TYPE

A stroke results from any disease process that disrupts vascular blood flow to a distinct region of the brain. Injury in stroke occurs from (1) ischemia due to vessel occlusion, which deprives neurons of needed oxygen and substrate; or (2) hemorrhage due to vessel rupture, with resultant injury by direct cellular trauma, mass effect, elevated intracranial pressure, and/or the release of deleterious biochemical substances. From 80 to 85 percent of all strokes are ischemic, whereas 15 to 20 percent are hemorrhagic.

Ischemic Stroke

Ischemic stroke can be subdivided into three major categories: thrombotic, embolic, and hypoperfusion. The majority of all strokes are caused by vessel thrombosis, which occurs when clot formation is superimposed upon gradual vessel narrowing or alterations in the luminal lining of the vessel. Atherosclerotic disease is the most common cause of thrombotic stroke in the United States. Atherosclerosis primarily affects the larger intracranial and extracranial arteries and causes hyperplasia and fibrous deposition in the subintimal area with plaque formation. Plaques cause luminal narrowing and platelet adhesion, which lead to vessel thrombosis. Other causes of thrombosis include vasculitis, dissection, polycythemia, and hypercoagulable states. Less common causes are infectious diseases, such as HIV, syphilis, tuberculosis, aspergillosis, and trichinosis, that lead to vessel wall injury. The signs and symptoms of a thrombotic stroke usually develop gradually over minutes to hours and may wax and wane in severity. Upon questioning, patients often give a history of similar but transient symptoms that have occurred in the past, suggesting a transient ischemic attack (TIA) in the same vascular distribution.

One-fifth of all strokes are embolic in nature. In embolism, intravascular material from a proximal source is released and then occludes a distal vessel. In contrast to thrombotic stroke, there is no intrinsic vascular disease in the occluded vessel. Thus, emboli are less adherent to the vessel walls and are more likely to fragment and move distally than are clots due to thrombosis. The most common sources of emboli are the heart and major vessels (aorta, carotid arteries, and vertebral arteries). Cardiac sources of emboli include valvular vegetations, mural thrombi (due to atrial fibrillation, myocardial infarction, or dysrhythmia), paradoxical emboli (due to an atrial or ventricular septal defect), or cardiac tumors (myxomas). Artery-to-artery emboli usually occur when a platelet-fibrin clump is dislodged from a tight stenotic lesion or from a large vessel atherosclerotic plaque. Rarer causes of embolic stroke include fat emboli, particulate emboli from intravenous drug injection, or septic emboli.

Systemic hypoperfusion is a less common mechanism of ischemic stroke than thrombosis or embolism. It is most commonly due to cardiac pump failure (myocardial infarction or dysrhythmias). Hypoperfusion leads to a more generalized or diffuse injury pattern than thrombosis or emboli. It is most evident in border zones or so-called watershed regions at the periphery of the major vascular-supply territories. Patients often have diffuse findings that wax and wane according to their hemodynamic status.

Hemorrhagic Stroke

Although hemorrhagic strokes comprise only one of every five strokes, they have a 30-day mortality rate of 30 to 50 percent and occur in a younger population of patients. Hemorrhagic strokes can be divided into two subtypes: intracerebral hemorrhage (ICH) and subarachnoid hemorrhage (SAH).

The majority of hemorrhagic strokes are intracerebral hemorrhages. In ICH, bleeding occurs directly into the brain parenchyma. Increasing age and a history of prior stroke are the leading risk factors for developing an ICH. Race also plays a prominent role, with Asians and blacks having a higher incidence relative to whites. Tobacco and alcohol abuse are additional risk factors. The majority of ICHs are associated with chronic hypertension. In hypertensive ICH, blood is thought to leak from small intracerebral arterioles damaged by chronically elevated blood pressure. Amyloidosis is another major cause of ICH, especially among elderly patients with lobar or multiple hemorrhages. Other causes of ICH include bleeding diathesis due to iatrogenic anticoagulation or thrombolytic use, vascular malformations, and

cocaine use.

SAH is half as common as ICH. In SAH, blood leaks from a cerebral vessel into the subarachnoid space. Blood from a ruptured artery is released at near systemic arterial pressure, in contrast to ICH, in which arteriolar rupture occurs more gradually at lower pressures. The sudden release of blood under high pressure leads to direct cellular trauma as well as a rapid increase in intracranial pressure. Half of all SAHs are due to berry aneurysm rupture, most commonly occurring at arterial bifurcations. Arteriovenous malformations make up another 6 percent of all SAHs.

PATHOPHYSIOLOGY

Basic knowledge of the anatomy and pathophysiology of the brain can assist physicians in identifying the location of a lesion and in understanding the rationale behind various therapeutic interventions.

Anatomy

The vascular supply to the brain is derived from two sources: the anterior and posterior circulations, which supply blood to different regions of the brain. Hypoperfusion of specific areas of the brain leads to typical neurologic findings that can help clinically differentiate the location of the lesion and the vessels that may be involved.

The anterior circulation, which supplies blood to four-fifths of the brain, originates from the carotid system. The common carotid arteries divide into the right and left internal and external carotid arteries at the level of the angle of the mandible. The internal carotid arteries then course intracranially along the sella turcica within the cavernous sinus. The first branch off the internal carotid artery is the ophthalmic artery, which supplies the optic nerve and retina. Sudden onset of painless monocular blindness (amaurosis fugax) identifies the stroke as involving the anterior circulation (specifically, the carotid artery) at or below the level of the ophthalmic artery. The internal carotid arteries terminate by branching into the anterior and middle cerebral arteries at the circle of Willis. The anterior circulation supplies blood to the optic nerve, retina, and frontoparietal and anterotemporal lobes of the brain.

Although the posterior circulation is smaller (supplying blood to only one-fifth of the brain), it supplies the brainstem, which is critical for normal consciousness, movement, and sensation. The posterior circulation is derived from the two vertebral arteries that ascend through the transverse processes of the cervical vertebrae. The vertebral arteries enter the cranium through the foramen magnum, supplying the cerebellum via the posteroinferior cerebellar arteries. They join to form the basilar artery, which branches to form the posterior cerebral arteries. The posterior circulation supplies the brainstem, cerebellum, thalamus, auditory and vestibular functions of the ear, medial temporal lobe, and the visual occipital cortex.

The extent of stroke also depends on the presence of collateral blood flow distal to the vessel occlusion. A patient with excellent collateral blood flow from the contralateral hemisphere may have minimal clinical deficits despite a complete carotid occlusion. In contrast, a patient with poor collateral flow may be hemiplegic with the same lesion.

Ischemic Stroke

Neurons are very sensitive to changes in cerebral blood flow. Brain cells die within a few minutes of complete cessation of blood flow. However, despite complete occlusion of a cerebral vessel during an acute ischemic stroke, some perfusion remains even in the center of the ischemic brain region, due to collateral flow and variations in local tissue pressure gradients. Cells vary from irreversibly injured neurons in the center of the ischemic region to reversibly injured neurons in the periphery (the penumbra). The degree and duration of occlusion determine the viability of the cells in the penumbra. Theoretically, the earlier reperfusion occurs, the greater is the chance of cell survival. The use of intravenous and intraarterial thrombolytic therapy for ischemic stroke is based on this rationale as well as on investigative trials involving the use of neuroprotectant drugs.

Hemorrhagic Stroke

In intracerebral and SAH, a cerebral blood vessel ruptures, with a dramatic increase in intracranial pressure and a decrease in global cerebral perfusion that can last for minutes. After these immediate changes, intracranial pressure and perfusion gradually improve, although not back to baseline. A marked reduction in cerebral perfusion occurs near the hematoma and is probably due to local compression. Areas of the brain remote from the bleed also have alterations in perfusion, which are thought to be due to vasoconstriction caused either by chemical release from blood breakdown products or by neuronal mediation (diaschisis).

CLINICAL FEATURES

The clinical presentation of stroke is often subtle and varied. Physicians must approach patients systematically and logically. Armed with the basic knowledge of the various stroke types and anatomy, the history taking and physical examination should be aimed at determining the underlying cause of the stroke and the location of the lesion.

History

A review of the patient's demographics and past medical history can often suggest the etiology of the stroke. A 40-year-old patient with a stroke syndrome is more likely to have a hemorrhagic stroke (rather than a thrombotic stroke) than a 65-year-old patient. A history of hypertension, coronary artery disease, and diabetes mellitus are all suggestive of underlying atherosclerotic disease and vessel thrombosis. In contrast, atrial fibrillation, valvular replacement, or recent myocardial infarction suggests a cardioembolic source of infarction.

Patients should be thoroughly questioned regarding recent history of TIAs, since this can help differentiate stroke types. A transient neurologic deficit in the same vascular distribution is suggestive of underlying vascular disease consistent with a thrombotic stroke, in contrast to multiple TIAs involving different vascular distributions, which suggest emboli.

Accurate and detailed histories of the presenting illness can further direct physicians to the cause of stroke. Initial onset of symptoms and any fluctuations in symptoms should be documented, since diagnostic studies and inpatient management may differ depending on this history. Sudden onset of symptoms suggests an embolic or hemorrhagic stroke, whereas a stuttering or waxing and waning deficit suggests a thrombotic stroke or a stroke due to hypoperfusion. Concomitant complaints such as headache, vomiting, or recent trauma should be recorded. Headache occurs in the majority of patients with hemorrhage but in only 10 to 20 percent of those with ischemic stroke. A recent history of neck injury, such as in a motor vehicle accident or a sports-related injury, suggests a carotid dissection.

Physical Examination

Prior to initiating a neurologic examination, a general physical examination should be completed. If a patient is febrile, the source of infection should be identified. An infection may be the cause of a patient's deterioration or may be a complication of the stroke (e.g., aspiration pneumonia). The skin should be examined for signs of emboli (e.g., Janeway lesions and Osler nodes) or bleeding dyscrasia (e.g., ecchymosis or petechiae). A funduscopic examination should be completed to identify signs of papilledema (suggesting a mass lesion or hypertensive crisis), preretinal hemorrhage (consistent with an SAH), or evidence of extensive hypertensive retinopathy. A history suggestive of possible cardiac disease such as myocardial infarction, angina, dysrhythmias, palpitation, or worsening of congestive heart failure should be investigated. Physical findings such as rales, an S3 gallop, or carotid bruit should be recorded.

Neurologic Examination

The goal of the neurologic examination is to localize the brain lesion and rule out other neurologic disease processes. The National Institutes of Health (NIH) stroke scale is a 15-item neurologic evaluation that is reproducible, correlates to infarct volume, and can be performed in less than 7 min (see Table 220-1). This allows a serial, standardized neurologic evaluation of a patient over time by either a nurse or a physician. [2] The neurologic examination can be broken down into six major areas: (1) level of consciousness, (2) visual assessment, (3) motor function, (4) sensation and neglect, (5) cerebellar function, and (6) cranial nerves.

TABLE 220-1 National Institute of Health Stroke Scale: A Rapid, Reproducible Neurologic Evaluation of Patients with Stroke

LEVEL OF CONSCIOUSNESS   A patient's level of alertness should be evaluated by asking simple questions (birth date or month of the year) and by having the patient follow simple commands (close their eyes, make a fist). Patients may be alert, drowsy (requiring minor stimulation to answer or obey), lethargic (requiring repeated or painful stimulation to respond), or obtunded (postures or is totally unresponsive). Several assessments are available for the mental status examination, such as the mini-mental, or the brief mini-mental, exam. Many of the elements are contained in the NIH stroke scale.

VISUAL ASSESSMENT   Evaluation of visual fields and extraocular movements can provide information regarding occipital lobe or brainstem lesions. Visual fields can be tested by confrontation, using finger counting or visual threat as appropriate. Gaze palsy can be assessed by evaluating both voluntary and reflex (by turning the patient's head) horizontal eye movements.

MOTOR FUNCTION   Upper extremity motor weakness is best determined by testing for pronator drift. Patients close their eyes and extend their arms with palms facing the ceiling. The test is positive if one arm pronates or drifts lower than the other within 10 s. Lower extremity strength can be similarly evaluated by a patient's ability to elevate each leg 45 degrees individually for 5 s while lying in bed. For subtle signs of lower extremity weakness, observe the patient's gait or have patients walk on their toes and then on their heels. Facial motor weakness (facial droop) due to a central nervous system (CNS) lesion can be distinguished from a peripheral seventh nerve palsy (e.g., Bell palsy) by a patient's ability to wrinkle the forehead on the affected side.

CEREBELLAR FUNCTION   Cerebellar function can be tested by observing a patient's gait, finger-to-nose testing, heel-to-shin testing, and by having patients stand with arms outstretched forward, palms up (Romberg test). These tests are all performed with the patient's eyes open and then closed to differentiate from posterior column disease (see Chap. 221, "Altered Mental Status and Coma").

SENSATION AND NEGLECT   Sensory deficits and neglect should be evaluated by pinprick testing, having the patient identify numbers gently written on the palm (graphesthesia), and by double-simultaneous extinction (the physician touches the patient's right and left limbs individually and then simultaneously). The double-simultaneous extinction test is positive if the patient feels the sensation in either limb individually but only on one side when touched simultaneously, and it suggests neglect. Neglect can be further confirmed by having the patient draw a box or house. Patients with neglect will often omit figures on one side of the drawing.

LANGUAGE   The terms dysarthria and aphasia are often erroneously interchanged. *Dysarthria* is a disturbance in articulation and is due to paralysis or incoordination of muscles used for speech. Dysarthric speech is often slurred. Having a patient repeat simple nursery rhymes can identify subtle cases. In contrast, *aphasia* is due to a disturbance in processing language (either written or spoken) and can be receptive (difficulty in comprehension), expressive (difficulty in communicating thoughts), or both. Receptive aphasia can be tested by having patients follow simple commands (either vocal or written). Having patients identify simple objects or describe what is happening in a magazine picture assists in evaluating an expressive aphasia. Patients with expressive aphasia will use inappropriate words or use nonfluent sentences, whereas the words of patients with dysarthria will be slurred.

CRANIAL NERVES   Cranial nerves should be individually tested in all patients to identify possible brainstem involvement. Unlike anterior circulation strokes, which cause contralateral motor deficits, brainstem involvement causes ipsilateral cranial nerve deficits with contralateral motor weakness.

STROKE SYNDROMES

After recording a complete medical history and performing a physical examination, the physician must integrate physical findings with brain anatomy and function to determine the anatomic location of the lesion and the possible vessels that may be involved. Physical findings often follow classic patterns that can assist a physician in localizing the lesion.

Transient Ischemic Attack

A TIA is a neurologic deficit that resolves within 24 h (although more than 80 percent resolve within 30 min) and is most commonly associated with thrombotic strokes. The incidence of prior TIAs is 50 to 75 percent in patients with subsequent thrombotic, extracranial carotid artery strokes, but only 10 percent in all other stroke types. TIAs have been thought to cause reversible brain injury; however, recent studies indicate that over 60 percent may be associated with computed tomography (CT) findings of infarction. The true significance of TIAs is their associated 5 to 6 percent risk of stroke per year.

Ischemic Stroke Syndromes

ANTERIOR CEREBRAL ARTERY INFARCT   Lesions of the anterior cerebral artery cause contralateral leg weakness greater than arm weakness with mild cortical sensory deficits. Patients may perseverate with speech or motor actions and respond slowly. Anarthria (speechlessness) with paraplegia may occur in a bilateral parasagittal infarct if the anterior cerebral arteries originate from an occluded common trunk.

MIDDLE CEREBRAL ARTERY INFARCT   A stroke involving the middle cerebral artery (MCA) territory is the most common and presents with contralateral weakness and numbness variably affecting the face and arm greater than the leg. If the dominant hemisphere is involved, aphasia (receptive, expressive, or both) is often present. Inattention, neglect, or extinction on double-simultaneous stimulation localizes the lesion to the nondominant hemisphere. Constructional apraxia in these patients can be demonstrated by the inability to draw a clock and fill in the appropriate numbers. Patients may be dysarthric but typically are not aphasic. In right-handed patients, and up to 80 percent of left-handed patients, the left hemisphere is the dominant hemisphere. A homonymous hemianopsia and gaze preference toward the side of the infarct may also be found.

POSTERIOR CEREBRAL ARTERY INFARCT   Patients with posterior cerebral artery (PCA) infarcts may be unaware of their deficits until formally tested. Motor involvement is minimal, and visual cortex abnormalities may go unrecognized. Light-touch and pinprick sensory modalities, however, may be significantly reduced. The anastomoses of branches of the PCA with arteries from the anterior cerebral artery and MCA territories are common locations of watershed infarcts in hypotensive states.

VERTEBROBASILAR SYNDROME   The posterior circulation supplies blood to the brainstem, cerebellum, and visual cortex. Signs and symptoms attributable to a stroke in this distribution may be subtle. They include findings such as dizziness, vertigo, diplopia, dysphagia, ataxia, cranial nerve palsies, and bilateral limb weakness, singly or in combination. The hallmark of posterior circulation stroke is crossed neurologic deficits (i.e., ipsilateral cranial nerve deficits with contralateral motor weakness).

The lateral medullary (Wallenberg's) syndrome is a specific posterior circulation infarct involving the vertebrobasilar arteries and/or the posterior inferior cerebellar artery and in its pure form has a good prognosis. Presenting signs include ipsilateral loss of facial pain and temperature sensation with contralateral loss of these

senses over the body, gait and limb ataxia, and an ipsilateral Horner syndrome (typically incomplete, with ptosis and miosis commonly found and anhidrosis absent).

BASILAR ARTERY OCCLUSION   Occlusion of the basilar artery causes severe quadriplegia, coma, and the locked-in syndrome. The locked-in syndrome occurs with lesions in the pontine tectum and causes complete muscle paralysis except for upward gaze.

CEREBELLAR INFARCT   An important subset of posterior circulation strokes involve the cerebellum. Patients commonly present following a "drop attack" with the sudden onset of inability to walk or stand. This is often accompanied by central vertigo, headache, nausea, vomiting, and neck pain. Cranial nerve abnormalities are often present. Bone artifact on CT imaging of the posterior fossa can obscure initial identification, and a high index of suspicion should be maintained in patients with appropriate findings. Typically, after a delay of 6 to 12 h, one-third of patients will develop significant edema with subsequent increased brainstem pressure and decreased level of consciousness. Surgical decompression, and diuretic and corticosteroid use for relief of pressure and/or edema prevention, may be lifesaving.

LACUNAR INFARCT   Lacunar infarcts are pure motor or sensory deficits that are due to infarction of small penetrating arteries and are commonly associated with chronic hypertension. Lesions are primarily located in the pons and the basal ganglia.

ARTERIAL DISSECTION   Dissections are often associated with severe trauma but can occur from such mild events as turning the head sharply. Patients may complain of severe neck pain or headache hours to days prior to onset of neurologic deficits. Dissections may occur in the carotid or vertebral circulation.

Hemorrhagic Stroke Syndromes

INTRACEREBRAL HEMORRHAGE   ICH may be clinically indistinguishable from cerebral infarction and also presents with contralateral hemiplegia, hemianesthesia, hemianopsia, and aphasia or neglect (depending on the hemisphere involved). The presentation may differ from infarction in that the patients are more commonly lethargic and may have marked hypertension. Headache, nausea, and vomiting often precede the neurologic deficit. The condition of patients can quickly deteriorate and require emergent intubation. Bleeding is usually localized to the putamen, thalamus, pons, or cerebellum (in decreasing frequency) in patients with hypertensive ICH. Lobar hemorrhages are suggestive of amyloid angiopathy and are associated with a better prognosis than are deep hypertensive bleeds. [3]

CEREBELLAR HEMORRHAGE   A patient presenting with sudden onset of dizziness, vomiting, marked truncal ataxia, and inability to walk must be immediately suspected of having a cerebellar infarction or hemorrhage. These findings may be associated with gaze palsies and increasing stupor. Patients may rapidly progress to coma and herniation unless surgical decompression and/or hematoma evacuation are quickly initiated.

SUBARACHNOID HEMORRHAGE   SAH occurs more commonly in women, but men dominate among patients younger than age 40. Patients present with sudden onset of a severe constant headache that is often occipital or nuchal. A recent history suggestive of a "sentinel hemorrhage" with a severe headache lasting for days can be obtained in 15 to 31 percent of cases. Vomiting often presents with the onset of headache, and patients may be noted to have a decreased level of consciousness. Presentation is usually sudden, and a carefully recorded history may reveal activities such as defecation or coughing at onset. Occasionally, the pain is only nuchal, misleading clinicians to consider only local C-spine etiologies. Neurologic deficits may be present due to the aneurysm compressing adjacent brain tissue or cranial nerves. A grading classification based on neurologic condition can aid in determining prognosis and eligibility for surgery (see   Table 220-2).

Classification	Symptoms
Grade I	Asymptomatic or minimal headache and mild nuchal rigidity
Grade II	Moderate to severe headache, nuchal rigidity, and no neurologic deficit other than cranial nerve palsy
Grade III	Drowsiness, confusion, or mild focal deficit
Grade IV	Stupor, moderate to severe hemiparesis, possible early decerebrate rigidity, and vegetative disturbance
Grade V	Deep coma, decerebrate rigidity, and moribund appearance

TABLE 220-2   Hunt and Hess Classification of Subarachnoid Hemorrhage

DIAGNOSIS

Differential Diagnosis: Other Central Focal Conditions

Although strokes are the most common cause of unilateral weakness, other causes must be considered (see Table 220-3). All patients with neurologic deficits should have the blood glucose checked for hypoglycemia. Bell's palsy (peripheral seventh cranial nerve palsy) usually occurs in younger patients, is associated with upper and lower facial paralysis, and does not involve the extremities. Evidence of trauma should be sought, since an epidural or subdural hematoma can mimic an acute stroke. Although stroke can present with marked hypertension, one can usually differentiate stroke from hypertensive encephalopathy by history and physical examination. Unlike stroke, the onset of hypertensive encephalopathy is more gradual, and focal neurologic deficits, if present, are superimposed upon global cerebral dysfunction (e.g., decreased level of consciousness) rather than isolated to one brain region. Papilledema, flame-shaped retinal hemorrhages, and acute renal failure may be seen with hypertensive encephalopathy but are not invariable findings. Other diseases that may mimic the mental status changes of stroke include diabetic ketoacidosis, hyperosmotic coma, and meningoencephalitis. Another mimicker of stroke is Wernicke's encephalopathy, with its triad of ataxia, ophthalmoplegia, and confusion, typically found in chronic alcoholics. Multiple sclerosis, presenting commonly in the third and fourth decades of life, with a female predominance, may present with focal deficits, depending on the area of demyelination. The onset of symptoms, however, is more gradual than those in acute stroke. Meniere's disease may be distinguished by its paroxysmal course of vertigo, tinnitus, and deafness. Drug toxicity may also masquerade as acute stroke, with lithium toxicity inducing dysarthria, cranial nerve deficits, and confusion. Phenytoin and carbamazepine toxicity may present with ataxia, vertigo, nausea, and abnormal reflexes.

Hypoglycemia
Postictal paralysis (Todd paralysis)
Bell palsy
Hypertensive encephalopathy
Epidural/subdural hematoma
Brain tumor/abscess
Complicated migraine
Meningitis/encephalitis
Diabetic ketoacidosis
Hyperosmotic coma
Wernicke's encephalopathy
Labyrinthitis
Meniere's disease
Demyelinating disease (multiple sclerosis)
Drug toxicity (lithium, phenytoin, carbamazepine)

TABLE 220-3   Differential Diagnosis of Acute Stroke

Diagnostic Tests

Although clinical data can direct physicians toward the diagnosis of stroke, including the cause and location of a lesion, diagnostic tests are often required to confirm

these suspicions and to rule out other etiologies. Tests that may require immediate emergency department interventions include a glucose determination, CT, and an electrocardiogram. The blood glucose level should be determined early (by prehospital providers, if possible) to rule out hypoglycemia as the cause of the neurologic deficit, and 50% dextrose should be administered immediately to any patients with neurologic deficit and hypoglycemia.

An emergent noncontrast CT of the head is essential because it can quickly differentiate ischemic infarction from hemorrhage particularly if the scan is obtained after 12 h of symptom onset. This information is crucial for subsequent therapeutic decisions. CT can identify almost all parenchymal bleeds greater than 1 cm and up to 95 percent of all SAHs. A lumbar puncture is required in all patients strongly suspected of having SAH when the CT scan is normal. Most ischemic strokes will not be visualized by routine CT for at least 6 h and often considerably longer, depending on the size of the infarct. In addition to distinguishing ischemia from hemorrhage, CT can also rule out other life-threatening processes, such as abscess, tumor, and subdural or epidural hematoma.

An electrocardiogram should be obtained to rule out an associated cardiac cause of the stroke. Atrial fibrillation and acute myocardial infarction are associated with up to 60 percent of all cardioembolic strokes. Untreated chronic atrial fibrillation may increase the risk of stroke up to 6 percent yearly. In addition, stroke occurrence is 2.5 percent among patients with acute myocardial infarction within the first 4 weeks of their cardiac event.

Blood tests that may be helpful include a complete blood count (CBC) with platelet count, coagulation studies, toxicologic screen, and cardiac enzymes. A hematocrit can identify polycythemia, which can affect blood flow by increasing viscosity. A platelet count can identify thrombocytosis or thrombocytopenia that may precipitate thrombosis or hemorrhage. Coagulation studies are especially helpful in patients with hemorrhagic stroke to rule out coagulopathy or excessive anticoagulation with warfarin. A toxicologic screen to rule out cocaine or amphetamine use should be obtained in patients with either ischemic or hemorrhagic stroke in which substance abuse is suspected, particularly young adults with stroke. Although of minimal use in the emergency department, determination of cardiac enzymes will assist inpatient evaluation for a possible myocardial infarction.

Other diagnostic tests that may be of assistance, depending on the circumstances, include an echocardiogram, carotid duplex scanning, angiogram, and magnetic resonance imaging (MRI) or magnetic resonance imaging angiography (MRA). An echocardiogram can identify a mural thrombus, tumor, or valvular vegetation in patients with a suspected cardioembolic stroke. Carotid duplex scanning may be helpful in patients with worsening neurologic deficit or crescendo TIAs with known or suspected high-grade carotid stenosis. Such patients may be candidates for emergent carotid endarterectomy or heparinization. Carotid duplex scanning can accurately identify carotid stenosis of greater than 60 percent, but an angiogram is required to distinguish 95 percent stenosis from complete occlusion.

Angiography is the definitive test to demonstrate stenosis or occlusion of both large and small blood vessels of the head and neck. It can detect subtle arterial abnormalities, such as dissection, which may be missed with other imaging techniques. Angiography is the "gold standard" for demonstrating the cause of SAH and for defining the anatomic relationships of aneurysms. Cost, availability, and invasiveness have limited its use.

MRI currently has a marginal role in the emergency department evaluation of stroke. MRI will visualize ischemic infarcts earlier than CT and is more effective than CT at identifying acute posterior circulation strokes. However, it is less accurate at differentiating ischemia from hemorrhage. Emergent MRI should be considered when a dural sinus thrombosis is suspected or confirmation of a brainstem lesion is required. MRA enables demonstration of large vessel occlusions at the base of the skull, but small intracranial vascular occlusion may not be readily apparent. Improvement in MRA speed and resolution may allow greater use of this technology, and MRAs may replace the need for angiograms in the future.

SPECIFIC ISSUES THAT IMPACT EVALUATION AND TREATMENT

Sickle Cell Disease

Stroke occurs by age 20 in over 10 percent of patients with sickle cell anemia and is the most common cause of ischemic stroke in children. The risk is inversely proportional to age, with the highest incidence noted between ages 2 and 5. Symptoms are similar to those in patients without sickle cell disease and range from brief TIAs to hemiparesis, depending on the vascular territory involved and duration of ischemia. Cerebral aneurysms also occur with increased frequency in patients with sickle cell anemia, and careful evaluation for SAH is mandated for patients presenting with headache and neurologic findings.

Emergent management of stroke in patients with sickle cell anemia includes supportive care with oxygen, intravenous fluids, and immediate CT scanning to evaluate for ruptured cerebral aneurysm or ICH. Initial laboratory studies should include CBC, reticulocyte count, and type and crossmatch for transfusion. Lumbar puncture is indicated in patients with suspected SAH and a nondiagnostic CT. If SAH is established, it is recommended delaying arteriography until hemoglobin-S levels are below 30 percent of the total hemoglobin concentration and generous hydration is established. This may avoid increased sickling as a result of vasospasm from hyperosmolar contrast media.

In sickle cell patients with ischemic stroke, emergent simple or exchange transfusion should begin as soon as blood is available to reduce hemoglobin S to less than 30 percent. This is targeted toward improving blood flow and oxygen delivery to the infarct zone. The same therapy is indicated in hemorrhagic stroke in order to reduce vasospasm and secondary ischemic infarction. Regular transfusion therapy reduces the rate of first-ever stroke in children with abnormal transcranial Doppler results and is recommended for patients following ischemic stroke, so as to reduce the risk of recurrence. The efficacy of the use of aspirin or warfarin sodium therapy following ischemic stroke in this population has not been established. Early consultation with a patient's hematologist and the neurology department are in order, and admission to an intensive care unit (ICU) setting is indicated for close neurologic monitoring for increased intracranial pressure. Patients with TIA should also undergo exchange transfusion to the above hemoglobin-S levels. [4]

Young Adults with Stroke

Particular care should be exercised when evaluating the young adult (ages 15 to 50) with acute stroke. In this group, arterial dissection accounts for 20 percent of all ischemic strokes and may often be preceded by only minor trauma. The young adult with a cardioembolic event may have mitral valve prolapse, rheumatic heart disease, or paradoxical embolism as the originating cause. Migrainous stroke in this age group is a potential, with a female predominance. Air embolism should be considered in patients with a history of recent scuba diving or an invasive medical procedure. Such patients should be placed in a left lateral decubitus position and also placed on 100% oxygen. Emergent recompression in a hyperbaric chamber should be arranged. Finally, this population is at risk for ischemic stroke from substance abuse, with heroin, cocaine, and amphetamines often implicated. Any drug with sympathomimetic effects increases the risk of hemorrhagic stroke.

Pregnancy

While early pregnancy itself has not been associated with an increased risk of stroke, the peripartum and postpartum periods (up to 6 weeks after birth) have been identified as having an increased incidence of both ischemic and hemorrhagic stroke. Potential contributors to this increased risk include the presence of preeclampsia/eclampsia and the decrease in blood volume and alterations in hormonal status following birth. [5] Treatment should be targeted toward the underlying etiology.

The Elderly

The fastest growing population in the United States are those aged 85 and over. The Census Bureau estimates a doubling in the size of this group from its current 3.6 million by the year 2025 and a fivefold increase to 18.2 million by 2050. There is no limitation on the basis of age on the use of intravenous recombinant tissue plasminogen activator (rt-PA) in patients meeting treatment criteria. In elderly patients with ICH, particular consideration should be given to amyloid angiopathy as a pathologic cause due to its increased incidence in the elderly.

Medicolegal Issues

Failure to record a complete history and perform a complete physical examination, with documentation of the necessary elements of the neurologic examination, is a common shortcoming in emergency departments. The chart note "Neuro: nonfocal" is insufficient in a patient in whom a focal CNS event is being sought. Nor should the diagnostic process end with the diagnosis of "stroke." A consideration of the probable etiology is in order. If a cerebellar infarct or hemorrhage is identified, early neurosurgical evaluation is warranted. Timing of initiation of anticoagulation in ischemic stroke or TIA is without a solid scientific basis and consultation with a

neurologist is recommended, particularly in a patient with a stuttering deficit.

With US Food and Drug Administration (FDA) approval of tissue plasminogen activator for the treatment of acute (0 to 3 h from symptom onset) ischemic stroke, the need for early identification of stroke in the emergency department has assumed increased importance. Delays in patient evaluation may prevent use of thrombolytic therapy when appropriate and place the physician at potential medicolegal risk.

TREATMENT

General Approach to Treatment of Ischemic Stroke

Upon entry of patients with ischemic stroke into the emergency medical service (EMS) or emergency department setting, priority should be given to airway management and oxygenation. Patients should be placed on oxygen, the head of the bed slightly elevated, and a monitor and intravenous line established. Unless there is hypotension, fluids should be administered judiciously to prevent cerebral edema. Volume depletion in patients with ischemic stroke deserves prompt treatment, because it may contribute to decreased cerebral blood flow in the ischemic region. Avoidance of dextrose-containing solutions is warranted except in those with proven hypoglycemia. Hyperglycemia has been associated with an increase in infarct volume and poor long-term outcome. [6,7] Patients with fever should have antipyretics promptly administered. Experimental studies suggest that hyperthermia increases CNS metabolic demands, whereas hypothermia has demonstrated neuroprotective effects.

The use of anticonvulsants is not recommended for seizure prophylaxis in ischemic stroke. If seizures occur, the patient should be treated acutely with benzodiazepines and then given a loading dose of phenytoin (20 mg/kg IV at 25 mg/min).

EMS protocols should be established to provide early notification to receiving hospitals of patients with new neurologic deficits. This facilitates early activation of acute stroke systems and preparations for rapid patient assessment. A proposed "out-of-hospital NIH stroke scale" uses an abbreviated three-item test (facial palsy, arm weakness, and abnormal speech) to identify stroke patients, and early evaluations have demonstrated a sensitivity of 100 percent and specificity of 88 percent in identifying stroke patients. [8]

A cautious approach to the management of elevated blood pressure is recommended in patients with acute ischemic stroke. In general, frequent monitoring of blood pressure in hypertensive stroke patients is indicated and only persistent, severe hypertension (greater than 220 mmHg systolic or more than 130 mmHg mean arterial pressure) should be considered for treatment. Pharmacologic lowering of systemic blood pressure may reduce perfusion to the penumbra, converting an area with reversible injury to an area of infarction. Recommended agents include parenteral drugs that are easily titrated and that have minimal effects on cerebral blood vessels, such as labetalol or enalapril. Sublingual use of calcium-channel antagonists should be avoided. [9] Numerous clinical case series have reported neurologic deterioration immediately following iatrogenic reduction of blood pressure. In contrast, elevating blood pressure by means of vasopressors may be indicated in patients with ischemic stroke and relative hypotension.

In hypertensive patients being considered for thrombolytic stroke therapy, the use of one or two doses of nitroglycerin paste or labetalol is acceptable to reduce blood pressure below 185/115 mmHg to allow treatment. Requirements for more aggressive treatment for blood pressure reduction below 185/115 mmHg exclude the use of tissue plasminogen activator in stroke patients. Following the use of rt-PA in acute stroke, however, aggressive treatment with the aforementioned agents or, if control is inadequate, nitroprusside is warranted to maintain the blood pressure below 185/115 mmHg. Hypertension is a significant cofactor in the risk of ICH in patients treated with thrombolytics. [10]

Thrombolysis in Acute Ischemic Stroke

BACKGROUND   Significant progress has been achieved in the last 10 years toward identifying potential therapies for ischemic stroke. The most important single step, however, has been the 1995 publication of the results of the NIH National Institute of Neurologic Disorders and Stroke (NINDS) trial evaluating the use of intravenous recombinant rt-PA. This trial demonstrated, for the first time, that stroke was a treatable disease in carefully selected patients who received rt-PA within 3 h of symptom onset. The time-critical nature of thrombolytic therapy highlights the need for the involvement of emergency medicine in a coordinated, multidisciplinary approach to the treatment of stroke patients.

The NIH/NINDS study was a randomized, double-blind, placebo-controlled trial conducted at 40 geographically diverse hospitals (30 community and 10 university settings) comparing intravenous rt-PA (0.9 mg/kg; maximum dose, 90 mg) against placebo in 624 patients meeting specific enrollment criteria. Neurologists in private practice treated many patients in the trial, and some were evaluated and treated by emergency physicians. At 3 months, patients treated with rt-PA were at least 30 percent more likely to have minimal or no disability as measured by four different neurologic outcome scales, with an absolute increase in favorable outcome of 11 to 13 percent. The odds ratio for a favorable outcome with rt-PA was 1.7 (95 percent CI, 1.2–2.6). Benefit was found regardless of ischemic stroke subtype and has been demonstrated to continue for up to 1 year following therapy. Symptomatic ICH attributable to drug occurred in 6.4 percent of treated patients compared with 0.6 percent in the placebo group. Despite this, the mortality rate at 3 months was not significantly different between treatment and placebo groups (17 percent, rt-PA patients; 21 percent, placebo; p = 0.3), and the percentage of patients left severely disabled was lower in those receiving rt-PA. [11]

Four other trials of intravenous thrombolysis have been published, and their conflicting results have generated reasoned debated within the medical community over the role of thrombolysis in stroke. One of these, the European Cooperative Acute Stroke Study (ECASS), also evaluated the use of rt-PA, though at a higher dosage (1.1 mg/kg; maximum dose, 100 mg) and longer time window (0 to 6 h). Though this was a negative study in that it failed to demonstrate a difference in its primary end points between treatment and placebo groups, it must be considered that 109 of the 620 enrolled patients had major protocol violations. After excluding protocol violators, neurologic recovery at 3 months was significantly better for patients treated with rt-PA. [12] The three trials of intravenous streptokinase in ischemic stroke were all halted prematurely for safety considerations. Potential explanations of the increased risk include the use of streptokinase itself, the high dosage used (1.5 million units), the allowance of concurrent heparin and aspirin use, and the time to treatment (the majority of patients were treated within 3 to 6 h). [13,14 and 15]

The use of intraarterial delivery of thrombolytics remains investigational. Advantages include specific evaluation of the occluded vascular territory, use of lower total doses of thrombolytic drugs, and the possibility of mechanical clot disruption. Early studies evaluating pro-urokinase given within 6 h of symptom onset found superior recanalization compared with placebo but with high rates of hemorrhagic complications. [16] Intraarterial thrombolysis may have a role in the treatment of patients with acute brainstem infarcts, as this tissue may tolerate longer periods of ischemia, compared with the cerebral cortex.

The US FDA approved the use of intravenous rt-PA in acute ischemic stroke in 1996 and approval was granted in Canada in 1999. The American Heart Association (grade A recommendation)[17] and the American Academy of Neurology[18] support its use under specified conditions. The American College of Emergency Physicians was invited to coendorse the aforementioned policies but issued a lower level of acceptance "Agree with Reservations." [19]

ROLE OF THE EMERGENCY DEPARTMENT   Specific critical pathways similar to those used for AMI (Door, Data, Decision, Drug) should be used to speed the evaluation of patients with acute stroke. Triage personnel should be educated to identify patients with symptoms of acute stroke and instructed to immediately place such patients in a monitored bed and initiate the aforementioned general recommendations. Automatic studies include a CBC with platelet count, coagulation profile, type and screen, bedside glucose determination, and an electrocardiogram. The emergency physician should be notified of a potential acute stroke, and an acute stroke system, if in place, should be activated.

Carefully identify the time of symptom onset, as this is the most difficult historical element to establish and no recommendation exists for the use of intravenous rt-PA beyond 3 h (Table 220-4). Exclusion and inclusion criteria based on Ct findings are shown in Table 229-2 in chap. 229. Taking the patient and family chronologically through the events immediately prior to the stroke is of particular help in unclear cases. Often families can utilize the timing of television or radio programming to identify time of onset accurately. Thrombolytic use in stroke is not recommended when the time of onset cannot be ascertained reliably. Strokes recognized upon awakening should be timed from when the patient was last known to be without symptoms. A focused neurologic examination should be completed; the NIH stroke scale is a useful tool for rapid evaluation. A review of rt-PA inclusion and exclusion criteria (Table 220-4) should be completed and an emergent noncontrast head CT and neurologic consultation arranged. The use of a preprinted informed consent document (where required) and/or patient education materials may assist the family's decision-making process.

TABLE 220-4   Criteria for Intravenous Thrombolysis in Ischemic Stroke

DOSING, ADMISSION, AND COMPLICATIONS   The total dose of rt-PA is 0.9 mg/kg, with a maximum dose of 90 mg; 10 percent of the dose is administered as a bolus, with the remaining amount infused over 60 min. Blood pressure and neurologic checks should be assessed every 15 min for 2 h after starting the infusion. Table 220-5 outlines the emergent management of hypertension following thrombolytic administration. No aspirin or heparin is given in the initial 24 h following treatment. Patients should be admitted to an ICU setting familiar with the use of thrombolytic drugs and neurologic monitoring. Intracerebral bleeding should be suspected as the cause of any neurologic worsening until repeat CT imaging is obtained. If bleeding is suspected, a CBC with platelet count, coagulation studies, fibrinogen and type and crossmatch for 4 units (U) packed red blood cells, 4 U cryoprecipitate or fresh-frozen plasma, and 1 U single-donor platelets should be obtained. An emergent hematology and neurosurgical consultation, as necessary, is appropriate. Patients may be cared for at hospitals without in-house neurosurgical availability as long as access, or transport, to neurosurgical care can be arranged while a patient is stabilized.

TABLE 220-5   Emergent Management of Hypertension Following the Use of rt-PA in Acute Stroke*

Subacute Ischemic Stroke

EMBOLIC STROKE   Patients with embolic stroke who have minor deficits should undergo anticoagulation. Older studies, which included patients with mechanical valves, found that 12 to 14 percent of stroke patients had recurrent emboli within 2 weeks of the initial event, some within 24 h. More recent trials found that only 1.5 percent of patients had recurrent embolism in the first 7 days,[20] suggesting immediate administration of anticoagulants is unnecessary. The exact timing, method, and degree of anticoagulation following a stroke remain controversial, with little clear data guiding its use. Consultation and/or locally approved specific protocols on its use are recommended. Anticoagulation with heparin should be withheld for 3 to 4 days following large cardioembolic stroke, because of the increased risk of spontaneous hemorrhagic changes associated with heparin in these types of strokes. The use of low-molecular-weight heparin and heparinoids in improving outcome remains to be proven.

THROMBOTIC STROKE   Treatment for stable completed thrombotic stroke is largely supportive. Anticoagulation has not proven beneficial and should not be used in patients with completed strokes. The use of aspirin (300 mg/day) significantly reduces the risk of recurrent ischemic stroke and death. [21] Large randomized stroke trials studying the efficacy of thrombolytic therapy within 3 to 6 h of symptom onset are currently under way. Consultation concerning heparinization should be considered in patients with stuttering or progressively worsening symptoms. Glycoprotein IIb/IIIa inhibitors, potent inhibitors of platelet aggregation, may have a future role in the treatment of subacute thrombotic stroke and are currently in clinical trials.

Emergency thrombectomy or endarterectomy in patients with persistent neurologic deficit due to cerebral ischemia is controversial and unproven. Some authors suggest that emergency surgery should be considered for progressive stroke in the extracranial anterior circulation where there are favorable angiographic findings such as stenosis greater than 90 percent, carotid dissection or aortic aneurysm, or intraluminal clot attached to a plaque.

VERTEBROBASILAR INFARCTION   Unfortunately, no study definitively establishes the advantages or disadvantages of a specific therapy for patients with acute, well-defined, occlusive vascular disease within the posterior circulation presenting later than 3 h after onset. Published studies are either small or not randomized. Most authors suggest the use of heparin in patients with posterior circulation TIAs or progressive vertebrobasilar strokes. The use of intraarterial thrombolysis may be of benefit beyond the 3-h treatment window recommended for intravenous thrombolysis.

CEREBELLAR INFARCTION   Early neurosurgical consultation is needed in the treatment of all patients with cerebellar infarction. Cerebellar swelling can lead to rapid deterioration with herniation, and consultation is required to determine the need for emergency posterior fossa decompression in these patients.

Secondary Stroke Prevention/Transient Ischemic Attacks

Although limited proven pharmacologic interventions exist to reverse an acute ischemic stroke, considerable options have been identified with regard to secondary stroke prevention in patients with a completed stroke or TIA.

Agents preventing platelet aggregation form the cornerstone of secondary prevention of stroke in those patients without atrial fibrillation or high-grade carotid stenosis as a contributing factor. The use of acetylsalicylic acid (aspirin) is associated with a stroke risk reduction of 20 to 25 percent compared with placebo. Aspirin decreases the synthesis of thromboxane A_2 by irreversibly inhibiting cyclooxygenase for the life of the platelet, causing decreased platelet aggregation. No dose-effect response has been identified between high (1000 to 1500 mg/day), medium (250 to 500 mg/day), and low (50 to 100 mg/day) doses,[22] suggesting that lower doses may be as effective and better tolerated.

Dipyridamole, another antiplatelet agent, acts via phosphodiesterase inhibition, thereby increasing cyclic AMP and inhibiting platelet function. Three small, early trials failed to establish the superiority of combination therapy of dipyridamole with aspirin over aspirin alone. A larger (6602 patients), more recent trial evaluating dipyridamole alone (200 mg bid), aspirin alone (50 mg/day), dipyridamole with aspirin, and placebo found that dipyridamole alone reduced the risk of stroke or death by 15 percent compared with placebo in patients with prior stroke or TIA. Importantly, this reduction appeared additive, such that dipyridamole combined with aspirin resulted in a 37 percent relative risk reduction compared with placebo. [23]

Ticlopidine (250 mg bid) acts via inhibition of ADP-dependent platelet activation and release and is marginally superior to aspirin in the prevention of secondary vascular events, but its use is limited by the frequency of adverse events, including diarrhea, nausea, skin rash, and neutropenia. Clopidogrel is pharmacologically related to ticlopidine and has similar efficacy, with few side effects. The use of clopidogrel (75 mg/day) in patients with atherosclerotic vascular disease resulted in a

statistically significant 0.5 percent absolute reduction in the annual risk of ischemic stoke, myocardial infarction, or vascular death when compared with aspirin (325 mg/day).[24] No combination studies have been reported. The use of clopidogrel is ideal for those patients who cannot tolerate, or fail, aspirin therapy.

The effectiveness of heparin is unproven in the management of acute stroke and is not recommended as routine therapy, either acutely or long term, for patients with TIAs. Its use should be considered, though, in patients with recent TIAs who are at high risk for recurrence. These include patients with (1) known high-grade stenosis in the appropriate vascular distribution for the symptoms, (2) a cardioembolic source (except infective endocarditis), (3) TIAs of increasing frequency (crescendo TIAs), and (4) TIAs despite antiplatelet therapy. Urgent carotid endarterectomy should be considered for TIAs that resolve within the first 6 h and are associated with 70 to 99 percent stenosis of the appropriate carotid artery. Endarterectomy has been shown to reduce the risk of future strokes significantly in these patients with anterior circulation TIAs.[25] The role of endarterectomy in patients with moderate-grade stenosis is currently under investigation. The role of angioplasty and cerebral artery stenting are unclear and they should be considered within the conduct of appropriately designed clinical trials.

General Approach to Hemorrhagic Stroke

After appropriate attention to the ABCs, early management of hemorrhagic stroke should focus on regulation of blood pressure, control of brain edema, and prompt neurosurgical evaluation.

INTRACEREBRAL HEMORRHAGE   To date, there are no large randomized studies evaluating the appropriate management of blood pressure in ICH. Current published recommendations are that only severe hypertension (i.e., greater than 220 mmHg systolic or more than 120 mmHg diastolic) be treated.[26] When treated, blood pressure should be lowered gradually to prehemorrhage levels by using either labetalol or nitroprusside. The exceptions to this rule are cases of ICH associated with cardiac failure or arterial dissection, in which more rapid reduction is required. If a patient is known to have chronic hypertension, the blood pressure should not be lowered to normotensive levels but rather to an approximation of the patient's usual hypertensive blood pressure.

The use of hyperventilation, mannitol, and furosemide (standard doses) is recommended in patients with evidence of increased intracranial pressure with features such as mass effect, midline shift, or herniation.

The role of acute surgical intervention remains controversial and depends on the neurologic status of the patient as well as the size and location of the hemorrhage. Surgical decompression and hematoma evacuation are strongly recommended in patients with cerebellar hematomas greater than 3 cm in diameter or those near the brainstem.

SUBARACHNOID HEMORRHAGE   Rebleeding and vasospasm are the major morbid complications in SAH. Risk of rebleeding is greatest in the first 24 h. Lowering systolic blood pressure to 160 mmHg and/or maintaining a mean arterial pressure of 110 mmHg has been associated with lower risk of rebleeding and a decreased mortality rate. Current recommendations are that blood pressure should be maintained at prehemorrhage levels.

Cerebral ischemia due to vasospasm occurs from 2 days to 3 weeks after aneurysm rupture. Nimodipine, given orally 60 mg every 6 h, has been found to reduce the incidence and severity of vasospasm and should be given to all patients with SAH who are in good neurologic condition (grades I to III). Preliminary studies indicate that tirilazad mesylate may also be beneficial in patients with SAH.

Seizures and persistent vomiting can cause elevations in systemic and intracranial pressure. Phenytoin loading is recommended as prophylaxis against seizures. Nausea and vomiting should be promptly treated with antiemetics. Pain should be appropriately managed.

Usually, candidates for early angiography and surgical intervention are stable patients with good neurologic condition (Hunt and Hess grades 1 to 3). However, there is little published evidence that this regimen reduces the long-term morbidity or mortality rates. Alternative approaches for patients with appropriate aneurysms include endovascular obliteration through the use of intraluminal platinum coils or detachable balloon embolization.

ADMISSION GUIDELINES

All patients with new-onset strokes should be admitted for further evaluation, education, and early rehabilitation. Patients with anterior circulation strokes should be evaluated for surgically correctable lesions and observed for any progression in their symptoms. Patients with vertebrobasilar strokes should be admitted for observation and possible heparinization.

Patients with new-onset TIAs should be evaluated for possible cardiac sources of TIAs or high-grade stenosis in the carotid arteries. The incidence of stroke after TIA in high-risk patients may be as high as 20 to 25 percent in the first year, with the greatest incidence in the first month. Because of the proven efficacy of carotid endarterectomy, patients should be admitted unless high-grade stenosis of the carotid artery can be ruled out in the emergency department. Patients without high-grade stenosis may be safely discharged on antiplatelet therapy with close follow-up.

Patients with a prior history of an anterior circulation stroke who have been previously studied, who present with a minor, completed (less than 24 h old), recurrent stroke or TIA, and who have a reliable support system may be discharged home after an appropriate emergency department workup. The use of aspirin, ticlopidine, or clopidogrel should be discussed with the family physician or neurologist, and follow-up within 48 h should be arranged. The patient and family members should be given clear instructions to return for further medical treatment if the patient experiences worsening of symptoms.

221 ALTERED MENTAL STATUS AND COMA

J. Stephen Huff

ALTERED MENTAL STATUS

Introduction and Definition

Consciousness has long been a perplexing subject for philosophers and physicians, and it may be argued that human consciousness is still poorly understood. However, emergency physicians need an operational definition for the disorders of consciousness that are frequently encountered in emergency departments. Dementia is a chronic state of reduced cognitive ability. The individual once was able to function but has lost intellectual skills and memory so that normal functioning has become impaired. The onset of dementia is typically difficult to pinpoint. Delirium or acute confusional state is typically of brief duration, and the degree of intellectual impairment often fluctuates rapidly. Thinking is disorganized and the ability to sustain attention is diminished. Psychosis indicates impairment of reality testing with delusions, hallucinations, disorganized behavior, or loosened associations (Table 221-1).

TABLE 221-1   Features of Delirium, Dementia, and Psychiatric Psychosis

One useful scheme is to divide consciousness into arousal and content functions. Arousal functions include wakefulness and basic eyes-open alerting functions. Anatomically, neurons responsible for these arousal functions reside in the reticular activating system, a collection of neurons scattered through the midbrain, pons, and medulla. The neuronal structures responsible for the content of consciousness reside in the cerebral cortex. Content of consciousness includes self-awareness, language, reasoning, spatial relationship integration, emotions, and the myriad complex integration functions that we regard basic to being human.

Following this model, disorders of consciousness may be divided into processes that affect either arousal functions, content of consciousness functions, or combinations of both functions. Dementia may be thought of as failure of the content portions of consciousness with relatively preserved alerting functions. Predominant arousal system dysfunction describes delirium, although content of consciousness is affected as well. Coma represents one extreme with failure of both arousal and content functions. Psychiatric disorders and altered mental states may share features such as hallucinations or delusion; some distinctions between the different states are summarized in Table 221-1.[1]

Mental status is the clinical state of emotional and intellectual functioning of the individual. Testing the mental status is done both formally and informally during patient evaluation. The higher mental or cognitive functions need specific tests for assessment; screening tests are described in the following section.

DELIRIUM

Introduction and Definition

Delirium, acute confusional state, acute cognitive impairment, acute encephalopathy, and other synonyms refer to a transient disorder where attention and cognition are impaired. Delirium represents a form of brain failure, but the patient is more alert than in coma. Alerting functions are working, perhaps overworking. The patient may have difficulty in focusing, shifting, or sustaining attention. The formal definition also includes disturbed wake-sleep cycles and a fluctuating waxing and waning course of confusion.

Epidemiology

The incidence of delirium in the ED population is not clear. One study showed that 5 percent of EMS transports in one system were for the sole reason of acute

cognitive impairment in the elderly.[2] This would seem to underestimate the problem if fever or respiratory distress, for example, were listed as a chief reason for transport. It is estimated that 10 to 25 percent of elderly hospitalized patients have delirium at time of admission. [3]

Pathophysiology

The functions of intellect as well as arousal are disordered in the central nervous system in delirium. Pathologic mechanisms are complex and are thought to involve widespread neuronal or neurotransmitter dysfunction. Four groups encompass most patients: primary intracranial disease; systemic diseases that secondarily affected the CNS; exogenous toxins; and drug withdrawal.[1] Delirium implies the presence of an acute reversible organic cause, unlike dementia, which is usually stable or slowly progressive and only sometimes amenable to treatment. Differentiation from acute psychosis on a pathophysiologic basis may be more problematic in that the psychosis may occur related to medical conditions in addition to psychiatric or functional conditions. Clinically, psychosis is less likely to have a waxing and waning pattern, and while reality perception is impaired, consciousness is not clouded (Table 221-1).

Clinical Features

Delirium, or acute confusional state, is acute in the sense that it is present over days to weeks; by definition less than 1 month, although rapid onset may be noted. Attention and the cognitive functions of perception, thinking, and memory are all distorted to varying degrees. Alertness (but not necessarily consciousness) is reduced. The patient may appear quite awake but attention is impaired. Activity levels may be increased with agitation or decreased in a quiet delirium. Three variants are described: a hypoalert-hypoactive type, a hyperalert-hyperactive type, and a mixed type. The patient with the mixed variety may fluctuate rapidly between hypoactive and hyperactive states. Symptoms may be intermittent, and it is not unusual for different caregivers to witness completely different behaviors within a brief time span.[3] The sleep-wake cycles are often disrupted with increased somnolence during the day and agitation at night. The increased nocturnal agitation is commonly referred to as "sundowning." Tremor or asterixis may be present in some patients. Associated symptoms may be present, such as tachycardia, sweating, hypertension, or emotional outbursts.

Hallucination, delusions, and illusions may be present in up to 40 percent of cases of delirium. [1] Hallucinations tend to be visual, though auditory hallucinations may occur.

Diagnosis

Both history and physical findings are necessary to confirm the diagnosis of delirium. The history is needed to confirm the acuity of the change in behavior and reveal the fluctuating confusion consistent with the delirium. The history from caregivers, spouse, or other family members is the primary mechanism for diagnosing delirium. [3] General physical examination is directed at discovering an underlying process such as an infection. Ancillary testing should include basic chemistries, urinalysis, and blood count, and a chest radiograph. Cranial CT and CSF analysis should be considered on an individual basis. The physician must decide if an identified acute illness is sufficient to cause the delirium or if further diagnostic workup is necessary; this is often not an easy decision. In absence of a definitive explanation, CT and CSF analysis are advised but, depending on the acuity of onset, could be deferred as part of a continuing inpatient workup.

One key feature of examination is the mental status examination. The standard mental status evaluation may be divided into six categories: appearance, behavior, and attitude; disorders of thought; disorders of perception; mood and affect; insight and judgement; and sensorium and intelligence (Table 221-2). The "standard" mental status examination is useful particularly to determine potential for a psychiatric condition. The emergency physician is unlikely to have time to perform the same detailed evaluation as a general psychiatrist or neurologist. However, the assessment of mood, affect, dress, situational behavior, and, in particular, speech content and process are key aspects in uncovering a psychiatric condition. While the standard mental status examination may not be as useful in the ED for assessment of cognitive function as the other approaches that are discussed later, assessment of orientation and level of consciousness are still helpful as initial screens, as these are usually unimpaired in pure psychiatric conditions, except possibly when the condition is severe. Thus, impairments in cognitive function uncovered with this examination suggest the presence of delirium or other organic mental disorder, and further evaluation along these lines is warranted.

TABLE 221-2 Six Elements of Mental Status Evaluation

The mini-mental state examination (MMSE) (Table 221-3) has withstood the test of time[4] and is perhaps the most familiar to consultants in neurology and psychiatry should they become involved. It is, for all intents and purposes, a subset of the "standard" mental status examination (Table 221-2), with a focus on determining the level of cognitive impairment. This test is valuable in directing the physician to study aspects of attention and memory that might not otherwise be formally tested. A score of 23 or less may indicate the presence of dementia or other cognitive dysfunction and, in an acute setting, indicates the need for further evaluation. [5] Age, education, and verbal abilities may all affect scores.

TABLE 221-3 The Mini-Mental State Examination

Several other shorter evaluation systems have been proposed. However, the brief mental status examination (BMSE) was developed specifically for emergency settings (Table 221-4)[6] but may not yet be widely practiced and may in fact be unknown to potential consultants. It also concentrates on determining level of cognitive impairment. It is simpler and requires less time to complete than the well accepted MMSE (see Table 221-3). The score attained on the BMSE (see Table 221-4) is indicative of the level of impairment.

TABLE 221-4   The Brief Mental Status Examination

Independent of these tests, the acute onset of attention deficits and cognitive abnormalities with fluctuating severity through the day and worsening at night is practically diagnostic of delirium. [7]

Specific Issues

The diagnosis of delirium prompts the search for an underlying disease process. The point that must be remembered is that delirium is secondary to another process that might or might not be related to the central nervous system. Making the diagnostic task more difficult is that chronic cognitive impairment may also be present in the individual patient, therefore making the assessment of the acuity of the mental status change difficult. The main features differentiating delirium from dementia and psychiatric conditions are the relative acute onset of the process (not a feature of dementia) and its fluctuating nature (not a feature of either dementia or psychosis).

Depression can resemble a hypoactive delirium with withdrawal, slowed speech, and poor results in cognitive testing being present in both conditions. Rapid fluctuation of the symptoms, however, is common in delirium but absent in depression. Additionally, clouding of consciousness is absent in patients with depression; usually testing finds them oriented and able to perform commands. [3] Table 221-5 lists common etiologies of altered sensorium (although not all cause delirium).

TABLE 221-5   Common Medical Causes of Altered Mental Status

Treatment

Treatment is directed at the underlying cause of the delirium. The patient must be protected while diagnostic workup is in progress. Delirium in the elderly is associated with a mortality rate of roughly 20 to 30 percent related to the underlying medical condition.

Medication history, including over-the-counter medications, should be examined in detail. In the elderly, medication side effects or toxicity may be observed in what are ordinarily regarded as therapeutic and safe doses.

Recognition, identification, and stabilization are the issues. The identification of a relatively common etiology does not necessarily exclude the possibility of a CNS infection (see Table 221-5). Hypoxia may also be present. Again, in the face of what appears to be adequate cause for the delirium, the physician must decide if further investigation is needed.

Environmental manipulations such as adequate lighting and psychosocial support may be helpful in enhancing the patient's ability to interpret the surroundings correctly. [3] Sedation may be needed to relieve severe agitation. Haloperidol at an initial dose of 1 to 5 mg may be given orally or parenterally. This may be repeated at 20- to 30-min intervals as the clinical situation indicates. It should be avoided if the underlying cause is seizure promoting or potentiates hypotension. Benzodiazepines such as lorazepam may be used in combination with haloperidol in doses of 1 to 2 mg, the dose varying widely because of the age and size of the patient and the degree of agitation. Any institutional confinement or restraint policies should be appropriately addressed. Sedation or restraint is no substitute for diagnostic activities and specific illness-targeted therapy.

Disposition

Unless a readily reversible cause for the acute mental status change is discovered, treatment initiated, and improvement and stability evident, the majority of patients will be hospitalized for further treatment and possibly additional diagnostic testing. This decision is individualized to the patient, the resources in the home or health care facility, and the individual risk profile of the patient.

DEMENTIA

Introduction and Definition

Dementia implies a loss of mental capacity; the individual who once functioned at a certain psychosocial level with certain cognitive abilities is now failing or behavioral problems have developed. The majority of dementias are idiopathic and are termed Alzheimer's disease (AD). The other large category is vascular dementia. However, many other disorders more treatable than Alzheimer's disease or vascular dementia may also cause dementia or simulate dementia. The largely untreatable dementias are thus to a degree diagnoses of exclusion; the physician must take care that a treatable dementia is not being overlooked (Table 221-6 and Table 221-7).

TABLE 221-6 Classifications of Dementia by Cause

D	Drugs (anticholinergic, narcotic, sedatives, phenothiazines, others)
E	Electrolytes, eye or ear problems (partial blindness or deafness)
M	Metabolic disturbances (thyroid disease, hepatic failure, others)
E	Emotional (depression, schizophrenia)
N	Nutritional (B_{12}, folate deficiency, Wernicke-Korsakoff), Normal pressure hydrocephalus
T	Trauma, tumor (includes subdural hematoma)
I	Inflammation (SLE, others) Infections (chronic meningitis, syphilis, Lyme, HIV)
A	Alcohol*

*Chronic effects of alcohol are not easily reversible; however, with abstinence and proper nutrition, even severely affected (ex-) alcoholics may show improvement.
Source: Modified from Tueth MJ: Dementia: Diagnosis and emergency behavioral complications. *J Emerg Med* 13:519, 1995.

TABLE 221-7 Mnemonic for Potentially Treatable/Reversible Causes of Dementia

The typical course of dementia is slow with insidious symptom onset; the abrupt onset of symptoms or rapidly progressing symptoms should prompt a search for another process simulating a dementia or a comorbid problem. The physician must look for compounding factors that may be exacerbating symptoms. Some sentinel occurrence or event usually precipitates presentation to the ED. Attention should be directed to discovering any comorbid process as well as discovering any treatable causes of dementia or dementia imitators.

Epidemiology

Dementia is found in all populations and is largely a disorder of the elderly. It is estimated that 1 percent of the U.S. population suffers from dementia at age 60, but by age 85, 50 percent may be affected.[8] Estimates are similar in other industrialized countries. Vascular disease may be the most common cause of dementia in Japan and Scandinavia. The frequency of the types of dementia is to some degree dependent on the age of the population. [9]

Pathophysiology

The majority of cases of dementia in the United States are due to Alzheimer's disease, with estimates up to 70 percent. Alzheimer's is a neurodegenerative disorder of unknown etiology. Pathophysiology of Alzheimer's disease is complex, with a reduction of neurons in the cerebral cortex as well as increased amyloid deposition into plaques and the production of neurofibrillary tangles. Other neurodegenerative diseases have their own unique pathology.

Vascular dementia accounts for the next largest number of individuals with dementia, with estimates of 10 to 20 percent. The pathology is that of cerebrovascular disease with multiple infarctions.

Clinical Features

Impairment of memory, particularly recent memory, is gradual and progressive. Remote memories are often preserved. Impairment of memory and orientation with preservation of motor and speech abilities is said to be characteristic of the onset of Alzheimer's disease. [10] Degenerative dementias, such as Alzheimer's disease, may be divided into early, middle, and late stages. [11] Early in the disease, complaints of memory loss, naming problems, or forgetting items are common. The middle stage shows progression of these problems plus loss of reading, decreased performance in social situations, and losing directions. Late stage of the illness may include extreme disorientation, inability to dress and perform self-care, and personality change. Typically, the onset of symptoms is slow and gradual; if the onset of symptoms is acute the possibility of a reversible process (Table 221-7) is increased. Clinical features of Alzheimer's disease or other dementias may include affective symptoms such as depression and anxiety, behavioral disorders, and speech difficulties.

Vascular or multi-infarct dementia has symptoms similar to AD but may have findings on physical examination of exaggerated or asymmetric deep tendon reflexes, gait abnormalities, or weakness of an extremity.[11]

Diagnosis

The history of memory problems is usually one of slow progression without landmark occurrences. If specific dates of worsening are noted, the possibility of a vascular dementia increases. Family history may be significant. One inherited dementia, Huntington's disease, has a clear autosomal dominant pattern of inheritance.

General physical examination does not determine the diagnosis of dementia as findings are largely nonspecific or normal. [9,12] The presence of focal neurologic signs may suggest vascular dementia or a mass lesion. Increased motor tone and other extrapyramidal signs such as rigidity or a movement disorder may suggest Parkinson's disease. Mental status testing should be performed as outlined previously (Table 221-2 , Table 221-3 , and Table 221-4).

Controversy exists about diagnostic testing in patients with typical features of Alzheimer's type dementia. Again, about 10 to 20 percent of patients may have a treatable form of dementia (see Table 221-7). The American Academy of Neurology has published a practice parameter that recommends complete blood count; serum electrolytes; calcium, glucose, BUN, creatinine, and liver function tests; thyroid function tests; serum B $_{12}$; and serology for syphilis. Other laboratory tests that are optional, but that may be helpful in certain circumstances, include sedimentation rate, serum folate level, HIV testing, chest x-ray, and urinalysis. [9] Neuroimaging such as CT or MR should be considered in every patient. CSF analysis is not recommended in every case but should be performed if clinical suspicion of a condition with an inflammatory CSF exists. Local practice patterns and the patient's social support will influence whether tests are done as inpatient or in the ED or other outpatient setting.

Diagnosis of probable vascular dementia not only requires cognitive dysfunction but also signs of cerebrovascular disease upon neurologic examination. The relationship between stroke and cognitive decline must be temporally related with dementia within 3 months of the stroke or abrupt deterioration of memory and other cognitive abilities. A fluctuating stepped course suggests vascular dementia. [13]

Specific Issues

The possibility of a comorbid condition suddenly worsening cognitive functioning should be strongly considered and often is the thrust of investigation in the ED. Urinary tract infection, congestive heart failure, or hypothyroidism are just a few of the conditions that may cause a mildly demented but functioning individual to

rapidly deteriorate. The condition blurs with that of delirium as discussed above. The differential diagnosis is important particularly for consideration of depression imitators, the so-called treatable causes of dementia (Table 221-7).

Depression may coexist with dementia; however, depression-imitating dementia (pseudodementia) should be considered. Appropriate inpatient or outpatient follow-up may be arranged for further psychiatric evaluation. If the patient is thought to be seriously depressed, consideration should be given to admission.

Treatment

All types of dementia are treatable at least to some degree by environmental or psychosocial interventions. Treatments for Alzheimer's disease are an intense area of research. Recently, tacrine, a cholinesterase inhibitor, was shown to improve cognitive function in patients with Alzheimer's disease. Tacrine has been approved by the FDA for AD treatment. It does not slow progression of the disease. This therapy is best initiated and monitored by caregivers that will follow the patient through the course of the disease. Other treatments are under active investigation with goals of reducing oxidative stress and inflammation, modifying protein processing, and prolonging neuronal life. [14]

The behavioral symptoms of patients with Alzheimer's may be disruptive to the home environment and distressing to the patient and caregivers. Hallucinations, delusions, repetitive behaviors, and depression are all common. Patients may misidentify other people and family members may be regarded as strangers, sometimes with apparent great fear. Antipsychotic drugs have been used for management of the psychotic and nonpsychotic behaviors, but treatment remains problematic because of adverse drug effects. Use of these drugs should be selective and reserved for patients with persistent psychotic features or those with extreme disruptive or dangerous behaviors. [15] Again, treatment is best coordinated with caregivers that are in a position to monitor the patient's behavior patterns over time.

Treatment of vascular dementia is limited to treatment of risk factors including hypertension.

If a treatable form of dementia is suspected or discovered during evaluation, efforts should be directed toward that underlying cause. Even so, treatments must be individualized. For example, the discovery of chronic subdural hematomas and subsequent evacuation may lead to improvement of a dementia for one patient, but at times an underlying dementia will remain unchanged for another.

The diagnosis of normal pressure hydrocephalus (NPH) is problematic. Excessively large ventricles discovered on CT may prompt consideration of a trial of ventricular shunting. The clinical suspicion of NPH should be increased with the presence of urinary incontinence and gait disturbance at a relatively early point in the disease. [16] Improvement in some individuals may be striking, but controversies remain on patient selection and the duration of improvement. [16,17]

Disposition

A new diagnosis of dementia may be entertained in the emergency department but the decision-making and depth of the workup usually exceeds the time available during the ED stay. A decision to admit or arrange an outpatient diagnostic plan is the usual course in the ED after the differential diagnosis has been considered. Attention should be directed to the possible presence of delirium or a treatable cause of dementia. After investigations have largely excluded any comorbid process acutely worsening symptoms, the patient who is functioning at baseline may be discharged to a safe home environment if caretakers are available. The existence of comorbid medical problems, a rapidly progressive or atypical clinical course, or an unsafe or uncertain home situation should prompt consideration for admission.

COMA

Introduction and Definition

Coma is difficult to define because brain failure exists along a spectrum of unresponsiveness. Both the alerting and the content portions of consciousness are impaired in coma. The definition of an eyes-closed state with inappropriate responses to environmental stimuli is still a useful one. A variety of terms are used to describe patients with lowered levels of consciousness; delirium is discussed in some detail above. Stupor, obtundation, and lethargy are so inexactly used that they have little meaning. A description of the patient's responses to stimuli at one moment in time is still the best assessment of level of consciousness. Though originally designed for statistical analysis of head-injured patients, the Glasgow coma scale is widely used in many clinical situations. Its advantages include a simple scoring system and assessment of separate verbal, motor, and eye-opening functions. Its disadvantages include lack of assessment of hemiparesis or other focal motor signs and lack of testing of higher cognitive functions.

Epidemiology

The epidemiology of coma in emergency departments has been little studied. Current estimate is that acute unresponsiveness is present in 0.5 to 1 percent of ED admissions, but that may vary depending on referral patterns, trauma volume, and toxicology volume of different institutions. The only paper addressing frequency of coma in the ED dates from 1934 and is of historic interest because it predates modern EMS and advanced life support procedures. In that 1934 study, 3 percent of the patients presented to the hospital in coma. [18] Some of the common causes of coma then as now were alcohol intoxication, trauma, cerebrovascular disease, poisoning, meningitis, and cardiopulmonary failure (Table 221-8). One striking difference was the lack of hypoglycemia; insulin therapy was not in widespread use at that time.

TABLE 221-8 Differential Diagnosis of Coma

Pathophysiology

The pathophysiology of coma is complex, but simplification is possible. As with delirium, deficiency of substrates needed for neuronal function may occur as with hypoglycemia or hypoxia secondary to many different causes. Coma may occur from processes primary to the CNS or from systemic causes (Table 221-8). With systemic causes, the brain is usually globally affected and signs that localize dysfunction to a specific area of the brainstem or cortex are usually lacking. In primary CNS causes, the coma may result from brainstem disease such as hemorrhage, herniation, vertebrobasilar artery thrombosis, or from bilateral cortical dysfunction. Signs localizing to specific areas of CNS dysfunction, such as hemiparesis or cranial nerve abnormalities, may be concomitantly present. A useful concept is that unilateral hemispheric disease, such as stroke, should not by itself result in coma. The function of either the brainstem and/or both hemispheres must be impaired for unresponsiveness.

A traditional view of reduced consciousness from mass lesions involves secondary compression of the brainstem by physical shifting of brain tissue. [19] In the uncal herniation syndrome, the most common of the herniation syndromes, the medial temporal lobe shifts to compress the upper brainstem, resulting in progressive drowsiness and then unresponsiveness. Usually, the pupillary light reaction on the same side of the mass is sluggish and the pupil may enlarge, eventually becoming widely dilated and nonreactive. The anatomic correlate of these events is suspected compression of the ipsilateral third cranial nerve by the medial temporal lobe herniating over the tentorium. In this scenario, the pupil ipsilateral to the mass first enlarges, then other signs of third nerve dysfunction progress with loss of

extraocular movements. Hemiparesis may develop contralateral to the mass from compression of the descending motor tracts in the ipsilateral cerebral peduncle, reflecting dysfunction of the descending motor tracts prior to their decussation in the medulla. The above is the usual presentation of temporal lobe or uncal herniation; that is, ipsilateral third nerve palsy with contralateral hemiparesis. Less commonly, so-called falsely localizing signs are present with third nerve dysfunction contralateral, or hemiparesis ipsilateral, to the herniating temporal lobe. This is referred to as Kernohan's phenomenon and is thought to reflect compression of third nerve and midbrain structures against the tentorium contralateral to the mass. A central herniation syndrome is also described. These models spring from postmortem examination of brains from patients with expanding mass lesions.

The herniation syndromes serve as models, but their exact mechanism has been questioned. The fact that herniation syndromes may be reversed by interventions is evidence against simple physical displacement of the tissues and physical distortion of the brainstem. Additionally, the amount of midline shift of structures as evaluated by neuroimaging seemingly correlates with the level of consciousness without invoking physical herniation. In the patient with an acute lesion, the patient may be awake with up to 3 to 4 mm of pineal shift, with unresponsiveness deepening as the pineal shift increases to 10 mm. [2c] The perimesencephalic cisterns are invariably diminished in patients with pineal shift of about 9 mm. [20] The shift is in true dimensions as adjusted from the CT scan, which typically displays a miniaturized image. Less correlation of midline shift and consciousness has been noted with more anterior structures such as the septum.

Ischemia from compression of vessels is undoubtedly a factor in cerebral edema and effects of increased intracranial pressure. Increased intracranial pressure (ICP) may occur within regions of the brain, perhaps initiating a herniation syndrome or midline shift as described above. Increased ICP may also occur diffusely resulting in widely distributed CNS dysfunction. Cerebral blood flow (CBF) is usually constant between mean arterial blood pressures (MAP) of approximately 50 to 100 mmHg through the process of cerebral autoregulation. At MAP outside this range, CBF is reduced and ischemia may develop. Cerebral perfusion pressure (CPP) is equal to the MAP minus the intracranial pressure (CPP = MAP – ICP). It follows that in extreme uncontrolled elevation of the ICP, cerebral perfusion pressure is inadequate or lost as ICP approaches the MAP, and ischemia develops. Some authorities suggest that the upper range of MAP that allows constant CBF is about 150 mmHg, at least in the uninjured brain. There are many opinions, but little data to substantiate the exact range. (See Chap. 247 for a more detailed discussion.)

Clinical Features

The clinical features of coma vary both with the depth of coma and the etiology of coma. Coma speaks to the unresponsive state. However, there is a spectrum of signs within unresponsiveness that may point toward an etiology.

A variety of abnormal breathing patterns may be seen in the comatose patient. They are of interest but offer little information in the acute setting. Pupillary findings, the results of other cranial nerve evaluations, hemiparesis, and response to stimulation are all part of the clinical picture that needs to be assessed. These findings help the clinician sort the cause of the coma into a likely etiology—diffuse CNS dysfunction (toxic-metabolic coma) or structural coma. A further division of structural coma into hemispheric (supratentorial) and posterior fossa (hemispheric) coma is often possible at the bedside.

Toxic and metabolic causes of coma result from a wide range of clinical conditions. In general, the diffuse nature of the CNS dysfunction is reflected by the lack of physical examination findings that might point to a specific region of dysfunction within the brain. For example, in toxic-metabolic coma, if the patient is having either spontaneous movements or reflex posturing, the movements are symmetric without evidence of hemiparesis. Reflexes are symmetric. Pupillary response is generally preserved in toxic-metabolic coma, unless the toxin specifically affects pupillary function. Typically the pupils are small but reactive in nonspecific toxic-metabolic coma. If extraocular movements are present, again they are symmetric. However, if extraocular movements are absent, it is of no value in differentiating toxic-metabolic from structural coma. A notable exception is severe sedative poisoning as with barbiturates; the pupils may be large, extraocular movements absent, muscle tone flaccid, and the patient apneic, simulating the appearance of brain death.

Coma from lesions of the hemispheres, or supratentorial masses, may present with progressive hemiparesis; asymmetric muscle tone and reflexes may also be present. A patient in coma with a hemispheric hemorrhage may still have some muscle tone; careful examination may allow detection of decreased muscle tone on the side of the hemiparesis. The hemiparesis may be suspected with asymmetric responses to stimuli or asymmetric extensor or flexor postures. Additionally, there may be ocular signs of the eyes conjugately deviated toward the side of the hemorrhage. With expansion of the hemorrhage and surrounding edema, and increase in intracranial pressure or brainstem compression, the unresponsiveness may progress to a complete loss of motor tone, as well as loss of the ocular findings. Frequently, large acute supratentorial lesions are seen without the features consistent with temporal lobe herniation. Coma without lateralizing signs may result from decreased cerebral perfusion secondary to increased intracranial pressure. Reflex changes in blood pressure and heart rate may be observed with increased ICP or brainstem compression. Hypertension and bradycardia in a comatose patient may represent the Cushing reflex from increased ICP.

Posterior fossa or infratentorial lesions comprise another coma syndrome. An expanding mass, such as cerebellar hemorrhage or infarction, may cause abrupt coma, abnormal extensor posturing, loss of pupillary reflexes, and loss of extraocular movements. The anatomy of the posterior fossa leaves little room for accommodating an expanding mass. Early brainstem compression with loss of brainstem reflexes may develop rapidly. Another infratentorial cause of coma is pontine hemorrhage, which may present with the unique signs of pinpoint-sized, seemingly unreactive pupils. If magnification is used, these pinpoint pupils may be seen to be reactive.

Vertebrobasilar occlusion by thrombosis or embolism may cause the "locked-in" syndrome, which may readily be confused with coma. These patients have lost voluntary movement, except perhaps for vertical eye movement. Consciousness and understanding may well be intact; the patient cannot move, speak, or interact with the environment except, again, by vertical eye movements. [21]

Pseudocoma or psychogenic coma is occasionally encountered and may present a perplexing clinical problem. Adequate history and observation of responses to stimulation will reveal findings that differ from the syndromes described above. Pupillary responses, extraocular movements, muscle tone, and reflexes will be shown to be intact on careful examination. Tests of particular value are observing the response of the patient to manual eye opening (there should be little or no resistance in the truly unresponsive patient) and extraocular movements. Specifically, if avoidance of gaze is consistently seen with the patient always looking away from the examiner, or nystagmus is demonstrated on caloric testing, this is strong evidence for nonphysiologic or feigned unresponsiveness.

Diagnosis

In the approach to the comatose patient, stabilization, diagnosis, and treatment actions overlap and are often performed simultaneously. Examination, laboratory procedures, and neuroimaging allow determination of the cause of coma in almost all patients in the ED. As with any patient, airway, breathing, and circulation issues need to be immediately addressed. Reversible causes of coma should always be considered. Hypoxia, hypoglycemia, hypo- and hypertension, and hyperthermia are readily diagnosed entities. Hypoglycemia is a frequent cause of acute coma. Rapid bedside determination of glucose may obviate the empiric administration of intravenous dextrose.

The paradox in evaluation of the comatose patient is that history often holds the key to diagnosis but the patient cannot verbally relate that history. Exploit all possible historical sources. EMS personnel frequently have valuable information about the scene including medication history or the possibility of poisoning or trauma. Caregivers, family, or witnesses may provide valuable information. Medical records may be of immense value if promptly available.

Knowing the tempo of onset of the coma is of great value. Abrupt coma suggests abrupt CNS failure with possible causes of trauma, catastrophic stroke, or seizures. Cardiac causes may also cause abrupt loss of consciousness. A slowly progressive onset of coma may suggest a progressive CNS lesion such as tumor or subdural hematoma. Metabolic causes such as hyperglycemia may also develop over several days.

The physical examination of the comatose patient presents other challenges. General examination and vital signs (including oxygen saturation and temperature) should receive special attention following stabilization and resuscitation. General examination may reveal signs of trauma or suggest other diagnostic possibilities of the unresponsiveness. For example, a toxidrome may be present that suggests diagnosis and therapy, such as the hypoventilation and small pupils found with opioid overdose.

Neurologic testing deviates from the standard examination. Fine tests of weakness in the alert patient, such as testing for pronator drift of the outstretched upper extremities, are not possible in the unresponsive patient. However, assessment of cranial nerves through pupillary examination, corneal reflexes, and oculovestibular reflexes may suggest focal CNS lesions. Abnormal extensor or flexor postures are nonspecific for localization or etiology of coma but suggest profound CNS dysfunction. Again, asymmetric muscle tone or reflexes raise the suspicion of a focal lesion. The goal of the physician is to rapidly determine if the CNS dysfunction is from diffuse impairment of the brain or if signs point to a focal (and perhaps surgically treatable) region of CNS dysfunction.

CT scanning is the neuroimaging procedure of choice. Acute hemorrhage is readily identified, as are midline shifts. No clear high-yield criteria for ordering CT scanning have been developed for the comatose patient. Because exceptions to the guideline for clinical assignment of patients to structural or nonstructural coma are frequent, CT is often obtained even in situations where the pretest probability is low. For example, detection of a clinically occult subdural hematoma might radically change management from supportive medical care to aggressive surgical intervention.

The medical community expects the emergency physician to stabilize the patient and to take initial diagnostic and therapeutic steps. The etiology of coma is discovered or strongly suspected in most patients during the ED evaluation. The system depends on the emergency physician to distribute the comatose patient to appropriate specialty services.

Specific Issues

Airway issues of importance in the comatose patient include concerns for cervical spine injury and increased intracranial pressure. If trauma is suspected, stabilization of the cervical spine during the diagnostic process must be maintained. Issues of intubation in the head-injured patient, or in a comatose patient with suspected increased intracranial pressure who needs modification of rapid sequence intubation techniques, are discussed at length in Chap. 15 and Chap. 247.

In the pediatric patient, causes of coma differ from the adult. Toxic ingestions, infections, and child abuse all assume a greater frequency.

Nonconvulsive status epilepticus, or subtle status epilepticus, is an area of increasing interest. Patients who have had generalized seizures and remain unresponsive may have a prolonged postictal state or be in a continuing state of electrical seizures without corresponding motor movements. This has been termed *electromechanical dissociation of the brain and body.* If the motor activity of the seizure has been stopped and the patient's level of consciousness has not lightened within 30 min, the existence of this subtle status epilepticus should be considered and urgent EEG or neurologic consultation sought.

Treatment

Treatment of coma involves identification of the etiology of the brain failure and initiation of specific therapy directed at the underlying cause. Brain-saving procedures must be performed while diagnostic steps are taking place. Again, stabilization with attention to airway, ventilation, and circulation assume priority. Attention should be paid to readily reversible causes of coma such as hypoglycemia and opioid toxicity. Management steps are summarized in Table 221-9.

TABLE 221-9 Management Steps for the Comatose Patient

The "coma cocktail" that was routinely given to all comatose patients has come under scrutiny. Certainly, hypoglycemia is common, but with rapid glucose determinations, empiric administration of dextrose is not always necessary. It has been axiomatic that thiamine should be administered before glucose administration. This may remain reasonable in a patient with a suspected history of alcohol abuse or malnutrition, but there is no empiric evidence that the administration of thiamine must precede glucose administration in any acute setting. Naloxone, an opiate antagonist, should be given with known or suspected opiate overdose. While administration of opiate antagonists need not be routine, anecdotal reports of opiate reversal when the condition was masked or unsuspected abound. Routine use of flumazenil in unknown coma is not recommended.[22]

Several rapid decisions face the emergency physician. An early decision involves assigning the patients to probable traumatic or structural coma etiology or to a toxic-metabolic etiology. History and physical examination allow that initial categorization with many patients but maintaining a low threshold for CT scanning is encouraged because exceptions to the tentative clinical diagnosis are frequent. Further, consultants will invariably request this investigative modality except when the emergency clinician misses an obvious reversible cause. However, patients should be stable prior to obtaining this test, and causes such as carboxyhemoglobinemia and hypothermia, conditions easy to overlook at times, should also be sought.

If history, physical, or neuroimaging suggests increased intracranial pressure, specific steps may be indicated to reduce or ameliorate any further rise in ICP. In the intubated patient, hyperventilation with Pa_{CO_2} to roughly 30 mmHg will reduce cerebral blood volume and transiently lower ICP. Any noxious stimulus including "bucking" the ventilator will increase ICP. Paralysis and sedation should be readily used. Osmotic diuretics such as mannitol (0.5 to 1 g/kg) will decrease intravascular volume and brain water and may transiently reduce ICP. In cases of brain edema associated with tumor, steroids such as dexamethasone will reduce edema over several hours. Data to recommend specific therapy is lacking, and preferences among individuals and institutions vary greatly; early communication is encouraged with consultants and admitting physicians. Management of ICP is discussed in detail in Chap. 247.

Disposition

Patients with readily reversible causes of coma, such as insulin-induced hypoglycemia, may be discharged if home care and follow-up care is adequate and a clear cause for the episode is suspected. For patients with enduring altered consciousness, admission is necessary. Most systems depend on emergency physicians to stabilize the patient and correctly assign a tentative diagnosis so that the patient may be admitted to the proper specialty service. For example, neurosurgery at most institutions will admit patients with isolated cranial trauma or intracranial hemorrhage. Medical intensivists commonly care for patients with toxic or systemic etiologies of coma. Neurologists may admit patients with primary CNS causes of coma. Patterns of admission vary among institutions. If the appropriate intensive care unit is not available, transfer should be considered after stabilization.

222 ATAXIA AND GAIT DISTURBANCES

J. Stephen Huff

Ataxia and gait disturbances are symptoms of a variety of disease processes and generally are not themselves diagnoses. Ataxia is the failure to produce smooth intentional movements. Gait disorders include ataxic gait, as well as a variety of other conditions. The presenting complaint may be articulated by the patient or family as weakness, dizziness, stroke, falling, or another nonspecific or even inaccurate chief complaint. These symptoms do not exist in isolation from the nervous system and must always be viewed in the context of the patient's overall clinical picture. For example, a patient with an acute intracerebral hemorrhage may be aphasic and hemiplegic with the inability to walk, yet no one would consider this primarily a gait disturbance. However, if the intraparenchymal hemorrhage were in the cerebellum, the inability to walk may be one of the dominating signs and symptoms. This chapter focuses on an approach to patients with ataxia or gait disturbance, the generation of a differential diagnosis, and diagnostic options. Acute ataxia are emphasized; chronic or progressive forms such as those associated with some inherited disorders are covered only in a list.

PATHOPHYSIOLOGY

Ataxia or gait disturbances may result from many conditions that affect different elements of the central and peripheral nervous systems (Table 222-1). Clinicians tend to think that these disorders result primarily from cerebellar lesions. Cerebellar lesions do cause ataxia, but isolated lesions of the cerebellum are not the most common cause of these complaints.

TABLE 222-1   Common Etiologies of Acute Ataxia and Gait Disturbances

The summation and integration of proprioceptive information from the joints and tendons, visual information, and vestibular inputs while the head, body, or limbs are moving, and the production of a smooth, steady muscular movement is a complex process involving different areas of the central nervous system (CNS) and elements of the peripheral nervous system. Transmission of proprioceptive information from the peripheral nervous system into the CNS is required, as well as integration and processing that does occur mainly in the cerebellum. Conscious and unconscious input from the cortex is also thought to occur. Visual input is involved in compensation of abnormal movements. The entire process is complex, intricate, and occurs continuously during voluntary and involuntary movements.

Ataxia may be roughly categorized into two types. Motor ataxias are usually due to disorders of the cerebellum; the sensory receptors and afferent pathways are intact, but integration of the proprioceptive information is faulty. Involvement of the lateral cerebellum (the cerebellar hemispheres) may lead to a motor ataxia of the ipsilateral limb. Lesions affecting primarily the midline portion of the cerebellum often cause problems with axial muscle coordination reflected in difficulty maintaining a steady upright standing or sitting posture. Motor ataxia is also referred to in the literature as cerebellar ataxia.

There are reports of lesions in what would seem to be unexpected locations producing motor ataxia. Supratentorial infarctions, particularly small deep infarctions or lacunes of the posterior limb of the internal capsule, have been reported to cause isolated hemiataxia. It is postulated that interruption of either ascending or descending cerebellar to cortical pathways are the cause of this motor-type ataxia. [1] Small infarctions or hemorrhages in thalamic nuclei may produce a clinical picture of motor or cerebellar like ataxia with hemisensory loss. These effects are seen contralateral to the lesion. [2] Lesions affecting the frontal lobe, such as tumor or hydrocephalus, may cause a motor ataxia of the contralateral extremities through poorly understood mechanisms. [3]

Sensory ataxia occurs with a failure in transmission of proprioception or position sense information to the CNS. This may occur in the peripheral nerves, spinal cord, or cerebellar input tracts. Coordinated motor performance is faulty even though motor systems and the cerebellum are intact. Sensory ataxia may be compensated to a degree consciously with visual sensory information. Loss of this visual information leads to the observation that sensory ataxia often worsens in poor lighting conditions and may by brought out during examination (see below).

CLINICAL FEATURES

Historical information should be collected about the entire symptom constellation in addition to complaints of headache, nausea, fever, weakness, or numbness. A history of febrile illness, medication history, or family history may be the key element leading to a correct diagnosis in individual cases. The nature of onset of symptoms and the time course of the process guide the pace of investigations. For example, abrupt onset of gait difficulty in a patient with severe headache, drowsiness, nausea, and vomiting should suggest an acute process within the CNS, possibly a hemorrhage into the cerebellum. The possible complications of that diagnosis are severe and require immediate attention. On the other extreme, a patient without significant medical history who is brought to the emergency department with a stumbling gait after an episode of binge drinking requires examination but may need nothing other than observation unless history or physical examination suggests trauma or some alternative cause for the symptoms.

The following discussion of the neurologic examination assumes that the gait disorder is the dominating abnormality, but a complete examination including testing of cranial nerves, mental status, or the motor system is always necessary and may yield findings that lead to an unanticipated diagnosis.

Gait testing is one of the most important parts of the directed neurologic examination. Observing the patient sit upright in the stretcher, rise, stand, walk, and turn gives information about many parts of the nervous system. The patient should be asked to walk at a normal speed, then walk on the heels, and then toes. Tandem gait is toe-to-toe walking and also tests many elements of the nervous system. Do not assume a normal examination without specifically testing gait or ambulation.

Cerebellar functions are tested by asking the patient to perform smooth voluntary movements and rapidly alternating movements; dyssynergia (breakdown of movements into parts), dysmetria (inaccurate fine movements), or dysdiadochokinesia (clumsy rapid movements) may be indicative of a problem in the lateral cerebellum. The thigh-patting test particularly examines rapidly alternating movements. This is correctly performed by patting the thigh with the palm then the back of the same hand in alternating fashion, making a sound with each rapid slap. The maneuver is performed with each hand in turn. The familiar finger-to-nose test (dyssynergia) may be helpful in distinguishing between cerebellar and posterior column lesions. Performing this test with the eyes closed tests proprioception in the

upper extremity. A test for cerebellar function that emphasizes the lower extremities (and another part of the cerebellum) is the familiar heel-to-shin test (also dyssynergia). In cerebellar disease, the knee may be initially overshot. In posterior column disease, there may be difficulty locating the knee but the ride down the shin weaves from side to side or falls off. Other tests commonly used for cerebellar function in the Stewart-Holme rebound sign (sudden release of the flexed forearm may rebound back and forth in several cycles).

The Romberg test is a test of sensation and, if positive, distinguishes sensory from motor ataxia. With the patient standing with arms outstretched and the eyes open, the patient is observed for signs of unsteadiness. The feet should be narrowly spaced, and the posture should be easily maintained. The inability to maintain a steady standing posture (or in extreme cases, a seated position) confirms that an ataxia is present but does not yet give any information about the type of ataxia. The patient is then asked to close the eyes with resulting loss of visual orienting information. If the ataxia worsens with this loss of visual input, then the Romberg sign is present or positive, suggesting a sensory ataxia with a problem of proprioceptive (posterior column) or vestibular function. In patients who show little or no change in their unsteadiness with eye closure (Romberg test negative), a motor ataxia is suggested with possible localization of that problem to the cerebellum. Note that many normal individuals will have some increase in unsteadiness with eye closure. Further neurologic examination is indicated to confirm the suspicion of sensory etiology of the ataxia.

In the last century, tabes dorsalis (neurosyphilis) was a common cause of sensory ataxia. The neuropathologic descriptions of this disorder and correlation with the physical examination were the foundation of modern principles of anatomic localization of neurologic function. [4] In tabes dorsalis, the posterior columns and posterior spinal roots degenerate, primarily in the lumbosacral region. The loss of proprioceptive information from the lower extremities renders the patient dependent on visual cues for correct gait. The classic description paints the picture of a patient who walks slowly with wide gait while staring at the ground. In darkness or with interruption of vision, the patient is unable to walk. The gait in this condition is peculiar with the foot first raised and then slapped to the ground with each step. These abnormalities reflect the loss of proprioceptive information from the posterior root and posterior column degeneration. The possibility of vitamin B$_{12}$ deficiency should always be a consideration in patients with evidence of posterior column disease. If left untreated, an initial unsteady gait progresses to weakness, spasticity, and ataxia. The finding of a megaloblastic anemia may be a clue, but it is not always present.

Sensory examination in a patient with unsteady movements should include position or vibration testing (posterior columns), as well as testing sensation to pinprick. Testing of the deep tendon reflexes will serve largely to discover asymmetry or spasticity that might suggest an alternative diagnosis. Acute cerebellar injury may result in muscle hypotonia for a few days or weeks.[5]

Nystagmus is seen in many different disorders due to lesions in a variety of different locations of the CNS, but this does suggest that the pathologic process is intracranial, and not in the spinal cord or peripheral nervous system (see Chap. 223, "Vertigo and Dizziness).

No organized classification scheme exists for gait disorders, and different authors categorize abnormal gaits largely in descriptive terms. A brief summary of some of more commonly used terms follows. A *cerebellar* or *motor ataxic* gait is wide-based with unsteady and irregular steps; compensation to barriers in the environment may be lacking. The gait of sensory ataxia resulting from loss of proprioception is notable for abrupt movement of the legs and slapping impact of the feet with each step.

An *apraxic* gait is one in which the patient seemingly has lost the ability to initiate the process of walking, a sort of "ignition failure." Apraxia describes the inability of a patient to perform a voluntary act even though the motor system and understanding are intact. This may occur with right or nondominant hemispheric lesions. Frontal lobe dysfunction may result in a similar gait. This may be seen in normal pressure hydrocephalus.

Foot drop from peroneal muscle weakness will be reflected in an *equine* (high stepping) gait. The high stepping from hip flexion is necessary for the foot to clear the ground.

The term *festinating* gait is used to describe narrow-based miniature shuffling steps. Once the walk begins, the steps may become more rapid. This is common in Parkinson's disease and may be accompanied by other elements of Parkinson's disease, such as increased muscle tone, lack of facial expression, slow movements (bradykinesia), and tremor.

An unusual gait with outward swinging or circumabduction of the leg suggests a mild hemiparesis reflecting the asymmetric weakness of the proximal lower extremity muscles. The examination should then be directed to find other signs of hemiparesis. This weakness of the trunk and pelvic girdle muscles may result in a waddling gait from failure to maintain the normal position of the pelvis relative to the lower extremities.

A *functional* gait disorder is one in which the patient is unable to walk normally though all motor pathways, sensory pathways, and cerebellar functions may be demonstrated to be functioning normally. The underlying problem is often a conversion disorder. These gaits may be bizarre, resembling a person wildly balancing on a tightrope and seemingly threatening to fall but not falling. The wildness of flailing movements without falling actually demonstrates that the strength, balance, and coordination are intact. This dramatic functional gait is termed *atasia-abasia.*

A unifying concept defines gait disorders according to the level of processing of neurologic information (Table 222-2).[6] Low-level gait disturbance refers to disorders of proprioception or dysfunction of the musculoskeletal system. Middle-level gait disturbance causes distortion of appropriate interaction of postural and motor processes or synergies. This might include stroke with paralysis, cerebellar dysfunction, or diseases of the basal ganglia such as Parkinson's disease. On examination, patients might have findings of spasticity, muscular tone, paralysis, or abnormal movements. High-level gait disturbances seemingly involve structures or processes that choose the appropriate responses for the support surface, body position in space, and intention of the patient. Cautious gait, apraxic gait, and the frontal gait disorder conceptually fall into this group with pathology that correlates with lesions in the frontal cortex or thalamus. This latter group is the least understood and the source of clinical confusion. This classification scheme is not ideal but does allow a thoughtful approach to patient diagnosis.

I. Low-level gait disorders
  A. Musculoskeletal problems
    1. Arthritic gait or other joint or skeletal problems
    2. Muscle weakness
  B. Peripheral sensory problems
    1. Sensory ataxia gait
    2. Vestibular problems

II. Middle-level gait disorders
  A. Hemiplegia
  B. Paraplegia
  C. Motor or cerebellar ataxia
  D. Parkinson's disease
  E. Dystonia, chorea, other movement disorders

III. High-level gait disorders
  A. Senile gait (cautious gait)
  B. Frontal ataxic gait
  C. Apraxic gait (gait ignition failure)
  D. Frontal disequilibrium

Note: ''Level'' refers to the level of processing of sensorimotor information.

TABLE 222-2 Classification of Gait Disorders

DIAGNOSIS

History and physical examination remain the key in evaluation of ataxia and gait disorders. If other symptoms or signs are present in addition to ataxia or gait disturbance, then the diagnostic approach might follow that clinical pathway. When the predominant complaint is ataxia or gait disturbance, determine whether ataxia is sensory or motor. Attempt to determine whether the primary process is systemic or within the nervous system. If within the nervous system, the next question is one of localization to the peripheral nervous system versus the CNS and perhaps to a more specific anatomic location. Finally, the tempo of the illness, comorbid diseases, and other clinical findings guide investigations and may allow a disease-specific diagnosis.

A patient with acute gait failure over hours to days needs thorough evaluation in the emergency department, consultation if available, and possible admission, in

contrast to a patient with gradual loss of abilities over weeks or months, where outpatient referral and evaluation may be appropriate.

SPECIFIC ISSUES THAT IMPACT EVALUATION AND TREATMENT

Geriatric Issues

The gait changes with advancing age. A typical constellation includes gait slowing, shortening of the stride, and widening of the base. This results in the appearance of a guarded gait, that is, the gait of someone about to slip and fall. Many patients are aware of the loss of speed and adaptive balance and acknowledge the need to be careful. The nature of this *senile* gait is not fully understood but may represent a mild degree of neuronal loss, failing proprioception, slowing of corrective responses, or weakness of the lower extremities. Senile gait disorder is thought to exist in up to one-quarter of the elderly population. Some authorities divide this disorder into components of gait ataxia with mild truncal instability and widened gait, and gait slowing with diminished spontaneous arm swing and bradykinesia. [7] However elements of the senile gait are also found in neurodegenerative diseases, and caution is urged to consider the possible presence of a neurodegenerative disorder such as Parkinson's disease in elderly patients with gait impairment. [7]

Pediatric Issues

In evaluating children with acute ataxia or gait disorder, examination must exclude weakness and musculoskeletal disorders. The child may be awake, alert, and playful but is visibly unsteady or wobbly sitting on a stretcher. The differential diagnosis is long (Table 222-3).

TABLE 222-3   Causes of Acute Ataxia in Children Roughly in Order of Frequency

Intoxications are a cause of ataxia in children, and the ingestion may be surreptitious. Though ethanol may be suspected by odor, other drugs such as phenytoin or carbamazepine will not be detected in that manner. History should include queries about any medications in the household.

Unusual metabolic disorders such as pyruvate decarboxylase complex deficiency may present with ataxia. Family history may or may not suggest a metabolic disorder. Typically, the onset is gradual, but abrupt decompensations may occur. Other systemic or CNS abnormalities will be present.

Posterior fossa mass lesions and other CNS masses may present with ataxia, though usually some abnormality of cranial nerves or strength will be discovered with careful examination. Attention is needed to exclude abnormalities on physical examination that might suggest problems not localized to the cerebellum. Abnormal ocular movements should increase the suspicion of a mass lesion.

Rarely, ataxia can follow immunizations, viral illnesses, or varicella but also has been rarely reported in the preeruptive phase of varicella. [8] Most children are in the 2- to 4-year-old range. The onset of gait ataxia is abrupt, and only occasionally is fever present at the time ataxia begins. The latency from the prodromal illness to the onset of ataxia is from 2 days to 2 weeks. Other neurologic findings encountered included truncal ataxia, dysmetria and, uncommonly, cranial nerve abnormalities. Varicella patients appear to have uniform excellent recovery compared with patients with acute cerebellar ataxia from other causes that may have some residual problems.[9] Little workup is needed if the ataxia occurs in the convalescent phase of varicella, and antiviral medications are not indicated. Otherwise, neuroimaging, lumbar puncture, and consultation are advisable. One study showed that while roughly half of the patients had cerebrospinal fluid inflammatory changes with pleocytosis or elevated immunoglobulin G index, magnetic resonance imaging (MRI) identified inflammatory changes in the cerebellum in only a minority of cases. [9] Another small report noted MRI abnormalities not only in the cerebellum but in other areas of the CNS. This "syndrome" may in fact consist of several subgroups, some of which involve transient demyelination.[10]

TREATMENT AND DISPOSITION

The underlying cause must be identified and any available therapy directed toward the primary disease process.

Disposition depends on the final diagnostic formulation and a risk assessment of likely progression of process and patient safety. At most centers, a suspicion of a mass lesion will have been addressed by the performance of a neuroimaging study, likely computed tomography because of availability, prior to any disposition decision.

Gait failure in the elderly is of specific concern, and the safety of patients must always be considered. Patients unable to walk or care for themselves should be admitted for supportive care. If the clinical course is one of slowly progressive impairment of gait or ataxia, then outpatient referral to the primary care physician or neurologist may be the proper course.

223 VERTIGO AND DIZZINESS

Brian Goldman

As many as 0.5 percent of the population consult their physician each year regarding vertigo, and 1 percent report dizziness. [1] The evaluation of dizziness can test the diagnostic skill of most emergency physicians. The difficulties begin with the patient's chief complaint. The term *dizziness* is nonstandardized and ambiguous. Dizziness may mean vertigo, syncope, presyncope, weakness, giddiness or anxiety, or a disturbance in mentation. The patient's symptoms should therefore be clarified as much as possible.

Vertigo is the perception of movement where no movement exists. Patients may describe themselves as moving or may describe the environment as moving in relation to themselves. The type of movement may be described as rotatory or vertical; alternatively, the patient may describe a sense of staggering, swaying, or being pulled or hurled to the side or onto the ground.

Syncope is a transient loss of consciousness that is accompanied by loss of postural tone with spontaneous recovery. It is associated with a transient reduction of cerebral blood flow, oxygen, and glucose to the reticular activating system. To meet the definition of syncope, no exogenous electrical or chemical cardioversion should be required to regain consciousness. Syncope accounts for 3 percent of emergency department (ED) visits and 1 to 6 percent of hospital admissions. Near-syncope is defined as light-headedness signifying an impending loss of consciousness without loss of consciousness actually occurring.

Psychiatric dizziness has recently been defined as a sensation of dizziness not related to vestibular dysfunction that occurs exclusively in combination with other symptoms as part of a recognized psychiatric symptom cluster.[2] In dizziness clinics, the frequency of this category can range between 20 and 50 percent of patients.

Disequilibrium is another term that is sometimes used to describe a feeling of unsteadiness or imbalance while walking. Some patients describe a sensation of feeling as if they were "floating." It is often due to decreases in visual acuity or proprioception.

PATHOPHYSIOLOGY

Equilibrium and spatial orientation are determined by a sophisticated network of complex interactions within the central nervous system (CNS). The CNS coordinates and integrates sensory input from the visual, vestibular, and proprioceptive systems. The three streams of information are combined in the brain to form an impression of the orientation of the head and body as well as of motion. Vertigo arises from a mismatch of information from two or more of the involved senses, which, in turn, is caused by dysfunction in the sensory organ or its corresponding pathway.

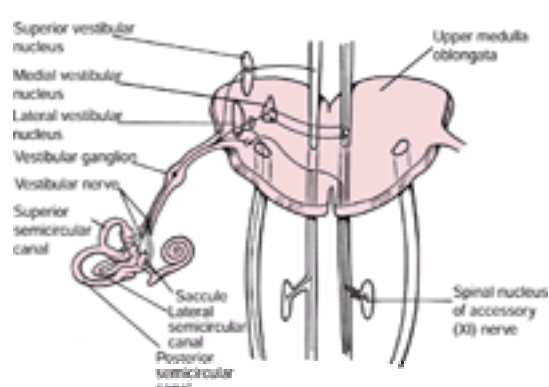
Visual inputs arise from the eyes, the optic pathways, and the visual cortex, providing spatial orientation. Proprioceptors that are located primarily in the joints and muscles of the limbs, neck, and trunk help convey a sense of movement and body position; they relate movements and indicate the position of the head relative to that of the body. In the vestibular system, the otoliths produce an orientation to gravity. The cupulae contain sensors that track rotary motion. The presence of embedded otoconia or particles on the cupulae may transform them into linear motion sensors capable of sensing gravity. There are three semicircular canals that sense orientation to movement and head tilts. The semicircular canals are filled with a fluid called endolymph, the water component of which derives from the perilymph. The striae vascularis are important in maintaining the ionic composition of the fluid. The endolymphatic sac produces glycoproteins that create an osmotic sink necessary to maintain flow. The movement of fluid in the semicircular canals causes specialized hair cells inside the canals to move, causing afferent vestibular impulses to fire. Sensory input from the vestibular apparatus travels to the nucleus of the eighth cranial nerve (Fig. 223-1).


FIG. 223-1. Vestibular innervation.

The CNS structures involved in integrating sensory input from all three sensory modalities include the medial longitudinal fasciculus, the red nuclei, the cerebellum, and the parietal lobes and superior temporal gyrus of the cerebral cortex. Connections between these structures and the oculomotor nuclei that drive the vestibuloocular reflex (VOR) complete the system. The VOR prevents retinal slip and thus visual blurring that would otherwise result from head movements and body sway.

Several neurotransmitters are involved in vestibular transmission. Glutamate is a major neurotransmitter of vestibular nerve impulses. Muscarinic cholinergic receptors involved in this system (chiefly the M2-type) have been found in the pons and medulla. Gamma-aminobutyric acid (GABA) is an inhibitory neurotransmitter found in connections between central vestibular and oculomotor neurons. Histaminergic receptors are located pre- and postsynaptically on vestibular cells. Both noradrenaline and dopamine have been found to have a modulating effect on the vestibular system. [3]

In the presence of balanced input from the vestibular apparatus on both sides, there is no perception of motion. Altering the symmetry of input from both sides produces vertigo. Thus, any unilateral lesion of the vestibular apparatus may produce vertigo. In addition, the apparatus on either side may be induced to fire excessively due to abnormal motion of the endolymph. Unlike the preceding example, although vertigo is produced, there is no other clinical evidence of damage to the vestibular apparatus. Rapid head movements induce vertigo by accentuating the imbalance. Damage to or dysfunction of any of the central structures mentioned previously can also lead to vertigo. Bilateral damage does not usually produce vertigo but may lead to truncal or gait instability.

The most striking clinical sign associated with vertigo is nystagmus. Nystagmus is a rhythmic movement of the eyes that has both a fast and a slow component. The direction of nystagmus is named by its fast component. The slow component is due to the vestibuloocular reflex and is generated by the excitation of the semicircular canal, producing eye movement away from that canal. The fast component of nystagmus is caused by the cortex, which exerts a quick corrective movement in the opposite direction. With disorders of the vestibular apparatus, the sensation of vertigo is usually associated with nystagmus. The nystagmus of vestibular injury or dysfunction is provoked when the affected side is in the dependent position, and the characteristic pattern is vertical and rotational or horizontal. When horizontal nystagmus is present, its slow-beating component points to the injured labyrinthe. Vertical nystagmus by itself (and not associated with a rotational component) usually indicates a brainstem abnormality.

The likelihood of vertigo and other forms of dizziness increases as people age. Decreases in visual acuity, proprioception, and vestibular input may occur. These may manifest as vertigo or unsteady gait that is reported as "dizziness" by the patient. The risk of near-syncope also increases due to causes such as dysrhythmias, orthostatic hypotension, and autonomic dysfunction. In addition, as people age, they are more likely to have free-floating otoconia within the semicircular canals. Otoconia are particles made of calcium carbonate that become displaced from the utricular maculae by aging, head trauma, and diseases of the labyrinth. The particles are heavier than the surrounding endolymph and tend to collect in the most dependent part of the endolymph system, where they tend to clump. It is unknown what percentage of people without symptoms have such particles. [4]

CLINICAL FEATURES

The conditions that cause vertigo are summarized in (Table 223-1). Vertigo is typically subdivided into peripheral and central causes. Unfortunately, clinical abilities to distinguish the severity of vertigo are limited since there is no measurement scale for vertigo. While the discussion below does classify vertigo somewhat by severity, the clinician must also use information such as age, comorbidity, and vascular disease to stratify the probability of central versus peripheral vertigo. Peripheral vertigo is caused by disorders affecting the vestibular apparatus and the eighth cranial nerve, while central vertigo is caused by disorders affecting central structures, such as the brainstem and the cerebellum. The characteristics distinguishing peripheral and central vertigo are found in Table 223-2. Figure 223-2 shows how the nystagmus pattern itself may help to differentiate peripheral and central vertigo.

Vestibular/otologic	Benign paroxysmal positional vertigo
	Traumatic: after head injury
	Infection: labyrinthitis, vestibular neuronitis, Ramsay Hunt syndrome
Syndrome	Ménière syndrome
	Neoplastic
	Vascular
	Otosclerosis
	Paget disease
	Toxic or drug-induced: aminoglycosides
Neurologic	Vertebrobasilar insufficiency
	Lateral Wallenberg syndrome
	Anterior inferior cerebellar artery syndrome
	Neoplastic: cerebellopontine angle tumors
	Cerebellar disorders: hemorrhage, degeneration
	Basal ganglion diseases
	Multiple sclerosis
	Infections: neurosyphilis, tuberculosis
	Epilepsy
	Migraine headaches
	Cerebrovascular disease
General	Hematologic: anemia, polycythemia, hyperviscosity syndrome
	Toxic: alcohol
	Chronic renal failure
	Metabolic: thyroid disease, hypoglycemia

TABLE 223-1   An Etiologic Classification of Vertigo

	Peripheral	Central
Onset	Sudden	Slow
Severity of vertigo	Intense spinning	Ill defined, less intense
Pattern	Paroxysmal, intermittent	Constant
Aggravated by position/movement	Yes	No
Associated nausea/diaphoresis	Frequent	Infrequent
Nystagmus	Rotatory-vertical, horizontal	Vertical
Fatigue of symptoms/signs	Yes	No
Hearing loss/tinnitus	May occur	Does not occur
Abnormal tympanic membrane	May occur	Does not occur
CNS symptoms/signs	Absent	Usually present

TABLE 223-2   Classification of Vertigo
FIG. 223-2. Schematic drawing of peripheral and central vestibular nystagmus with and without visual fixation. The direction of the arrows indicates the horizontal

direction of the fast phase of the nystagmus (a torsional component is not shown). The thickness of the arrows represents the relative intensity of the nystagmus. Panel A shows findings typical of peripheral nystagmus, which remains in the same direction when the direction of gaze changes, and central nystagmus, which changes direction when the direction of gaze changes. Removal of visual fixation increases the intensity of peripheral nystagmus but not of central nystagmus. Panel B illustrates how removal of fixation helps to differentiate peripheral from central nystagmus when the nystagmus is predominantly in one direction of gaze during fixation. With removal of fixation, peripheral nystagmus may increase in intensity and become apparent in more than one direction of gaze. (Reprinted by permission.)

Although disorders causing peripheral vertigo tend to produce more distressing symptoms, they are seldom life-threatening. Disorders causing central vertigo may produce less distressing symptoms and have a slower onset than those due to peripheral vertigo, but they are generally of a more serious nature, requiring urgent or semiurgent diagnostic imaging or consultation with a neurologist or neurosurgeon. Unfortunately, these clinical features of vertigo are not always sufficient or specific enough to clearly classify the disorder as central or peripheral.

DISORDERS CAUSING PERIPHERAL VERTIGO

Peripheral vertigo is noted for its abrupt (often explosive) onset. Peripheral vertigo produces an intense sensation of spinning or hurtling toward the ground or surrounding walls. It is typically worsened by rapid movement and by changes in head position. Peripheral vertigo is frequently associated with nausea, often severe vomiting, and diaphoresis; it may be associated with signs of increased vagal tone such as bradycardia and hypotension.

Benign Paroxysmal Peripheral Vertigo

Benign paroxysmal peripheral vertigo (BPPV) is one of the most common causes of peripheral vertigo, accounting for as many as 17 to 22 percent of patients presenting to dizziness clinics.[5] The incidence of BPPV has been estimated as being as high as 64 per 100,000 per year.[6] This estimate was derived from patients seen only by ear/nose/throat (ENT) specialists, omitting those seen only by primary care physicians. Thus, the incidence may be underestimated. BPPV is defined as a mechanical disorder of the inner ear causing transient vertigo (with autonomic symptoms) and associated nystagmus that is precipitated by certain head movements. The condition was first described by Barany in 1921, and most of the essential clinical features were described by Dix and Hallpike in 1952.[7]

The most widely accepted hypothesis to explain BPPV is known as *canalolithiasis.* According to this hypothesis, BPPV is caused by inappropriate activation of the posterior semicircular canal (typically unilateral) by the presence of free-floating particles or otoconia. The otoconia become displaced from the utricular macula by aging, head trauma, or labyrinthine disease. Because the particles are heavier than the surrounding endolymph, they tend to collect in the long arm of the posterior semicircular canal, the most dependent part of the endolymph system. Once the particles clump in sufficient mass, changes in head position cause gravitation of the particles, which creates a hydrodynamic drag (or plunger effect) on the endolymph, causing the cupula to be displaced. This results in aberrant neural firing, causing both vertigo and nystagmus.

BPPV can occur at any age, but the average age of onset is in the mid-fifties. Women are twice as likely to be affected as men. The onset is sudden, and an attack is typically precipitated by rolling over in bed, assuming a supine position, leaning forward, looking up at the sky or ceiling, or turning the head. Nausea is often present, although vomiting is unlikely because of the transient nature of the symptoms. Because the symptoms fatigue, they tend to be worse in the morning and become less pronounced as the day progresses. Patients may eliminate the offending activities. There is no associated hearing loss or tinnitus and no physical findings on examination of the external auditory canal.

Several findings support a diagnosis of BPPV (Table 223-3). There is a latency period of 1 to 5 s between assuming the offending head position and onset of vertigo and nystagmus. Both the vertigo and nystagmus crescendo to a peak of intensity, then subside within 5 to 40 s. BPPV is diagnosed using the Dix Hallpike position test. Although Nylen and Barany are sometimes credited with discovering the maneuver, Dix and Hallpike clearly published the first description of the test in wide use today.[8] When the head is rotated 30 to 45° toward the affected side and the patient is brought to the supine position with the head lying 30° below the level of the examining table, this brings the affected ear into the dependent position. After a latency of 1 to 5 s, this causes rotatory nystagmus with a fast-beating component toward the undermost ear. The nystagmus may reverse direction as the head is returned to the erect position. The response to repeated provocative testing fatigues, causing the vertigo and nystagmus to disappear.[8]

1. There is a latency period of 1–5 s between the provocative head position and onset of nystagmus.

2. The intensity of nystagmus increases to a peak before slowly resolving.

3. The duration of vertigo and nystagmus ranges from 5–40 s.

4. If nystagmus is produced in one direction by placing the head down, then the nystagmus reverses direction when the head is returned to the sitting position.

5. Repeated head positioning causes both the vertigo and accompanying nystagmus to fatigue and subside.

TABLE 223-3   Supportive Findings in Benign Paroxysmal Peripheral Vertigo

Meniere's Disease

Meniere's disease is a disorder associated with an increased volume of endolymph within the cochlea and labyrinth. It occurs equally in men and women, with onset in middle age. The disease is usually unilateral to begin with and often becomes bilateral over time. The precise pathogenesis is unknown, but evidence suggests that patients have difficulty regulating the volume, flow, and composition of endolymph. Histologic studies have demonstrated that the endolymphatic sac contains immunologically active tissue, raising the possibility of an autoimmune mechanism. As with BPPV, the onset of vertigo is usually sudden. However, the duration of vertigo ranges from 20 min to 12 h (typically 2 to 8 h). It is associated with nausea, vomiting, and diaphoresis. The frequency of attacks can vary from several times per week to several times per month. Between attacks, the patient is usually well, although deafness may persist. Other hallmarks of the diagnosis include associated symptoms such as roaring tinnitus, diminished hearing, and fullness in one ear. Current treatments offer symptomatic relief without altering the course of the disease.

Perilymph Fistula

A perilymph fistula is an opening in the round or oval window, permitting pneumatic changes in the middle ear to be transmitted to the vestibular apparatus. Trauma, infection, or a sudden change in the pressure inside the cerebrospinal fluid may cause the tear. The diagnosis is suggested by the sudden onset of vertigo associated with flying, scuba diving, severe straining, heavy lifting, coughing, or sneezing. The diagnosis is confirmed by nystagmus elicited by pneumatic otoscopy (Hennebert sign).

Vestibular Neuronitis

Vestibular neuronitis is a disorder of suspected viral etiology that causes intense peripheral vertigo. The location of the viral infection is unknown, although inflammation of the eighth cranial nerve or brainstem has been suspected. Unlike BPPV and Ménière disease, vestibular neuronitis typically lasts several days and does not recur. The onset is usually sudden, and the patient is otherwise well except for possible symptoms of an upper respiratory infection. The vertigo is often so intense that the patient requires several days of bed rest; it then usually decreases dramatically, resolving completely over several weeks. Elderly patients may have

persistent unsteadiness of gait. Unilateral loss of hearing and tinnitus may occur. Positional nystagmus is evident in up to one-third of cases.

Labyrinthitis

Labyrinthitis is an infection of the labyrinth that produces peripheral vertigo associated with hearing loss. The precise etiology is often unknown. The infection may be viral, in which case the clinical course is similar to that of vestibular neuronitis. Cases have reportedly been associated with measles and mumps. Bacteria may also cause labyrinthitis. Although unusual, an infection within the labyrinth can develop from otitis media, in which bacteria and toxins diffuse across the membrane of the round window. A cholesteatoma can erode into the inner ear, creating a portal of entry for bacteria. Other possible antecedents for bacterial labyrinthitis include otitis media with fistula, meningitis, mastoiditis, and dermoid tumor. The hallmarks of this disease include sudden onset of vertigo with associated hearing loss and middle ear findings. Serous labyrinthitis may occasionally produce vertigo.

Ototoxicity

Aminoglycoside antibiotics produce hearing loss and peripheral vestibular dysfunction by accumulating inside the endolymph, where they cause the death of cochlear and vestibular hair cells. However, since both inner ears are affected, vertigo is uncommon. Typical clinical manifestations include ataxia and oscillopsia, which is defined as an inability to maintain visual fixation while moving. The damage is irreversible, although the degree of toxicity depends on the dose and duration of treatment with antibiotics. Loop diuretics (furosemide and ethacrynic acid) also cause irreversible vestibular and ototoxicity. Cytotoxic agents associated with vestibular damage include vinblastine and cisplatin. The antiarrhythmic drug quinidine and antimalarial drugs derived from quinine, such as chloroquine and mefloquine, can also cause vestibular symptoms that may be irreversible (Table 223-4).

Agent	Dose Dependent	Reversible
Aminoglycosides	Yes	No
Erythromycin	No	Yes
Minocycline	No	Yes
Quinolones	No	Yes
NSAIDs	Yes	Yes
Loop diuretics	No	Can be irreversible
Cytostatic drugs	Yes	No
Antimalarials	No	Yes

TABLE 223-4 Ototoxic and Vestibulotoxic Agents

Reversible causes of vestibular damage and ototoxicity include minocycline, erythromycin, and some quinolones. Isolated cases of unsteady gait have been observed with antiviral and antiparasitic agents. Acetyl salicylic acid (ASA) in toxic doses causes tinnitus and hearing loss but is unlikely to cause vertigo. Other nonsteroidal anti-inflammatory drugs such as indomethacin, ibuprofen, and naproxen may cause the same symptoms. The lesion is metabolic rather than destructive and readily resolves with discontinuation of therapy.

Numerous solvents and other chemicals can cause both peripheral as well as central vestibular symptoms. These include propylene glycol, mercury, and hydrocarbons. Drugs that induce a central vestibular syndrome include anticonvulsants, tricyclic antidepressants, neuroleptics, opiates, and alcohol. Phencyclidine is a prominent example of a recreational drug that causes central vestibular symptoms, including nystagmus and ataxia. Drugs causing irreversible cerebellar toxicity include phenytoin and toluene as well as cancer chemotherapeutic agents. In general, most patients adapt to vertigo that is chronic by relying on increased sensory input from unaffected modalities such as proprioception and vision. However, certain drugs that are used as antivertigo therapy may exacerbate preexisting chronic vertigo by delaying or inhibiting such compensation. These drugs include alcohol, benzodiazepines, barbiturates, and neuroleptics. Thus, with chronic vertigo, antivertigo therapy should not be used on a long-term basis.

Benign Paroxysmal Vertigo of Childhood

This disorder is so named because it causes severe yet brief attacks of vertigo in children less than 3 years of age. This is now generally recognized as a phenomenon related to migraine headaches. The vertigo tend to be self-limited and to resolve within childhood, sometimes giving rise to migraine headaches. Since vertigo may represent the aura of a seizure, referral to a pediatric neurologist for an assessment and an electroencephalogram (EEG) might be warranted in some cases.

Eighth-Nerve Lesions

Lesions of the eighth cranial nerve may produce vertigo. Meningiomas and acoustic schwannomas are typical causes. The onset of vertigo is usually gradual, remaining constant until central compensation can take place. It is seldom as intense, and may manifest only as unsteadiness. The vertigo is usually preceded by hearing loss. Tumors involving the cerebellopontine angle may also cause symptoms such as ipsilateral facial weakness, impaired corneal reflex, and cerebellar signs.

Herpes zoster oticus, also known as the Ramsay Hunt syndrome, is a neuropathic disorder characterized by deafness, vertigo, and facial nerve palsy. The diagnosis is made by the presence of grouped vesicles on an erythematous base inside the external auditory canal.

Cerebellopontine Angle Tumors

Vertigo is sometimes associated with tumors of the cerebellopontine angle. Such tumors include acoustic neuromas, meningiomas, and dermoids. They usually present with a cluster of findings including deafness and ataxia as well as ipsilateral facial weakness, loss of the corneal reflex, and cerebellar signs.

Posttraumatic Vertigo

Closed head injuries account for a significant percentage of patients with vertigo. Vertigo or gait unsteadiness is a common complaint following a head injury. Acute posttraumatic vertigo is caused by a direct injury to the labyrinthine membranes. Its onset is immediate following the head injury, and it produces constant vertigo, nausea, and vomiting. Such patients may have sustained a concomitant fracture of the temporal bone. Vertigo immediately associated with a closed head injury warrants computed tomography (CT) or magnetic resonance imaging (MRI) to rule out an extradural or intradural hematoma. Vertigo due to direct labyrinthine trauma tends to resolve within several weeks. Closed head trauma can also displace otoconia from the utricular maculae, precipitating an attack of BPPV. Some patients with a history of a closed head injury develop a postconcussive syndrome. Although true vertigo is uncommon with this disorder, gait unsteadiness or a vague sense of dizziness are quite common. Such patients should be referred to a neurosurgeon or neurologist for special imaging and neuropsychiatric testing.

DISORDERS CAUSING CENTRAL VERTIGO

Central vertigo is caused by disorders affecting the cerebellum and the brainstem. It can produce a strikingly different clinical picture from that of peripheral vertigo. The onset is usually gradual, the sensation less intense, and symptoms are not provoked by changes in position. Central vertigo is unlikely to be associated with nausea, vomiting, or diaphoresis. Unlike conditions causing peripheral vertigo, both tinnitus and hearing impairment are unlikely. Nystagmus is more likely to be vertical than horizontal or rotatory and may be present in the absence of vertigo. Oscillopsia is a common finding. Central vertigo tends to be accompanied by other signs of brainstem disease, such as ataxia, blurred vision, long tract signs, dysphagia, dysarthria, and diplopia.

Cerebellar Hemorrhage and Infarction

Cerebellar hemorrhage typically manifests symptoms such as acute vertigo and ataxia. Headache, nausea, and vomiting may or may not be present. The vertigo is not as intense and is not similar to the sense of hurtling that characterizes peripheral vertigo. Instead, the patient may complain of a sense of side-to-side or front-to-back motion. He or she will have truncal ataxia and may not be able to sit without support. Romberg testing and tandem gait will be abnormal. Occasionally, there may be a sixth cranial nerve palsy, or conjugate eye deviation away from the side with the hemorrhage. Cerebellar infarction has a similar clinical presentation.

Wallenberg Syndrome

A lateral medullary infarction (Wallenberg syndrome) of the brainstem can cause vertigo as part of its clinical presentation. Classic ipsilateral findings include facial numbness, loss of corneal reflex, Horner syndrome, and paralysis or paresis of the soft palate, pharynx, and larynx (causing dysphagia and dysphonia). Contralateral findings include loss of pain and temperature sensation in the trunk and limbs. Occasionally, lesions of the sixth, seventh, and eighth cranial nerves can occur, causing vertigo, nausea, vomiting, and nystagmus.

Vertebrobasilar Insufficiency

Transient ischemic attacks (TIAs) of the brainstem due to vertebrobasilar insufficiency (VBI) can produce vertigo. Such patients should present with the usual risk factors for cerebrovascular disease. As with other symptoms of a TIA, the vertigo may be of sudden onset and typically lasts minutes to hours. By definition, it should completely resolve within 24 h. VBI-induced vertigo can be accompanied by other manifestations such as diplopia, dysphagia, dysarthria, bilateral long-tract signs, and bilateral loss of vision. As diagnostic modalities improve, it is becoming clear that VBI may present without these additional symptoms. Unlike other causes of central vertigo, VBI may be provoked by position. Turning the head partially occludes the ipsilateral vertebral artery. If the contralateral artery is stenotic, head turning could cause transient ischemia to the brainstem, causing VBI. A sufficient loss of brainstem circulation caused by a head turn could affect the reticular activating system, causing near-syncope or syncope.

Multiple Sclerosis

Demyelinating disease may cause isolated areas of demyelination in the brainstem, causing vertigo. The vertigo tends to occur as a discrete episode lasting several hours to several days or weeks. It is usually nonrecurrent. Other manifestations of multiple sclerosis such as ataxia or optic neuritis may be present or may have occurred previously. The vertigo is less intense than that experienced in peripheral conditions and is accompanied by nystagmus. The nystagmus may be more prominent than the vertigo reported by the patient.

Neoplasms

Neoplasms of the fourth ventricle can cause brainstem signs and symptoms, including vertigo. Such tumors include ependymomas in younger patients and metastases in older patients.

Migraine-Related Dizziness and Vertigo

Vertigo can be a symptom of an aura, an analogue or equivalent of the headache phase itself, or as an associated symptom to the migraine prodromes. Basilar migraine is a migraine headache in which the aura is associated with clinical manifestations similar to those of VBI. The International Headache Society's diagnostic criteria for basilar migraine[9] are shown in Table 223-5. These include vertigo, decreased hearing, tinnitus, bilateral long-tract signs, bilateral visual disturbances, dysarthria, diplopia, and decreased level of consciousness. Vertigo as an aura should develop over 5 to 20 min and should subside within 60 min. Vertigo as a symptom of a migraine aura may precede the headache or may occur in the absence of a headache. The headache is typically occipital in location, throbbing in character, and associated with nausea and vomiting.

Bilateral visual symptoms in both the nasal and temporal fields

Vertigo

Tinnitus

Decreased hearing

Diplopia

Dysarthria

Ataxia

Bilateral paresis

Bilateral paresthesias

Decreased level of consciousness

*Fulfills criteria for migraine with aura (two or more of the above aura symptoms).

TABLE 223-5 Diagnostic Criteria for Basilar Migraine*

Aside from basilar migraine, a strong association has been found between migraine and cochleovestibular disturbances. True episodic vertigo has been shown to occur in 26 to 33 percent of unselected migraine patients seen in large head clinics. Such patients may complain of episodes of constant vertigo, positional vertigo, or nonvertiginous dizziness. In cases of true vertigo, the vertigo may accompany the headache or may occur independently. Such episodes of vertigo are of two typical durations. Some patients complain of vertigo lasting from several minutes to 2 h, while others experience vertigo lasting longer than 24 h. The pathogenesis of migraine-related dizziness has not been determined, but probably relates to a centrally mediated excess sensitivity to vestibular stimuli. The diagnostic criteria for migraine-related vertigo include a history of vertigo not attributable to other known conditions, along with a present or past history of migraine or a strong family history. Successful treatment has been reported with pharmacologic agents used to treat migraine, such as tricyclic antidepressants, calcium channel blockers, b blockers, and clonazepam.

Physiologic Vertigo

Physiologic vertigo is vertigo not caused by disease of the cochleovestibular system. It results from a mismatch between visual, proprioceptive, and vestibular input. This may be the pathogenesis of motion sickness as well as the transient vertigo associated with watching a film that captures the visual sensation of motion without the corresponding vestibular or proprioceptive input ("visual vertigo"). Visual vertigo is triggered by complex visual environments such as shopping malls and by viewing complex floor or wallpaper patterns.

OTHER CONDITIONS

Disequilibrium of Aging

Disequilibrium of aging is a condition manifesting as ill-defined dizziness and gait unsteadiness. Loss of hearing and balance occur normally with age. Patients over the age of 70 may have a 20 to 40 percent loss of vestibular hair cells. In addition, elderly patients often experience a decrease in visual as well as proprioceptive input, a decline in central integration and processing, as well as a decrease in motor responses. Approximately 50 percent of individuals over the age of 70 experience imbalance; of those, more than half report falls.[10] The disequilibrium of aging may be precipitated or exacerbated by diminished ambient light (with worsening of symptoms at night), unfamiliar surroundings, and the use of benzodiazepines and drugs with anticholinergic effects such as tricyclic antidepressants and neuroleptic agents. The concomitant presence of near syncope or risk factors for near syncope may complicate the diagnosis.

Near Syncope

Near syncope is a feeling of light-headedness, which, in its most severe form, leads to loss of consciousness (syncope). Some patients with near syncope may refer to the sensation of light-headedness as dizziness. Syncope and near syncope differ only in their severity. The most common categories of near syncope are vasovagal, situational, orthostatic hypotension, and drug-induced syncope. Cardiac causes such as valvular heart disease as well as cardiac dysrhythmias are also significant causes. The cause of near syncope is not determined in a significant percentage of patients. Recent evidence suggests that the majority of patients with unexplained presyncope may have vasovagal presyncope. Sole reliance on the typical clinical presentation of vasovagal presyncope may lead to underdiagnosis. Positive upright tilt testing, in which the patient is placed in the passive upright position at 60° for 45 min, is generally recommended. [12] Some protocols involve the use of isoproterenol. The end points of a positive tilt test include the development of syncope or presyncope associated with hypotension, bradycardia, or both. In normal subjects, tachycardia usually results from a passive tilt test. [11]

Syncope and near syncope in the elderly are associated with daily events, including micturition, defecation, postural changes, meals, laughing, coughing, and swallowing. Orthostatic hypotension is extremely common in the elderly and is associated with volume depletion, venous insufficiency, poor conditioning, polyneuropathy, preganglionic autonomic dysfunction (Shy-Drager syndrome), as well as the use of medications including vasodilating drugs, diuretics, other antihypertensive agents, and antiparkinsonian and anticholinergic medications. According to a position paper by the American College of Physicians, syncope in the elderly often results from polypharmacy and abnormal responses to daily events.

A new diagnostic entity has emerged called postural orthostatic tachycardia syndrome. This is a relatively mild disorder associated with a fall in blood pressure in which patients experience near-syncope, nonvertiginous dizziness, and symptoms suggestive of TIA. This condition may involve less dramatic falls in blood pressure than those seen in syncope. The pathogenesis is thought to be mild autonomic dysfunction. Findings on tilt testing include an increase in heart rate of 30 beats per minute over baseline within the first 10 min of testing (unassociated with profound hypotension), along with recurrence of the symptom complex. [12]

Convulsive Disorders

Nonconvulsive status epilepticus (NCSE) is characterized by altered mental status without loss of consciousness or tonic-clonic phenomena associated with electroencephalographic (EEG) evidence of seizure activity. The incidence is unknown because some cases may either go undetected or be attributed to other causes of altered mental status. With NCSE, patients have vague or nonspecific changes in mentation and behavior, although they may be able to answer questions and complete complex tasks. Some will complain of nonvertiginous dizziness. Symptoms may last for hours to days. The diagnosis is made by EEG as well as by determining the underlying mechanism for the seizure. [13] In addition, some patients presenting to the emergency department with nonvertiginous dizziness may be postictal.

Hyperventilation Syndrome

Patients with primary hyperventilation may experience nonvertiginous dizziness or near syncope during an episode. However, such symptoms can usually be reproduced by asking the patient to hyperventilate.

Psychiatric Dizziness

Psychiatric dizziness is defined as dizziness that occurs in combination with other symptoms as part of a recognized psychiatric disorder or symptom complex that is not related to known vestibular disorders. Although such dizziness has been characterized as nonvertiginous dizziness in the past, it is now recognized that patients with certain psychiatric disorders can present with true vertigo as part of their presenting symptoms. Dizziness is the second most common symptom reported by patients with panic disorder. In addition, a large percentage of patients with dizziness meet the criteria for panic or mood disorder. A majority of patients with panic disorder have objective abnormalities on testing of vestibular function. The strongest correlation is with patients who suffer from agoraphobia. Such patients suffer from what is known as "space and motion discomfort" (SMD). SMD is defined as comprising uncomfortable symptoms such as dizziness, imbalance, and anxiety occurring in situations delineated by certain spatial or motion characteristics. Generally, these are complex visual environments such as shopping malls. Agoraphobia may develop as a way to combat the symptoms. [13]

Psychiatric dizziness should not be confused with the phenomenon of psychogenic overlay. In the latter, the patient may manifest some symptoms of neurootologic disease, but illness behavior is augmented by the presence of psychiatric conditions. These include hypochondriasis and personality disorders. Patients who are withdrawn from serotonin reuptake inhibitors used on a long-term basis may experience nonvertiginous dizziness, along with gastrointestinal and flu-like symptoms, sleep deprivation, altered sensations, anxiety, and irritability. [14]

DIAGNOSIS

History

The diagnosis of vertigo or nonvertiginous dizziness rests largely upon a detailed history and physical examination, including provocative testing (Fig. 223-3). Determine early whether the patient is suffering from vertigo, near syncope, loss of consciousness, or less worrisome symptoms such as nonvertiginous dizziness or mild unsteadiness. Thus, the key purpose of history taking is to obtain an accurate unprompted description of what the patient means by dizziness. It is important to avoid leading questions, as they may bias the patient's responses. If the patient has difficulty describing the dizziness, it is useful to ask him or her to describe the initial episode in detail. Often this is the most vivid episode, and the patient is more likely to recall key precipitants. Further history taking depends on how the dizziness is categorized.

FIG. 223-3. Guideline approach to vertigo.

If the patient has experienced true vertigo, the next step is to determine whether the vertigo is of peripheral or central origin. Although the symptoms of central vertigo may not be severe, they are more likely to represent potentially life-threatening disorders. The temporal pattern and precipitating causes can help to distinguish the different etiologies of vertigo (Table 223-6 and Table 223-7). Peripheral vertigo is more likely than central vertigo to be intense and to be associated with nausea, vomiting, diaphoresis, tinnitus, hearing loss, and photophobia. Central vertigo is more likely to be associated with neurological symptoms and signs such as diplopia, dysarthria, and bilateral visual and sensory abnormalities. An associated headache or history of headache suggests migraine or a space-occupying lesion. Inquiry into history of head trauma and medications is required, as these can precipitate episodes of dizziness or interfere with central adaptation.

Pattern	Conditions
Seconds	BPPV,* postural hypotension
Minutes	TIAs†
Hours	Ménière disease
Days	Viral labyrinthitis
Constant	Nonspecific dizziness

*Benign paroxysmal peripheral vertigo.
†Transient ischemic attacks.

TABLE 223-6   Temporal Patterns Seen in Vertigo

Precipitant	Conditions
Head movements	BPPV*
Ingestion of salty foods	Ménière disease
Assuming a supine position	BPPV
Assuming a standing position	Orthostatic hypotension
Coughing, straining	Perilymph fistula
Specific environment	Visual vertigo, panic disorder, agoraphobia

*Benign paroxysmal peripheral vertigo.

TABLE 223-7   Precipitants of Dizziness

Because of central adaptation, true vertigo is unlikely to be constant. Thus, constant symptoms are more likely to represent nonvertiginous dizziness and psychogenic complaints. A history of numerous chronic somatic complaints increases this possibility. When such a pattern emerges, it is prudent to obtain a psychiatric history and to ask about panic disorder and agoraphobia. However, the diagnosis of psychogenic symptomatology should only be entertained after other potential causes have been ruled out, and thus it is rarely if ever appropriate to entertain in the ED. Constant oscillopsia suggests a central neurologic diagnosis.

Physical Examination

The physical examination is directed by the history obtained. General physical examination should include vital signs, orthostatic blood pressure measurements where appropriate, plus cardiac and chest examinations. In elderly patients, the carotids and vertebrobasilar system should be auscultated. Carefully check the deep tendon reflexes and sensation in the lower extremities to identify peripheral neuropathy. Always check gait and tandem gait, and perform the Romberg test. Observe whether the patient can sit up and get off the stretcher unaided. Truncal ataxia will often be precipitated during such actions.

Patients with vertigo should have ear, neurologic and vestibular examinations. The external auditory canal and tympanic membrane should be examined for evidence of otitis media, cholesteatoma, and other pathology. Insufflation of air by use of a pneumatic otoscope that precipitates a burst of vertigo with nystagmus is diagnostic of an inner ear fistula. Hearing should be screened by whispering questions to the patient in one ear while lightly covering or rubbing one's fingers in front of the contralateral ear. Patients with decreased hearing should have Webber and Rinne testing to distinguish between conductive and sensorineural hearing loss.

Neurologic and vestibular examinations overlap. The cranial nerves should be examined in detail, especially the eighth cranial nerve. Where central vertigo is considered, note abnormalities such as absent corneal reflex, facial paresis, difficulty swallowing, dysphonia, and depressed gag reflex. Test cerebellar function by rapid alternating movement. The vestibulospinal system and cerebellum are tested by tandem gait and Romberg testing. Proprioception and vibration should also be tested.

Nystagmus is the principal objective sign of vertigo. The eyes should be examined for spontaneous nystagmus, and the direction of such nystagmus should be noted. Because visual fixation can suppress nystagmus, the patient should ideally be wearing a pair of Frenzel glasses, which are high-diopter lenses in a frame equipped with a light source. Examine for nystagmus while testing extraocular movements to 40° from the midline. Note that several beats of nystagmus at the extremes of lateral gaze is a normal finding. Nystagmus on gaze testing suggests peripheral or central vertigo. The nystagmus pattern and behavior can assist in determining whether the lesion is central or peripheral (Fig. 223-2).

To diagnose BPPV, perform a Dix-Hallpike position test. This test should not be performed on patients with carotid bruits. It may be performed on patients with cervical spondylosis provided that the neck is not hyperextended. The patient should be cautioned that the test might provoke vertigo. Pretreatment with dimenhydrinate 50 mg IM or IV may make the test more tolerable but will not obliterate nystagmus. Patients should keep their eyes open at all times and stare at the examiner's nose or forehead. The initial position of the patient on an examining table is upright and seated, close enough to the head of the table so that when the patient lies down, the head will be able to extend backward an additional 30 to 45°. To test the right posterior semicircular canal, the head is initially rotated 30 to 45° to the right. Keeping the head in this position, the patient is rapidly brought to the recumbent position until the head is 30 to 45° below the level of the stretcher or examining table. A positive test is indicated by rotatory nystagmus following a latency of 1 to 5 s; the nystagmus exhibits rapid eye torsions toward the affected ear and lasts for 10 to 40 s. The patient is then returned to the upright sitting position and the test is repeated on the left side. The side exhibiting the positive test is the side of the lesion.

Patients with suspected near-syncope should have a detailed cardiovascular examination. Orthostatic hypotension is defined as a drop in systolic blood pressure of greater than 20 mmHg with reproduction of symptoms for up to 2 min upon standing. Orthostatic blood pressure measurements are notoriously unreliable, especially in elderly patients and even in patients with documented blood pressure changes. A study of elderly patients demonstrated that blood pressure readings tended to be more reliable when taken in the morning.[15] On cardiac examination, note the heart rate and rhythm and evaluate the patient for evidence of valvular disease.

ANCILLARY TESTS

Laboratory investigations should be used as confirmatory tests. Most patients with peripheral vertigo do not require emergent laboratory investigations. If bacterial labyrinthitis is within the differential diagnosis, blood for a complete blood count (CBC) and blood cultures should be obtained. Vertigo associated with a closed head injury warrants a CT scan or MRI to rule out intracranial bleeding. Patients with near syncope should have an electrocardiogram (ECG) and cardiac monitoring as well as a CBC if anemia is suspected. Ambulatory Holter monitoring may be indicated if an dysrhythmia is suspected. Emergent echocardiography is not generally indicated unless symptomatic valvular heart disease (such as aortic stenosis) or conditions causing compromised cardiac output are suspected. Electrolytes, glucose, and renal function tests are occasionally of value in patients with nonvertiginous dizziness, such as disequilibrium of aging. Thyroid testing may be of use if anxiety due to thyrotoxicosis is suspected.

Patients with suspected central vertigo may require more urgent investigations. If a cerebellar hemorrhage or infarction is suspected, a CT scan should be obtained immediately. If a cerebellopontine angle tumor is suspected, an immediate CT scan or MRI is not required unless the patient has signs and symptoms of increased intracranial pressure. Patients with suspected VBI require an ECG, cardiac monitoring and echocardiography if cardiac emboli are suspected. With VBI, it is sufficient to leave investigations such as duplex ultrasound of the cartotids and MRI with MRA to the consulting neurologist. A psychiatric assessment for consideration of panic and/or mood disorders might be warranted in patients with persistent unexplained dizziness. In addition, patients with agoraphobia suggestive of SMD might warrant a

full neurologic assessment.

Detailed testing of cochleovestibular function such as electronystagmography, posturography, and rotating chair tests are not necessary in the emergency management of peripheral vertigo. They can be left to the otologist or ENT specialist.

TREATMENT

The key principle guiding therapy is to determine the nature of the patient's dizziness. In general, short-term treatment with pharmacotherapy is the mainstay for patients with peripheral vertigo (see Table 223-8). However, such medications may exacerbate symptoms in patients with nonvertiginous dizziness. Specific treatment varies somewhat with the etiology of peripheral vertigo.

Anticholinergics	Scopolamine	0.5 mg transdermal patch q 3–4 days (behind ear)
Antihistamines	Dimenhydrinate	50–100 mg IM or PO q 4 h
	Diphenhydramine	25–50 mg IM or PO q 6 h
	Cyclizine	50 mg PO q 4 h (not to exceed 200 mg/24 h)
	Meclizine	25 mg PO q 8–12 h
Antiemetics	Hydroxyzine	25–50 mg q 6 h
	Promethazine	25–50 mg q 6–8 h
Benzodiazepines	Diazepam	2 mg PO q 8–12 h
	Clonazepam	0.5 mg q 12 h
Calcium antagonists	Cinnarizine	15 mg PO q 8 h
	Flunarizine	10 mg PO qd

TABLE 223-8   Pharmacotherapy of Acute Peripheral Vertigo

Drug Therapy

The goals of pharmacotherapy are the reduction or elimination of vertigo, the enhancement or noncompromise of vestibular compensation, and the reduction of accompanying symptoms such as nausea, vomiting, and anxiety. Many of the agents used in the treatment of vertigo may suppress both vertigo and vestibular compensatory mechanisms.

Drugs with anticholinergic effects can be quite effective in the treatment of vertigo. The current agent of choice is transdermal scopolamine. Antihistamines are the most commonly prescribed drugs for the treatment of vertigo. Their mechanism of action is not precisely known. Although they have prominent anticholinergic effects, some antihistamines such as astemizole have antivertigo properties without appreciable anticholinergic effects. A separate central action is also postulated. H_1 antihistamines are considered effective against vertigo, but H_2 antihistamines are not. The calcium channel blocker flunarizine is useful in the treatment of vertigo. Its mechanism of action remains unknown, but flunarizine does possess significant antihistaminic activity. Antidopaminergic (neuroleptic) agents such as promethazine have also been shown to be effective in the treatment of vertigo. Such agents reduce neurovegetative symptoms such as nausea and vomiting by blocking dopaminergic receptors in the area postrema of the brainstem. They also possess antihistamine and anticholinergic effects. Prochlorperazine and chlorpromazine should not be used in the management of vertigo as they tend to cause excesive orthostatic hypotension, which can exacerbate the underlying dizziness. [3] Case reports have indicated that ondansetron, a serotonin 5-HT$_3$ receptor antagonist, may be useful in the treatment of intractable vertigo accompanying brainstem disorders. The lack of controlled data and its high cost make it difficult to recommend this drug for use in emergency management. [16]

Despite lack of evidence for efficacy, benzodiazepines continue to be used widely in the United States. By binding to GABA receptors in the brainstem, benzodiazepines may act centrally to suppress vestibular responses. They may also impair vestibular compensation. Their only indication should be in the relief of severe anxiety accompanying vertigo. Small doses of medium-duration benzodiazepines such as diazepam and clonazepam are recommended.

There are several recognized complications of symptomatic therapy. Antihistamines can cause sedation and anticholinergic adverse effects. Antidopaminergic neuroleptic agents can induce or exacerbate orthostatic hypotension. These drugs can also cause somnolence and acute dystonia and can exacerbate anticholinergic adverse effects. Because of overlapping anticholinergic and antidopaminergic effects, anticholinergic, antihistaminic, and neuroleptic drugs should never be used in combination. Benzodiazepines may interfere with central compensatory mechanisms.

Vestibular neuronitis is treated symptomatically. Antihistamines and antinausea drugs should be used at the outset and withdrawn after several days if possible. Patients with bacterial labyrinthitis may benefit from symptomatic treatment but also require antibiotics and referral to an otologist or ENT specialist for likely admission and possible surgical drainage. Meniere's disease is managed symptomatically, as current drug therapy does not alter the degenerative process. Standard antihistamines and antinausea agents have been shown to be more effective than placebo in relieving acute symptoms. Treatment with a combination of the diuretics triamterene and hydrochlorthiazide has been shown to be effective in controlling vertigo. Betahistine, a histadine analogue, has been widely used in Europe for the treatment of vertigo due to Meniere's disease. The dosage of betahistine is 8 to 16 mg PO tid. None of these drug treatments improves hearing. A salt-restricted diet (less than 1 g/day of added salt) continues to be recommended. Invasive treatments for patients with Meniere's disease include surgical intervention and intratympanic applications of aminoglycosides such as gentamicin or streptomycin. Perilymph fistula is managed with symptomatic treatment and bed rest, with referral to an ENT specialist for surgical repair.

Patients with vertiginous migraine headaches should be referred to a neurologist for outpatient assessment. Initial management is symptomatic, with antivertigo therapy; migraine prophylactic agents such as b blockers and calcium channel antagonists may be instituted. Patients with nonvertiginous dizziness and disequilibrium of aging should not be treated with antivertigo medication. Patients with psychiatric dizziness related to panic disorder may be treated with a brief course of benzodiazepines. The long-term use of benzodiazepines and tricyclic antidepressants in the treatment of panic and mood disorders can worsen ataxia and further compromise central compensatory mechanisms in maintaining balance.

Vestibular Rehabilitation Exercises

Vestibular exercises are indicated for patients with BPPV, chronic vertigo, and psychiatric dizziness. [17] They are relatively simple to teach and can be quite helpful in giving patients a measure of control over their own symptoms. The principle behind vestibular exercises is the fatiguing response observed with Dix-Hallpike testing. Exercises developed by Brandt and Daroff have been shown to be efficacious. (1) The patient sits in the middle of the examining table with legs over the side. (2) The patient is then instructed to lie to one side of the table and to remain in that position until the vertigo has subsided. He or she is then asked to sit up, waiting again for any symptoms to subside. (3) The patient repeats the same maneuver, this time by lying down on the opposite side of the examining table. (4) These exercises are repeated in one session until no further vertigo is provoked. Brandt-Daroff exercises can be repeated at 3-hourly intervals at home.

Particle Repositioning Maneuver

The development of the "canalolithiasis" hypothesis for BPPV has led to a new form of treatment. The principle behind the particle repositioning maneuver is to use gravity to induce the particles to move along the semicircular canals until they end up inside the utricle, where they are unlikely to exert a plunger effect and cause vertigo. The maneuver is also known as the canalith repositioning maneuver or "Epley" maneuver. [18]

A modified form of the Epley maneuver is as follows. The affected ear is determined by Dix-Hallpike position test. An antihistamine or antiemetic may be administered prior to the maneuver for the patient's comfort. (1) The patient is seated as in the Dix-Hallpike position test and the head is turned 45° toward the affected ear. (2) The patient is gently brought to the recumbent position with the head hanging 30 to 45° below the examining table. (3) The head is gently rotated 45° to the midline. (4) The head is then rotated a further 45° to the unaffected side. (5) The patient rolls onto the shoulder of the unaffected side, at the same time rotating the head a further

45°. (6) The patient is returned to the sitting position and the head is returned to the midline.

Each portion of the maneuver should be done slowly and evenly to permit the particles to traverse their intended course. If the maneuver is done correctly, nystagmus in the same direction as that observed during Dix-Hallpike position testing may be observed. If nystagmus in the opposite direction is observed, then the particles have moved back toward the cupula; this portends an unsuccessful maneuver. The maneuver is repeated several times until both the vertigo and accompanying nystagmus have disappeared. To prevent the particles from traveling retrograde to the semicircular canal, some authors recommend that patients sleep upright for 48 h following successful treatment and avoid provocative head movements. Several randomized trials have demonstrated subjective improvement as well as objective improvement as evidenced by Dix-Hallpike testing. Although spontaneous recovery from BPPV is the usual outcome, the Epley maneuver appears to hasten complete recovery.

The Epley maneuver should not be performed on patients with cervical spondylosis or back pain that might be exacerbated. The maneuver has several potential adverse effects. As many as 20 percent of patients may experience light-headedness or mild imbalance for 1 or 2 days following treatment. In addition, a small number of patients may experience exacerbation of their vertigo accompanied by a change in the precipitating movements. The mechanism is a movement of the particles from the posterior to the anterior or horizontal canals, which resolves upon further treatment. This underscores the need for careful follow up by an ENT specialist or physician familiar with the maneuver and its potential complications. [19]

DISPOSITION

The disposition of the patient depends on the cause of the dizziness. Inability to classify the disorder as either peripheral or central is an indication for neurologic consultation. Patients with peripheral vertigo may in general be safely discharged from the ED. The criteria for admission for peripheral vertigo include vertigo with intractable nausea and vomiting as well as bacterial labyrinthitis. An accompanying fever that is unexplained should increase suspicion of a more serious process and may warrant admission. All patients with a first episode of peripheral vertigo should follow up with their primary care physician or be referred directly to an otologist or ENT specialist for further testing. It would be helpful for the emergency physician to convey the results of Dix-Hallpike position testing (paying close attention to the type and direction of nystagmus on testing) as well as caloric testing if done. Patients with BPPV who have had a particle repositioning maneuver should be referred to an otologist or ENT specialist for follow-up. The specialist should be notified that the maneuver has been carried out and given the results of follow-up Dix-Hallpike testing.

Patients with central vertigo require a consultation with a neurologist or a neurosurgeon. Patients suspected of having cerebrovascular disease (including VBI, lateral medullary syndrome, and cerebellar infarction) should be referred for neurologic consultation and possible admission. Patients suspected of having a seizure should be referred to a neurologist and possibly be admitted. On the other hand, patients suspected of having less urgent causes of central vertigo such as multiple sclerosis and migraine headache may be referred to a neurologist as outpatients. Patients suspected of having a cerebellopontine angle tumor or cerebellar hematoma should have an emergent CT scan or MRI or be referred to a neurosurgeon immediately if such imaging is unavailable. The presence of cranial nerve abnormalities should be mentioned to the consultant, as well as the presence or absence of vertical nystagmus.

Patients with near-syncope should be referred on an outpatient basis to a cardiologist for tilt testing, an echocardiogram, and Holter monitoring. Elderly patients should be referred for admission to a cardiologist if they have symptomatic coronary artery or valvular disease, exhibit a potentially life-threatening dysrhythmia, or have a past history of syncopal episodes.

In general, psychiatric consultation should only be considered once organic causes of vertigo have been ruled out. This can rarely if ever be accomplished in the ED. Psychiatric consultation may be considered for patients with dizziness not related to vestibular dysfunction that occurs exclusively in combination with other symptoms as part of a recognized psychiatric symptom cluster or for patients in whom dizziness appears to be amplified by psychogenic overlay. In addition, patients with SMD and other symptoms suggestive of panic disorder with or without agoraphobia should also be referred for outpatient psychiatric consultation.

224 SEIZURES AND STATUS EPILEPTICUS IN ADULTS

Christina Catlett Viola

INTRODUCTION

A seizure is an episode of abnormal neurologic function caused by an abnormal electrical discharge of brain neurons. The seizure is the clinical attack experienced by the patient; some patients with "epileptic" electroencephalographic (EEG) discharges may not experience any clinical symptoms. Conversely, some seizure-like clinical episodes may be due to causes other than abnormal brain electrical activity; such attacks, however impressive, are not true seizures (see below).

Epilepsy is a clinical condition in which an individual is subject to recurrent seizures; it implies a more or less fixed condition of the brain responsible for the seizures. Ordinarily, the term *epileptic* is not used to refer to an individual with recurrent seizures caused by reversible conditions such as alcohol withdrawal, hypoglycemia, or other metabolic derangements.

The occurrence of one or more seizures indicates abnormal function of cerebral neurons. When this occurs in patients who are otherwise normal and in whom no evident cause for the attacks can be discerned, the seizures are referred to as *primary* or *idiopathic.* Seizures that occur as a consequence of some other identifiable neurologic condition, such as a mass lesion, are referred to as *secondary* or *symptomatic.* Any individual can have a seizure under appropriate conditions. Electrical stimulation of the brain, convulsant potentiating drugs, profound metabolic disturbances, or a sharp blow to the head may induce seizures (termed *reactive seizures*) in otherwise normal individuals. Such attacks are generally self-limited, and such persons are not considered to have a seizure disorder or epilepsy.

Seizures are very common. There are approximately 100,000 new cases diagnosed in the United States each year. An estimated 6 to 10 percent of individuals will experience at least one seizure during their lives, and 1 to 2 percent of persons are subject to recurrent seizures. Hauser and Hesdorffer[1] from the Epilepsy Foundation of America analyzed reports of incidence and prevalence of seizures and epilepsy worldwide and deduced an overall age-adjusted incidence of 30.9 to 56.8 per 100,000. Incidence rates are highest among people less than 20 years old, with a second peak in incidence in those older than 60 years, reflecting a difference in seizure etiology between these two groups. There is a slightly higher male predominance (estimated 1.1 to 1.7 greater incidence).

The mechanisms involved in generating clinical seizures appear to be multifactorial, requiring intense and prolonged neuronal electrical discharges, and failure or inhibition of normal protective mechanisms. Scars from previous insults, such as penetrating head trauma or stroke, can act as epileptogenic foci. Factors such as medical noncompliance, fever, sleep deprivation, convulsant drugs, alcohol withdrawal, and infection can lower the seizure threshold.

SEIZURE CLASSIFICATION

Many attempts have been made to provide a clinically useful classification of seizure types, both to facilitate communication among physicians and to provide a basis for treatment decisions. Formerly, seizures were identified using the terms grand mal, petit mal, and psychomotor. The International League Against Epilepsy[2] recommends dividing seizures into two major groups: *generalized seizures* and *partial seizures* (Table 224-1). When there is inadequate data to categorize the seizure, the seizure is called *unclassified.*

Generalized seizures (consciousness always lost)
  Tonic-clonic seizures (grand mal)
  Absence seizures (petit mal)
  Myoclonic seizures
  Tonic seizures
  Clonic seizures
  Atonic seizures

Partial (focal) seizures
  Simple partial (no alteration of consciousness)
  Complex partial (consciousness impaired)
  Partial seizures (simple or complex) with secondary generalization

Unclassified (due to inadequate information)

TABLE 224-1 Classification of Seizures

Generalized Seizures

Generalized seizures are thought to be caused by a nearly simultaneous activation of the entire cerebral cortex, perhaps caused by an electrical discharge originating deep in the brain and spreading outward. The attacks begin with abrupt loss of consciousness. This may be the only clinical manifestation of the seizures (as in absence attacks), or there may be a variety of motor manifestations (myoclonic jerks, tonic posturing, clonic jerking of the body and extremities, etc.).

Generalized tonic-clonic seizures (*grand mal*) are the most familiar and dramatic of the generalized seizures. They begin with abrupt loss of consciousness; there is usually no warning or aura. In a typical attack, the patient suddenly becomes rigid, trunk and extremities are extended, and the patient falls to the ground. Patients are often apneic during this period and may be deeply cyanotic. They often urinate and may vomit. As the rigid (tonic) phase subsides, there is increasing coarse

trembling that evolves into a symmetrical rhythmic (clonic) jerking of the trunk and extremities. As the attack ends, the patient is left flaccid and unconscious, often with deep, rapid breathing. Typical attacks last from 60 to 90 s (occasionally longer). Bystanders generally overestimate the duration of the seizure. Consciousness returns gradually, and postictal confusion and fatigue may persist for several hours or longer.

Absence seizures (*petit mal*) are very brief, generally lasting only a few seconds. The patients suddenly lose consciousness without losing postural tone. They appear confused, detached, or withdrawn, and current activity ceases. They may stare and have twitching of their eyelids. They do not respond to voice or to other stimulation, exhibit voluntary movements, or lose continence. The attack ceases abruptly, and the patients are able to resume their previous activity with no postictal symptoms. Both the patients and witnesses may be unaware that anything has happened. Classic absence seizures are limited to school-aged children and are often attributed by parents and teachers to daydreaming or not paying attention. The attacks may be very frequent, sometimes occurring 100 or more times daily, and may result in poor school performance. Petit mal attacks may occur alone or in association with other kinds of seizures. They usually resolve as the child matures. Similar attacks in adults are more likely to be minor complex partial seizures and should not be called absence. The distinction is important, because the causes and treatment of the two seizures are quite different.

There are four less-common seizure classifications with which the clinician should be familiar. *Myoclonic seizures* are characterized by brief, "shock-like" muscular contractions that may be generalized or limited to one or more extremities. *Clonic seizures* involve repetitive clonic jerks without the tonic element. *Tonic seizures* have a prolonged, strained, contraction of the body with deviation of the head and eyes. The patient becomes pale, flushed, then cyanotic, and the body may rotate around in position. *Atonic seizures* are characterized by a sudden loss of postural tone in the head, trunk, and/or limbs, which may be associated with a brief loss of consciousness.

Partial (Focal) Seizures

Partial seizures are due to electrical discharges, which begin in a localized region of the cerebral cortex; the discharge may remain localized or may spread to involve nearby cortical regions or the entire cortex. Focal seizures are generally thought to be *secondary* seizures, their occurrence implying a localized structural lesion of the brain.

In **simple partial focal seizures**, the seizure remains localized, and consciousness and mentation are not affected. It is possible to deduce the likely location of the initial cortical discharge from the clinical features at the onset of the attack. Unilateral tonic or clonic movements, often limited to one extremity, suggest a focus in the motor cortex, while tonic deviation of the head and eyes suggests a frontal lobe focus. Sensory hallucinations (e.g., paresthesias or numbness) suggest a discharge in the sensory cortex. Visual symptoms, especially flashing lights or distortions of vision, suggest an occipital focus. Bizarre olfactory or gustatory hallucinations suggest a focus in the medial temporal lobe. Such sensory phenomena, known as *auras*, are often the initial symptoms of attacks that then become more widespread, and that are termed *secondary generalization.*

Complex partial seizures are focal seizures in which consciousness and/or mentation *are* affected. They are often caused by a focal discharge originating in the temporal lobe and are sometimes referred to as *temporal lobe seizures.* Because of their alterations of thinking and behavior, they are occasionally called *psychomotor seizures.* As such seizures may originate from brain regions other than the temporal lobes, and to avoid any confusion with psychiatric illness, the term complex partial seizures is preferred. Often thought to be rare, they are, in fact, quite common.

Because of their frequently bizarre symptoms, complex partial seizures are commonly misdiagnosed as psychiatric problems. Their symptoms may include automatisms, visceral symptoms, hallucinations, memory disturbances, distorted perception, and affective disorders. Automatisms are typically simple, repetitive, purposeless movements such as lip smacking, fiddling with clothing or buttons, or repeating short phrases. More complex behaviors may occur, but well-organized, purposeful activity is unlikely. Visceral symptoms often consist of a sensation of "butterflys" rising up from the epigastrium. Hallucinations may be olfactory, gustatory, visual, or auditory. There may be complex distortions of visual perception, time, and memory. Affective symptoms may include intense sensations of fear, paranoia, depression, or, rarely, elation or ecstasy.

As noted, a focal seizure discharge may spread to involve both hemispheres, mimicking a typical generalized seizure. This is termed *secondary generalization.* For the purpose of classification, diagnosis, and treatment, such attacks are regarded as focal seizures. In some patients, the discharge may spread so rapidly that no focal symptoms are evident, and the correct diagnosis may depend on demonstration of the focal discharge on an EEG recording.

CLINICAL EVALUATION OF SEIZURE PATIENTS

The first step is to determine whether the attack was truly a seizure. The physician should take a detailed history and perform a careful physical. Laboratory tests, radiologic studies, and consultations may be obtained if clinically indicated.

History

A careful history of the details of the attack should be obtained from the patient, if possible, and from any bystanders who actually witnessed the attack. Only a physical description of the attack should be sought as witnesses, even physicians, may mislabel the activity or even mistake nonseizure activity as a seizure.

Important avenues of inquiry include preceding aura, abrupt or gradual onset, progression of motor activity, loss of bowel or bladder control, and whether the activity was local or generalized, symmetrical or not. Finally, the duration of the attack and any postictal confusion or lethargy should be sought. The patient should be asked whether he or she has any recollection of the attack.

Next, the clinical context in which the attack occurred should be determined. If the patient is a known epileptic, the baseline seizure pattern should be established. In patients presenting with an attack consistent with their previously documented seizures, the history should be directed toward factors that may have precipitated epileptic activity. Missed doses of antiepileptics or recent alterations in medication, including dosage change or conversion from brand name to generic formulation, may be the inciting element. Other possible factors that might provoke a seizure include sleep deprivation, alcohol withdrawal, infection, and use or cessation of other drugs.

If there is no previous history of seizures, a more detailed history is needed. Symptoms that might suggest previous unwitnessed or unrecognized seizures, such as blank or staring spells in school, involuntary movements, unexplained injuries, nocturnal tongue biting, and enuresis, may be clues to a more long-standing problem. A history of recent or remote head injury should be sought. Persistent, severe, or sudden headache should prompt a search for intracranial pathology. Concurrent pregnancy or recent delivery suggests the possibility of eclampsia. A history of metabolic derangements or electrolyte abnormalities, hypoxia, systemic illness (especially cancer), coagulopathy or anticoagulation, drug ingestion or withdrawal (licit and illicit), and alcohol use, may help identify factors that predispose patients to seizures (Table 224-2).

Intracranial hemorrhage (subdural, epidural, subarachnoid, intraparenchymal)
Structural abnormalities
   Vascular lesion (aneurism, arteriovenous malformation)
   Mass lesions (primary or metastatic neoplasm)
   Degenerative diseases
   Congenital abnormalities
Trauma (recent or remote)
Infection (meningitis, encephalitis, abscess)
Metabolic disturbances
   Hypo- or hyperglycemia
   Hypo- or hypernatremia
   Hyperosmolar states
   Uremia
   Hepatic failure
   Hypercalcemia, hypomagnesemia (rare)
Toxins and drugs (many)
   Cocaine, lidocaine
   Antidepressants
   Theophylline
   Alcohol withdrawal
   Drug withdrawal
Eclampsia of pregnancy (may occur up to eight weeks postpartum)
Hypertensive encephalopathy
Anoxic-ischemic injury (cardiac arrest, severe hypoxemia)

TABLE 224-2 Causes of Secondary Seizures

Physical Examination

The general physical examination should be directed toward discovering any injuries, especially head or spine, that might have resulted from the seizure. Seizures may cause injuries such as fractures, sprains, and bruises; posterior dislocations of the shoulder are common and may be overlooked. Tongue lacerations and aspiration are frequent sequelae. A search for any systemic illness that may have caused the attack should be undertaken. Temperature should be noted, and a bedside glucose determination should be obtained.

A directed neurologic examination should be performed with follow-up serial exams. Level of consciousness and mentation should be followed closely. Profound obtundation that improves steadily is likely benign; however, progressive deterioration requires prompt intervention. Signs of increased intracranial pressure should be sought. Any focal neurologic deficit should be noted. A transient focal deficit following a simple or complex focal seizure is referred to as *Todd's paralysis,* and should resolve within 48 hours.

Differential Diagnosis

Many episodic disturbances of neurologic function may be mistaken for seizures (Table 224-3). A complete review of these conditions is too lengthy for inclusion here, but several of the more important entities should be mentioned.

Seizures
Syncope
Pseudoseizures
Hyperventilation syndrome
Migraines
Movement disorders
Narcolepsy/cataplexy

TABLE 224-3   Paroxysmal Disorders: Differential Diagnosis

Syncope usually is attended by premonitory symptoms such as dizziness, diaphoresis, nausea, and "tunnel vision." Patients often are aware that they are going to faint and can clearly describe the onset of the attacks. Cardiac syncope, however, may occur suddenly without any warning. Injury or incontinence may attend syncope; in addition, some patients may experience brief tonic-clonic activity, especially if they are prevented from falling. Recovery is usually rapid, with few or no postictal-like symptoms.

Psychogenic seizures, or *pseudoseizures,* are common and may be extremely difficult to distinguish from true seizures in the emergency department. They may occur, as well, in a patient who has a documented seizure disorder. They are psychiatric, rather than neurogenic, in origin, and are not accompanied by an alteration in brain activity. They are often associated with a conversion disorder, panic disorder, psychosis, impulse control disorder, Munchausen's syndrome, or malingering. The patients are usually female, and there may be a history of physical or sexual abuse. The diagnosis of pseudoseizures should be suspected when seizures occur regularly in response to emotional upset or when seizures only occur with witnesses present. The attacks are often very bizarre and highly variable. Patients often are able to protect themselves from noxious stimuli during the attack. Characteristic movements include side-to-side head thrashing, rhythmic pelvic thrusting, and clonic extremity motions that are alternating rather than symmetric. Incontinence and injury are uncommon, and there is usually no postictal confusion.

Accurate diagnosis of pseudoseizures may require prolonged EEG or video monitoring to demonstrate the presence of normal EEG activity during an attack. The lack of lactic acidosis, as evidenced by the presence of an anion gap acidosis on serum electrolytes drawn within 10 to 15 min of the cessation of seizure-like activity, makes generalized seizures unlikely.

Hyperventilation syndrome is common and is often misdiagnosed as a seizure disorder. A careful history will reveal the gradual onset of the attacks with shortness of breath, anxiety, and perioral numbness. Such attacks may progress to involuntary spasm of the extremities and even loss of consciousness. The episodes often are reproduced easily by asking the patient to hyperventilate.

Movement disorders, such as dystonia, chorea, myoclonic jerks, tremors, or tics, may occur in a variety of neurologic conditions. Consciousness is always preserved during these movements. Though involuntary, the movements can often be temporarily suppressed by the patient.

Migraines may be preceded by an aura similar to that seen in some partial seizures. The most common migraine aura is the scintillating scotoma. Migraines may also be accompanied by focal neurologic symptoms such as homonymous hemianopsia and hemiparesis.

Narcolepsy is characterized by brief attacks of uncontrollable daytime sleepiness. Patients are able to feel their attacks coming on and can sometimes control them with judiciously timed naps. Other symptoms of narcolepsy include vivid dreams, often at the onset of sleep or immediately upon awakening, and attacks of sleep paralysis. An associated symptom is *cataplexy,* characterized by a sudden brief loss of postural muscle tone that is often triggered by emotional upset, laughter, or crying. The patient collapses but remains fully conscious; there are no involuntary movements.

Clinical features that help to distinguish seizures from other kinds of mimicking attacks include:

1. Abrupt onset and termination. Although some focal seizures are preceded by auras that last 20 to 30 s (or more), most attacks begin abruptly. Attacks that develop over several minutes, or longer, should be regarded with suspicion. Most seizures last only one or two minutes, unless the patient is in status epilepticus.
2. Lack of recall. Except for simple partial seizures, patients usually cannot recall the details of an attack, the responses and acts of bystanders, and so forth.
3. Movements or behavior during the attack generally are purposeless or inappropriate. Rare exceptions have been described.
4. Most seizures, except for simple absence attacks (petit mal) or simple partial seizures, are followed by a period of postictal confusion and lethargy.

Although a clinical diagnosis of seizures often can be made with a high degree of certainty, there are occasions when the presentation is not convincing. In such cases, it is better to admit uncertainty and provide follow-up for exact diagnosis, not to use the term seizure, or to begin inappropriate and potentially hazardous treatment. Multiple EEG recordings, prolonged EEG monitoring, and neurologic evaluation may be necessary.

Laboratory Examination

The need for laboratory studies must be assessed on an individual basis. In a patient with a well-documented seizure disorder who has had a single unprovoked seizure, the only test that may be needed is an anticonvulsant level.

In the case of a patient with a first seizure or when the history is unclear, more extensive studies may be helpful. A serum glucose should be obtained, and serum electrolytes, blood urea nitrogen (BUN), and creatinine, calcium, and magnesium, a pregnancy test, and a toxicology screen may be indicated depending on the clinical context. If the patient's urine is positive for hemoglobin, but there are no red cells in the urine, a CPK should be done to rule out rhabdomyolysis.

The patient should demonstrate a wide anion gap metabolic (lactic) acidosis following a major seizure, which should correct spontaneously within one hour. [3] The

majority will clear within 30 min. If the diagnosis is in doubt, serum lactate can be drawn within 15 min of the episode. The blood prolactin level may also be elevated for a brief period (15 to 60 min) immediately following a seizure and may be helpful in distinguishing a true seizure from a pseudoseizure; [4] a normal prolactin level, however, is not helpful.

The presence of anticonvulsant drugs in the blood of a patient from whom no history is available suggests (but does not prove) the presence of a seizure disorder. Anticonvulsant drug levels must be interpreted with caution, as the time the last dose was taken needs to be known to properly interpret levels. The usual therapeutic and toxic levels indicated in laboratory reports are helpful only as rough guides. The therapeutic level of a drug is that level that provides adequate seizure control without unacceptable side effects. A phenytoin level of 15 mg/mL may be toxic in a given patient; conversely, a phenytoin level of 24 mg/mL may result in excellent seizure control and be well tolerated. A marked change in previously stable drug levels may indicate noncompliance, a change in medication (e.g., from one brand name or generic to another), malabsorption of a drug (as in severe diarrhea or vomiting), or ingestion of a potentiating or competing drug.

Radiographic Studies

The issue of neuroimaging following seizures remains controversial. In 1996, the American College of Emergency Physicians (ACEP) [5] in conjunction with a panel of neurologists, neurosurgeons, and neuroradiologists, developed a practice parameter outlining the role and timing of neuroimaging following seizures. In patients with a febrile seizure or seizure typical of their documented epilepsy, radiographic studies usually are not indicated. However, for patients with a first seizure or a change in their established seizure pattern, CT scanning of the head is appropriate to identify a structural lesion. Table 224-4 lists guidelines for emergent CT scanning following a seizure. Noncontrast CT is an appropriate screening tool. [6]

New focal deficits
Persistent altered mental status
Recent head trauma
Fever
Anticoagulation therapy
Known or suspected HIV-positive
History of cancer
Persistent or severe headache
Change in seizure pattern

TABLE 224-4   ACEP Recommendations for Obtaining Emergent Neuroimaging Following a Seizure[5]

If the patient does not meet the above criteria, has recovered from the seizure, and no metabolic cause for the seizure has been identified, a head CT may be obtained later as part of the disposition in conjunction with follow up with a neurologist.

Because many important processes, such as metastatic or primary tumors or vascular anomalies, may not be evident on noncontrast studies, a follow-up enhanced CT or MRI may be arranged. MRI is more sensitive than CT in detecting subtle alterations of brain structure and is often the study of choice in the evaluation of patients with seizures. In patients with uncomplicated first seizures, it is reasonable to omit the CT scan and obtain an MRI instead. Consultation with a neurologist or radiologist may be helpful in choosing the best approach and avoiding unnecessary examinations.

Other radiographic studies may be indicated in some cases. Radiographs of the cervical spine or neck should be obtained if there is suspicion for head trauma. Chest x-rays may reveal primary or metastatic tumors. There may be evidence of aspiration, although related radiographic findings are usually delayed. Skull x-rays are generally not indicated. Special examinations, such as angiography, are rarely part of the emergency department evaluation.

ELECTROENCEPHALOGRAPHY

While EEG may be very helpful, it is not readily available in most emergency departments. Emergency EEG can be considered in the evaluation of a patient with persistent, unexplained, altered mental status to rule out nonconvulsive status epilepticus; to evaluate a paroxysmal attack when a seizure is suspected; or in status epilepticus to detect ongoing seizures after paralysis for intubation, or induction of general anesthesia. [7]

In the outpatient setting, the EEG may be used to distinguish generalized from focal seizures and to identify specific epileptic syndromes. The diagnostic yield of EEG recordings can be increased by appropriate patient preparation (especially sleep deprivation) or by activation techniques such as hyperventilation, photic stimulation, and sleep recordings. More elaborate examinations, such as 24-h recordings or video-EEG recordings, may also be used. Consultation with a neurologist ensures that the appropriate studies are chosen.

TREATMENT

Certain general measures should be taken for any seizure patient. A patent airway must be assured and vital signs should be stabilized. Initial interventions should include an IV, oxygen, pulse oximetry, bedside glucose determination, and a cardiac monitor, if warranted. Intubation should be considered for prolonged seizures, persons that require GI decontamination, and patients who may need to be transferred off-site. In and of themselves, simple seizures do not usually warrant intubation. Standard measures for management of any unconscious patient should be employed. The likelihood of trauma should be assessed. Care should be taken to identify and treat any underlying metabolic disorder.

The first objective is to make an accurate diagnosis; only in patients with status epilepticus is it necessary to initiate specific treatment before diagnostic evaluation has been completed.

Specific management is reviewed of these four clinical situations: the patient who is actively seizing; the patient with previous epilepsy who has a seizure; the patient with a first seizure; and status epilepticus.

The Active Seizure

There is little to be done during the course of an actual seizure other than to protect the patient from injury. Gentle but firm restraint should be used to prevent falls. If possible, the patient should be turned to one side to reduce the risk of aspiration. It is usually not possible to insert a bite block between the teeth without using considerable force and risking damage to teeth. If a bite block is used, be certain that it cannot be aspirated or swallowed. It is usually not necessary or even possible to ventilate a patient effectively during a seizure, but once the attack subsides, ensure a clear airway. Suction and airway adjuncts should be readily available. There is no indication for intravenous anticonvulsant medications during the course of an uncomplicated seizure. Expectant treatment is best. Seizure activity should be observed to determine if it is focal. Unnecessary sedation at this point will complicate evaluation and result in a prolonged decrease in level of consciousness. Seizures that fail to abate are considered status epilepticus (see below).

Patients with Previous Seizures

Proper management of a patient with a well-documented seizure disorder who presents after one or more seizures depends on the particular circumstance of the case. Potential precipitants that may lower seizure threshold should be sought. Many such seizures occur because of failure to take anticonvulsant medication as prescribed. Some anticonvulsants have short serum half-lives (Table 224-5), and missing even a single dose may result in a sharp drop in serum levels.

Drug	Oral Dose, mg/day*	Therapeutic Level, μg/mL†	Days to Reach Steady State‡	Serum Half-life, h
Phenytoin	300–600	10–20	5–10	7–42
Carbamazepine	400–1200	3–14	2–4	12–17
Phenobarbital	100–300	10–40	14–21	48–144
Primidone	750–2000	5–12	4–7	10–21
Valproic acid	750–2000	50–150	2–4	12–18
Ethosuximide	500–1500	40–100	5–10	40–60
Clonazepam	1.5–20	20–80	?	19–39

*Average therapeutic dose. Initiation dosing may be different. Daily dose must be individualized for each patient. Drug-drug interactions may dramatically change daily doses in patients receiving multiple drugs.
†See text for definition of therapeutic and toxic levels.
‡Indicates time required to establish stable serum levels after any change in dose.
Information obtained from McEvoy GK (ed): *American Hospital Formulary Service Drug Information.* Bethesda, MD, Society of Health-Systems Pharmacists, 1998.

TABLE 224-5 Properties of Commonly Used Anticonvulsant Drugs

If anticonvulsant levels are very low, supplemental doses may be given and the patient restarted on his or her regular regimen. Without a loading dose, the patient may not achieve anticonvulsant effects for two days to three weeks (see Table 224-5). An oral loading-dose of phenytoin (usually 18 mg/kg po, that is often divided into 3 doses given q2h) will achieve therapeutic serum concentrations in 2 to 24 h. Alternatively, the same loading dose of IV phenytoin (no faster than 50 mg/min) achieves anticonvulsant effects in 1 to 2 h. Carbamazepine can be loaded using the oral suspension at a dose of 8 mg/kg.

If anticonvulsant levels are adequate and the patient has had a single attack, specific treatment may not be needed if the pattern and frequency of occurrence falls within the expected range for the patient. Even well-controlled patients may have occasional breakthrough seizures. Any precipitants that have lowered the seizure threshold should be identified. If there has been a recent change in the frequency or pattern of breakthrough seizures, a change in, or adjustment of, medication may be needed. These include factors such as infection, sleep deprivation, stress, or injury. The primary care physician or neurologist should make this decision. If a medication's maintenance dose is increased, only very small increments should be made, and follow-up within one to three days should be provided, because even small dose changes may result in dramatic increases in serum levels. If the problem is noncompliance or missed medication, the patient's primary care physician or neurologist should be made aware of the situation and participate in decision making.

The Patient with a First Seizure

There has been considerable controversy about the appropriate management of a patient who has experienced an apparent first seizure. The decision to begin outpatient treatment with antiepileptics depends on the risk of recurrent seizures weighed against the risk/benefit ratio of anticonvulsant therapy. Until recently, reliable data on these questions have been unavailable. Previous studies have suggested rates of recurrence ranging from 23 to 71 percent. Some studies have found no benefit from treatment, while others have reported a 50 percent reduction in the risk of recurrence.

A careful analysis[8] found that in patients with an apparent first seizure, the most important predictors of the risk of recurrence were the etiology of the seizure and the results of the EEG. In patients with idiopathic seizures and a normal neurologic exam, the risk of a recurrent seizure within two years was 24 percent if the EEG was normal and 48 percent if the EEG was abnormal. In patients with previous neurologic injury or illness or an abnormal neurologic exam, the risk was 48 percent if the EEG was normal, and 65 percent if the EEG was abnormal. Neither family history, age, sex, nor the presence of status epilepticus at the time of the first seizure was a strong predictor of the risk of recurrence. Unfortunately, EEG results are often not available to the emergency physician who must make a treatment decision.

A randomized multicenter clinical trial of 397 patients demonstrated that treatment of first unprovoked seizures appears to reduce the risk of recurrent seizures from 51 to 25 percent during two years of follow-up.[9] Given these two studies, some general recommendations can be made. Patients with secondary seizures due to an identifiable neurologic condition should generally be treated, as their risk of recurrence is quite high (48 to 65 percent). In patients with idiopathic seizures, the decision is less clear. Their risk of recurrence may be as low as 24 percent if the EEG is normal. Given the expense, inconvenience, and potential side effects of treatment, some patients may wish to defer a decision about treatment until an EEG and neurologic consultation are obtained. In these patients, the only realistic approach is a full discussion of the risks and benefits of treatment. Often, a decision need not be made in the emergency department and patients can be referred to their regular physicians within one week for further evaluation and management.

The ideal antiepileptic regimen is a single-drug therapy that controls seizures with minimum toxicity. If treatment is initiated, drug selection is based on the type of seizure (Table 224-6). For generalized tonic-clonic or focal seizures, either phenytoin or carbamazepine would be an appropriate choice for most adults (see above for loading information), both drugs are equally as efficacious and have similar side effect profiles. Valproate, phenobarbital, and primidone may also be used. For absence seizures, ethosuximide or valproate may be used (see Table 224-5 for dosing). Gabapentin (900 mg to 1.8 g daily) and lamotrigine (300 to 500 mg daily) are newly approved drugs useful as adjunctive therapy.

Seizure Category	Drug of Choice	Alternatives
I. Generalized seizures		
Tonic-clonic seizures:	Carbamazepine Phenytoin Valproic acid	Phenobarbital Primidone
Absence seizures:	Ethosuximide Valproic acid	Clonazepam
Myoclonic seizures	Valproic acid	Clonazepam
Atonic seizures	Valproic acid	Clonazepam *Felbamate
II. Partial seizures: (simple or complex, with or without generalization)	Carbamazepine Phenytoin Valproic acid	Phenobarbital Primidone *Gabapentin *Lamotrigine

*Adjunctive therapy.

TABLE 224-6 Anticonvulsant Drugs: Indications

Determining Need for Consultation and Admission

ACEP guidelines[6] recommend *neurologic consultation* for patients with first-time seizures, seizures with persistent altered mental status, new focal neurologic deficits, and new intracranial lesions (Table 224-7). Pregnant patients and those with a marked change in seizure pattern or poorly controlled seizures may also warrant consultation. *Hospital admission* is recommended for patients with persistently altered mental status, and for patients with seizures due to CNS infections, new intracranial lesions, or clinically significant hypoxia, hypoglycemia, hyponatremia, or dysrhythmias (Table 224-8). Patients with status epilepticus or seizures in the setting of eclampsia or head trauma should also be admitted. Alcohol or drug-related seizures do not necessarily require admission, although detoxification or withdrawal should be addressed.

New onset seizures

Focal neurologic exam

Persistent altered mental status

New intracranial lesion

Marked change in seizure pattern

Poorly controlled seizures

Pregnant patient

TABLE 224-7   ACEP Guidelines for Obtaining Neurology Consultation[6]

Persistent altered mental status

   Dysrhythmia
   Significant alcohol withdrawal

Acute head trauma

Status epilepticus

Eclampsia

TABLE 224-8   ACEP Guidelines for Hospital Admission of Patients with New-Onset Seizure[6]

Disposition

There are no evidence-based rules for how long a patient must be observed prior to discharge. Some clinicians discharge patients with nontherapeutic anticonvulsant levels after administration of a loading dose of an anticonvulsant, if vital signs are normal and the mental status is at baseline. As previously discussed, therapeutic serum concentrations can be achieved as early as one hour after IV-loading of phenytoin. Patients given oral loading doses should be warned of continued risk for seizures until anticonvulsant effect has been achieved. If possible, the patient should be discharged with a reliable family member or friend, with imperative medical follow-up arranged in a week.

Patients should be instructed to take precautions to minimize the risks for injury from further seizures. Swimming should be avoided. Working with hazardous tools or machines and working at heights should be avoided. The emergency physician should be familiar with driving regulations and reporting requirements, which vary from state to state. Regardless of local laws, it is prudent to advise patients against driving and other hazardous activity until they have stabilized and have been seen in follow-up. The emergency department record should reflect the precise instructions given to the patient.

SPECIAL CONSIDERATIONS

Seizures in the HIV-Positive Patient

Seizures are a common manifestation of CNS disease in patients infected with HIV, although the etiology of seizures in this population differs somewhat from immunocompetent patients (Table 224-9). Mass lesions, HIV encephalopathy, and meningitis are seen more frequently.[10,11] The most common mass lesion is caused by toxoplasmosis, followed by lymphoma. Cryptococcal, bacterial, or aseptic meningitis, or encephalitis due to herpes simplex, varicella zoster, or cytomegalovirus may cause seizures. HIV encephalopathy or AIDS dementia complex is an under-recognized etiology of seizures for HIV-infected patients. Other etiologies to consider are progressive multifocal leukoencephalopathy, CNS tuberculosis, and neurosyphilis.

Mass lesion
   Toxoplasmosis
   Lymphoma

Meningitis/Encephalitis
   Cryptococcal
   Bacterial/aseptic
   Herpes zoster
   Cytomegalovirus

HIV encephalopathy/AIDS dementia complex

Progressive multifocal leukoencephalopathy

CNS tuberculosis

Neurosyphilis

TABLE 224-9   Causes of Seizures in the HIV Patient

While the evaluation of seizures in HIV-positive patients should include a search for metabolic or toxicologic causes, the high incidence of space-occupying lesions mandates a thorough ED evaluation. If no space-occupying lesion is identified on noncontrast head CT scan, and there is no evidence of increased intracranial pressure, a lumbar puncture should be performed to rule out meningitis. Finally, if the initial head CT scan is negative or no other explanation for seizures is found, a contrast-enhanced head CT or an MRI may be obtained in the ED, or arranged by the primary physician as part of the disposition. Some HIV patients will have no discernible cause for seizures after a thorough evaluation, particularly if the neurologic examination in the interictal period is normal.

Treatment of the first-time seizure in the HIV patient is controversial. Most authorities recommend treatment with phenytoin or phenobarbital because the seizure recurrence rate in this population is high, but there is a 10 percent incidence of hypersensitivity reactions to phenytoin in patients with HIV.

Seizures in Pregnancy

The management of seizures during pregnancy requires a multidisciplinary approach. Antiepileptic drugs have been associated with neural tube defects, fetal facial dysmorphism, cleft lip and palate, heart defects, and digital defects. Despite the potentially teratogenic effects of anticonvulsants, the risks of uncontrolled seizures to the mother and fetus warrant continuation of seizure medications in the known epileptic during pregnancy. Ideally, counseling of the mother regarding risks and benefits should begin prior to conception.

Efforts can be made to reduce the risk to the fetus. For example, single-drug regimens are preferred to multidrug regimens, dosing can be split to avoid high peak levels of drugs, and supplementation of folic acid and vitamin K may be given to reduce the risk of neural tube defects and neonatal hemorrhage. Compliance can be

a problem during pregnancy, often due to the mother's concern for drug toxicity.

Initial evaluation of a pregnant woman with a seizure is generally as discussed above, with some important distinctions. An obstetrical evaluation is needed to determine gestational age and fetal well-being. Since pregnancy is a hypercoagulable state, stroke as an etiology for the seizure should be considered. Head CT scan may be performed with lead shielding of the abdomen. MRI is also considered safe in pregnancy, although this has not been well studied.

When a woman beyond 20 weeks of gestation develops seizures in the setting of hypertension, edema, and proteinuria, her condition is referred to as *eclampsia.* Attention should be paid to signs and symptoms associated with eclampsia such as headache, blurry vision, confusion, hyperreflexia, and epigastric pain. Rarely, eclampsia may occur up to eight weeks postpartum.

The decision to initiate treatment for a first-time seizure in a pregnant female is complex and should involve the obstetrician and neurologist. The emergency physician should not make definitive treatment decisions alone. There are many factors involved, including cause and type of seizure, risk of recurrence, and gestational age of the fetus.

Although a healthy fetus should tolerate a single generalized seizure, there are two situations, eclampsia and status epilepticus, which can be life-threatening to both the mother and the fetus. Although not an anticonvulsant per se, magnesium sulfate (4 to 6 g IV followed by 1 to 2 g/h IV drip) has been used to treat eclampsia with good results since 1925. An international multicenter, randomized, clinical trial involving 1687 eclamptic women compared magnesium sulfate to diazepam and phenytoin. The study demonstrated a 52 percent lower risk of recurrence of seizures in women allocated magnesium sulfate rather than diazepam. Furthermore, the women allocated magnesium sulfate had a 67 percent lower risk of recurrence than those given phenytoin. The women administered magnesium sulfate also had a lower incidence of pneumonia, ICU admission, and assisted ventilation than those administered phenytoin. [12] A review of randomized, controlled trials of eclamptic women derived a seizure recurrence rate following phenytoin of 23.1 percent, whereas the recurrence rate following magnesium sulfate was 9.4 percent. [13] The definitive treatment of eclampsia is delivery of the fetus. This topic is discussed in greater detail in Chap. 101.

Status epilepticus may occur in both epileptics and nonepileptics. Treatment should proceed as for any nonpregnant patient, but should include fetal monitoring as well as assistance from an obstetrician and neonatologist if delivery is a possibility. Lorazepam and diazepam are the two benzodiazepines of choice; phenytoin or phenobarbital may be used as second-line choices (see Fig. 224-1 for doses). EEG should be used to confirm seizure cessation. Because both the seizure and the treatments can cause respiratory depression or hypotension, close monitoring is necessary.

FIG. 224-1. Guidelines for management of status epilepticus. (Adapted from Lowenstein and Alldredge. [14])

Seizures in the Alcohol Abuser

Seizures and alcohol are associated through missed doses of medication; sleep deprivation as an epileptogenic trigger; propensity for head injury; toxic coingestions; electrolyte abnormalities; alcohol withdrawal seizures; and alcohol-related seizures. *Alcohol-related seizures* are precipitated by alcohol intake.

The *alcohol withdrawal syndrome* involves a spectrum of symptoms that follow reduction or cessation of alcohol. Minor symptoms of alcohol withdrawal, which can begin within 24 h of cessation of drinking, include tremulousness, nausea, anxiety, tachycardia, hypertension, and insomnia. When autonomic hyperactivity becomes more pronounced, disorientation, visual hallucinations, paranoid ideation, or delirium may occur, in the symptom complex of *delirium tremens.*

Classic *alcohol withdrawal seizures* usually occur within 6 to 48h after reduction or cessation of alcohol, but may occur up to 1 week later. The seizures are generalized, and the interval EEG is usually normal. There may be several seizures occurring over several hours.

The alcohol-abusing patient with a first seizure should be evaluated and treated as any patient with a first-time seizure (see previous discussion), with additional evaluation for toxic-metabolic abnormalities, and intracranial bleeding. For suspected head injury, focal findings on neurologic exam, deteriorating mental status, or prolonged postictal state, head CT scan is needed. Cervical spine precautions should be taken as appropriate.

Most authorities agree that patients with alcohol withdrawal seizures usually do not require chronic anticonvulsant therapy. Acute or chronic treatment with phenytoin is neither necessary nor effective. [15] Use of benzodiazepines such as chlordiazepoxide, diazepam, oxazepam, and lorazepam, in doses sufficient to manage withdrawal will usually afford adequate protection from acute seizures. The exception is withdrawal that is complicated by status epilepticus, which requires prompt treatment. Patients with epilepsy exacerbated by alcohol withdrawal should be managed as any other seizure patient with recurrent seizures.

If the clinical presentation and evaluation are consistent with alcohol withdrawal seizures, and the patient remains stable and seizure-free for several hours, the patient may be discharged and referred for detoxification. Outpatient detoxification with a benzodiazepine regimen is most appropriate for patients with mild to moderate withdrawal symptoms, no significant medical or psychiatric problems, no concurrent drug use, and no history of DTs. Patients with more than two seizures should be admitted.

STATUS EPILEPTICUS

There are an estimated 100,000 to 150,000 cases of status epilepticus per year in the United States, with 55,000 deaths. In 12 to 30 percent of these, status is the first epileptic event. [14,16] Estimations of acute mortality range from 1 to 10 percent.

Status epilepticus is defined as either continuous seizure activity 30 min or more, or two or more seizures that occur without full recovery of consciousness between the attacks. It remains unclear how long a seizure can occur before permanent neurologic sequelae ensue. Although this question has never been satisfactorily answered, it does appear that permanent CNS injury is more likely to occur the longer seizures are allowed to progress. [17,18] Thus treatment should be initiated as soon as possible in all patients with continuous seizure activity lasting more than 10 min. The longer the seizure is allowed to continue the more difficult it will be to control. [19]

The diagnosis of status epilepticus is usually obvious in patients with continuous tonic-clonic movements. However, convulsive activity may gradually lessen over time or with partial treatment, giving the impression that the seizures have been controlled, with continued subtle signs such as nystagmus, or twitching of the face, hands, or feet. Correct diagnosis requires a high index of suspicion, a perceptive physician, and sometimes an EEG. Any type of seizure may occur continuously or in rapid succession, fulfilling the criteria for status epilepticus. *Epilepsia partialis continua* is repeated partial seizures without loss of consciousness and often with one's ability to follow simple commands retained. Altered mentation, diminished responsiveness, confusion, amnesia, or dream-like states without motor symptoms suggest continuous absence seizures.

Treatment

The goal of treatment of convulsive status epilepticus and epilepsia partialis continua is seizure control within 30 min of presentation (Fig. 224-1). Morbidity is due hypoxemia, hyperthermia, circulatory collapse, and eventual neuronal injury.

A brief history and physical examination should be directed toward discovery of the cause of the seizures and to any injury that may have resulted. Any of the causes of seizures (see Table 224-2) may result in status epilepticus; in many patients, no specific etiology is found.

A large-bore IV line should be established and a bedside glucose determination made. Use of an IV fluid without glucose will facilitate administration of anticonvulsant drugs (glucose is not compatible with phenytoin). The patient should be placed on oxygen, a cardiac monitor, and pulse oximeter.

Despite periods of apnea and cyanosis, which can occur during seizure activity, most patients can be maintained on nasal cannula or oxygen mask with a nasopharyngeal device if the gag reflex and airway are intact. Endotracheal intubation should be performed if there is any concern about the adequacy of ventilation or safety of the airway. Many prefer orotracheal intubation because the patient is likely to undergo diagnostic imaging and may require procedures. If a paralytic agent is used to assist with intubation, a short-acting agent, such as vecuronium, should be used as the physician will be unable to monitor ongoing seizure activity during the period of paralysis.

Initial laboratory evaluation should include blood glucose, metabolic panel including calcium and magnesium, and, if appropriate, a pregnancy test, a toxicology screen, and anticonvulsant levels.

Thiamine (100 mg) and glucose (25 to 50 g) should be given IV if hypoglycemia is suspected or confirmed. There is no benefit to giving additional glucose to normoglycemic patients. Rectal temperature should be monitored, and hyperthermia should be treated with passive cooling. A Foley catheter should be placed to monitor urine output and the nasogastric tube to minimize aspiration.

If ingestion is suspected as the cause of seizures, GI decontamination should ensue. Emergency lumbar puncture should not be attempted during status epilepticus. If bacterial meningitis is suspected, empiric antibiotic therapy should be started. Status epilepticus can induce a brief peripheral leukocytosis as well as a mild CSF pleocytosis. Radiographic studies (such as a CT scan) will usually need to be delayed until the seizures are controlled.

Anticonvulsant Drugs in Status Epilepticus

The drugs most often used in the therapy of status epilepticus are the benzodiazepines (diazepam or lorazepam), phenytoin or fosphenytoin, and phenobarbital (Fig. 224-1).

Benzodiazepines are used in patients with continuous or very frequent seizures to temporarily control the seizures until more specific agents can be given. A double-blind, randomized, controlled study of IV lorazepam (4 to 8 mg) and IV diazepam (10 to 20 mg) demonstrated equal efficacy in controlling status epilepticus. [20] Although diazepam has a slightly faster onset than lorazepam (2 min vs. 3 min), lorazepam has a significantly longer duration of action (12 to 24 h) as compared to diazepam (15 to 30 min), and is considered the agent of choice. Lorazepam is also more effective than phenytoin or phenobarbital as the initial drug. [21] Respiratory depression and hypotension may occur when benzodiazepines are used, especially in young children and in patients who have taken alcohol, barbiturates, narcotics, or other sedatives. Although diazepam enters the brain readily, it is redistributed quickly to fatty tissues, so serum concentrations fall rapidly. Therefore, a longer-acting agent such as phenytoin should follow diazepam.

Phenytoin is the most important drug used in the management of status epilepticus. It may be given immediately after a benzodiazepine or may be used as primary therapy in patients whose seizures are less frequent. The recommended loading dose is 18 to 20 mg/kg IV; note that doses well in excess of the usual 1000 mg are required for many adults. A smaller loading dose (15 mg/kg) may be used in the elderly, but the loading dose is not reduced in patients with renal or hepatic disease. Due to the myocardial depression and the effects of ethylene glycol, the diluent, phenytoin should be infused at a rate not greater than 50 mg/min; a rate of 25 mg/min is safer in the elderly. Phenytoin should not be mixed with any glucose-containing IV fluid and should not be given intramuscularly due to erratic absorption. The drug is contraindicated in the presence of second- or third-degree AV block, or during a MI or CHF. Adverse effects include significant infusion-site reactions, hypotension, and cardiac dysrhythmias, so continuous cardiac monitoring is needed. If side effects develop, the infusion should be stopped and may be restarted at a lower rate when the side effects have resolved; in some cases, patients are unable to tolerate the drug.

Fosphenytoin is a water-soluble pro-drug of phenytoin that is rapidly converted to phenytoin in the plasma. In status epilepticus, fosphenytoin has similar time of onset, effectiveness, and cardiac effects as phenytoin. Its advantages include fewer infusion-site reactions due to the lack of propylene glycol and ethanol as the diluents. Secondly, fosphenytoin may be infused at a faster rate. Fosphenytoin dosing is expressed as "phenytoin equivalents (PE)" to prevent confusion. The loading dose is 15 to 20 mg PE per kg, which can be infused at 100 to 150 mg PE per minute. Unlike phenytoin, fosphenytoin can be given intramuscularly, which is useful if the patient is not in status epilepticus. The only apparent drawback is the cost. Fosphenytoin can cost 10 to 60 times more than phenytoin.

Phenobarbital (up to 20 mg/kg IV) is usually used as a second-line drug in patients who are unable to tolerate phenytoin or in patients whose seizures are not controlled despite full loading doses of benzodiazepines and phenytoin. Respiratory depression and hypotension are common, especially at higher doses or when diazepam or lorazepam is also given. Because of very slow elimination, large doses of phenobarbital may result in prolonged obtundation.

In a few patients, seizure control is not obtained with these regimens and further treatment is needed.

Refractory Status Epilepticus

The standard regimens of benzodiazepines, phenytoin, and phenobarbital suffice to control status epilepticus within 30 min of presentation in most patients. In a few cases (generally patients with structural lesions or CNS infections), seizures continue even after such treatment. Various approaches have been advocated, including IV infusions of midazolam, propofol, or barbiturates to induce anesthesia (see Fig. 224-1). These modalities are best used in an intensive care setting, as advanced respiratory and cardiovascular support, as well as continuous EEG and invasive hemodynamic monitoring, may be needed. Consultation from an anesthesiologist and neurologist should be obtained.

Anesthesia may be induced to treat refractory status epilepticus by administering infusions of midazolam or propofol for 12 to 24 h. [22,23,24 and 25] General anesthesia may also be obtained with IV barbiturates such as thiopental and pentobarbital. Midazolam and propofol have the advantage over barbiturates of having a short half-life and rapid clearance, allowing for earlier extubation and earlier clinical assessment; midazolam also causes less hypotension.

Neuromuscular blocking agents (usually pancuronium or vecuronium) are sometimes helpful. These drugs will abolish tonic-clonic movements and may facilitate ventilation and other measures; they have no effect on abnormal neuronal activity. EEG monitoring is necessary to assess the effectiveness of anticonvulsant therapy when neuromuscular blockers are utilized.

225 ACUTE PERIPHERAL NEUROLOGIC LESIONS

Michael M. Wang

When confronted with a patient with neurologic complaints, one should first localize the problem anatomically based on the history and physical examination. In the process of localization, one of the initial distinctions that should be made is whether the pathologic process involves the peripheral or central nervous system. Sometimes the distinction is not clear. The purpose of this chapter is to focus on the diagnosis of peripheral nervous system disease and to discuss the approach and management in the emergency setting. Myasthenia gravis is discussed in Chap. 226.

HALLMARKS OF PERIPHERAL NERVOUS SYSTEM DISORDERS

The peripheral nervous system serves sensory, motor, and autonomic functions. The patient with a peripheral nerve problem thus may have symptoms reflecting disorder of any or a combination of these functions. Sensory symptoms may include numbness, tingling, dysesthesias, pain, and ataxia due to proprioceptive dysfunction. Motor symptoms are predominantly weakness. Autonomic disability can include orthostatic symptoms, bowel or bladder dysfunction, gastroparesis, and sexual dysfunction.

On physical examination, the most important finding in a peripheral nerve process is reduction or absence of reflexes. The sensory examination, which includes tests of proprioception, vibratory sensation, and pain and temperature sensibility, is also often abnormal. When the motor system is involved, in addition to weakness, wasting and fasciculations may be seen. Autonomic dysfunction can cause hair loss, anhidrosis, pupillary dysfunction, orthostatic hypotension, and tachy- and bradyarrhythmias.

Similar symptoms and signs may be seen in disorders of the central nervous system (CNS). Weakness and numbness can be seen in both peripheral and central disorders. Hyporeflexia sometimes occurs with acute central lesions, but hyperreflexia and spasticity invariably develop later. Peripheral nervous system disorders, like CNS diseases, affect bulbar structures, resulting in diplopia, dysarthria, or dysphagia. Nevertheless, CNS disorders frequently have other features that are not seen in peripheral diseases. For example, aphasia, apraxia, and visual loss are hallmarks of cortical disease. Signs on examination such as hyperreflexia and clear lateralization of weakness should prompt evaluation for CNS disorders.

LOCALIZATION OF NEUROLOGIC DISEASE

Once a peripheral disorder has been established, it is necessary to determine which part of the peripheral nervous system is involved. A localized process, such as numbness and tingling of the fifth and half of the fourth digits of one hand, strongly suggests a focal lesion (ulnar nerve). The lesion may involve the nervous system at a number of locations: the nerve, plexus, or root. Basic knowledge or the aid of an anatomy text or neurology handbook should be sufficient to accurately localize focal lesions of these types. Figure 225-1 shows a schematized view of the peripheral nervous system and illustrates the signs associated with disease of specific parts of the neuromuscular system. Most muscle-related processes result in weakness of large proximal muscles, and patients may have a difficult time lifting their arms over their heads or arising from a seated position. Pain and tenderness of the muscles occur commonly (although usually these are not predominant symptoms and if not accompanied by weakness rarely indicate myopathy), and creatine phosphokinase (CPK) is usually elevated, sometimes dramatically. Diseases that affect other components of the peripheral nervous system seldom cause muscle tenderness and elevations in CPK. Neuromuscular junction processes also affect large proximal muscles and frequently affect the bulbar musculature, resulting in pupillary dysfunction, diplopia, dysarthria, or dysphagia. Unlike muscle and neuromuscular junction disease, neuropathies frequently affect both the motor and sensory systems; because these diseases most severely affect longer nerves, distal power is reduced most dramatically. Polyradiculopathy, which frequently follows a progressive and stepwise course, usually results in electrical pain sensations, assorted sensory abnormalities, areflexia, and weakness.

FIG. 225-1. Schematic view of the neuromuscular system and typical findings with disease of each component of the system. *Abbreviations:* DRG, dorsal root ganglion; NMJ, neuromuscular junction.

Once localization of the peripheral problem is accomplished, efforts should be made to pinpoint the etiology. Specific historical points that always should be addressed include the time course of the illness, whether there are diurnal fluctuations in the symptoms, other systemic symptoms or conditions, a review of medications, and antecedent illnesses. A serum chemistry and metabolic profile and creatine kinase are frequently useful blood tests in the emergency department (ED) setting. Further testing is usually deferred in the acute setting but may include a variety of blood tests, nerve conduction studies, electromyography, lumbar puncture, and nerve/muscle biopsy.

TREATMENT: GENERAL CONSIDERATIONS

Management of peripheral nervous system disorders depends on the specific diagnosis. However, a few general remarks about care should be made. When a peripheral disorder is suspected or diagnosed in the ED, one should arrange for neurologic consultation for further specific treatments. Many neuromuscular disorders are difficult to diagnose and require complex treatments such as immunomodulation with intravenous immunoglobulin, immunosuppressive drugs, and plasmapheresis. Given potential morbidity from the therapies themselves, it is prudent to refer the patient to a neurologist and have the diagnosis confirmed with contemporary diagnostic tools.

Careful supportive care is mandatory for severe, life-threatening neuromuscular diseases and should begin in the ED. Patients with the potential to experience respiratory failure, aspiration, and lethal cardiac dysarrhythmias should be monitored appropriately. Where the presentation warrants, baseline forced vital capacity or

negative inspiratory pressure should be measured in the ED to assess whether there is need for imminent respiratory support or admission to an intensive care unit.

With few exceptions, admission to the hospital is generally required for acute peripheral neurologic conditions in which there is danger of respiratory or autonomic compromise or in cases of debilitating or rapidly progressing weakness. Admission allows rapid initiation of the diagnostic workup and treatment and intensive rehabilitation, which is frequently delayed in the outpatient setting. Specific indications for hospital admission are discussed below for individual disease entities.

SPECIFIC NEUROMUSCULAR DISORDERS

The number of neuromuscular disorders is extensive and cannot be discussed fully in this text; this section thus covers the most common and most important disorders to recognize and the diseases that have acute therapies available.

Myopathies

Polymyositis is an inflammatory myopathy that affects individuals over the age of 30, with a slight propensity for women. [1] Usually, patients present with chronic complaints of proximal symmetric weakness, although the disorder occasionally presents subacutely. Some patients will have dysphagia, and a few will progress to respiratory failure. There may be muscle pain and tenderness. On examination, there is reduced proximal strength, which may best be tested by asking the patient to arise from a chair with his or her arms crossed or to lift a light object over his or her head. There is no sensory loss, and unless weakness is profound, reflexes should be intact. If deep tendon reflexes are diminished, neuropathy should be considered. Laboratory testing may reveal an elevated erythrocyte sedimentation rate (ESR), leukocytosis, and creatine kinase. The differential diagnosis includes Lambert-Eaton myasthenic syndrome, inclusion body myositis, toxic myopathies, dermatomyositis, endocrinopathies, and an assortment of muscular dystrophies.

Patients with newly suspected polymyositis should be assessed for potential respiratory compromise and aspiration risk in the ED. Admission is usually warranted in cases of newly suspected polymyositis to monitor progress, rapidly work up the patient, and begin treatment. Further diagnostic studies likely pursued under the direction or consultative advice of a neurologist typically include electromyography (EMG) and muscle biopsy. Long-term treatment consists of immunosuppressive agents such as steroids and methotrexate.

Dermatomyositis, unlike polymyositis, can affect children and, like polymyositis, affects mostly women. [1] The clinical manifestations of dermatomyositis are similar to those of polymyositis, except for the usual appearance of a violaceous rash typically over the face and hands. The neurologic examination shows a myopathic distribution of weakness without sensory or reflex abnormalities in most cases. The laboratory findings are also similar, with an elevated ESR and CPK in most instances. Despite similarities in the clinical presentation compared with polymyositis, the pathology and pathophysiology of the two disorders are quite distinct. [1] Treatment is aimed at immunosuppression.

Other Myopathies   A large number of substances, including environmental (alcohol), occupational, and pharmacologic agents (steroids, cholesterol-lowering drugs, AZT), can cause myopathy. Several important medication-induced myopathies are summarized in Table 225-1. Although usually chronic, some present subacutely and cause a predominantly proximal pattern of weakness with normal sensation and preserved tendon reflexes (except with severe weakness). CPK is usually elevated. Viral myositis causes an acute myopathy, occasionally involving the heart, and is usually associated with a febrile illness, myalgia, and elevated CPK levels. Trichinosis should be suspected in patients with myalgias, bulbar and proximal muscle weakness, facial edema, and eosinophilia; symptoms occur within days of ingesting undercooked pork. Definitive diagnosis is made on visualization of parasitic cysts on muscle biopsy.

Chloroquine	ε-Amino-caproic acid	Thiazides
Emetine	D-Penicillamine	Amphotericin
Corticosteroids	Chlorpromazine	Amphetamines
Amiodarone	Zidovudine	Toluene
Adriamycin	Colchicine	Ethanol

TABLE 225-1   Drugs That Cause Myopathy

Disorders of the Neuromuscular Junction

Myasthenia gravis is discussed in Chap. 226.

Botulism   Ingestion of foods contaminated with *Clostridium botulinum* toxin causes botulism, an acute disease marked by weakness and gastrointestinal slowing. Adults whose disease is caused not by bacterial infestation but by ingestion of botulinum toxin may report exposure to foods such as home-canned vegetables in the preceding 1 to 2 days. Unlike adults, infants, whose guts are not colonized fully, are susceptible to infection with viable bacteria that elaborate toxin. Parents of infants should be questioned for possible ingestion of *C. botulinum* spores, commonly transmitted by feeding honey. Infants may present with poor sucking. Botulism caused by infection through a wound is rare. On examination, mentation is normal, but there may be bulbar weakness. The extraocular movements are sometimes abnormal, and an important diagnostic clue is the absence of the pupillary light reflex, which distinguishes this disorder from myasthenia gravis. There is proximal limb weakness, sensation is intact, and reflexes generally are normal except in the case of severe weakness.

Botulism is treated with antibiotics (infants only) and immune serum, which is obtained from the Centers for Disease Control and Prevention (Atlanta). The serum, derived from immunized horses, is first used in skin tests to rule out hypersensitivity. For adults, 10,000 units is administered the first day, and thereafter, the patient is given 50,000 units daily until improvement is seen. [2] Patients should be admitted to the hospital for treatment, monitoring, and testing. In cases where the diagnosis is not clear, treatment with immune serum, which has potential morbidity, should be withheld until electrodiagnostic studies are performed. Nerve conduction studies show an incremental response on repetitive nerve stimulation.

Acute Peripheral Neuropathies

Guillain-Barré syndrome (GBS) affects individuals of all ages and is the most common form of acute generalized neuropathy. Frequently, patients report an antecedent viral illness, especially gastroenteritis. There is an association between acute *Campylobacter jejuni* infection and development of GBS. Sometimes the patient first notices numbness and tingling of the lower extremities. This is followed by weakness of thighs, legs, and then arms. There are numerous variants of the syndrome, and some patients may experience facial weakness, which can mimic Bell's palsy, ophthalmoparesis, severe shooting pains, or ataxia caused by proprioceptive difficulty. In most, but not all, cases, GBS is caused by an autoimmune attack on myelinated motor nerves.

In classic cases, there is symmetric extremity weakness, more pronounced in the legs. Despite subjective sensory disturbances, sensation on examination is usually normal. The hallmark finding in GBS is the lack of deep tendon reflexes. In variant cases, there may be ophthalmoplegia and pupillary disturbances. Occasionally, there may be facial weakness involving the forehead. Autonomic instability, marked by brady- and tachycardia or blood pressure fluctuation, may be apparent in a few cases. Where ophthalmoparesis is present, there may be a marked limb ataxia, and the patient may not be able to walk or stand despite reasonable strength. In all forms of the disease, there is a chance of developing respiratory failure and lethal autonomic fluctuations.

Lumbar puncture should be performed when acute disease is suspected. The classic laboratory finding in GBS is a high cerebrospinal fluid (CSF) protein with normal glucose and cell count. However, the protein will not be elevated until after the first week of symptoms and may not be present even after 1 week. Though many

patients will have a modest CSF pleocytosis (up to 100 lymphocytes/mm^3), the presence of cells in the CSF should prompt consideration of other systemic diseases sometimes associated with GBS, such as HIV infection, lupus, and lymphoma. Lyme disease can present with a clinical picture similar to GBS and would be suggested by a CSF pleocytosis in combination with a history of tick bites or the presence of CSF Lyme antibodies. Carcinomatous meningitis also can present with similar symptoms but will be evident with malignant cells in the CSF or extremely high protein or low glucose levels. Tick paralysis mimics GBS, and all patients with suspected GBS should be examined thoroughly for ticks. Acute intermittent porphyria (discussed below) and spinal cord compression should be considered in the differential diagnosis; the presence of upper motor neuron signs and bowel and bladder incontinence would suggest the latter.

Patients with GBS should be admitted to the hospital for monitoring and treatment. When forced vital capacity (FVC) is under 1 L, the patient should be intubated. No specific treatment is warranted in the ED; treatment is composed of plasma exchange or intravenous immunoglobulin, which both have been shown in controlled studies to shorten the duration of the illness. [2]

Acute intermittent porphyria is a rare autosomal dominant condition in which patients suddenly experience the symptom triad of weakness, psychosis, and abdominal pain. Seizures can occur. The three occasionally occur together, but in many cases occur independently. The disease activates acutely in flares that are usually precipitated by medications such as barbiturates, phenytoin, sulfonamides, and estrogen.

The major neurologic findings are weakness and diminished reflexes, particularly of the lower extremities, which are the direct consequence of an acute peripheral neuropathy. There may be sensory findings such as diminished pain and temperature sensation, although these signs are usually outweighed by motor deficits. In the acute setting, basic ancillary laboratory studies may be normal. Further testing reveals elevation in urine d-aminolevulonic acid and porphobilinogen.

The key management issue is recognition of the disorder and identification and discontinuation of the offending drug. Care also must be taken to avoid overtreatment of symptoms such as pain and seizures with medications that may exacerbate the illness. Other treatment modalities include supportive care, glucose infusions to prevent heme biosynthesis, vitamin B$_6$, and hematin (4 mg/kg daily for 1 to 2 weeks). The differential diagnosis includes other disorders that cause pain and lower extremity weakness. Spinal cord compression causes back pain, which frequently radiates around the trunk and is followed by lower extremity weakness, but reflexes in this situation are brisk with upgoing toes (positive Babinski's reflex). An aortic aneurysm or dissection also can cause abdominal pain and lower extremity weakness if spinal arteries are occluded by the expanding aneurysm.

Entrapment Neuropathies

The most common entrapment neuropathies are discussed below. For the most part, the nerve damage is reversible, and referral to the appropriate specialist for relief on entrapment is necessary.

Carpal tunnel syndrome (CTS) is the most commonly seen entrapment neuropathy. Patients describe intermittent pain and/or numbness in the thumb and first two fingers, prominently at night. Symptoms frequently awaken the patient from sleep, occur in both hands independently, and may be poorly localized (i.e., numbness is often described going up to the elbow). The symptoms usually can be reproduced by compression of the nerve over the carpal tunnel or by tapping on the nerve, although these signs are neither sensitive nor specific. Occasionally, these symptoms are mistaken for cerebrovascular disease until a history of bilateral, repeated, and stereotypical nocturnal occurrence is obtained. When symptoms become long-standing and severe, weakness of the thenar musculature develops. Wrist splints worn at night are useful in the conservative management of CTS. Patients should be referred to a hand surgeon as an outpatient for further diagnostics and management. A carpal tunnel release may be performed in patients who fail to respond to conservative management.

Ulnar nerve entrapment, usually occurring at the elbow, produces numbness in the fifth digit and medial half of the fourth finger, but symptoms are frequently poorly localized. Weakness and wasting of the hypothenar muscles occur very late in the course. The patient should be referred to a specialist for electrodiagnostic confirmation because occasionally C8 radiculopathy can mimic this common condition. Severe cases are treated surgically with ulnar nerve transposition.

Entrapment of the deep peroneal nerve at the fibular head can cause footdrop and numbness of the web between the great and second toes. This condition occurs in the setting of injury to the leg, rapid weight loss, or habitual crossing of the legs. Peroneal entrapment should be confirmed by EMG to be differentiated from lumbar root disease or motor neuron disease. Almost all cases are treated conservatively and improve without specific therapy.

Meralgia paresthetica is entrapment of the lateral cutaneous nerve of the thigh. The diagnosis is often overlooked in the ED, being mistaken for a hip-related orthopedic disorder. Patients describe numbness and dysesthesias of the lateral aspect of the upper leg. This occurs after weight loss and notably following pelvic surgery or obstetric procedures where the legs are abducted and flexed for a prolonged period of time. Tricyclic antidepressants (TCA) are useful in the management of the dysesthesias associated with meralgia paresthetica. The condition resolves without sequelae and requires no specific therapy.

Mononeuritis multiplex is a syndrome of multiple nerve dysfunctions caused by a vasculitis. Patients experience multiple deficits in a stepwise fashion, usually involving both sides of the body. For example, a patient may experience wristdrop on the right, followed by footdrop on the left, and then footdrop on the opposite side a few weeks later. This condition requires urgent referral to a neurologist to determine the etiology and initiate treatment, usually in collaboration with a rheumatologist. Frequently this disorder is caused by a systemic vasculitis, and a thorough serologic examination and nerve biopsy are required to establish specific treatment plans. The condition must be differentiated from multiple compression neuropathies and from multifocal motor neuropathy.

Bell's palsy should be viewed as a diagnosis of exclusion. It is the most common cause of acute facial paralysis but is similar to other processes that are important to recognize. Patients with Bell's palsy complain of sudden facial weakness, difficulty with articulation, problems keeping an eye closed, or inability to keep food in the mouth on one side. Because the seventh cranial nerve also serves other functions, the patient may have variable degrees of dry eye, metallic taste of the mouth, and facial pain, commonly around the ear. The examination is notable for one-sided weakness of the face involving the forehead. There may be decreased sensation along the external acoustic meatus (Hitselberger's sign). Other cranial nerves are normal. Diminished reflexes suggest a different diagnosis.

Several alternative diagnoses should be considered. Stroke can lead to sudden facial weakness that involves only the lower face but also leads to neurologic involvement below the neck or other cranial neuropathies. Lyme disease and GBS can cause facial paralysis, as discussed elsewhere in this chapter. In patients with cancer, facial weakness may herald the metastatic spread of malignancy. The ear should be inspected carefully to rule out ulcerations caused by cranial herpes-zoster activation (Ramsay Hunt syndrome), which should be treated with oral acyclovir. Facial paralysis also can be seen in sarcoidosis, collagen vascular disease, and polio. All patients with facial weakness should be screened for HIV risk factors, since seventh nerve palsy can occur at the time of seroconversion.

The treatment of Bell's palsy with steroids is controversial. While some believe that they have no role, most neurologists argue in favor of a short course of prednisone in individuals with low risk for complications from corticosteroids. The recommended dose is 50 mg per day for 7 days. More recent studies [3] have suggested that steroids in combination with acyclovir (200 mg five times a day for 10 days) leads to better outcomes. If the patient is seen more than a week after paresis began, steroids generally are not given.

Eye care must be meticulous to avoid corneal abrasions. Patients are instructed to tape the affected eye so that the palpebral fissure is narrowed to prevent drying of the cornea. Patients should apply Lacrilube and patch the eye before sleeping.

Lyme disease affects individuals exposed to the tick-born pathogen *Borrelia burgdorferi*. Although its neurologic manifestations are multiple, one of the most common sites of involvement is the peripheral nervous system. [4] Patients often, but not always, report prior tick exposure and have spent time in areas known to have deer ticks. Initial manifestations of Lyme disease include arthralgias and fatigue. Neurologic complications ensue in the following weeks. A common neurologic sign of Lyme infection is seventh nerve palsy, which should not be confused with Bell's palsy. Lyme disease affects the peripheral nerves and the nerve roots. The patient may describe the acute or subacute progression of weakness and sensory loss, sometimes associated with radicular pain. On examination, the patient will have one of several signs. Unless there is encephalitis (a rare complication of Lyme disease), mental status will be normal. Apart from seventh nerve involvement, there may be weakness in the limbs, and if there is localized radicular inflammation, there will be a patchy myotomal pattern. Similarly, depending on the regional involvement of the disease, selected deep tendon reflexes will be diminished. Laboratory features suggestive of Lyme disease include serum and CSF Lyme antibodies. A CSF pleocytosis and increased protein with a normal glucose is the most common abnormality. When the diagnosis is made with confidence and other entities such as syphilis, carcinomatous meningitis, and sarcoidosis excluded, a 3-week course of intravenous antibiotics, either ceftriaxone or doxycycline, is given. Further discussion and treatment of Lyme disease are found in Chap. 145.

Plexopathies

Brachial neuritis is an acute condition that tends to affect younger individuals with a slight male predominance. Patients report excruciating shoulder, back, or arm pain followed by weakness of the arm or shoulder girdle. In a third of cases, it is bilateral. The cause is idiopathic, but cases have been reported following immunizations or viral infections. On examination, the patient has weakness in various distributions of the brachial plexus. The upper trunk is the preferred site of involvement, affecting strength of proximal arm and shoulder musculature. The anterior interosseous nerve is also affected preferentially, causing inability to form a pincer with the index finger and thumb. Sensory abnormalities are found but are not as profound as the motor dysfunction. Reflexes are diminished in the affected limb.

The differential diagnosis includes multiple cervical radiculopathies, Pancoast tumors, and neoplastic or inflammatory infiltration of the plexus. The diagnosis is usually clear, since a history of pain followed by weakness that plateaus in a week or two makes other diagnoses unlikely. A chest x-ray should be performed to look for mass lesions involving the brachial plexus. CSF analysis is required if there is a suspicion of other etiologies. Spine imaging and EMG may be performed outside the ED setting.

The management of brachial plexitis is conservative, and no therapies have been shown to affect the course of the illness. The prognosis is good, with most patients experiencing full recovery in months. If careful follow-up with a neurologist can be arranged and other causes or symptoms are excluded, admission to the hospital is elective.

Lumbar plexopathy, or diabetic amyotrophy, occurs in diabetic patients and presents with back pain followed by weakness. Patients report the acute onset of ipsilateral back pain, followed within days by progressive leg weakness. Sensory findings are absent. The examination reveals decreased leg power in a variety of patterns reflecting impairment of plexus function with relatively symmetric sensation. There may be muscle wasting in affected limbs in long-standing disease. Deep tendon reflexes may be diminished on the affected side. Bowel and bladder functions are not affected.

Laboratory studies are generally not helpful in the emergency setting. In the ED, routine plain films of the lumbar spine are useful to screen for spine compression from degenerative or neoplastic disease, and MRI is usually ultimately needed. The differential diagnosis also includes the cauda equina and conus medullaris syndromes and compression from arteriovenous malformations. CT scanning of the abdomen is useful to rule out aortic aneurysm and psoas muscle masses, which also lead to asymmetric lower extremity weakness. Patients with acute weakness from lumbar plexopathy should be admitted to the hospital for testing and rehabilitation to definitely determine the cause of weakness.

HIV-Associated Peripheral Neurologic Disease

HIV infection, its complications, and its pharmacologic treatments are associated with a number of peripheral neurologic disorders. Fortunately, the most common of these, HIV neuropathy and drug-induced neuropathy, are chronic processes that do not cause sudden disability or symptoms. HIV-infected patients also have a higher rate of *mononeuritis multiplex* and an inflammatory myopathy resembling *polymyositis.*

Occasionally, patients will complain of weakness that progresses over the course of days. Patients in the early stages of HIV infection have greater susceptibility to GBS. The presentation is similar to that of the non-HIV-infected patient, except that a CSF pleocytosis is seen commonly. Such patients should be treated as discussed earlier.

Cytomegalovirus (CMV) Radiculitis   In the latter stages of AIDS, patients may suffer from an acute radiculitis caused by CMV infection. These patients almost always have evidence of CMV infection elsewhere in the body and may have ongoing CMV retinitis. Patients become acutely weak, with primarily lower extremity involvement, and may have variable degrees of bowel and bladder dysfunction. The examination shows primarily lower extremity weakness and hyporeflexia, with decreased sensation in the lower extremities and groin. Rectal tone may be impaired. Lumbar puncture reveals a pleocytosis with predominantly polymorphonuclear cells and modestly increased protein; viral DNA is detected by polymerase chain reaction in most patients and is highly specific. MRI of the lumbosacral spine demonstrates swelling and clumping of the cauda equina. Imaging of these patients is mandatory to rule out mass lesions of the lower spine or nerve roots. The treatment of CMV radiculitis is intravenous ganciclovir, started at 5 mg/kg every 12 h for 14 days, which may be initiated prior to definitive diagnosis.

CHRONIC CONDITIONS

Patients with some frequency present to the ED with neuropathy associated with an underlying condition. Many are of a chronic nature, and a few are subacute. Most of these do not present acute management issues. However, conditions such as syphilis, Lyme disease, and vitamin B$_{12}$ deficiency benefit from early detection. A detailed discussion of neuropathies associated with underlying medical illness is worthy of an entire text. The interested reader is referred to standard neurology texts.[5] Table 225-2 shows the expected presentations for some diseases associated with peripheral neuropathies.

226 CHRONIC NEUROLOGIC DISORDERS

Edward P. Sloan

The chronic neurologic disorders discussed in this chapter include amyotrophic lateral sclerosis (ALS), multiple sclerosis (MS), myasthenia gravis (MG), Parkinson's disease (PD), and poliomyelitis and its late sequelae, postpolio syndrome. A knowledge of these diseases and their treatments is necessary in order to address complications, especially acute respiratory failure.

AMYOTROPHIC LATERAL SCLEROSIS

Amyotrophic lateral sclerosis (ALS) is characterized by rapidly progressive muscle wasting and weakness resulting from the degeneration of both upper and lower motor neurons. ALS causes varying degrees of spasticity, hyperreflexia, and muscle paralysis, eventually leading to pulmonary complications and the need for mechanical ventilatory support. Because there is no curative therapy for this disease, symptomatic management is directed at prevention of deaths caused by respiratory failure and pulmonary infections.

Epidemiology

There are three forms of ALS, the most common, sporadic ALS (sALS); familial ALS (fALS), which is genetically present in only 149 patients from 53 families worldwide (including a rare juvenile form); and an endemic focus of ALS in the western Pacific.[1] The worldwide annual incidence rate for sALS is 0.6 to 2.0 per 100,000, and the prevalence is 4 to 6 per 100,000.[2] The mean age of onset for sALS is 56 years, with no gender differences noted. The incidence of fALS is only 10 percent of that of sALS, with a 1.5-fold higher disease rate for men. There are no race differences with either form of ALS. There is a higher prevalence of ALS in individuals older than 60 years, and the annual worldwide ALS mortality rate is 1 per 100,000.

Pathophysiology

Current theories for cell death include excitotoxins (glutamate), free radicals, heavy metals, viral agents, and autoimmune reactions against such tissues as spinal cord collagen.[3] Programmed cell death due to apoptosis is also being studied as a possible etiology. The most likely cause of ALS is genetic superoxide dismutase dysfunction related to a variety of environmental insults.[4]

Gross central nervous system (CNS) pathology includes frontal cortical atrophy, degeneration of the corticospinal and spinocerebellar tracts, a reduction in large cervical and lumbar motor neurons, and cranial nerve nuclei degeneration. Both motor and sensory peripheral nerves are noted to undergo axonal degeneration and segmental demyelination, including motor end plate and axon terminal involvement.

Clinical Presentation

Upper motor neuron dysfunction causes limb spasticity, hyperreflexia (including Babinski's sign and a brisk jaw-jerk reflex), and emotional lability. Lower motor neuron dysfunction causes limb muscle weakness, atrophy, cramps, and fasiculations, as well as dysarthria, dysphagia, and difficulty in mastication. At the time of initial presentation, extremity cramping, fatigue, and weakness are seen, as well as muscle fasciculations and atrophy.[5] These symptoms are more prominent in the upper extremities, with asymmetric weakness seen commonly. Regardless of the initial symptomatology, widespread motor and respiratory dysfunction progresses within weeks to months. Atrophic, fasciculating, hyperreflexic extremities are seen, as well as foot drop and claw deformity of the hand. Patients also may present with an atrophic fasciculating tongue and monotonous speech, with relative sparing of facial and eye movements. Patients with fALS more often present with isolated lower extremity weakness and atrophy at the time of diagnosis. Some patients eventually diagnosed as having ALS present initially with cervical or back pain consistent with an acute compressive radiculopathy, leading to surgery. Despite successful operative intervention, these patients develop significant muscle wasting consistent with motor neuron dysfunction shortly after the procedure.[6]

Progressive respiratory muscle weakness causes dyspnea with mild activity, until dyspnea at rest occurs. Dementia and parkinsonism also may be seen in up to 15 percent of patients, especially those with fALS. Other cognitive problems such as apathy, poor attention and motivation, and altered social skills may be noted in patient with ALS.

Clinical Diagnosis

The clinical diagnosis of ALS is suggested when there are signs of both upper and lower motor neuron dysfunction without other CNS dysfunction. ALS-like symptoms can be seen with other systemic illnesses such as diabetes, dysproteinemia, thyroid dysfunction, vitamin B$_{12}$ deficiency, lead toxicity, and vasculitis, as well as CNS and spinal cord tumors. The diagnosis of ALS also requires that other inflammatory neuropathies such as myasthenia gravis be excluded. Established criteria for the diagnosis of ALS, the El Escorial criteria, have been developed by the World Federation of Neurology. [7]

Electromyography (EMG) is the most useful diagnostic tool, showing decreased muscle action potential amplitude and decremental responses to repetitive nerve stimulation

Disease Management

Therapy is designed to enhance muscle function, especially those which support breathing, swallowing, and speech, in order to avoid malnutrition, recurrent aspiration, or choking. Two drugs that may delay disease progression include riluzone and gabapentin, both of which prevent cell toxicity through modulation of the excitotoxin glutamate. Respiratory insufficiency is suggested by atrophy of the deltoids and trapezii, and a decrease in forced vital capacity by 50 percent increases the risk of respiratory failure. Pulmonary function testing, respiratory therapy, incentive spirometry, and intermittent positive-pressure breathing, intermittent negative-pressure (external) ventilation, and long-term assisted ventilation all can enhance the quality of life as diaphragm weakness progresses.

Emergency Diagnosis and Management

Patients with ALS most often will not present to the emergency department (ED) undiagnosed unless there is extremely rapid disease progression or a long period without medical care. Emergency management usually is required for acute respiratory failure, aspiration pneumonia, choking episodes, or trauma related to extremity weakness. A vital capacity drop below 25 mL/kg increases the risk of aspiration pneumonia and respiratory failure. Blood gas determination does not reliably predict impending respiratory failure, since mild hypoxia and hypercarbia may exist throughout the disease course. Although no acute therapies exist for worsening ALS, therapies that optimize pulmonary function (e.g., nebulized medications, steroids, antibiotics, intubation) are indicated. Because the need for long-term ventilatory assistance rarely reverses, it is important to establish the patient's preference regarding intubation via a living will or the power of attorney for health care. Hospitalization is indicated with impending respiratory failure, pneumonia, the inability to control secretions, or a worsening overall status that requires social service intervention for long-term placement.

Long-Term Outcome

ALS causes a consistent, predictable deterioration in motor function, leading to tracheostomy in most patients within 2 to 4 years. [8] ALS leads to complete respiratory failure in 80 percent and complete limb paralysis in 45 percent of patients. Although early diagnosis and aggressive management have increased the median survival of sALS, 50 percent of patients die within 3 years of diagnosis, and only 10 percent survive beyond 10 years. Patient diagnosed prior to age 40 may live up to four times longer than those diagnosed after age 60, especially if swallowing and airway control are spared. Survival in fALS is shorter, with a median survival of 2 years and a 23 percent 5-year survival rate. Long-term outcome is currently being followed in a longitudinal European survey termed the European ALS Health Profile Study.

MULTIPLE SCLEROSIS

Multiple sclerosis (MS) is a neurologic disorder that causes variable motor, sensory, visual, and cerebellar dysfunction due to multifocal areas of CNS myelin destruction. Paresthesias, gait difficulty, extremity weakness, poor coordination, and visual disturbances occur most often with a relapsing and remitting clinical course. Despite the lack of a definitive cure, immunosuppression and immunomodulation provide adequate symptomatic therapy in the majority of patients. Most patients with MS sustain only mild to moderate lifetime morbidity without a reduction in overall life expectancy.

Epidemiology

Three clinical courses are noted in patients with MS. Roughly two-thirds have a relapsing and remitting course, with relapses lasting weeks to months. The remaining one-third of patients have either a relapsing and progressive course or a chronically progressive clinical course, which is more common with advanced age. The incidence of MS is 4.5 to 8 per 100,000, and the prevalence is greater than 50 per 100,000. [9] In the United States, the peak age of onset for either sex is during the third decade of life. Females are two to three times more likely to contract MS, and they do so at a younger age than men. Males, however, are more likely to have a chronically progressive disease course from the onset of symptoms. MS is two times more likely in whites than in blacks, and it is rare in Asian populations. There is a geographic MS distribution, with temperate climates of economically developed countries experiencing a higher prevalence. Communities of northern Europe and the United States have prevalence rates of up to 173 per 100,000 in the white population. In the northern hemisphere there is a diminishing MS prevalence gradient that runs from north to south, while the opposite is true in the southern hemisphere. In general, 5 to 10 percent of MS patients will sustain a malignant course, and 20 to 35 percent will have a very benign disease course. Pregnancy reduces by 50 percent the MS relapse rate, but relapse risk increases up to sixfold during the postpartum period.

Pathophysiology

Although the etiology of MS is unknown, it is best described as an inflammatory disorder resulting in scattered neuron demyelination. The most frequently postulated theory for MS is a genetic predisposition triggered by a virus (such as herpes or HTLV-1) or environmental toxins that induce an immune-mediated neuronal inflammation and demyelinization. [10] MS causes a dysfunction in oligodendrocytes such that the axonal myelin sheaths are damaged, slowing nerve impulse conduction. These scattered cerebral and spinal plaques cause gliosis primarily in the white matter, with relative axon sparing.

These plaques occur in multiple areas, including the cerebrum, brainstem, spinal cord, and cranial nerves. The brain may have variable amounts of atrophy and ventricular dilatation. Nerves in the corticospinal tracts, posterior columns, and spinothalamic tracts will cause upper motor neuron, proprioception/vibration, and pain/temperature dysfunction, respectively. Cranial nerve dysfunction most often causes optic neuritis, but facial motor and sensory deficits are also common.

Clinical Presentation

MS is suggested when a young person presents multiple times with neurologic symptoms that suggest different areas of pathology, often with resolution of the prior symptoms. Most MS patients will have more severe lower extremities symptoms as compared with the upper extremities. For example, a young person might complain of an inability to walk on a street without tripping over a curb or uneven sections of pavement.

The physical examination may reveal decreased strength, increased tone, hyperreflexia, clonus, Babinski's reflex, a decrease in vibration sense and joint proprioception, as well as a reduction in pain and temperature sense. Although sensory and motor deficits are present initially in only one-third of patients, all patients will experience a deficit at some point during the disease course. Patients describe these deficits as a heaviness, weakness, stiffness, or extremity numbness. Lhermitt's sign is commonly experienced during the course of MS and is described as an electric shock sensation, a vibration, or dysesthetic pain radiating down the back and often into the arms or legs resulting from the flexion of the neck.

Rarely, patients with established MS may present with complete or near-complete loss of motor function, termed *acute transverse myelitis* (ATM). Cerebellar lesions may cause a kinetic tremor, saccadic dysmetria, and/or truncal ataxia. Vertigo also may be seen as a result of brainstem MS lesions.

Optic neuritis, which usually causes a subacute or acute central vision loss, may be the initial sign of MS in up to 30 percent of patients. The loss, which occurs over several days and is usually unilateral, often is preceded by retrobulbar pain or extraocular muscle pain that may be reproduced with periorbital palpation. Optic neuritis may cause an afferent pupillary defect, or Marcus Gunn pupil. Although funduscopy is most often normal in the acute setting, the optic disk may be noted to have pallor due to axonal loss and gliosis. Although the ocular pain most often resolves over several days, it may take up to months for the visual disturbances to resolve. Most MS patients at some time experience blurred vision, compromised color vision, and/or eye pain due to optic neuritis. In fact, visual acuity may worsen

due to increases in body temperature, known as *Uhthoff's phenomenon*. Nystagmus and diplopia are often seen in MS, as is internuclear ophthalmoplegia (INO). INO causes abnormal adduction and horizontal nystagmus, usually bilaterally. When bilateral INO is seen acutely in an otherwise healthy young person, it is highly suggestive of MS.

Dysautonomias can cause vesicourethral, gastrointestinal tract, and sexual dysfunction. Vesicourethral dysfunction results in urinary retention, urgency, frequency, detrusor-external sphincter dyssynergia (DESD), and stress or overflow incontinence. Constipation and fecal incontinence both can occur often with MS. Sexual dysfunction, especially in males, may be the presenting MS symptom and is correlated with other types of urologic dysfunction.

Cognitive and emotional changes, including dementia, decreased motivation, and/or mood disorders (depression, bipolar), occur in most MS patients. Cerebral MS, which affects only 5 percent of MS patients, can cause a severe, disabling decrease in intellect as well as focal seizures.

MS symptoms often will worsen with increases in body temperatures, as seen with exercise, fever, or even hot baths. Most initial MS attacks or exacerbations will progress over several days, peaking at about 1 week, with resolution over several weeks to months. Complete recovery from an acute attack or exacerbation is more common early in the course of the disease.

Clinical Diagnosis

The diagnosis of MS is clinically based, relying heavily on the neurologic history and physical examination. The diagnosis is suggested when a patient has either two or more prolonged (days to weeks) episodes with neurologic dysfunction that suggests distinct white matter pathology or spinal cord dysfunction that worsens over several months.[11] Optic findings, lack of focal pathology, clinical remissions, cerebrospinal fluid (CSF) findings, and typical features such as dysautonomias all suggest the diagnosis of MS.[12] Symptoms that mimic MS are seen with systemic lupus erythematosus (SLE), Lyme disease, neurosyphilis, and HIV disease. The clinical features of these other diseases, as well as the presence of consistent laboratory and neuroimaging findings in MS, can help to confirm the diagnosis of MS.

Nearly all MS patients will demonstrate some CNS pathology using magnetic resonance imaging (MRI). T2-weighted scans demonstrate either discrete lesions in the supratentorial white matter or homogeneous borders surrounding the ventricles. Although computed tomography (CT) is not as sensitive as MRI, it may show cerebral atrophy, ventricular enlargement, and low-density focal lesions in the cerebrum, brainstem, or optic nerves.

CSF protein and gamma-globulin concentrations are elevated in many MS patients. A slight increase in CSF white blood cells (up to 25/hpf) is also seen, most of which are T lymphocytes. Evoked potentials (EP) demonstrate scattered slowing in CNS pathway conduction in the majority of MS patients.

Disease Management

The long-term management of MS is directed at slowing the progression of the disease and providing symptomatic relief during exacerbations. In order to modify the disease and its exacerbations, immunomodulation with adrenocorticotropic hormone (ACTH), corticosteroids, interferon, and other immunosuppressive drugs has been studied. High-dose methylprednisolone therapy may shorten the duration of exacerbations, especially early in the disease course. Several weeks of oral prednisone therapy can be added to the initial IV steroid therapy, but the effect on the disease is unclear. Alternatively, ACTH can be given. Diets high in fruits, vegetables, and grains may protect against the development of MS symptoms.[13] Intravenous immunoglobulins are probably not effective in the treatment of MS. [14]

Emergency Diagnosis and Management

Emergency therapy is directed at minimizing the complications of acute MS exacerbations. Fever must be reduced in order to minimize the weakness caused by elevated temperature. Seizures can be treated with the standard benzodiazepine, phenytoin, and barbiturate regimen. Optic neuritis, severe constipation, and worsening muscle weakness also may complicate an MS exacerbation.

Respiratory infections and distress must be managed aggressively. Endotracheal intubation should proceed with caution, using the Sellick maneuver, because of an increased aspiration risk due to decreased gastric motility. Respiratory function in MS patients who require emergent surgery should be assessed and stabilized. Also, because many MS patients have labile autonomic nervous system function, they are at greater risk of developing hypotension with both emergent intubation and surgical anesthesia.

Urinary tract infections (UTIs) and pyelonephritis must be excluded during any MS exacerbation, especially those associated with a residual urine greater than 100 cc.[15] A postvoid residual urine determination should be made whenever there is clinical evidence of a UTI or significant bacteriuria. A urine culture should be performed, and antibiotic therapy initiated. When possible, discharged patients should manage elevated residual urine volumes with intermittent sterile catheterization as opposed to placement of a Foley catheter.

Hospitalization is indicated for any exacerbation that puts the MS patient at risk of further complications or when IV antibiotic or steroid therapy needs to be initiated. Admission is also indicated when depression and a significant risk of suicide require inpatient management.

Long-Term Outcome

Staging of the severity and progression of MS is characterized using a neurologic impairment scale, the Expanded Disability Status Scale (EDSS). [16] Up to one-third of MS patients can live a relatively unencumbered life despite having MS. Generally, sensory and cranial nerve symptoms predict a more favorable outcome than those caused by motor nerve or cerebellar dysfunction. Exacerbations are to be expected in the face of significant physical and emotional stress, with disease progression occurring over decades. For those with the most severe progression, severe disability can occur over months to years. In these patients, the risk of suicide is over seven times greater than for the population as a whole. Regardless of the rate of progression, most significant complications and mortality are due either to suicide or to neurologic, pulmonary, and renal dysfunction seen with advanced disease and age. Mean life expectancy exceeds 30 to 40 years after the time of initial diagnosis.

MYASTHENIA GRAVIS

Myasthenia gravis (MG) is an autoimmune disease characterized by muscle weakness and fatigue, seen especially with repetitive use of voluntary muscles. Acetylcholine receptor (AChR) antibodies impair the function of the AChR at the neuromuscular junction, causing variable amounts of muscle weakness. The muscle weakness is seen most often in proximal muscles, generally is relieved by rest, and requires long-term immunotherapy. Because the mechanism and optimal therapies for MG are well understood, much of the morbidity and mortality associated with the disease can be avoided. Aggressive management of respiratory complications associated with a myasthenic crisis is the most important issue for MG patients and emergency physicians.

Epidemiology

The incidence of MG is less than 1 case per 100,000, and the prevalence is 10 to 15 per 100,000. [17] There are about 25,000 cases in the United States and 100 million cases worldwide. The most common age of onset for females is in the second and third decades. In males, the peak onset age is in the seventh and eighth decades. Although females were believed to have up to a 4-fold higher disease prevalence, with aging of the population, the higher prevalence has shifted to males. There is a slightly higher prevalence in the African-American population. Although family members of patients with MG are much more likely to develop MG, the disease is not transmitted by traditional Mendelian inheritance.

Pathophysiology

In the normal neuromuscular junction, acetylcholine (ACh) release by the nerve fiber causes a localized end-plate potential that leads to muscle fiber contraction. In MG there is a marked decrease in the number and function of the muscle fiber ACh receptors (AChR) despite normal nerve anatomy and function. Failure to respond to ACh stimulation causes decreased muscle fiber potential amplitudes, causing some fibers to fail to function and leading to decreased muscle strength.

The autoimmune etiology of MG is demonstrated by the consistent presence of AChR autoantibodies in nearly all MG patients. These antibodies react to the AChR, can be transferred passively (causing the disease), and can be induced by immunization with the AChR proteins, and disease severity can be correlated with AChR

autoantibody levels. These autoantibodies cause accelerated AChR degradation and blockade and also cause receptor dysfunction through complement activation.

The etiology of the pathologic autoimmune response is believed to be due to dysfunction of either the thymus gland or the immune response to exogenous infectious antigens. The thymus is found to be abnormal in 75 percent of MG patients, most often with hyperplasia or the presence of a thymoma. Thymectomy resolves or improves the symptoms in most MG patients. It is possible that the AChR autoantibodies arise following exposure to similar antigens, such as those caused by herpes simplex virus or bacteria infection. These antigens, because of their resemblance to the AChR, cause a pathologic attack on the ACh proteins.

Clinical Presentation

The symptoms of MG can mimic the symptoms seen in many other chronic neurologic disorders, such that some call it "the great imitator." Prior to the establishment of a definitive diagnosis, most MG patients have general weakness, especially of the proximal extremities muscle groups, neck extensors, and facial or bulbar muscles. Ptosis and diplopia are the most common presenting symptoms, but oropharyngeal symptoms (dysphagia and dysarthria) and limb weakness also can be seen. Although 10 percent of patients will have weakness that is restricted only to the ocular muscles, most MS patients subsequently will develop weakness in the oropharyngeal and limb muscles. The maximum extent of this weakness usually becomes manifest within the first year of diagnosis. These symptoms can fluctuate throughout the day, usually worsening as the day progresses or with prolonged muscle group use, such as with prolonged reading or prolonged chewing during a meal. Despite the presence of profound muscle weakness, there usually is no deficit in sensory, reflex, or cerebellar functioning. There may be a coexistent endocrine disorder, and the disease is often associated with thymoma.

MG in elderly patients can be misdiagnosed as ischemic stroke, especially when new-onset facial weakness is seen. [16] In very rare instances, undiagnosed MG patients may present with extreme weakness in the muscles of respiration, resulting in respiratory failure. This life-threatening situation, termed *myasthenic crisis,* can be seen prior to MG diagnosis or as a result of inadequate drug therapy or drug tolerance. The complications associated with the respiratory failure seen in acute myasthenic crisis are the leading cause of death in MG patients.

Clinical Diagnosis

The diagnosis of MG should be considered in any patient who complains specifically of ocular disturbances or proximal limb muscle weakness not associated with systemic causes of generalized fatigue. Involvement of the facial muscles, muscles of mastication, and those which facilitate swallowing all may suggest MG, as well as the observations that the symptoms worsen as the day progresses and that rest alleviates the symptoms. MG is graded as being either focal, generalized with mild to severe weakness, or myasthenic crisis, which may require ventilatory support.

Other causes of symptoms that suggest MG include congenital MG, Lambert-Eaton syndrome (seen with oat cell lung tumors), drug-induced myasthenia (e.g., penicillamine, procainamide, quinines, aminoglycosides), botulism, thyroid disorders, and other causes of ocular disorders, such as progressive external ophthalmoplegia or intracranial mass lesions.

The diagnosis of MG is established through the administration of edrophonium chloride (an acetylcholinesterase inhibitor), EMG, and serologic testing for AChR antibodies. In the presence of abnormal neuromuscular transmission, edrophonium or neostigmine is expected to improve muscle strength in objectively weak limb muscles and in weak ocular and pharyngeal muscles. Because these drugs also can cause profound weakness in the presence of other disorders that impair neuromuscular transmission, one must be ready to provide ventilatory support or intubation as a complication of testing. EMG testing with repetitive nerve stimulation demonstrates a rapid reduction in the size of the muscle action potential, a finding that correlates with the clinical observation of enhanced weakness with prolonged or repetitive muscle use. AChR antibody testing is the most specific test for MG, but up to 15 percent of MG patients may have undetectable AChR antibody titers, especially those who have isolated ocular disturbances.

Other tests that may be necessary to confirm the diagnosis of MG or exclude other etiologies of muscle weakness include mediastinum imaging, laboratory testing for lupus and thyroid disorders as well as tuberculosis, and pulmonary function testing.

Disease Management

The management of MG includes the administration of acetylcholinesterase inhibitors, thymectomy, chronic immune suppression, and acute immune modulation (plasma exchange, IV immune globulin), when indicated. Muscle weakness usually does not return to normal with the use of these modalities, and there can be great temporal variability in the nature and amount of muscle weakness. Under- or overdosing can cause significant complications. Variability in the amount of muscle weakness can be seen in response to asthma exacerbations, infections, menstruation, pregnancy, emotional stress, hot weather, and other disorders that alter the response to medication, such as renal and gastrointestinal disease.

Most MG patients show a favorable response to thymectomy. Most show improvement with oral corticosteroids, although some patients initially become weaker prior to symptom improvement when high-dose steroids are administered. Severe MG symptoms often require the use of IV immunoglobulins or a combination of high-dose steroids and plasma exchange.

Emergency Management and Diagnosis

Respiratory failure is usually precipitated by infection, surgery, or the rapid tapering of immunosuppressive drugs. Otherwise minor illnesses, such gastroenteritis or upper respiratory infections, can worsen MG. The neurologist always should be consulted before making a disposition.

Several drugs are known to affect neuromuscular function, and caution must be exercised with their use in MG patients. Drugs that should be avoided are listed in Table 226-1. If a drug is absolutely necessary, such as steroids for status asthmaticus, equipment for emergency endotracheal intubation should be immediately available because respiratory failure can develop rapidly.

TABLE 226-1   Drugs That Should Be Used With Caution in Myasthenia Gravis

Myasthenic patients being treated in the ED for other conditions should receive their usual dose of cholinergic inhibitors such as pyridostigmine (Mestinon). The dose is often 60 to 90 mg PO every 4 h. If a dose has been missed, the next dose is usually doubled. If the patient is NPO or intubated, one-thirtieth the oral dose of pyridostigmine is given by slow intravenous infusion. Neurology consultation generally is needed to determine the optimal intravenous dose, rate of infusion, and timing of repeat doses.

The most feared complication of MG in the ED is respiratory failure. Intubation should be considered in patients with a forced vital capacity of less than 1 L. Blood gases have a poor predictive value for intubation. Because of the increased sensitivity of MG patients to neuromuscular junction inhibitors, if avoidable, patients

preferably should not receive either depolarizing or nondepolarizing paralytic agents in preparation for intubation. Even small doses may have profound effects. Short-acting agents such as etomidate or fentanyl can be used instead and in smaller doses. [19] Propofol is an alternative agent in the operating suite. Patients with myasthenia are extremely sensitive to both depolarizing and non-depolarizing paralytic agents. Paralytic effects can be expected to persist at least 2–3 times longer than in normal patients.

Fortunately, the need for paralytic agents for emerging intubation of myasthenic patients is rare. If etomidate or fentanyl are ineffective and paralytic agents are necessary, some have recommended utilizing one-half the dose of paralytic agents, although there are no clinical studies supporting this recommendation.

Differentiation of myasthenic crisis (disease exacerbation or inadequate drug therapy) from cholinergic crisis (excessive drug delivery) is by means of the Tensilon test. Edrophonium chloride (Tensilon) is used because of its rapid onset (30 s) and the short duration (approximately 5 to 10 min) of its effects. A positive result, one that suggests that the symptoms are due to a myasthenia exacerbation, is characterized by the resolution of muscle weakness within a few minutes.

In order to establish that the patient does not react adversely to edrophonium, suggesting that the symptoms are due to excessive cholinergic effects, 1 to 2 mg IV should first be injected. The occurrence of muscle fasiculations and respiratory depression within a few minutes suggests that the muscle weakness is related to a cholinergic crisis, and further edrophonium administration is contraindicated. If there is no evidence of a cholinergic crisis, up to 10 mg of edrophonium should be administered in order to demonstrate benefit in the face of a presumed myesthenic crisis.

If the Tensilon test is positive, indicating a myasthenic crisis, neostigmine can be given parenterally or orally. IM or SC neostigmine is given in 0.5 to 2 mg doses, with clinical effectiveness by 30 minutes, lasting for up to 4 h. Alternatively, 15 mg neostigmine tablets can be given, each having a clinical effect comparable with that of a 0.5 mg parenteral injection.

In children, the total edrophonium IV dose is 0.15 mg/kg, not to exceed 10 mg. To test hypersensitivity in children, an initial IV edrophonium dose one-tenth that of the total dose can be given. For children weighing up to 75 lb (34 kg), a test dose of 1 mg is appropriate, and a total dose of 5 mg can be used in 1 mg increments. In infants, or when IV access is not available in children up to 75 lb, IM edrophonium at 0.5 to 2 mg can be given as a test dose.

Caution should be exercised when administering edrophonium to patients with cardiac disease, since it rarely may cause bradycardia, atrioventricular (AV) block, and cardiac arrest. Although atropine will counteract these muscarinic effects of edrophonium, it is ineffective in reversing the nicotinic effects, such as skeletal muscle paralysis, that can occur in the face of a cholinergic crisis.

Acute respiratory failure can result from either acute myasthenic or acute cholinergic crisis. Cholinergic crisis patients who fail the Tensilon test may require immediate intubation and management of excessive secretions and acute bronchospasm. Other complications of muscle weakness, such as impaired swallowing, aspiration pneumonia, dehydration, and decubitus ulcers, also must be considered.

LAMBERT-EATON MYASTHENIC SYNDROME

Lambert-Eaton Myasthenic Syndrome (LEMS) is predominantly a disease associated with lung cancer, affecting mostly older men. Patients complain of chronic weakness and fatigue along with autonomic symptoms (e.g. dry mouth and impotence), and the examination shows signs of proximal muscle weakness. Repeated examination of the same limb can sometimes elicit improved strength initially. Eye movements are unaffected except for the pupillary reaction in some cases. Reflexes are diminished. The sensory examination can be normal, but because LEMS is associated with cancer, paraneoplastic or chemotherapy induced neuropathy can lead to a superimposed sensory deficit. Routine laboratory testing may be normal. The differential diagnosis includes myopathies and neuromuscular junction disorders listed above.

The acute treatment of LEMS is supportive. Only in rare cases does this disease progress to respiratory or bulbar failure. Chronic treatment includes eradication of neoplasia, steroids, 3,4-aminopyridine, and anticholinesterases. Hospital admission is reserved for the most severe cases of debilitating weakness or where there is a danger of respiratory compromise.

PARKINSON'S DISEASE

Parkinson's disease (PD) is the most common of the chronic neurodegenerative diseases, affecting many older patients to varying degrees. It is an extrapyramidal movement disorder characterized by the presence of a resting tremor, cogwheel rigidity, bradykinesias or akinesias, and impaired postural reflexes. Although the etiology of the disease is unknown, PD patients consistently are seen to have a reduced number of functional dopaminergic receptors in the substantia nigra. Drug therapy enhances central dopaminergic activity and decreases the relative excess in central cholinergic activity. The availability of multiple drug therapies has improved the symptoms associated with PD, although the disease still progresses without symptom remission in most patients.

Epidemiology

Although the etiology of PD is unknown, epidemiologic studies suggest that it is caused primarily by environmental factors in patients who possibly may have a genetic predisposition to the disease. The overall U.S. incidence is 16 cases per 100,000 persons and is as high as 200 per 100,000 in patients in their seventh and eighth decades of life. The average onset age is between 55 and 60 years, with the peak age of onset between 70 to 79 years.

Pathophysiology

Although the etiology of PD is unknown, the disease is characterized by consistent CNS neuropathology. Cellular changes include the presence of cytoplasmic inclusions termed *Lewy bodies.* There are also extracellular pigment granules that stimulate macrophage activity. A disturbance in oxidative phosphorylation that causes the formation of free radicals is thought to be one possible mechanism for these changes. [20]

In the pigmented areas of the midbrain, especially the substantia nigra, there is depigmentation, dopaminergic neuron loss, and gliosis. These cellular changes result in the loss of functional dopaminergic receptors, causing a decrease in the overall level of striatal dopamine.

Clinical Presentation

The clinical diagnosis of PD is based on the presence of one or more of four hallmark neurologic signs, including resting tremor, cogwheel rigidity, bradykinesia or akinesia, and impairment in posture and equilibrium. Besides these signs, identified in the mnemonic *TRAP,* there also may be other signs, including facial and postural changes, voice and speech abnormalities, depression, and muscle fatigue. Prior to the diagnosis of PD, most patients will have symptoms for months to years, including a general feeling of slowness or stiffness and/or difficulties with handwriting and other skills that require manual dexterity.

Most often patients will complain initially of a unilateral arm resting tremor. The tremor is a repetitive movement of low amplitude that occurs five or more times per minute. This alternating movement is described as "pill rolling" because it involves repetitive movements of the fingers and thumb. These tremors also can be seen in the legs or face and most often dissipate when intentional movement is performed. The resting tremor of PD can be differentiated from the kinetic tremor of other neurologic disorders by asking the patient to perform the finger-to-nose maneuver. The resting tremor of PD will become less prominent with the performance of this test and resume once the purposeful movement is ended and the limb is supported and at rest.

Cogwheel rigidity is elicited by causing passive movement of the limb through a full range of motion. As the limb is moved, the muscles will develop an increased tone, and a ratchet-like movement is noted. Bradykinesia, the general sense of slowness of voluntary movement, is often felt to be the most debilitating symptom of PD. In its most extreme form, PD causes akinesia, the inability to perform the movements necessary for daily living, such as turning over in bed, rising from a seated position, or walking. When PD impairs postural reflexes, patients may have an impaired ability to turn or change direction while walking or may lose their balance and fall.

Clinical Diagnosis

The clinical diagnosis of PD is easy to recognize, given the presence of the TRAP symptoms. Once noted, the patient should be questioned about any family history

of neurologic disorders, a prior history of encephalitis or other CNS infections, concurrent drug use, and any exposure to toxins or street drugs. The symptoms of PD also can be seen in postencephalitis patients and those with other infections such as neurosyphilis, subacute spongiform encephalopathy, and AIDS. Parkinsonism also can occur as a result of street drugs, toxins, neuroleptic drugs, hydrocephalus, head trauma, and with more rare and complex neurologic disorders such as progressive supranuclear palsy, striatonigral degeneration, and corticobasal ganglionic degeneration. Although thought to be a common cause of parkinsonism, cerebral infarction is now considered an unusual cause of these symptoms.

In drug-induced PD, akinesia is the most common sign, with resting tremor less commonly observed. Other characteristics of drug-induced parkinsonism include a history of drug ingestion known to interfere with central dopamine activity, short interval between symptom onset and maximal disability, bilateral presentation of motor dysfunction, and the presence of other drug-related motor abnormalities.

There is no definitive laboratory or neuroimaging study that is pathognomonic for PD. Although positron emission tomographic (PET) scans may be useful in demonstrating this CNS pathology, CT and MRI most often only show CNS atrophy.

Disease Management

Although currently available therapies do not change the underlying pathology of PD, their use can significantly reduce symptoms. These drugs include anticholinergics such as trihexyphenidyl and benztropine; drugs that increase central dopamine levels such as amantadine, levodopa, and carbidopa; and dopamine receptor drugs such as bromocriptine and pergolide. When PD symptoms cause severe motor dysfunction, the monoamine oxidase (MAO) inhibitor selegiline HCl and the COMT inhibitors entacapone and tolcapone may be effective through the prevention of dopamine metabolism.

Levodopa, which is converted into dopamine by decarboxylases that are present peripherally, can cause symptoms such as anorexia, nausea, and vomiting due to excess peripheral dopamine levels. When levodopa is combined with carbidopa, a peripheral decarboxylase inhibitor, smaller doses of levodopa are required for effectiveness, and side effects are reduced. Over time, the effectiveness of levodopa will diminish, requiring the additional use of dopamine receptor agonist therapy. PD patients who are fully mobile, in the "on" state, can suddenly convert to the "off" state and become akinetic, especially in the morning shortly after rising and prior to taking the initial daily dose. This "on-off" phenomenon is treated by the use of controlled-release preparations of the combined carbidopa-levodopa therapy.

When drug therapy effectiveness diminishes over time, or when significant motor or psychiatric complications occur, a "drug holiday" lasting about 1 week is often attempted. Despite the fact that withdrawal of dopaminergic therapy can worsen PD symptoms, functioning actually can improve once therapy is resumed, lasting weeks to months. Patients who are refractory to optimal medical management may benefit from posteroventral pallidotomy, a sterotactic neurosurgical procedure that maintains medical therapy benefit and reduces overall symptom severity. [21,22]

The treatment for drug-induced parkinsonism, which most often presents with akinesia, is termination of the causative agent, which presumably either acts to block central dopamine receptors (neuroleptics, metoclopramide) or reduces central dopamine levels (reserpine).

Emergency Diagnosis and Management

Although most PD patients present to the ED already diagnosed, some might present undiagnosed with motor or sensory symptoms that may not be related immediately to the diagnosis of PD. Patients may experience motor symptoms such as freezing episodes, dysphagia, or abnormalities of whole-body movement. Sensory complaints may include akathesias, paresthesias, muscles aches, or extremity pain. Although severe pain is usually related to the loss of medication efficacy, it can be the prominent symptom of undiagnosed PD.

Complications related to the motor, gait, and truncal disability of PD include deep venous thrombosis, pulmonary embolism, aspiration pneumonia, and compressive neuropathies. Trauma related to falls is common. Autonomic disturbances such as orthostatic hypotension, intestinal motility disorders, and bladder dysfunction can occur. Facial seborrhea also is common. Behavior abnormalities caused by frontal lobe dysfunction and dementia also are seen.

Dyspnea, respiratory distress, and pneumonia are more likely during the "off" periods, when drug efficacy is reduced. The most common cause of death in severe PD is respiratory failure.

Dopaminergic therapy toxicities can include psychiatric and sleep disturbances, cardiac dysrhythmias, orthostatic hypotension, dyskinesias, and dystonias. Patients may manifest lingual, facial, or bucchal dystonias and can demonstrate choreic movements similar to those seen with Huntington's chorea or tardive dyskinesia. These drug effects unfortunately are relatively common but can be alleviated with a drug holiday or a decrease in levodopa dosage. Depression and panic attacks are also common, independent of dopaminergic therapy.

Psychiatric complication can occur with dopaminergic therapy, including sleep disturbances, vivid nightmares, auditory and visual hallucinations, paranoia, and frank psychosis. The severity of psychiatric side effects, especially visual hallucinations, is related to the treatment dose and duration and can be improved by a drug holiday or a reduction in drug dosage. Psychotropes that are known to cause tardive dyskenesia, such as haloperidol, must be used cautiously in patients with PD due to an increased risk of this complication.

Adjustment of chronic PD therapies should be done in consultation with the patient's primary care physician, who can help determine which symptoms reflect dopaminergic excess and whether prior drug holidays have improved the patient's symptoms.

POLIO MYELITIS AND POSTPOLIO SYNDROME

Poliomyelitis is a neurotropic enterovirus that causes paralysis through motor neuron destruction and muscle denervation and atrophy. Despite the eradication of most polio cases through effective use of the polio vaccine in the United States, there are still cases that occur in children who are immunized and in populations that are not immunized. An important sequelae of acute poliomyelitis is postpolio syndrome, also termed *postpoliomyelitis progressive muscular atrophy* (PPMA). This disorder is characterized by the recurrence of motor symptoms following a latent period of several decades after the resolution of the motor symptoms caused by the initial infection.

Epidemiology

Poliomyelitis, an infection caused by a group of enteroviruses, leads to significant striated muscle paralysis in less than 5 percent of infected patients. [23] Prior to mass immunization, virtually all children were exposed to and developed antibodies to this enterovirus infection by age 4 years. A 1952 polio epidemic caused 14 new cases of paralytic polio per 100,000 persons, a rate similar to that seen in developing countries that are unable to provide mass immunization. Polio rates as high as 600 cases per 100,000 were seen as recently as the early 1980s in India. Mass immunization with the inactivated poliovirus vaccine (IPV) or attenuated oral poliovirus (OPV) has dramatically reduced the incidence of polio, which was 0.003 cases per 100,000 persons in the United States in 1981. Polio outbreaks still occur in populations that are not consistently immunized, such as was seen in the 1979 U.S. Amish epidemic, which was caused by the wild poliovirus type 1. Outbreaks also have been seen in association with inadequate immunization with modified poliovirus type 3, as was seen in the Finland outbreak in 1984–1985. With the use of OPV, some immunized children will develop polio, as will some young adults who are exposed to children who have been vaccinated with the OPV vaccine. Immunocompromised patients are at greater risk for contracting polio after exposure to children who were vaccinated with the OPV vaccine. In developing countries, recent IM injections, tonsillectomy, and strenuous exercise all have been associated with increased polio infection severity.

The prognosis for most enteroviral CNS infections is favorable with the exception of paralytic poliomyelitis and those enteroviral infections which occur during the first year of life.

The postpolio syndrome (PPMA) is expected to afflict up to 100,000 of the 250,000 U.S. adults with a prior history of polio. Since the majority of these polio cases occurred prior to mass immunization, these patients most likely will be older than age 50. There in no gender predisposition for PPMA. Although PPMA most often occurs after a stable, disease-free period of 20 to 30 years, there are risk factors that predict an earlier onset of postpolio syndrome. These include greater age at the time of initial polio infection, greater residual motor disability, residual bulbar or respiratory signs, and the occurrence of recent injuries that require limb

immobilization.

Pathophysiology

In developed countries the viral transmission is oral to oral, whereas in developing countries where the sanitation is poor the transmission is fecal to oral. Acutely, the polio enterovirus enters the body via the gastrointestinal tract and reproduces in the gastrointestinal lymphoid tissue, termed *gut-associated lymphoid tissue* (GALT). Oral secretion of the virus takes place for several days and stool excretion for several weeks.

At a critical concentration, the virus spreads to the large motor nuclei of the spinal cord, the brainstem, and the reticular formation. The vestibular and brainstem motor nuclei, hypothalamus, thalamus, cerebellum, and the precentral motor cerebral cortex also can be infected by the poliovirus. The infected neurons, because of Nissl granule dissolution, are phagocytosed by inflammatory cells, causing neuronal loss and gliosis. Most affected neurons have an altered morphology, and half are destroyed during the first week of acute paralysis. Neuron loss then causes a cycle of muscle denervation and reinnervation, resulting in muscle loss of function.

The pathology of the postpolio syndrome remains unclear. It is suggested that postpolio fatigue is similar to that seen in chronic fatigue syndrome, both of which may cause fatigue by causing a relative depletion of central dopamine. [24] This theory is supported by preliminary data that suggest a decrease in postpolio symptoms with the use of bromocriptine, the same drug used for relief of PD symptoms. [25]

Clinical Presentation

Polio infection remains asymptomatic in over 90 percent of cases. The majority a symptomatic polio infections involve only a minor viral illness that causes no paralysis, termed *abortive polio.* After an incubation period of a few days, symptoms may include fever, malaise, headache, sore throat, and gastrointestinal symptoms. Some of the patients who experience the minor viral illness, especially young children, may develop aseptic meningitis as the infection resolves. Only 1 to 2 percent of all poliovirus infections result in the major illness associated with neurologic involvement. Often there is resolution of the minor viral illness symptoms prior to development of neurologic symptoms, such that it is difficult to identify the preceding minor viral illness. Muscle pain, stiffness, and weakness during the early viral syndrome may suggest the later occurrence of paralysis. Because exercise can exacerbate the severity of the subsequent paralysis, patients with these symptoms suspected of having polio should be advised to avoid exercise.

When the major illness occurs, most commonly the spinal cord anterior horn cells are affected, causing asymmetric proximal limb weakness, especially in the legs. Spinal polio is characterized by flaccid and weak muscles, absent tendon reflexes, and fasciculations. Although pain, paresthesias, and transient sensory abnormalities are noted by polio patients, sensory deficits are usually not found on clinical examination. Maximal paralysis usually occurs within 5 days, and muscle wasting then occurs over several weeks. Autonomic dysfunction, including sweating disturbances, urine retention, delayed gastric emptying, and constipation, is commonly found. Nearly all spinal polio patients will demonstrate improved motor function, with paralysis resolution occurring within the first year after the acute infection.

Up to 20 percent of polio patients with paralysis will develop bulbar polio, which causes speech, swallowing, facial muscle, and rarely extraocular muscle dysfunction. Acute polio infection also can cause encephalitis and can disturb the reticular formation, resulting in cardiac dysrhythmias, blood pressure alterations, hypoxia, and hypercarbia. Patients who survive the acute episode of encephalitis normally will recover without residual affects.

Patients who present with postpolio syndrome complain of muscle fatigue, joint pain, worsening of skeletal deformities, or weakness in muscles that were spared during the initial viral infection. [26] These complaints can occur decades after maximal resolution of the neurologic symptoms caused by the initial polio infection. When muscle weakness is observed, atrophy, pain, and fasciculations may be noted both in previously unaffected muscle groups and in those previously involved. Patients with PPMA also may present with new bulbar, respiratory, or sleep difficulties. For example, laryngeal muscle weakness can cause progressive dyspnea, dysphagia, and/or hoarseness. Some patients complain of abnormal movements in sleep that disturb normal sleep, requiring therapy with benzodiazepines or dopaminergic drugs. [27] These symptoms occur independent of any concurrent neurologic, orthopedic, psychiatric, or systemic medical illness.

Clinical Diagnosis

Acute paralytic poliomyelitis should be considered whenever an at-risk patient presents with an acute febrile illness, aseptic meningitis, and asymmetric flaccid paralysis associated with the loss of deep tendon reflexes and normal sensation. As with other causes of aseptic meningitis, the CSF reveals pleocytosis during the first week after paralysis onset. The CSF white cell count can elevate into the hundreds, with a predominance of neutrophils early in the disease course. These cells allow noninflammatory causes of paralysis to be excluded from the differential diagnosis. Although the poliovirus can be cultured from the CSF early in the disease course, throat and rectal swabs will provide a greater yield. When a particular viral serotype is identified, serial serum antibody titers can be used to verify the cultures.

The most important cause of paralysis that must be excluded is Guillain-Barré syndrome, which, unlike the acute polio infection, causes more symmetric muscle weakness. Acute paralysis can result from peripheral neuropathies caused by infectious mononucleosis, Lyme disease, or porphyria. Paralysis also can result from inflammatory myopathies, electrolyte abnormalities, toxins, or other viruses, such as Coxsackie, mumps, echoviruses, and nonpolio enteroviruses. Paralysis also can result from acute spinal cord compression, vascular lesions, and myelitis, all of which should produce a sensory level and sphincter disturbances. In children, it is necessary to rule out spinal muscular atrophy, which can be undiagnosed until it is manifested by dramatic limb weakness caused by an acute febrile illness.

In order to diagnose postpolio syndrome, the patient should have a history of acute paralytic poliomyelitis with stable recovery of motor function associated with residual muscle atrophy, weakness, and areflexia with normal sensation in at least one limb. Additionally, there should be new muscle symptoms or weakness not attributable to an acute injury, neuropathy, radiculopathy, or systemic, neurologic, or psychiatric illness.

Disease Management

Treatment of the new muscle weakness seen with PPMA is primarily symptomatic, with analgesic and anti-inflammatory medications. Dyspnea, respiratory dysfunction, sleep disorders, and psychiatric disorders all must be addressed in patients with worsening PPMA. [28]

227 MENINGITIS, ENCEPHALITIS, AND BRAIN ABSCESS

Keith E. Loring
David C. Anderson
Alan J. Kozak

In cases of bacterial meningitis, the two most critical actions in the emergency department are to suspect it and begin empirical treatment promptly. It is often impossible to distinguish with certainty meningitides due to viruses, fungi, and other organisms or those due to neoplastic, toxic, and autoimmune processes from bacterial meningitis on the basis of clinical findings and even lumbar puncture (LP) results. Although obtaining appropriate studies, particularly cultures, is enormously helpful in eventually arriving at an appropriate diagnosis, the prompt initiation of therapy must take priority over all diagnostic maneuvers when bacterial meningitis is part of the differential diagnosis. If the clinical situation and the emergency physician's practice environment permit, the diagnostic groundwork can be laid for establishing alternative diagnoses, but never at the expense of initiating timely therapy against likely bacterial pathogens.

Epidemiology

Approximately 25,000 cases of bacterial meningitis occur yearly in the United States. Attack rates are age specific, ranging from almost 400 per 100,000 in neonates to 1 to 2 per 100,000 in adults. Two-thirds of cases are in children. The mortality rate is about 5 percent in children beyond infancy, 25 percent in neonates, and 25 percent in adults.[1,2] Long-term complications, such as cognitive deficits, epilepsy, hydrocephalus, and hearing loss, affect about a quarter of survivors. Prior to 1985, three species accounted for the majority of bacterial meningitis: *Haemophilus influenzae* (45 percent), *Streptococcus pneumoniae* (18 percent), and *Neisseria meningitidis* (14 percent). However, the specific cause of bacterial meningitis has changed in the era of vaccination against *H. influenzae* type b. From 1985 to 1991, the incidence of *H. influenzae* meningitis dropped 82 percent in children under 5 years old. Hence, *S. pneumoniae* and *N. meningitidis* have become the predominant causes of meningitis in children 1 month of age or older.[3] Antibiotic resistance of *S. pneumoniae* to penicillins and ceftriaxone is becoming more prevalent in the United States. While such resistance has been encountered to date mostly in children, the clinician should consider modifying antibiotic selection for both children and adults with suspected pneumococcal meningitis (Table 227-1). The following discussion focuses on bacterial meningitis in adults.

TABLE 227-1   Guidelines for Empiric Treatment of Bacterial Meningitis* with No Organisms on Gram Stain

Pathophysiology

Bacterial meningitis begins with the entry of organisms into the well-defended subarachnoid space. The ability to infect the subarachnoid space is not shared equally by all bacteria. The dominance of three organisms— *S. pneumoniae, H. influenzae* type b, and *N. meningitidis*—which cause over two-thirds of bacterial meningitis, is no accident. These encapsulated organisms share the ability to invade the host through the upper airway, survive dissemination through the bloodstream, and then gain access to the subarachnoid space. The subcapsular constituents of these organisms are a strong trigger of inflammatory cascades in the host. Inflammation produces the clinical picture of fever, meningismus, and eventually altered mental status, which are the hallmarks of the disease.[4]

Stimulation of pain-sensitive structures in meninges and posterior spinal roots leads to headache and meningeal signs. The brain and meninges, encased in the fixed-volume skull, become edematous. Cerebrospinal fluid (CSF) drainage is reduced by interference with its flow in the subarachnoid pathways as well as its absorption by the arachnoid granulations. Hence, the quantity of CSF increases, causing communicating or noncommunicating hydrocephalus. Intracranial blood vessels initially expand, increasing the volume occupied by that compartment. The brain itself swells by several mechanisms. Disruption of the blood-brain barrier allows entry of protein and ultimately water (vasogenic edema), while hydrocephalus forces CSF into the periventricular parenchyma (interstitial edema). Eventually, cell membrane homeostasis may be compromised, leading to increased intracellular water (cytotoxic edema).

The sum of these expanded volumes overwhelms the compensatory displacement of CSF into the more compliant spinal compartment, and intracranial pressure rises as a result. Since brain perfusion depends on arterial pressure's exceeding tissue pressure (in this case intracranial pressure), ischemia may develop. Diminished perfusion is all the more likely, since the vascular supply is burdened with an inflammatory infiltrate whose functional and structural consequences include faulty autoregulation, inflammatory narrowing, and a prothrombotic milieu. There are some variations on the pathophysiologic themes described above. For example, organisms sometimes gain entry to the CSF, not by hematogenous seeding, but through direct contiguity. Such direct spread may be from infected parameningeal structures (e.g., brain abscess, otitis media, and sinusitis), traumatic or congenital communications with the exterior, or neurosurgery. The bacteriologic characteristics of these infections may vary. Immunologic deficiency states are increasingly common and predispose to yet other organisms. The clinical and pathophysiologic effects of organisms other than *S. pneumoniae, H. influenzae* type b, and *N. meningitidis* depend on their capacity to stimulate the host's immune processes and the host's response.[5]

Clinical Features

SIGNS AND SYMPTOMS   Definitive diagnosis is based on demonstrating bacterial organisms in the subarachnoid space along with a corresponding inflammatory response. The possibility of meningitis must be considered if the diagnosis is to be made. In classic and fulminant cases, about 25 percent of adult cases, there is little diagnostic challenge. The patient presents with rapidly developing fever, headache, stiff neck, photophobia, and altered mental status. Seizures occur in 25 percent of adults and at least that many children. In some patients, typically the very young and the elderly, the clinical features are nonspecific.

Certain historic data should increase the suspicion of meningitis and suggest specific pathogens. Several areas deserve special attention: living conditions, trauma, immunocompetence, immunization history, and antibiotic use. Army barracks and college dormitories are typical environments in which clusters of cases due to *N. meningitidis* occur. Day-care centers may become a source for multiple cases due to *H. influenzae* type b. A history of head trauma (*S. pneumoniae*) or neurosurgery (staphylococcal species or gram-negative rods) may be significant. Conditions that affect immunocompetence (e.g., history of surgical or functional splenectomy, glucocorticoid therapy, and HIV) should be sought. On the other hand, a history of immunization to *H. influenzae* type b in the past will make meningitis due to this organism unlikely. It is important to inquire about recent exposure to antibiotics, which may influence the clinical course, and CSF findings.

Examination must include assessment for meningeal irritation with resistance to passive neck flexion, Brudzinski sign (flexion of hips and knees in response to passive neck flexion), and Kernig sign (contraction of hamstrings in response to knee extension while hip is flexed). Examination of the skin is also crucial for seeking the purpuric rash characteristic of meningococcemia and, less commonly, other pathogens. Cutaneous stigmata suggesting microembolization (e.g., petechiae, splinter hemorrhages, and pustular lesions) should be aspirated when possible for Gram stain and culture. Paranasal sinuses should be percussed, and ears examined for evidence of primary infection. Fundi must be assessed for papilledema or absence of venous pulsation, indicating increased intracranial pressure. Neurologic examination should seek evidence of focal neurologic dysfunction, such as disordered eye movements, homonymous visual field deficits, facial asymmetry, and hemiparesis.[4,5]

LUMBAR PUNCTURE   Blood cultures (two specimens drawn 15 min apart) yield the responsible organism in about 50 percent of cases of bacterial meningitis, but CSF analysis is paramount. Appropriate sequencing of LP, cranial imaging studies, and initiation of empirical antibiotics are further discussed below. However, LP should be carried out as quickly as possible.

LP should be performed if intracranial mass lesions and coagulopathy are unlikely on historical or clinical grounds. Specifically, patients with coma, papilledema, or focal neurologic findings require cranial imaging before LP. Prior to imaging, blood cultures should be obtained and empiric antibiotic therapy should be instituted. LP can then proceed if no intracranial mass lesion or mass effect exists. Antibiotic therapy given up to 2 h prior to lumbar puncture will not decrease the diagnostic sensitivity if CSF bacterial antigens assays are obtained along with CSF culture. [6]

Local anesthetic should be used to improve patient comfort, relaxation, and cooperation. Anxiolitics such as benzodiazepines, which are helpful adjuncts in the performance of painful procedures, can cloud the patient's sensorium and confuse subsequent clinical assessment. The L3–L4 interspace should be punctured (L4–L5 in newborn infants) while the patient is curled as tightly as possible in a fetal position. In adults, a line drawn between the iliac crests crosses the spine at the L3–L4 interspace. Alternatively, the patient may be seated on the edge of a bed or cart leaning over a tray stand. The latter technique is particularly useful when landmarks are uncertain, as they may be in an obese patient. The site should be prepared with povidone-iodine and allowed to dry thoroughly to avoid introduction by puncture and the production of chemical arachnoiditis. A $2\frac{1}{2}$-in. 22-gauge needle should be used in children and a $3\frac{1}{2}$-in. 20-gauge needle in adults. Although useful, the opening pressure is not critical for interpretation of the procedure. To obtain meaningful results, the pressure must be measured with the patient lying extended on his or her side. Pressures measured with the patient still curled in extreme flexion or while sitting will be artificially elevated. Normal pressure is less than 170 mm-H_2O. Careful repositioning (straightening the curled patient or helping the seated patient to a lying position on his or her side) is safely performed with the needle in situ.

Four tubes, each containing at least 1 mL of CSF, are typically obtained. More volume —up to 5 mL—may be preferable in patients who are immunocompromised. Red and white blood cell counts with differential counts are requested for tubes 1 and 4. The two-tube assessment helps detect a traumatic tap because the rate of bleeding changes rapidly, causing a difference in red blood cell count between the two tubes. Tube 4 may also be used for culture and Gram stain. Tube 2 is sent for determination of protein and glucose levels. Tube 3 should be saved for other studies, discussed below, if necessary. Closing pressure is not necessary. [7]

Diagnosis

The differential diagnoses may be categorized into parenchymal or meningeal disorders. When fever and focal neurologic symptoms and signs predominate, parenchymal central nervous system infections are concerns (e.g., brain abscess, viral encephalitis, cerebral toxoplasmosis, and other parenchymal processes). When meningeal signs predominate, other infectious meningitides, meningeal neoplasm, and subarachnoid hemorrhage are possible.

For evaluation of parenchymal brain infections, LP is unhelpful and potentially dangerous, since it can lead to transtentorial or tonsillar herniation. A cranial computed tomography (CT) scan should be done first if the patient exhibits papilledema or focal neurologic signs. A cranial CT scan is also the preferred mode in diagnosing subarachnoid hemorrhage.

For meningeal disorders other than subarachnoid hemorrhage, CSF examination is most helpful. Typical CSF findings for bacterial, viral, neoplastic, and fungal meningitides are displayed in Table 227-2, but there is considerable overlap in findings. Some bacteria (e.g., *Mycoplasma, Listeria,* spirochetes, syphilis, *Leptospira,* and *Borrelia*) produce CSF alterations that in Table 227-2. An aseptic profile, suggesting viral infection, is typical of partially treated bacterial infections (one-third or more of pediatric cases have received antimicrobial treatment before presenting with meningitis). The same is true of untreated bacterial infections adjacent to but not communicating with the subarachnoid space, such as abscesses of the brain and subdural or epidural spaces. The percentage of polymorphonuclear cells may be higher in early viral meningitis, and glucose levels may be reduced in some viral cases.

Parameter (Normal)	Bacterial	Viral	Neoplastic	Fungal
OP (<170 mmCSF)	>300 mm	200 mm	200 mm	300 mm
WBC (<5 mononuclear)	>1000/μL	<1000/μL	<500/μL	<500/μL
% PMN (0)	>80%	1–50%	1–50%	1–50%
Glucose (>40 mg/dL)	<40 mg/dL	>40 mg/dL	<40 mg/dL	<40 mg/dL
Protein (<50 mg/dL)	>200 mg/dL	<200 mg/dL	>200 mg/dL	>200 mg/dL
Gram stain (–)	+	–	–	–
Cytology (–)	–	–	+	+

Abbreviations: OP, opening pressure; PMNs, polymorphonuclear cells; and WBC, white blood cells.

TABLE 227-2   Typical Spinal Fluid Results for Meningeal Processes

Additional helpful tests may include viral cultures in suspected viral meningitis, tests for *Borrelia* antibodies in patients with possible Lyme disease, india ink and latex agglutination assay for fungal antigen in cryptococcal meningitis (serum cryptococcal antigen, if available, obviates this CSF analysis), acid-fast stain and culture for mycobacteria in tuberculous meningitis, and latex agglutination or counterimmune electrophoresis for bacterial antigens in potentially partially treated bacterial cases. Assays are most widely available for *S. pneumoniae,* other group *B streptococci, H. influenzae* type b, and *N. meningitidis.* Rarely, CSF may be normal or nearly so in very early bacterial meningitis, especially during meningococcemia. Empiric antibiotic treatment, admission, and repeated LP are appropriate if clinical suspicion is great despite negative initial CSF results. [8]

Treatment

Ideal management has several goals. The first priority is the rapid administration of a bactericidal antibiotic that gains rapid entry to the subarachnoid space. A secondary priority in some cases is use of an anti-inflammatory agent to suppress the normal inflammatory processes, which are amplified by antibiotic-induced bacteriolysis. A tertiary concern is to counter the adverse effects of increased intracranial pressure and vasculopathy, which may lead to brain ischemia. Finally, when several options that accomplish these goals are available, those with the lowest expense and rates of treatment morbidity should be employed.

Agents to which local bacterial resistance has developed should be avoided. Currently, for example, about 30 percent of *H. influenzae* type b isolates are resistant to ampicillin. Bacteriostatic agents should not be used alone or in combination with a bactericidal agent, since they are antagonistic. Agents of current choice for given bacterial meningitides are indicated in Table 227-1. Empiric therapy in cases warranting antibiotics before LP or when results of Gram stain are negative (about 30 percent of untreated cases, 50 percent of those receiving antibiotics before LP) is based on the patient's age and should also take risk factors into consideration. [9]

Empiric treatment for bacterial meningitis is based on the likelihood of certain pathogens (Table 227-1) and results of CSF Gram stain. For patients aged 18 to 50 with no organisms evident on Gram stain, ceftriaxone 2 g intravenously every 12 h is the current recommendation. For patients with Gram stain suggestive of *S. pneumoniae* (gram-positive cocci in clusters), a broad-spectrum cephalosporin and vancomycin should be given to ensure coverage of resistant organisms. For gram-negative cocci, presumed *N. meningitidis,* penicillin G is still effective. For gram-ppositive rods, *Listeria monocytogenes* is the presumed agent, and the recommended regimen is ampicillin and gentamicin. For gram-negative rods, the recommendation is ceftazidime and an aminoglycoside.

A variety of inflammation suppressants have been shown to improve outcome in experimental bacterial meningitis. Only glucocorticoids, and specifically dexamethasone, have been tested in clinical trials. Evidence is persuasive that dexamethasone given before or at the time of the first antibiotic dose most effectively reduces morbidity rates of bacterial meningitis due to *H. influenzae* type b. Many authorities now recommend intravenous dexamethasone, 0.15 mg/kg, as adjunctive therapy in children with this infection. A lower but clear efficacy has been shown in children with *S. pneumoniae* meningitis, and dexamethasone is thus recommended in these cases as well. Some would extrapolate the favorable results noted in children to adults, especially those with a heavy burden of organisms (reflected by a positive CSF Gram stain results) or evidence of increased intracranial pressure. Dexamethasone at the same dosage would seem to be the glucocorticoid of choice for these patients as well, but no adequate studies of efficacy and safety exist to date, and therefore it is not recommended. [10,11 and 12]

Also important in management is surveillance for and correction of complications, including seizures, hyponatremia, hydrocephalus, and cerebrovascular accidents. General treatment measures include maintenance of normal blood volume. Hypotonic fluids should be avoided. The serum sodium level should be monitored serially to detect a syndrome of inappropriate antidiuretic hormone or cerebral salt wasting. Hyperpyrexia should be treated. Coagulopathies should be corrected using specific replacement therapies. Phenytoin loading is indicated in patients who develop seizures. For marked cerebral edema, as evidenced by clinical or CT findings, the following are indicated: head elevation, hyperventilation to a P_{CO_2} of 25 to 30 mmHg, and use of mannitol. Measurement of intracranial and systemic arterial pressure is useful in severe cases to enable monitoring of cerebral perfusion pressure.

Chemoprophylaxis is indicated for high-risk contacts of patients with documented *N. meningitidis* or *H. influenzae* type b, including household contacts; school or day-care contacts in the previous 7 days; those who have had direct exposure to the patient's secretions through kissing, shared utensils, or shared toothbrushes; and those who have performed mouth-to-mouth resuscitation or have intubated the patient while unprotected with a face mask. First-line treatment is with rifampin 10 mg/kg (to a maximum of 600 mg per dose) every 12 h for four doses. Alternatives are ceftriaxone, ciprofloxacin, and sulfisoxasole. High-risk contacts should be instructed to return at once if they develop symptoms.[13]

VIRAL MENINGITIS

A number of viruses can cause aseptic meningitis, including nonpolio enteroviruses, mumps, cytomegalovirus, herpes simplex virus, lymphocytic choriomeningitis, adenovirus, and HIV. Specific diagnosis depends on isolation of the virus or positive results on immunoassay of the CSF. Nonpolio enteroviruses (echovirus, coxsackievirus, and enterovirus) account for about 85 percent of all cases of viral meningitis in the United States.

While the diagnosis of viral meningitis is often straightforward (Table 227-2), there can be overlap of CSF findings with early bacterial meningitis and partially treated bacterial meningitis, making specific diagnosis for some cases difficult in the emergency department. Neutrophils may predominate in the CSF for the first 24 h in viral meningitis. Standard references report up to a 10 percent incidence of lymphocytic predominance in CSF with bacterial meningitis, more common with *L. monocytogenes* and in neonatal meningitis. Depending on clinical diagnostic certainty, a range of approaches can be employed in the management of presumed viral meningitis, from admission with empiric antibiotic therapy until culture results return, to discharge from the emergency department with follow-up in 24 h.

VIRAL ENCEPHALITIS

Viral encephalitis is a viral infection of brain parenchyma that produces an inflammatory response. It is distinct from, although often coexists with, viral meningitis, in which the infectious agent and inflammatory response are in the subarachnoid space. Clinically the distinction is made by the presence of neurologic abnormality in encephalitis, whereas only meningeal symptoms and signs (e.g., photophobia, headache, and stiff neck) occur in meningitis. The true incidence of viral encephalitis is difficult to estimate because of the variability of clinical expression, ranging from profound neurologic involvement to clinically silent cases, as well as variability in reporting policies. Several thousand cases are reported yearly in the United States.

Epidemiology

The incidence of the various types of viral encephalitis varies from year to year, depending on whether sporadic or epidemic outbreaks occur. In relative terms, the incidence is about one-tenth that of bacterial meningitis. Arboviruses account for 10 percent of cases during times of sporadic, isolated cases but can account for up to 50 percent of cases during epidemic outbreaks. The four most common arboviral encephalitides in the United States are the California encephalitis serogroup, St. Louis equine encephalitis, western equine encephalitis, and eastern equine encephalitis. California encephalitis is reported most often, with 76 cases reported in 1994. It is seen in the midwestern and eastern United States exclusively, despite its name. Ninety percent of reported cases occur in children. St. Louis encephalitis is seen throughout the United States in periodic outbreaks, with the yearly incidence ranging from 20 reported cases to 2000. It is seen primarily in young children and the elderly and has a 20 percent mortality rate in the latter. Western equine encephalitis prevails in the western United States and Canada. Disease is most severe in the very young, causing seizures in 90 percent of affected infants and permanent neurologic deficits in 50 percent. Eastern equine encephalitis is prevalent in the Atlantic and Gulf coast regions and accounts for the most severe cases of arboviral encephalitis. It tends to occur in sporadic epidemics and has a mortality rate of nearly 70 percent.

Herpes simplex virus type 1 (HSV-1) and herpes simplex virus type 2 (HSV-2) encephalitis occurs in 1 in 250,000 to 1 in 500,000 cases annually in the United States. HSV-1 is typically seen in older children and adults as reactivation disease, while HSV-2 is seen in neonates as a result of perinatal transmission and generally leads to devastating neurologic outcomes.

Pathophysiology

In North America, viruses that cause encephalitis include the arboviruses, HSV-1, herpes zoster, Epstein-Barr virus (EBV), and rabies. Entry portals are highly virus specific for the encephalitis-producing viruses. The arboviruses (*arbo* meaning "arthropod borne") are transmitted by mosquitoes and ticks, and rabies is transferred by the bite of an infected animal. Impaired immune status may play a role in herpes zoster and cytomegalovirus (CMV) encephalitis. Common to all is preliminary viral invasion of the host at a site where replication takes place that is outside the central nervous system. Most viruses then reach the nervous system hematogenously during viremia. However, at least three important viruses—rabies, herpes simplex virus (HSV), and herpes zoster—reach the spinal cord and eventually the brain by traveling backward within axons from a distal site where they have gained access to nerve endings.

Once in the brain, the virus enters neural cells. Neurologic dysfunction and damage are caused by the disruption of neural cell functions by the virus and by the effects of the host's inflammatory responses. Gray matter is predominantly affected, resulting in cognitive and psychiatric signs, lethargy, and seizures. Multifocal white matter damage occurs predominantly in postinfectious encephalomyelitis and rarely during acute encephalitis. Sensorimotor deficits referable to one

hemisphere or to the spinal cord are more typical of this immune-mediated pathologic process, which may follow viral encephalitis and meningitis of any type.

Clinical Features

Encephalitis should be considered in patients presenting with the following clinical features singly or in combination: new psychiatric symptoms, cognitive deficits (e.g., aphasia, amnestic syndrome, or acute confusional state), seizures, and movement disorders. Features of meningeal involvement, such as headache and photophobia, are usually, but not invariably, present. The same is true for fever.

Patients with herpes zoster (shingles or chickenpox), EBV, or CMV encephalitis (lymphadenopathy and hepatosplenomegaly) may have a history and signs typical of clinical syndromes caused outside the central nervous system by these viruses. Other circumstances of the case may suggest both the broad diagnosis of encephalitis and a specific viral cause (Table 227-3). For example, a late-summer encephalopathy suggests the possibility of an arbovirus encephalitis, and an animal bite for which no antirabies treatment was obtained has obvious relevance.

Virus	Clinical Clues	Diagnosis	Prognosis
HSV-1	"Psychiatric" presentation	MRI, EEG, PCR of CSF, biopsy	30% die, 30% have deficits
Herpes zoster	Shingles, chickenpox, immunosuppressed state	Skin vesicle or CSF culture, serology	Mortality 14–20%
EBV	Mononucleosis	Serology	5–10% die
Rabies	Animal bite	Saliva or CSF culture, biopsy, serology	90% die
Arboviruses	Seasonal		
California	Midwest, children	CSF or blood culture, serology	Good
St. Louis	Midwest, older urban dwellers	As above	5–30% die
Western equine	West, outside workers	As above	5–30% die
Eastern equine	Southeast, outside workers	As above	50% die

TABLE 227-3   Viral Pathogens Causing Encephalitis in North America

Signs of meningeal irritation and increased intracranial pressure should be sought. Neurologic findings reflect the areas of involvement. A careful assessment of cognition is crucial. Sensorimotor deficits are not typical. Encephalitides may show special regional tropism. Herpes simplex virus (HSV) involves limbic structures of the temporal and frontal lobes, with prominent psychiatric features, memory disturbance, and aphasia. Some arboviruses predominantly affect the basal ganglia, causing choreoathetosis and parkinsonism. Involvement of the brainstem nuclei that control swallowing leads to the hydrophobic choking response characteristic of rabies encephalitis. [14,15]

Diagnosis

Diagnosis rests on imaging studies using magnetic resonance imaging (MRI) or CT if MRI is not reasonably available, electroencephalography (EEG), and LP. Imaging not only excludes other potential lesions, such as brain abscess, but also may display findings that are highly suggestive of HSV encephalitis, a treatable infection, with involvement of medial temporal and inferior frontal gray matter. MRI is more sensitive than CT in this regard. EEG is quite useful in establishing the broad diagnosis as well. Almost by definition, the EEG findings are abnormal in encephalitis, in contrast to isolated viral meningitis or to a primary psychiatric disorder. Furthermore, HSV produces an almost pathognomonic picture in the setting of acute febrile encephalopathy, with the EEG showing periodic, usually asymmetric sharp waves. These findings can be present before any abnormality is visible on MRI. Realistically, LP is the most useful diagnostic procedure in the emergency department once imaging studies, if clinically indicated and available, rule out the risk of uncal herniation. Findings of aseptic meningitis are typical on CSF examination. It is at least theoretically possible to have encephalitis without meningitis, but it is quite rare.

The differential diagnosis depends on the nature of the presentation. When fever and meningeal symptoms predominate, bacterial meningitis is suspected. In less fulminant meningeal cases, Lyme disease; tuberculous, fungal, and neoplastic meningitis; and subacute subarachnoid hemorrhage are part of the differential diagnosis. When parenchymal features are prominent, brain abscess, bacterial endocarditis, postinfectious encephalomyelitis, and toxic or metabolic encephalopathies should be considered.

The clear diagnostic imperative in the emergency department is to exclude the most immediately life-threatening alternative processes requiring immediate treatment. The two most important are bacterial meningitis and acute subarachnoid hemorrhage. Once that is satisfactorily accomplished, the mandate is less definite. Of the viruses causing encephalitis, only HSV has been shown by clinical trial to be responsive to antiviral therapy. HSV can be isolated in as many as 50 percent of neonatal infections but is rarely found in older children and adults. The polymerase chain reaction (PCR) analysis of CSF has 95 percent sensitivity and 100 percent specificity in the diagnosis of HSV infection with respect to brain biopsy. Regardless of diagnostic approach, because current antiviral treatment is relatively risk and side effect free, empiric therapy is recommended in cases of clinical encephalitis. [16] Of the other viral encephalitides, CSF culture results are positive for 50 to 70 percent of patients with enteroviral meningitis but for a much smaller percentage of those with isolated enteroviral encephalitis. The use of PCR techniques for the enteroviruses is also showing promise for central nervous system diagnosis in the future.

Treatment

The agent of choice for HSV is acyclovir 10 mg/kg every 8 h for 14 to 21 days. Based on anecdotal data, patients with herpes zoster and CMV encephalitis may also benefit from antiviral therapy: acyclovir for herpes zoster and ganciclovir for CMV encephalitis.

Prognosis depends on the virus and host. Rabies encephalitis, while rare, continues to be neurologically devastating and usually fatal. Eastern equine encephalitis and HSV also have high mortality rates and frequently produce residual deficits. For the others, adverse outcome is seen mainly in elderly patients or in those with compromising preexisting systemic or neurologic conditions.

Disposition

Patients with encephalitis should in general be admitted. The outcome in cases of HSV encephalitis is related to the neurologic condition at the time that antiviral therapy is initiated. Patients who are already in coma do very poorly, making timely diagnosis and therapy a priority for this form of encephalitis. Empiric initiation of acyclovir 10 mg/kg in the emergency department in encephalitis suspects should be highly considered. [14,15]

BRAIN ABSCESS

A brain abscess is a focal pyogenic infection. When fully developed, it is composed of a central pus-filled cavity, ringed by a layer of granulation tissue and an outer fibrous capsule. Surrounding this is edematous brain tissue infiltrated with inflammatory cells. It is a pathologic response typical of a relatively competent immune system against a bacterial invader. Focal brain infections due to other organisms, such as granulomas due to tuberculosis, necrotic lesions of toxoplasmosis in immunocompromised patients, or cystic lesions of cysticercosis, are not abscesses in the pathologic sense. These nonpurulent focal lesions are not considered here.

Epidemiology

Brain abscess is rather uncommon, accounting for 1 in 10,000 hospitalizations. This incidence is much less than that of bacterial meningitis and is only 2 percent that of brain tumors. The rate has gradually fallen over the past century, probably reflecting the effect of antibiotics on predisposing conditions, such as otitis media. Mortality rates for diagnosed cases have also fallen, from about 50 percent in the early twentieth century to a current level of 10 to 20 percent. Long-term sequelae are seen in about a third of survivors.

Age distribution corresponds to the various predisposing conditions. Most patients with brain abscess related to a paranasal sinus focus are in the 10- to 30-year-old range. When the source is otic, a bimodal incidence occurs in ages less than 20 and greater than 40 years. Twenty-five percent of cases occur in children under 15 years old, with the majority occuring in the 4- to 7-year-old range. Pockets of higher incidence occur along the lines of age, origin of initial infection, and, in some cases, gender.

Pathophysiology

Organisms reach the brain by one of three known routes: hematogenously (one-third of cases); from contiguous infections of middle ear, sinus, or teeth (one-third of cases); or by direct implantation by neurosurgery or penetrating trauma (about 10 percent of cases). The route is unknown in about 20 percent. Circumstances that reduce oxygenation of brain parenchyma are important predisposing factors for bacterial invasion. For example, spread from a contiguous infection usually involves intervening cerebral thrombophlebitis, with congestive ischemic hypoxemia of tissue destined to become infected. Hematogenous seeding is facilitated by systemic hypoxemia, as in congenital heart diseases with right-to-left shunt and chronic pulmonary suppuration. This is demonstrated by the prominent role of anaerobic bacteria in brain abscesses. The source of brain abscess should be identified for the dual purpose of eliminating the source itself and gaining insight into the probable bacteriologic characteristics of the abscess. For example, gram-negative rods, especially *Bacteroides*, are the usual pathogens in otogenic brain abscesses, which are typically single and located in the adjacent temporal lobe or cerebellum. Anaerobic and microaerophilic streptococci are the most common pathogens in sinogenic and odontogenic abscesses and are more typically located in the frontal lobes. Abscesses formed from hematogenous spread are often multiple and polymicrobial, with anaerobic and microaerophilic streptococci commonly represented. Staphylococci are typical pathogens in abscesses due to direct implantation. Gram-negative rods are also suspected in cases related to a neurosurgical procedure.

Clinical Features

Presenting features of brain abscess are notoriously nonspecific. Patients rarely appear acutely ill, and the classic triad of headache, fever, and focal neurologic deficit is present in less than one-third of all patients. As a result, the diagnosis is often delayed. Symptoms reflect the infectious and neurologic (focal and mass effect–producing) aspects of the disease. The most common symptom is headache, which is a complaint in almost all cases. Fever is present in about half of all cases, and neck stiffness in fewer than half. Toxic appearance is rare until late in the disease process. Focal neurologic symptoms, such as hemiparesis or seizures, are present in about a third. Other symptoms of increased intracranial pressure, such as vomiting, confusion, or obtundation, are present in about half of cases. The presentation may be dominated by the origin of the infection (e.g., ear or sinus pain).

Meningeal signs are present in less than half of cases on examination. Papilledema is noted on funduscopy in about a third of patients. Focal neurologic signs reflecting the site of the lesion (e.g., frontal lobes, hemiparesis; temporal lobes, homonymous superior quadrant visual field deficits or aphasia; or cerebellum, limb incoordination or nystagmus) are present in about 60 percent of patients on careful examination. Discovery of potential sites of origin may raise suspicion of brain abscess when the presentation is otherwise nonspecific (e.g., otitis media, sinus tenderness, evidence of pulmonary suppuration, or right-to-left shunting) in a patient with subacute headache and lethargy.

Diagnosis

Brain abscess is diagnosed by imaging studies. CT with contrast infusion classically demonstrates one or several thin, smoothly contoured rings of enhancement surrounding a low-density center and surrounded by white matter edema. Early in the course, a ring may be thicker and less well defined, with the only CT finding being an area of focal hypodensity. Suspected brain abscess is one of the rare instances in the emergency department when a contrast-enhanced study is preferred over a noncontrast study. MRI usually demonstrates a ring, even without gadolinium enhancement. Both types of studies are highly sensitive, and one imaging modality has no real advantage over the other except that CT is usually more readily available in the emergency department. Other studies, such as blood analysis, EEG, and CSF examination, are too nonspecific for definitive diagnosis, and LP is contraindicated when suspicion is high and when focal neurologic signs are present. Cultures of blood or other sites of infection may guide future management and should always be obtained.

Differential diagnosis of the clinical presentation is broad because of its nonspecific and variable nature. A sudden onset with focal features may suggest cerebrovascular disease. Prominent fever, stiff neck, and confusion may suggest meningitis. A protracted course with features of increased intracranial pressure may suggest neoplasm. Brain neoplasm, subacute brain hemorrhage, other focal lesions, and other focal brain infections, such as toxoplasmosis, may mimic the imaging findings of brain abscess. Biopsy or aspiration for confirmation of diagnosis as well as for bacteriologic studies is necessary in most cases.

Treatment

The cornerstone of early ED treatment of brain abscess is antibiosis. The susceptibility of the likely pathogen and the penetration of the agent into the lesion should be considered when choosing an antibiotic. The bacteriologic characteristics of the lesion may be inferred if the origin is obvious. Initial empiric antibiotic choice should take advantage of such information. Initial treatment in a suspected otogenic case is with a third-generation cephalosporin, such as cefotaxime, or trimethoprim-sulfamethoxazole with metronidazole or chloramphenicol. For presumed abscess of sinogenic or odontogenic origin, high-dose penicillin is a good choice. Penicillin is also appropriate for an abscess of hematogenous origin. Chloramphenicol or metronidazole, which by virtue of their lipophilic nature penetrate abscesses very well, is usually added to these penicillin regimes. When communication with the exterior is suspected, as in penetrating trauma or after neurosurgery, nafcillin or vancomycin are indicated. Addition of ceftazidime may be required if gram-negative aerobes are suspected. For patients in whom no mechanism is apparent or suspected, the combination of a third-generation cephalosporin, such as cefotaxime, and metronidazole provides good coverage.

Most cases require neurosurgery for diagnosis and bacteriologic analysis, if not for definitive treatment. Total excision has become necessary less often with the availability of imaging techniques for following the course of abscesses treated medically after surgical aspiration. In cases in which intracranial pressure is high, excision is still carried out. The role of glucocorticoids is controversial. Steroids may produce temporary improvement of increased intracranial pressure. [17,18]

CEREBROSPINAL FLUID SHUNTS

The shunting of cerebrospinal fluid (CSF) was first described in 1895, but it was not until the 1950s that shunting ventricular CSF became a routine procedure. [1,2] Hydrocephalus has an incidence of 3 cases per 1000 live births. Mechanical shunting is the primary treatment as there is usually no alternative corrective surgical or medical therapy for this disorder. Each year there are approximately 18,000 CSF shunts inserted, making it the most common pediatric neurosurgical procedure performed in the United States.[1] The CSF shunt is also the neurosurgical procedure with the highest incidence of postoperative complications. [1,2]

Many types of CSF shunt systems exist. Most systems consist of three components beginning with a silastic tube passed into the ventricle via a burr hole. This tubing is tunneled subcutaneously to a valve chamber. The valve chamber, the second component, establishes a pressure gradient that ensures drainage of fluid away from the ventricle. The valve chamber, or in some cases a separate reservoir, allows access to the shunt system for patency testing, pressure measurement, CSF sampling, medication injection (e.g., chemotherapy, antibiotics), or contrast administration. Distal tubing, which is the third component, connects the valve chamber to a drainage point. The most common drainage site is the peritoneal cavity. Other drainage sites include the right atrium, gallbladder, pleural cavity, and ureter.

Shunt Malfunction

Shunt malfunctions are the most common complications encountered with CSF shunts, occurring in up to 67 percent of patients during their lifetime. Obstruction is the most common type of shunt malfunction and most commonly occurs in the proximal tubing followed by the distal tubing, and, finally, the valve chamber. Proximal obstructions usually occur within the first two years after shunt insertion. Causes include tissue debris, chorioid plexus, clot, infection, catheter-tip migration, or following a localized immune response to the tubing. Kinking or disconnection of the tube, pseudocyst formation, or infection can cause distal obstruction. Distal obstruction is the most frequently encountered obstruction in shunts in place for longer than two years. [1,2]

SLIT VENTRICLE SYNDROME   Overdrainage and the slit-ventricle syndrome are seen in approximately 5 percent of shunted patients. Due to overdrainage, the tissues actually occlude the orifices of the proximal shunt apparatus. As ICP increases, the same occluding tissue is disengaged, allowing drainage to resume. This phenomenon is cyclical and is responsible for the episode or waxing and waning aspect of the presenting complaint. Patients present with episodes of elevated intracranial pressure caused by a transient obstruction of the ventricular catheter from a collapsed ventricle. Decreased cerebral compliance may prevent the ventricles from fully expanding as intracranial pressure and volume increase, further contributing to ventricular collapse. Newer shunt systems with antisiphon devices and improved shunt valves have a lower rate of this complication.[1,2]

CLINICAL PRESENTATION   Symptoms of shunt malfunction usually develop over several days although rapid deterioration within 24 h has been reported. Clinical features include mental status changes; headache; nausea; vomiting; abdominal pain; lethargy; decreased intellectual performance; ataxia; coma; and autonomic instability. Often the presenting complaint is vague. As intracranial pressure increases, paralysis of upward gaze or sundowning, dilated pupils and papilledema may develop. "Sundowning" is due to impingement of the brainstem by the third ventricle as it engorges. Symptoms of slit ventricle syndrome are exacerbated or precipitated by standing or exercise due to excessive CSF drainage and relieved by lying down or the Trendelenburg position.

SHUNT EVALUATION   Identification of shunt type is important although frequently difficult. Many different types exist and appropriate assessment is dependent on the apparatus implanted. Shunt function is evaluated by manual testing and radiologic studies. Palpation of the shunt allows the physician to locate the valve chamber. Shunt patency is evaluated somewhat differently for each type of device depending on such features as valves, dome or cylinder-shaped reservoirs. Generally, testing follows intuitive expectations but may yet prove perplexing to inexperienced clinicians. For a simple device, once the chamber is located, it is gently compressed and observed for refill. Difficulty compressing the chamber indicates distal flow obstruction, while slow refill, defined as greater than 3 s, following compression indicates a proximal obstruction. Clinicians should realize that compression is inaccurate in identifying shunt obstruction as up to 40 percent of obstructed shunts have normal refill during manual palpation. [2] In any case, further evaluation is required.

A shunt series of plain films includes an AP and lateral radiographs of the skull, and an AP view of the chest and abdomen (for ventriculoperitoneal shunts). While plain radiography will identify kinking, migration or disconnection of the shunt system, CT is required to evaluate ventricular size. Comparison to previous CT scans is needed as many shunted patients have an abnormal baseline ventricular size. In one series, using CT, or both CT and plain films, 25 percent of patients with documented shunt malfunction had no radiologic evidence of shunt malfunction. [3] Therefore, in patients with suggestive clinical features, unimpressive CT and/or shunt series cannot be relied on to exclude shunt obstruction. In this instance, obtain neurosurgical consultation whenever shunt malfunction is suspected.

A shunt tap may need to be performed to make the diagnosis of shunt malfunction, rule out infection, or to alleviate life threatening increased intracranial pressure. The shunt tap should be performed by a neurosurgeon if available. Emergency physicians should be prepared to perform a shunt tap if a neurosurgeon is unavailable or if a shunt tap is needed to control life threatening increased intracranial pressure.

To perform a shunt tap, locate and sterilely prepare the site over the valve system or reservoir. The scalp should be shaved. A 23-g needle or butterfly attached to a manometer is inserted into the reservoir. If no fluid returns or flow ceases, a proximal obstruction is likely. The opening pressure should be measured while occluding the reservoir outflow. An opening pressure of 20 cm or greater indicates a distal obstruction while low pressures indicate a proximal obstruction. The normal basal intracranial pressure is around 12 ± 2 cm.

MANAGEMENT   Surgical intervention is generally required for shunt obstruction. As a temporizing measure intracranial pressure can be lowered by standard methods—hyperventilation and osmotic diuresis (mannitol). If these measures fail and surgical intervention is not immediately available, the emergency physician can lower intracranial pressure when the malfunction is distal by removing CSF via the reservoir as previously described. To prevent choroid plexus bleeding, CSF is removed slowly, and the process is discontinued when intracranial pressure reaches 10 to 20 cm. Stable patients with suspected obstruction require admission and neurosurgical consultation. These patients should be observed for any neurologic changes, abdominal complaints, or development of fever.

Shunt Infection

Infection was a common complication of CSF shunts, occurring in up to one-third of shunted patients. With improved techniques and shunts, infection rates have decreased to 5 to 8 percent per procedure.[2] The highest rates of infection are found in the very young and old, and in patients who have had multiple shunt revisions. There is no association between shunt type and infection rates.

Half of all shunt infections present within the first two weeks of placement, 70 percent present within two months of placement, and 80 percent of shunt infections present within six months of placement. CSF shunt infection can be categorized into internal and external infections. An internal infection involves the shunt and the CSF contained within that shunt. External infections involve the subcutaneous tract around the shunt, which is usually tender and there is often an associated fluid collection within the skin. If diagnosed and treated in a timely fashion, mortality from shunt infections is low. However, if ventriculitis develops, mortality is 30 to 40 percent, underscoring the need for prompt diagnosis and aggressive management. [1,2]

BACTERIOLOGY   CSF shunt infections are typically caused by low-virulence organisms. The most commonly cultured agent is *Staplylococcus epidermidis,* which accounts 50 percent of all shunt infections; *Staplycococcus aureus,* the next most commonly cultured agent, accounts for 25 percent of all shunt infections. Gram-negative, anaerobic and mixed infections account for approximately 5 to 10 percent of shunt infections. Gram-negative infections are associated with the highest mortality. Patients with CSF shunts have a higher risk of developing meningitis from typical pathogens (e.g., *Haemophilus influenzae, Streptococcus pneumoniae,* and *Neisseria meningitidis*) compared to the general population. This increased risk may be due to disruption of the blood-brain barrier by foreign material.

CLINICAL FEATURES   The clinical presentation varies with the virulence of the organism and the severity of the infection. Typically, patients will present with obstructive and possibly meningeal symptoms, including mental status changes, headache, nausea, vomiting, and irritability. Fever, meningismus and abdominal pain may also be present. Unfortunately, these signs are not universally present. In fact, the finding of fever is highly variable and meningismus may only be present in only a third of patients with shunt infection.[2] Abdominal pain may be the predominant symptom in patients with ventriculoperitoneal shunts. Swelling, erythema, and tenderness along the site of the shunt tubing are highly suggestive of external shunt infection.

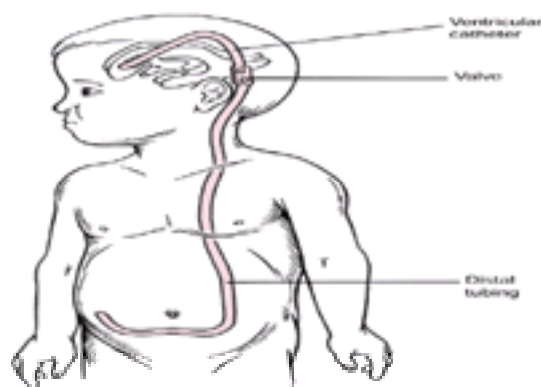
EVALUATION   To exclude CSF shunt infection, a shunt tap is required (Fig. 228-1) (see evaluation of shunt malfunction). This procedure should be performed by a neurosurgeon or by an emergency physician only after consultation with a neurosurgeon. A traditional lumbar puncture often misses CSF shunt infection and has no meaningful role in the evaluation when infection is suspected.


FIG. 228-1. Ventriculoperitoneal shunt system.

The cell count of patients with infected CSF shunts usually reveals an elevated leukocyte count, elevated protein, and normal glucose levels. Almost one-fifth of patients evaluated for shunt malfunction may have positive CSF culture despite normal CSF analysis. Non-CSF lab values are rarely helpful in diagnosing CSF shunt infection. CT scan and plain radiographs of the shunt (shunt series) are required to exclude mechanical shunt malfunction, which often coexists with shunt infection.[3] Abdominal ultrasound or CT scan are indicated if an abdominal fluid collection, pseudocyst, or abscess is suspected.

MANAGEMENT   All patients with CSF shunt infection or suspected shunt infection require emergent neurosurgical consultation and admission. Most neurosurgeons advocate replacement of the infected shunt, external CSF drainage and administration of intravenous and intrathecal antibiotics. This combination of therapy has a 96 percent success rate. Until the infecting agent is identified, broad-spectrum antibiotics effective against typical pathogens are recommended (e.g., intravenous third-generation cephalosporin and aminoglycoside, plus intravenous or intrathecal vancomycin). Meningitis caused from typical pathogens has been successfully treated with antibiotics alone.

HALO DEVICES

The Halo vest provides one of the most rigid types of cervical immobilization available. The Halo consists of a lightweight radiolucent ring attached to a lightweight adjustable vest. Current vests allow adjustment of the cervical spine in multiple planes. Titanium pins that do not interfere with MRI images, are stronger, lighter, and more expensive than older stainless steel pins. Pins are usually tightened to 6 to 8 in lb.[4,5]

INDICATIONS   Halo devices are indicated for stabilization of an unstable cervical spine, including fractures, dislocations, subluxations, and alignment of severe kyphotic and scoliotic spines. A halo is not applied if there is a sensory deficit that extends beneath the Halo vest as this leads to a higher risk of skin breakdown and infection. Pin sites are chosen to avoid nerve vessels and muscle while attempting to place the pins in the thickest area of calvarium possible. Four pins are usually used. The anterior pins are placed in the frontal or temporal regions. Posterior pins are placed relatively opposite to the anterior pin sites.

COMPLICATIONS   Pin loosening is the most common complication encountered in the emergency department. It occurs in 36 to 60 percent of patients with halo devices.[5,6] Neurosurgical consultation should be obtained, and infection of the pin site ruled out. If resistance is met within the first rotations, the pin can usually be retightened to 6 to 8 in lb. If no resistance is met, the pin has to be removed. This is usually done by the neurosurgeon after placement of a new pin is completed to avoid any loss of stability in the halo device.

If pin loosening has caused movement of the Halo device, assume that the cervical spine is unstable, immobilize the cervical spine using an alternate technique, and obtain plain radiographs to assess for proper alignment. Tangential plain radiographs, CT, or MRI can be used to rule out penetration of a pin through the inner table of the skull.

Pin-site infection is second most frequently encountered complication. It occurs in about 20 to 22 percent of patients with halo devices.[5,6] Careful examination is required to differentiate a localized pin-site infection from less common, more serious infection, such as cellulitis, osteomyelitis, and abscess formation. Patients with cellulitis usually have fever, and systemic signs and symptoms of infection. Patients with osteomyelitis usually have a prolonged infection, pin-site loosening, and radiologic abnormalities. Patients who develop an abscess usually have neurologic changes and evidence of inter-table penetration (CSF leak, trauma). Local pin-site infections are commonly managed with local wound care. The skin around the pin site must be pulled away to allow thorough cleaning of the skin beneath the pin and skin-pin interface with soap and water four times a day. Culture the wound site. If antibiotics are administered, agents effective against skin pathogens (e.g., staphylococcus and streptococcus species) are used. If local infection does not respond to treatment, or if cellulitis, osteomyelitis, or abscess is suspected, neurosurgical consultation is required for admission, IV antibiotics, and possible surgical intervention.

Pin-site discomfort occurs in 18 percent of patients.[5,6] It is most commonly a result of local inflammation. Examine the patient to exclude a localized or systemic infection, or other local complication. Sensory and motor deficits or paresthesias indicate nerve damage or pressure, while painful mastication indicates temporalis muscle inflammation. After excluding infection a short course of analgesics is recommended. Neurosurgical consultation is required if pain continues or a serious complication is suspected.

Ring migration and/or loss of immobilization occurs in 10 to 13 percent of patients.[5,6] Suspect loss of immobilization in patients complaining of neck pain and or mobility, and change in fit or position of the ring or vest. Immediately immobilize the cervical spine using an alternative technique (e.g., hard collar plus backboard). Obtain plain films to assess for changes in alignment and neurosurgical consultation for reapplication of the Halo.

Skin breakdown and pressure sores occur in 4 to 11 percent of patients.[5,6] If these are present, inspect the vest for adequate padding and strap position. Urgent referral to a neurosurgeon for refitting may be required.

Dysphagia occurs in 2 percent of patients.[5,6] Immobilization holding the head in exaggerated extension is the usual cause of the dysphagia. Halo adjustment will remedy this problem. Alternatively, dysphagia can occur following anterior displacement of a bone graft. This diagnosis can be made by plain films and/or a

swallowing study and will require emergency surgical intervention.

Dural punctures occur in 1 percent of patients and are due to halo system trauma. [5,6] Symptoms include headache, malaise, or visual changes. Physical exam may reveal a CSF leak or evidence of skull fracture. All patients require admission and neurosurgical consultation. Treatment includes elevation of head, IV antibiotics, and pin removal.

Rarely, CPR is required in patients with Halo devices. To perform chest compressions, remove the anterior portion of the vest. Instructions for removing the halo vest are printed on the front of most vests. Perform intubation with the Halo in place. If orotracheal intubation is unsuccessful, attempt nasotracheal intubation (if respirations are present) or cricothyrotomy.

OTHER CENTRAL NERVOUS SYSTEM DEVICES

Intrathecal Baclofen Infusions

Generalized dystonia occurs in 15 to 25 percent of patients with cerebral palsy. These patients typically respond poorly to medical and surgical treatment plans aimed at controlling their dystonia. Baclofen, a g-aminobutyric acid agonist that acts at the level of the spinal cord by impeding the release of excitatory neurotransmitters, decreases spasticity. Oral baclofen offers patients only mild relief because of its inability to cross the blood-brain barrier, because it is poorly lipid soluble. Intrathecal administration is more effective, requires lower doses, and leads to higher CSF levels. Intrathecal baclofen reduces spasticity, improves gait, sitting ability, and upper extremity function in most patients.[7,10] Complications observed in patients receiving continuous intrathecal baclofen include hypotension, bradycardia, apnea, oversedation, respiratory depression, local infection, meningitis, and CSF fistula formation. Newly available intrathecal catheters cause fewer complications compared to original catheters. More experience is needed with continuous intrathecal baclofen to determine the long-term benefits and complications. Currently, it appears that complication occurs in approximately 20 percent of cases, while infection requiring removal occurs in about 5 percent of cases. [7,8,9 and 10]

Implantable CNS Stimulators

The pathogenesis of Parkinson's disease is thought to involve unregulated activity of the subthalamic nucleus and globus pallidus intermedius. Neurophysiologists have shown that high-frequency stimulation can reversibly inactivate nerve conduction in these areas. [11,12]

High-frequency stimulation with implantable CNS devices are being used for suppression of parkinsonian and essential tremors. This neurostimulation is typically used if drug therapy has failed to control tremors. Neurostimulation is as efficient at controlling tremors as classic thalamotomy, but is less invasive.

Little has been reported about complication rates for these neurostimulators and there is little ED experience related to complications to date. Limited studies suggest that neurostimulation has a lower risk of physical or cognitive impairment compared to thalamotomy. Patients may present to the emergency department with varied complaints including problems related to the subcutaneous pulse generator, temporary or permanent paresthesias, dysarthria, dysequilibrium, or failure of the neurostimulator to suppress tremors. Neurosurgical consultation is needed as these complaints may represent lead displacement or migration requiring surgical correction or replacement. If the diagnosis remains uncertain, observation may be required with the stimulator in the off position to help differentiate mechanical failure from an acute neurologic deficit.[11,12]

229 APPROACH TO NEUROIMAGING IN THE EMERGENCY DEPARTMENT

Norman J. Beauchamp, Jr.

GENERAL OVERVIEW OF COMMON TECHNIQUES

Although a more thorough discussion of techniques is provided in other chapters of this textbook, a brief introduction to the more common techniques will be beneficial to understanding the optimal approach to cranial neuroimaging. Plain films are an essential tool. X-rays generate two-dimensional images based on attenuation of a collimated beam. The attenuation is proportional to the electron density of the structures through which it passes with the final image reflective of tissue density. This results in high spatial resolution and thus sensitivity for the detection of fractures. However, detection of abnormalities requires that there be no obscuration of the region of interest by overlying bone or other dense material. Thus, whereas a skull fracture of the calvarium is often readily detected, a fracture involving the skull base is typically obscured due to overlying bone. Plain films also provide a coarse view of the extracranial soft tissues, but intracranial soft tissues are obscured. Because the primary goal of ED neuroimaging is the detection of intracranial soft tissue abnormalities, the role of plain films is largely limited to the primary assessment of spinal trauma, the assessment of some facial fractures, assessment of some subtle, linear skull fractures oriented in the axial plane of acquisition, or as part of the skeletal survey for child abuse.

Computed tomography (CT) has largely supplanted plain films for neuroimaging. CT images are generated using a rotating x-ray tube that projects a collimated beam through the brain with resultant attenuation of the beam proportional to the electron density (tissue density) of the tissue through which it passes. Thus, rather than interrogating the tissue of interest from one direction (as in conventional x-rays), computerized processing of the circumferentially projected attenuated rays enables reconstruction of tissue maps largely unobscured by overlying tissues. Differentiation of adjacent tissues such as bone, gray and white matter, and cerebrospinal fluid (CSF) is possible due to perceivable differences in tissue density. Vasogenic and cytotoxic edema and hemorrhage alter the density of the tissue effected, making CT highly sensitive in the detection of disease. Further, the fine anatomic detail enables detection of morphologic alterations such as fractures and parenchymal swelling.

Magnetic resonance imaging (MRI) involves placing a patient inside an externally applied magnetic field. Due to its odd number of nuclides, hydrogen will align with this magnetic field. These "magnetized" hydrogen atoms are then "energized" by the input of an applied radiofrequency pulse and the pattern of energy release provides information about the biophysical properties of the tissue being evaluated. The shifts in water (hydrogen) distribution that characterize all pathologic processes alter these biophysical properties. Detectable changes occur prior to a detectable change in tissue density. Thus, MRI is more sensitive than CT in detecting parenchymal pathologic processes such as cerebral ischemia, infection, or metastases. Equally important is that the presence of certain blood products (deoxy- and methemoglobin, hemosiderin) develops over time postbleeding. These cause a detectable alteration in local magnetic field. MRI is thus nearly equivalent to CT in the detection of fresh bleeding, but is much more sensitive in the detection of staid blood. Blood becomes CT "normal" in density 7 to 10 days postbleed, but can generate an abnormal magnetic field for months to years. Lastly, MRI enables multiplanar acquisition while the patient remains supine. In CT, imaging requires patient positioning specific for the plane of interest. This can be difficult for the very young, the elderly, and for trauma patients.

Notably, cortical bone is relatively depleted of hydrogen. Thus, the cortex of bone is nearly invisible on MRI. Although this is of benefit in that parenchyma can be assessed without compromise from adjacent dense bone (e.g., infratemporal region and posterior fossa assessment is slightly limited in CT due to artifact from the adjacent skull base) (Fig. 229-1 A and Fig. 229-1B), MRI is inadequate for the assessment of bony integrity. Compared to CT, MRI is frequently less (or even not) available in many Emergency Departments; is contraindicated in the presence of devices such as pacemakers, cochlear implants, and metallic foreign matter near vital structures; requires greater patient cooperation; and impedes monitoring of critically ill patients. As a result, despite its superior sensitivity to most pathological processes, MRI plays an important but more limited role in the ED.
FIG. 229-1. **A.** Axial CT obtained in a patient presenting with a left cerebellar infarct. Initial CT demonstrates a focal area of decreased attenuation in the left cerebellar hemisphere difficult to detect due to artifact generated by adjacent bone (*arrow*). Incidental note is made of similar obscuration of the inferior temporal lobe by artifact (*arrowheads*). **B.** Axial MRI clearly demonstrates an area of infarction in the left cerebellum. Visualization is clear with no artifact generated despite proximity to bone.

Ultrasound generates images based upon transmittance of sound waves. In general, sonographic imaging enables evaluation of soft tissue structures provided that air or bone does not obscure the area of interest. In neuroimaging, most of the structures of interest are obscured by the calvarium. However, in infants, patency of the fontanel provides an adequate sonographic window enabling high sensitivity for the detection of intracranial masses, hemorrhages, or hydrocephalus. In infants and very young children, ultrasound is the study of choice for intracranial assessment.

Ultrasound can also be used to assess for traumatic globe injury or masses. However, this technique is highly operator-dependent, is limited in the assessment of the orbital apex, and is typically performed by an ophthalmologist.

Ultrasound images can be generated in which flowing blood produces color images scaled to flow velocity. These images give information on lumen caliber and hemodynamic alterations (such as occur with a distal occlusion or proximal stenosis). Ultrasound has become the screening technique of choice in assessing for common carotid bifurcation atherosclerotic disease. Transcranial Doppler and power Doppler ultrasound enables assessment of the distal most aspects of the internal carotid arteries, the proximal cerebral arteries, the circle of Willis, and the superficial parenchyma. Assessment of the posterior circulation and deeper parenchyma remains limited.

The vasculature can also be assessed noninvasively with CT angiography (CTA) or MR angiography (MRA). CTA and MRA are appealing techniques because they are noninvasive and can be incorporated into a comprehensive CT or MR examination with minimal additional time or difficulty (Fig. 229-2A and Fig. 229-2B). MRA utilizes a gradient echo pulse sequence that results in increased intravascular signal intensity with normal flow. CTA is performed following the peripheral venous administration of iodinated contrast. An image similar to a conventional arteriogram can be reconstructed from the axial images. Both are sensitive to large vessel occlusion or narrowing in the internal carotid, vertebral, basilar, and first and second segments of the anterior, middle, and posterior cerebral arteries. Furthermore, both techniques can be modified to look at venous structures (i.e., CTV or MRV). CTA requires less patient cooperation with an assessment of the vasculature complete in approximately 30 s. However, vascular detail is limited when vessels are in direct apposition to bone. Vascular assessment with MRA is not limited in the presence of bone. It is useful for assessing the vertebral arteries as they course through the bony transverse foramina and skull base, and in assessing the cephalad

course of the internal carotid artery.
FIG. 229-2. **A.** MR angiogram demonstrates an area of focal stenosis involving the basilar artery (*curved arrow*). However, the right posterior cerebral artery is clearly demonstrated excluding large vessel occlusion (*straight arrow*). **B.** MR axial FLAIR image demonstrates and area of hyperintensity corresponding to an acute right parietal infarct (*arrowhead*).

Both CTA and MRA techniques have resolution inferior to catheter angiography. For example, neither CTA nor MRA can reliably detect intracranial aneurysms less than 3 mm. The primary use of both techniques is as a screening tool for vascular occlusion and generally should be supplemented with catheter angiography when clinical suspicion remains. Catheter angiography utilizes plain x-rays in conjunction with administration of intra-arterial contrast through a catheter placed from a femoral artery approach and positioned proximal to the vasculature to be assessed. The intra-arterial contrast delineates vascular anatomy and detects pathologic changes such as narrowing and occlusion. It is the definitive procedure for assessment of the intra- and extracranial vasculature. However, there is a 1 to 2 percent risk of stroke associated with catheter angiography.

Near infrared spectroscopy (NIRS) measures changes in absorbance of an infrared light beam projected transcranially. Specifically, near infrared light (700 to 1000 nm) has relatively good transcranial penetration and hemoglobin (Hb) has characteristic absorption spectra. The absorbance of light is dependent on the presence of Hb and the oxygen content of the Hb. Thus, this technology can be used to assess for the presence of hemorrhage and to assess the oxygen state of the superficial microcirculation. For example, in one investigation, 24 of 27 patients with delayed traumatic intracranial hemorrhages demonstrated increases in the NIRS absorbance.[1] NIRS units are portable and relatively inexpensive, but the role for NIRS remains to be determined.

Radioisotope scans are performed following the administration of radioisotopes that emit photons. Photon imaging studies can be used to assess ventriculoperitoneal shunt patency, CSF leaks, hydrocephalus, Ommaya reservoirs, and brain death. Anatomic scans can also be performed that enable detection of space-occupying lesions. In general, nuclear medicine neuroimaging studies are infrequently utilized in the ED setting due to the superior resolution, increased availability, and expedience of CT and MR.

There are numerous available neuroimaging techniques for cranial imaging. Fortunately, the majority of imaging can be performed with plain films, CT, or MR. The choice of modality varies depending on the clinical question to be answered, the availability of the modality, and the ability of the patient to tolerate the examination. Although a consensus is often difficult to attain, some guiding principles exist. The remainder of this review focuses on guiding principles for the assessment of the most common emergency neurologic complaints.

HEADACHE

Recommendations for which subset of patients with acute headache requires some form of neuroimaging are as varied as they are numerous. However, neuroimaging has been accepted as the standard of care in specific clinical situations (Table 229-1). In addition to atypical headache (associated with neurologic signs), severity of headache is an indicator for imaging. Specifically, acute onset of the "worst headache of my life" raises concern for subarachnoid hemorrhage. Identification is essential because rupture of an intracranial aneurysm is the most common cause of nontraumatic subarachnoid hemorrhage. Furthermore, if subarachnoid hemorrhage (SAH) remains undetected, there is a 50 percent two-week risk of rebleeding with an associated 50 percent mortality. In this instance, nonenhanced head CT is the recommended study (Fig. 229-3). Its sensitivity in the detection of SAH is within 93 to 100 percent if performed within 12 to 24 h of the event. [2] In addition to the demonstration of high-density acute blood in the subarachnoid spaces, it also demonstrates other manifestations of SAH, including intraventricular and intraparenchymal hemorrhage and hydrocephalus. With small amounts of acute hemorrhage, SAH can be overlooked and the sensitivity of CT decreases to about 80 percent after 24 h,[2] and continues to diminish significantly over time to less than 30 percent 3 days postrupture. Thus, if the CT is negative, lumbar puncture is necessary. A positive CT or LP requires conventional angiography.

Unexplained mental status change or focal neurological signs

"Worst headache of life" of sudden onset

Unexplained fever

Meningismus

Extremes of vital signs (blood pressure, bradycardia or respiratory rate, although seldom an isolated finding)

TABLE 229-1   **Considerations for Nonenhanced Head CT for Headache**

FIG. 229-3. Axial CT demonstrates areas of increased density compatible with subarachnoid hemorrhage (SAH) (*straight arrows*). There is also early hydrocephalus with the temporal horns dilated (*curved arrow*).

Headache associated with unexplained fever is also an indication for neuroimaging, particularly when there is associated meningismus and photophobia. Although diagnosis is made by lumbar puncture, imaging is typically recommended to exclude hydrocephalus. Despite the absence of scientific validation, it has become the standard of care to precede lumbar puncture with nonenhanced head CT (NECT). Secondary hydrocephalus tends not to obviate performing lumbar puncture, but it will lead the physician to performing a low-volume lumbar puncture. Further, it can alert the physician to the possible need for shunt placement.

Acute or recurrent hydrocephalus can present with headache as well as nausea, incontinence, and ataxia. There is generally an increase in the intraventricular volume. Hydrocephalus can be caused by a number of processes including prior subarachnoid hemorrhage, prior trauma, meningitis, masses obstructing the ventricular system, or masses external to the ventricles but causing obstructing compression due to size or edema. In the evaluation of patients with suspected hydrocephalus, NECT is an adequate evaluation. It will enable detection of patients requiring emergency placement of intraventricular shunt catheters. If hydrocephalus is identified and the etiology remains undefined, a contrast-enhanced MRI examination with its superior ability to image in multiple planes should be performed. Lastly, in examining patients with an intraventricular shunt catheter and suspected recurrent hydrocephalus, the NECT should be accompanied with a plain film shunt series. The latter will detect possible kinks or disruptions of the catheter (see Chap. 228 for detailed discussion).

Generally an intraparenchymal mass, large enough to cause headache will be associated with neurologic signs prior to, or concurrent with, the development of headache. Thus, in instances where tumors are associated with headache, they are large and readily detectable on NECT; indirect effects, such as obstruction to CSF outflow, will also be evident on NECT.

MENTAL STATUS CHANGE

The issue of whether to image patients under the influence of alcohol or other substances to also consider other etiologies as a possible explanation for mental status change frequently arises in ED practice. The approach is discussed in detail in Chap. 221 and Chap. 247. Generally, patients with Glasgow Coma Score (GCS) of 13 or less, those that fail to improve with time, or those in whom alcohol or drug levels are not in keeping with the clinical findings, require imaging.

An initial NECT can be performed in patients with mental status changes who also have a known primary tumor, or who have a suspected metastases or primary brain tumor. This will suffice in detecting lesions resulting in mental status change, such as marked cerebral edema, herniation, and intracranial hemorrhage, that require emergent intervention. However, the optimal choice of imaging is based on the availability of imaging resources as well as the clinical suspicion. For example, contrast MRI is the more sensitive test and is typically required for patients in which clinical concern persists, even if the initial CT is normal. However, if MRI resources were immediately available, it would be more appropriate in instances of high suspicion to proceed directly to MRI and avoid unnecessary time delay and additional imaging costs to the patient. Contrast-enhanced CT subjects patients to the small, but unnecessary, risk of iodinated contrast, and is less sensitive than MRI.

Proceeding directly to imaging with MRI when available, is also indicated with certain cerebral infections. Encephalitis presents as acute mental status change and fever. Herpes type 2 encephalitis is a particularly devastating form, but can have a good clinical outcome if diagnosed and treated early in the course of the disease. Herpes often has a characteristic appearance in which the temporal lobes are first effected (Fig. 229-4). Due to the difficulties assessing parenchyma in direct apposition to bone structures, detection of the subtle early findings of cytotoxic edema involving the temporal lobes can be difficult when utilizing NECT in the first three days. Sensitivity is not increased by the addition of intravenous contrast. Conversely, MR is highly sensitive to the early manifestations of encephalitis. It is often positive in the first 24 h and can be helpful in expeditious diagnosis.

FIG. 229-4. Axial CT scan demonstrates decreased attenuation in the right temporal lobe (*straight arrow*). In a young patient with acute onset mental status change, this is highly suggestive of herpes encephalitis. Note the normal left temporal horn (*curved arrow*) as compared to the effaced right temporal horn.

The approach to imaging the HIV-positive patient with mental status change is greatly debated (see Chap. 139). There is a tendency to provide an emergent screening examination with NECT followed by nonemergent performance of contrast-enhanced MRI as indicated. Using this approach, processes creating vasogenic edema and those requiring immediate intervention, such as toxoplasmosis and lymphoma, will undoubtedly be detected. However, further investigation using contrast MRI is often requested to better characterize these lesions and for the detection of HIV encephalopathy and progressive multifocal leukoencephalopathy. A cost-effective approach of proceeding directly to MRI has also been recommended. This largely depends on the institutional availability of MRI and the management practices of clinicians.

SEIZURES

In recurrent seizures, determination of a sole cause such as noncompliance typically eliminates the need for imaging. Similarly, neuroimaging is not indicated for the evaluation of children with simple febrile seizures. However, the optimal approach for the evaluation of first-time seizures is debated. The American College of Emergency Physicians Special Panel suggests CT scanning for first-time seizures. [3]

CT is nearly 100 percent sensitive for etiologies of seizures that require emergent intervention such as brain abscesses, hemorrhage, or other space-occupying lesions. However, the neurologist may additionally request multiplanar MRI emergently or electively depending on the clinical situation, although not necessarily while the patient is in the ED.

STROKE

Although presented elsewhere in this textbook (Chap. 220), determining the optimal approach to imaging cerebral infarction is becoming increasingly complex and is thus relevant to the discussion of modality selection in neuroimaging.

FDA guidelines require performance of a NECT prior to the institution of thrombolytic therapy. Intravenous contrast administration is of limited value in the CT evaluation of acute stroke. Contrast enhancement is generally not seen during the first three days. Experience from the European Cooperative Acute Stroke Trial (ECASS) has demonstrated that efficacy of treatment is contingent on accurate CT interpretation. [4] Specifically, treated patients who had evidence of extensive infarction on CT had a worsened outcome. These patients should be excluded from treatment. However, this can be challenging because the signs of infarction initially are quite subtle. For example, trained readers did not detect 12 percent of areas of advanced infarction in the ECASS study. [4] Optimal treatment is most likely to occur when all members of the treatment team are familiar with the early signs of infarction (Table 229-2). Briefly, the presence of hemorrhage or evidence of progressive infarct are contraindications to treatment (Fig. 229-5). The sensitivity of CT for the detection of hemorrhage has been previously discussed. An important sign of acute stroke is the hyperdense middle cerebral artery (HMCAS) sign. This corresponds to a thrombus (angiographically) and is demonstrable at the time of ictus. The early CT findings of infarction are due to cytotoxic edema—cellular injury with influx of fluid in the intracellular space. The four CT signs that can be seen in the acute period are: (1) blurring of the clarity of the internal capsule; (2) loss of distinctness of the insular ribbon cortex; (3) loss of differentiation between the cortical gray and the subjacent white matter; and (4) swelling of the cortical gray matter resulting in effacement of interposed sulci. In addition to the attenuation changes,

morphologic changes occur due to the accumulation of intracellular fluid causing *swelling* of the cortical gyri. This results in effacement of the spaces demarcated by the gyral infoldings (sulci) and is referred to as "sulcal effacement." The extent of these changes determines whether treatment with thrombolysis is indicated.

Grade 0—Normal CT

Grade 1—Possible early signs of infarction: May still give rt-PA depending on the clinician's judgement
 Vague blurring of gray-white boundaries
 Slight attenuation of the insular ribbon
 Slight indistinctness of basal ganglia gray matter
 Suggestion of crowding of sulci

Grade 2—Subtle but definite signs of early infarction: likely will not treat
 Same as above except findings are distinct

Grade 3—Prominent signs of early infarction: contraindication to treatment
 Mass effect—i.e., ventricular effacement, subfalcine or uncal herniation
 Clearly demonstrated hypodensity
 Intracranial hemorrhage
 Note: In the ECASS study, the major early signs of infarction included: diffuse swelling of the affected hemisphere and effacement of the cerebral sulci in more than 33% of the MCA territory.

TABLE 229-2 CT Appearance Exclusion and Inclusion Criteria for the Administration of rt-PA in Patients Presenting Within 3 H of Ictus. Based on Recommendations by the American Heart Association and Experience from the NINDS and ECASS Trials

FIG. 229-5. Axial CT demonstrating clear evidence of decreased attenuation compatible with infarction (*straight arrow*). Additional, there is a focal area of hemorrhage (*curved arrow*), which further obviates thrombolysis.

MR has a greater sensitivity and specificity than CT for the acute changes of stroke. In the first 24 h, over 80 percent of MR scans are positive as compared to 60 percent of CT scans. MR is particularly superior for the detection of stroke in the posterior fossa where CT is limited due to a beam-hardening artifact from the adjacent skull base (Fig. 229-1). The earliest MR changes are morphologic swelling of the gray matter, increased signal intensity on the T2W and SDW (referred to as T2 hyperintensity), and loss of normal intravascular flow voids (see Chap. 297 for details on the physics of MR). More importantly, MRI can be combined with MRA for the detection of large vessel occlusion.

Although superior to CT, conventional MRI remains incapable of demonstrating the parenchymal changes of infarction during the first three hours. A recently developed advanced MR technique known as MR diffusion imaging utilizes pulse sequences sensitive to small-scale water-molecule motion (i.e., diffusion). [5] Alterations in water motion indicative of infarction can be detected within four minutes of vascular occlusion. This sensitivity dramatically improves that ability to determine extent of infarction and thus should improve the safety profile of rt-PA administration.

Neither clinical examination, CT, nor conventional MR imaging techniques provides information on the ischemic penumbra. Two advanced MR imaging techniques, MR perfusion and MR spectroscopic imaging, appear capable of providing this information (see Chap. 297). Perfusion imaging is performed following the bolus administration of intravascular contrast that result in changes in signal intensity proportional to regional cerebral blood volume and relative cerebral blood flow. [6] When ischemia is present, perfusion imaging shows a delay in peak signal loss in the affected distribution. MRS generates maps of hydrogen spectra containing major resonances from N-acetyl aspartate (NAA) and lactate. [7] Signals from lactate are not normally detected, but are demonstrated in the presence of ischemia and acute infarction. NAA is thought to be a marker of neuronal viability with decreased NAA a marker for cell death. Clinical MRS has demonstrated central areas of infarction with decreased NAA that corresponded to areas of T2W signal increase. Peripheral areas with elevated lactate, but normal NAA is felt to correspond to the ischemic region at risk for infarction. Future studies are needed to validate these findings and to determine which, if any, interventions may improve outcome in the penumbral region and when intervention is indicated. As the logistic difficulties associated with MRI are resolved, the ability to detect regions of infarction and ischemia suggest that CT will eventually be replaced in the evaluation of acute ischemia.

HEAD TRAUMA

Debate remains whether imaging is required for GCS of 15. Clear indications for neuroimaging include GCS less than 15; unexplained transient or persistent loss of consciousness; other forms of altered sensorium; focal neurologic signs; depressed skull fractures; seizure; persistent variations; progressive headache; and penetrating injuries.[8,9] In these instances, NECT plays an essential role for diagnosis and for detecting processes that require emergent intervention, such as epidural and subdural hematomas, increased intracranial pressure, and depressed skull fractures. Although discussed elsewhere, a number of points related to optimal imaging are worthy of emphasis.

The differential density of blood facilitates the detection of intraparenchymal and extraaxial hemorrhage. Density is displayed on a relative scale referred to in Hounsfield Units (HU). For example, water or CSF is assigned a value of zero, bone or metal varies between 100 and 1000 HU (hyperdense), fat is approximately −100 HU (hypodense), and air is −1000 HU. Further, acute blood has a density of 60 to 100 HU, and normal brain parenchyma has a density of approximately 35 (white matter) to 40 HU (gray matter). This differential density enables the increased density of blood or the decreasing density with accumulating edema to be detectable. Images are filmed in a manner that accentuates differences in the parenchymal range of densities. To optimize sensitivity for detecting parenchymal injuries, a gray scale is assigned such that regions of higher density are not easily differentiable. As such, blood in proximity to bone can be difficult to detect using parenchymal windows (Fig. 229-6*A* and Fig. 229-6*B*).
FIG. 229-6. A. Axial CT demonstrates a somewhat subtle left subdural hematoma (*curved arrows*). Note secondary signs of mass effect with the contralateral sylvian fissure detectable but compressed on the side of the subdural hematoma (*straight arrow*). **B.** Axial MR demonstrating the increased conspicuity of blood due to the

lack of obscuration by adjacent bone.

When evaluating for the presence of subdural and epidural collections it is important that images are formatted in a fashion so that the high densities are also distinguishable (i.e., blood windows). At many institutions it may not be routine to print these windows due to associated added film costs, but at a minimum, images should be reviewed on the CT console to exclude small blood collections. This is particularly true in the pediatric population where subdural hematomas can be a marker of intentional trauma. Detection is also facilitated by attention to the subtle secondary signs of extra-axial blood including loss of sulcal demarcation, mass effect on a ventricle, or displacement of the gray white junction from the inner table (Fig. 229-6). These secondary signs are also important because not all acute blood is hyperdense. In anemic patients (hemoglobin level 8 to 10 g/dL) or patients with a coagulopathy, acute blood may be isodense and thus difficult to visualize.

Occasionally, MRI can be of value in assessing trauma patients. For example, in assessing for small acute subdural hematomas or for subacute/chronic hematomas, CT may be limited due to the hematomas' proximity to bone or because over time the density of blood becomes isodense to normal brain (subacute) or to normal CSF (chronic) (Fig. 229-6 *B*). However, these blood products will remain abnormal with MRI for months to years. This can be of value in children when new and old coexistent extra-axial hematomas are essentially pathognomonic for child abuse.

MRI is also more sensitive in detecting diffuse axonal injury in which differential movement of parenchyma results in neuronal shearing. Diffuse axonal injury should be suspected when coma occurs immediately after severe injury and the degree of compromise is out of proportion to the CT findings. MR may be beneficial in that it will show multiple punctate areas of blood products below the threshold of CT detection. Specific anatomic structures that tend to be involved include the corpus callosum, adjacent to the superior cerebellar peduncle, the internal capsule, and gray-white matter junction.

Intra- or extracranial arterial dissection may be the result of trivial trauma, blunt trauma, or penetrating injury. MR can detect the presence of an acute dissection with T1 hyperintense blood seen in the vessel wall. In combination with MR angiography, it provides a fairly sensitive screening for a dissection. It enables an adequately sensitive but noninvasive method for vascular assessment and simultaneous assessment of the brain parenchyma and the extra-axial spaces. Other vascular lesions associated with trauma are pseudoaneurysms, which may occur in any dissected vessel, both intracranially and extracranially, and are prone to bleed. Catheter angiography remains the gold standard, but should be restricted to those patients with equivocal or abnormal MRA findings or a high-level of clinical suspicion.

Catheter angiography is also recommended in all patients with penetrating injuries to zone 1 and zone 3 of the neck, although assessment of zone 3 injuries is slightly more equivocal.[10] This is imperative for evaluating vessels of the thoracic inlet and above the mandible, respectively, because they are not accessible to visual inspection. Further, surgical exploration when indicated will require a vascular road map. Zone 2 injuries can be observed without angiography, which is recommended for expanding hematomas or where there is the development of respiratory or neurologic compromise.[11]

230 OCULAR EMERGENCIES

John D. Mitchell

A wide range of ocular emergencies, conditions, and manifestations of systemic illness are regularly encountered in the emergency department (ED). The recognition of these conditions and comfort in diagnosing and treating them are important to both the patient and the physician. As with any other part of the body, proper and early intervention can significantly enhance recovery and outcome. The ED physician should be comfortable with the use of a slit lamp, Tonopen and/or Schiøtz tonometer, and direct ophthalmoscope and be familiar with ocular anatomy (Fig. 230-1 , Fig. 230-2) and neuro-ophthalmology. The approach to the patient should proceed in typical fashion with a good history and physical examination, with treatment of life-threatening conditions taking priority.
FIG. 230-1. Anatomic diagram of eye and adnexa.
FIG. 230-2. Horizontal cross-sectional diagram of eye.

EYE EXAMINATION

History

A detailed history of the chief complaint and circumstances surrounding the onset should be obtained. The past ocular and medical history will provide additional information and help you arrive at a differential diagnosis. With this information you can then focus your physical examination and enhance your opportunity to correctly diagnose and treat the condition. A history of sudden, painless monocular visual loss associated with a history of atrial fibrillation or carotid stenosis would suggest a central retinal artery occlusion, while a history of eye pain occurring while hammering metal on metal would suggest a projectile corneal or intraocular foreign body. Past visual acuity and presence of a refractive error (need for glasses or contact lenses) provides information on acuity testing expectations. Use of soft contact lenses, especially the extended-wear type, is associated with a higher incidence of corneal ulceration from microbial infection. Flashing lights and a "curtain or veil" obstructing a portion of the visual field suggests a retinal detachment. A history of diabetes or chronic hypertension and acute isolated sixth-nerve palsy suggests an ischemic cranial neuropathy. A careful medical history and history of present illness (HPI) will guide you toward an accurate differential diagnosis in the majority of cases.

Physical Examination

The physical examination typically proceeds in a sequential fashion unless the circumstances require otherwise (i.e., chemical ocular injuries require intervention *prior* to assessment of visual acuity). The glossary of terms and abbreviations below is useful in documenting the findings. The typical eye examination sequence is as follows.

VISUAL ACUITY   An attempt should be made to obtain an assessment of visual acuity in each eye in all consciously alert patients. Each eye should be tested individually. If the patient uses glasses or contacts but the glasses are not available, pinhole testing can be performed to obtain an estimate of corrected visual acuity. Distance charts are preferable but are not practical with patients confined to a stretcher. Nearsighted patients and those under age 45 can use a near card to test their visual acuity. Patients in their midforties or older may require reading glasses or bifocals to read a near card because of presbyopia. If these patients do not have their glasses available, a pinhole occluder, again, can be used with a near card. The patient with a corneal abrasion or foreign body is frequently experiencing significant photophobia, pain, and tearing; here, a drop of a topical anesthetic will often reduce the patient's discomfort sufficiently to allow a more accurate assessment of visual acuity. Documentation of best acuity in each eye and whether prosthetic devices were used (glasses, pinhole) should be noted. If the patient cannot read the chart or near card, try asking him or her to count how many fingers you are holding up and record the furthest distance at which the fingers can be counted correctly (e.g., at 4 ft). If the patient is unable to count fingers, assess his or her ability to detect hand motion 1 to 2 ft in front of the eye. If the patient is unable to detect hand motion, turn off all the lights in the room, fully occlude the contralateral eye, and test for light perception. In recording the results of visual acuity testing, refer to the glossary of abbreviations, terms, and notations below.

EXTERNAL EYE   Examine the periorbital skin and lids for trauma, infection, dysfunction, or deformity. Proptosis should be recognized and recorded. Subcutaneous emphysema can be found with blowout fractures of the medial orbital wall (ethmoid). The orbital rims should be palpated for step-off deformities in trauma cases.

CONFRONTATION VISUAL FIELDS   Testing of the gross confrontation visual field of each eye can provide additional supportive diagnostic information if the history suggests a process that typically causes a field loss [i.e., bitemporal hemianopia in pituitary adenoma, homonymous hemianopia associated with some cerebrovascular accidents (CVAs), and monocular field cuts sometimes seen with significant retinal detachments].

PUPILS   Pupil assessment should be performed under slightly dim lighting conditions in testing for an afferent pupillary defect (Fig. 230-3). A positive afferent pupillary defect (APD) is indicative of an optic nerve disorder, and it is important to note that the pupils will be equal in size *prior* to testing because of the consensual light response. Therefore an APD does not cause a baseline anisocoria and will be discovered only if it is specifically tested for. Causes of unequal pupils (anisocoria) can range from an acute emergency [posterior communicating artery (PCA) aneurysm], to chronic baseline conditions such as previous intraocular trauma or surgery. A careful history is important to determine whether the anisocoria is preexistent. Ocular medications such as pilocarpine can cause extreme miosis, resulting in small, nonreactive pupils. Some patients with uveitis will be using a cycloplegic agent (scopolamine, cyclopentolate, or atropine) and have a chemically dilated, unreactive pupil. It is not worthwhile to attempt to "reverse" a chemically altered pupil in the ED, as the results are variable and unreliable.

FIG. 230-3. "Swinging flashlight test" revealing an afferent pupillary defect (Marcus-Gunn pupil) of the left eye.   **B.** The test is positive when the affected pupil dilates in response to light.

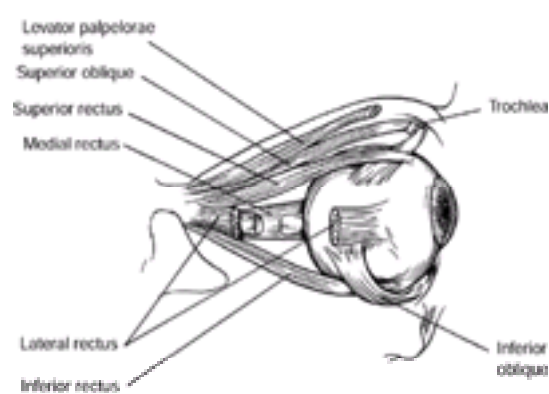
OCULAR MOTILITY   Eye movements are controlled by the six extraocular muscles attached to each eye (Fig. 230-4 and Fig. 230-5). These muscles are innervated by cranial nerves III, IV, and VI. Cranial nerve IV controls the superior oblique muscle, cranial nerve VI controls the lateral rectus muscle, all other extraocular muscles are controlled by cranial nerve III. Ocular motility can be impaired by restriction, interrupted or decreased innervation, or trauma. Examples of restriction include thyroid orbitopathy, myositis, and mechanical entrapment of a muscle secondary to an orbital blowout fracture. Cranial nerve palsies or paresis may be caused by CVAs, myasthenia gravis, diabetes, hypertension, tumors, aneurysms, infections, and trauma. Penetrating or blunt traumatic injury to an extraocular muscle can also result in motility disturbance. Diplopia may develop, especially when the patient is attempting to look in the direction of the malfunctioning muscle. Ocular alignment should be evaluated in primary gaze initially (looking straight ahead), followed by testing in all fields of gaze.


FIG. 230-4. Extraocular muscles of the eye.
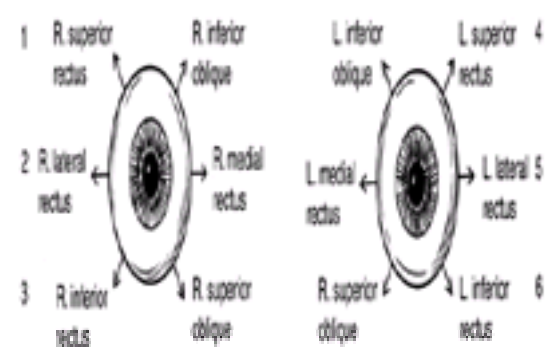

FIG. 230-5. Cranial nerve IV, superior oblique muscle; cranial nerve VI, lateral rectus muscle; cranial nerve III, superior rectus, inferior rectus, inferior oblique, and medial rectus muscles.

ANTERIOR SEGMENT   The conjunctiva, cornea, anterior chamber, iris, lens, and ciliary body make up the anterior segment. All of these structures except the ciliary body can be inspected directly on slit-lamp examination. A slit lamp is a biomicroscope that affords an excellent view of these structures and should be used whenever possible. The conjunctiva should be inspected for hemorrhages, discharge, inflammation, trauma, and foreign bodies. The upper lid should always be everted anytime a foreign-body sensation or abrasion is present. The cornea should be assessed by narrowing the light source to produce a slit beam and optically sectioning the cornea (Fig. 230-6), which allows an oblique section to be seen and facilitates evaluation of the entire corneal thickness. This is a particularly important technique when one is trying to determine if a corneal foreign body has caused a full-thickness penetration. Fluorescein dye should be instilled and the cobalt-blue filter used to identify corneal abrasions, dendrites, and perforations. The modified Seidel test is useful in identifying corneal perforations. The eye is anesthetized and held open and the cobalt-blue filter is used to observe the eye while a moistened fluorescein strip is "painted" across the suspicious site. Leakage of aqueous through a penetrating wound will appear as a lime-green fluid oozing onto the dark violet corneal surface (Fig. 230-7, Plate 9). The anterior chamber should be checked for clarity and the presence of a hyphema (Fig. 230-8, Plate 10) or hypopyon (Fig. 230-9, Plate 11). Cell and flare may be present in acute injuries or in chronic uveitis/iritis conditions and should be checked for as follows: The slit beam should be shortened to about 1 mm and all of the room lights should be out. The high-magnification position should be selected. The incident light source should create an angle of 45 to 60° with the objective (similar to optical sectioning). The light beam should be focused on the pupillary margin, then pull back on the joy stick to focus on the cornea, then move the focus inward halfway between the iris and cornea, with the pupillary aperture as a dark backdrop. This will place your focus in the center of the aqueous, and the light beam will illuminate cells slowly drifting up and down in the aqueous convection currents. Flare is typically described as the appearance of "headlights in a fog" and represents the ability to see the course of the normally transparent light beam through the aqueous. This is caused by increased aqueous protein content, which is commonly seen with inflammatory conditions. The iris should be inspected for tears and foreign bodies if trauma occurred. The lens should likewise be inspected for injury, subluxation, and foreign bodies.
FIG. 230-6. Optical sectioning: By creating an angle of 45 to 60° between the slit-beam light source and the observer's biomicroscope objective, the cornea can be optically "sectioned" obliquely. This allows a cross-sectional view of the cornea and is helpful in ascertaining depth of penetration of corneal foreign bodies and injuries.
FIG. 230-7. (Plate 9). Positive Seidel test showing aqueous leaking through a full-thickness corneal wound. Aqueous will turn fluorescein lime-green under a cobalt-blue light as it oozes through the wound while being observed at the slit lamp.
FIG. 230-8. (Plate 10). Hyphema secondary to blunt trauma. Note the blood filling the lower half of the anterior chamber and hazy appearance of cornea suggesting increased IOP.
FIG. 230-9. (Plate 11). Corneal ulcer with hypopyon. The ulcer is seen as a shaggy white corneal infiltrate surrounding the borders of the epithelial defect. The hypopyon represents the accumulation of white cells layering out in the lower one-sixth of the anterior chamber.

FUNDUS   The optic nerve, macula, and retina can be viewed with a direct ophthalmoscope in the ED. A dilated pupil makes it easier to see these structures, and unless the patient has a rare contraindication (narrow angles without a previous peripheral iridectomy), dilation can be performed if a posterior segment view is needed. Dilation can be achieved by using one drop of 1% tropicamide (Mydriacyl) in Caucasians and one drop each of 1% tropicamide and 2.5% phenylephrine

(Neo-Synephrine) in all others. A dilated examination is particularly important if an intraocular foreign body, central retinal artery occlusion (CRAO), or retinal detachment is suspected. A vitreous hemorrhage from diabetes or trauma can obscure or significantly reduce the view of the posterior pole. In these patients an ophthalmologist may need to perform an ultrasound-B scan to evaluate the posterior segment. An indirect ophthalmoscope provides an excellent three-dimensional view of the optic nerve and retina but requires extensive practice to use and generally is not a tool for the nonophthalmologist.

INTRAOCULAR PRESSURE   The eye remains consistently "inflated" because of a delicate balance between intraocular aqueous fluid production and outflow. Intraocular pressure [(IOP)/tension] can decrease due to reduced ciliary body production (some cases of iritis and uveitis) or loss of globe integrity (perforating injury). An increase in IOP occurs when intraocular fluid production exceeds outflow (glaucoma, hyphema). The normal IOP is 10 to 21 mmHg, and three main methods are used to achieve a measurement. Applanation tonometry is the preferred method by ophthalmologists and physicians trained in using this slit-lamp attachment. Practice and previous experience is recommended, however. The Tonopen, a handheld instrument for measuring intraocular pressure, has gained popularity because it is easier for a nonophthalmologist to use and has reasonable accuracy on edematous corneas owing to high intraocular pressure (attacks of acute angle closure). The Schiøtz tonometer is another instrument that can be readily used if a Tonopen is not available. All methods require an anesthetized cornea and a cooperative patient. Care must be taken to avoid any pressure on the globe with your fingers when holding the lids open, as this will cause a falsely high reading. The lids should be held open, with the fingers compressing the lids against the bony rims of the orbit. The method used should always be recorded. In recording the IOP, refer to the glossary of terms, abbreviations, and notations.

GLOSSARY OF TERMS, ABBREVIATIONS, AND NOTATIONS

It is important to understand the terms and abbreviations used in ophthalmology, not only to be more effective and precise when interacting with consultants but also to aid you in interpreting their written consultations.

AC: Anterior chamber, the first portion of the anterior segment
Anisocoria: Unequal pupil size under equal lighting conditions
Anterior segment: Consists of the anterior chamber and posterior chamber. Aqueous is produced in the posterior chamber of the anterior segment and circulates through the pupil into the anterior chamber of the anterior segment.
APD: Afferent pupillary defect (Fig. 230-3)
CF: counting fingers (visual acuity assessment)
CVF: Confrontation visual fields
EOM: Extraocular muscle
HM: hand motion (visual acuity assessment)
Hyphema: Red blood cells in the anterior chamber
Hypopyon: White blood cells in the anterior chamber
INO: Internuclear ophthalmoplegia
IOFB: Intraocular foreign body
IOP: Intraocular pressure (mmHg)
Limbus: Circumferential border where clear cornea ends and white sclera begins
NLP: no light perception (blind)
OD: Oculus dexter (right eye)
OS: Oculus sinister (left eye)
OU: Oculus uterque (each eye)
PH: pinhole visual acuity
RD: Retinal detachment
Tonopen: a handheld, pen-shaped device for measuring intraocular pressure
T_{tono}: Tension (IOP) with subscript representing method used (tono = Tonopen, S = Schiøtz, A = applanation).
V_{Ac}: visual acuity with correction (glasses or contact lenses)
V_{As}: visual acuity without correction

By convention, in documenting the visual acuity (V_A) or IOP, the right eye is listed above the left, as follows:

$$V_{Ac} < \frac{20/20}{20/30}$$

This represents a visual acuity *with* glasses/contacts of 20/20 right eye and 20/30 left eye.

$$V_{As} < \frac{20/400 \rightarrow 20/30}{CF\ at\ 8\ ft \rightarrow 20/40}$$

This represents a visual acuity *without* glasses/contacts of 20/400 in the right eye, improving to 20/30 with pinhole testing; counting fingers at 8 ft in the left eye, improving to 20/40 with pinhole testing.

Pinhole testing is helpful in assessing the visual acuity of someone who has a refractive error but does not have corrective lenses available. The pinhole allows only parallel rays (collimated light) to fall on the macula, thereby reducing the refractive error and allowing an estimate of the person's corrected visual acuity.

$$T_{tono} < \frac{14}{15}$$

This represents an intraocular pressure of 14 mmHg in the right eye and 15 mmHg in the left eye measured by Tonopen.

INFECTIONS

Lids

STYE (EXTERNAL HORDEOLUM)   A stye is an acute staphylococcal infection of an oil gland associated with an eyelash. It is located at the lash line and has the appearance of a small pustule. It can be either ruptured or left alone. Warm compresses and erythromycin ophthalmic ointment bid for 7 to 10 days is usually sufficient treatment.

CHALAZION (INTERNAL HORDEOLUM)   A chalazion is an acute or chronic inflammation of the eyelid secondary to blockage of one of the meibomian oil glands in the tarsal plate. A reddened, tender lump develops in the lid or at the lid margin. Initial conservative treatment consists of warm, moist compresses three or four times a day and erythromycin ophthalmic ointment applied to the eyelid margin qid. Some ophthalmologists will also add a 14- to 21-day course of doxycycline (tetracycline derivatives are secreted in the oil glands). The patient should follow up with an ophthalmologist in about 6 weeks or less if any worsening occurs. Chronic inflammation will induce a cystic wall, and a discrete lump develops that is usually both palpable and visible in the lid. Chalazions can cycle between being quiet or acutely inflamed. The patient with a chronic, recurrent chalazion should be referred to an ophthalmologist for surgical excision and curettage, which is the definitive procedure.

Treatment:

1. Warm moist compresses three to four times a day.

2. Erythromycin ophthalmic ointment applied to lid margins qid.
3. Consider doxycycline 100 mg PO bid for 14 to 21 days if chronic and recurrent.
4. Ophthalmology referral 4 to 6 weeks.

Conjunctivitis

BACTERIAL CONJUNCTIVITIS   Bacterial conjunctivitis generally presents with a mucopurulent discharge and inflammation of the conjunctiva. Often the eyelids are stuck together upon awakening. The condition can be monocular or binocular. The cornea is clear *without* fluorescein staining. Frequently there is a history of recent exposure to someone with "pink eye." Treatment consists of a topical ocular antibiotic for 5 to 7 days qid. Treatment with a broad-spectrum agent is safe for patients 2 months of age and older; Polytrim (trimethoprim and polymyxin B), for example, is very effective and avoids potential allergies to sulfa and neomycin preparations. Wearers of soft contact lenses should be treated with a fluoroquinolone (Ciloxan, Ocuflox) or aminoglycoside (Tobrex) to cover for *Pseudomonas*. With the expanding choices of well-tolerated topical antibiotic drops, gentamicin is now seldom used by ophthalmologists because of the high incidence of ocular irritation associated with it.

Treatment:

1. Fluorescein stain cornea (especially infants) to avoid missing a corneal abrasion, ulcer, or dendrite.
2. Non-contact-lens wearer: broad-spectrum topical antibiotic (Polytrim), one drop qid for 5 to 7 days.
3. Contact-lens wearer: fluoroquinolone (Ciloxan or Ocuflox) or aminoglycoside (Tobrex), one drop qid for 5 to 7 days.

VIRAL CONJUNCTIVITIS   Viral conjunctivitis tends to follow an antecedent upper respiratory infection and often will have a palpable preauricular node, which aids in confirming the diagnosis. Generally one eye will be involved initially, with the other eye becoming involved within days. The discharge tends to be watery and the conjunctiva is reddened and edematous (chemosis). The cornea is clear, with occasional punctate staining with fluorescein dye (multiple tiny dots of stain uptake seen only on slit-lamp examination). It is important to stain the cornea to avoid missing a herpes dendritic keratitis. Treatment consists of cool compresses; Naphcon-A, one drop tid as needed for redness and conjunctival congestion; and artificial tears five or six times a day. Viral conjunctivitis can take 1 to 3 weeks to run its course and is highly contagious. The physician examining a patient with possible conjunctivitis should wear gloves in order to avoid self-contamination. If, after a history and physical examination, it is still uncertain if the conjunctivitis is viral or bacterial, it is not unreasonable to add an antibiotic eyedrop until the patient can be reexamined by an ophthalmologist.

Treatment:

1. Fluorescein stain the cornea to avoid missing a herpes dendrite.
2. Cool compresses qid.
3. Naphcon-A one drop tid or qid as needed for conjunctival congestion/itching.
4. Consider a topical antibiotic if there is uncertainty as to whether an infection is viral or bacterial.
5. Ophthalmology follow-up in 7 to 10 days if cornea is clear.

ALLERGIC CONJUNCTIVITIS   Allergens can cause ocular discharge, redness, and itching. Itching is a very common and consistent symptom seen with allergic conjunctivitis. Treatment consists of cool compresses qid, antihistamine/decongestant drops (Patanol bid or Naphcon-A qid), and artificial tears as needed.

NEONATAL CONJUNCTIVITIS (OPHTHALMIA NEONATORUM)   Newborns with conjunctivitis require a careful history to elicit exposure to herpesvirus, *Chlamydia,* or *Neisseria gonorrhoeae* in the maternal birth canal. Conjunctivitis occurring in the first 28 days needs to be cultured with immediate Gram staining followed by the institution of both topical and systemic antibiotics. A careful examination to rule out systemic infection is essential. Infection with *N. gonorrhoeae* and herpes simplex virus (HSV) II can occur in the first 3 days of life; the former can cause rapid corneal ulceration and perforation if not treated. HSV II can occur in the first 3 to 15 days, and concomitant systemic involvement can be devastating. *Chlamydia, Haemophilus, Staphylococcus aureus,* and *Streptococcus pneumoniae* usually present 5 to 10 days after delivery. Treatment for *N. gonorrhoeae* consists of topical erythromycin ointment qid and systemic ceftriaxone (1 g IM or 30 to 50 mg/kg per day IV). HSV II requires topical Viroptic q 2 h and pediatric consultation for systemic evaluation and consideration of systemic acyclovir. *Chlamydia* requires topical and oral erythromycin treatment and awareness that the neonate is at increased risk for concomitant chlamydial pneumonia. *Haemophilus* should be treated with topical erythromycin and a systemic cephalosporin. Staph and strep can be treated with topical erythromycin. A typical standard treatment approach to the neonate with conjunctivitis is as follows:

Treatment:

1. Obtain cultures, Gram stain.
2. Institute topical erythromycin ointment and systemic ceftriaxone.
3. Assess neonate for possible systemic involvement and consult pediatrics for possible admission/septic workup.

Herpes Simplex Virus

HSV can affect the eyelids, conjunctiva, and cornea. Skin involvement has typical vesicular eruptions and the conjunctiva can also become inflamed. Ocular HSV can alternately present with only corneal findings on physical examination. The "dendrite" of herpes keratitis is an epithelial defect that can be seen with fluorescein staining and has a linear branching pattern with terminal bulbs (Fig. 230-10, Plate 12). An initial outbreak of HSV involving the lids and conjunctiva can be treated with an oral acyclovir derivative such as Zovirax or Famvir and topical antiviral drops (Viroptic five times a day without corneal involvement, nine times a day with corneal involvement). Erythromycin ophthalmic ointment can be added to prevent secondary infection of the vesicular eruption. HSV keratitis can progress to corneal scarring and requires prompt treatment with topical antiviral agents. Viroptic—one drop nine times a day—represents standard treatment, and Vira-A ointment five times a day or Stoxil can be substituted for those who are allergic to Viroptic. Topical steroids should be strictly avoided, and all patients should be referred to an ophthalmologist for outpatient follow-up.

FIG. 230-10. (Plate 12). Herpes simplex corneal dendrite seen with fluorescein staining and cobalt-blue light.

Treatment:

1. If the initial outbreak lasts longer than 3 to 4 days, consider oral acyclovir-class medications.
2. Erythromycin ophthalmic ointment qid to skin and conjunctival lesions to avoid secondary bacterial infection.
3. HSV *without* corneal involvement: Viroptic one drop five times a day.
4. HSV *with* corneal involvement: Viroptic one drop nine times a day.

5. Ophthalmology follow-up in 1 to 3 days.

Herpes Zoster Ophthalmicus

Herpes zoster ophthalmicus (HZO) represents shingles in the trigeminal nerve distribution with ocular involvement. When the cutaneous lesions include the tip of the nose (Hutchinson sign), the nasociliary nerve is involved and the eye frequently becomes inflamed. An iritis can occur with photophobia and pain. Cutaneous lesions and conjunctival involvement is treated with erythromycin ointment to prevent secondary bacterial infection. The cornea can have a "pseudodendrite," which is a poorly staining mucous plaque with no epithelial erosion (unlike HSV, which has a true dendrite with epithelial erosion and staining). The anterior chamber on slit-lamp examination can show manifestations of iritis (cell and flare). Iritis can be treated with topical steroids prednisolone acetate 1% (Pred Forte), one drop four to five times a day, and pain reduction can be achieved with topical cycloplegic agents (scopolamine 0.25% one drop tid or cyclopentolate 1% one drop tid). If HZO is diagnosed, admission and intravenous acyclovir should be considered, especially if any intracranial symptoms are present.

Treatment:

1. Erythromycin ophthalmic ointment to lesions to prevent secondary infection.
2. Oral narcotic analgesia if necessary.
3. Pred Forte one drop five times a day if iritis present and *no corneal epithelial defect* is seen on fluorescein staining and slit-lamp examination.
4. Cycloplegic pain reduction with 0.25% scopolamine or 1% cyclopentolate one drop tid.
5. Consideration for admission and intravenous acyclovir—dosage 30 mg/kg per day divided tid if creatinine is below 2.

Preseptal Cellulitis (Periorbital Cellulitis)

Preseptal cellulitis is a periocular superficial cellulitis that has not breached the orbital septum. The eyelids become edematous, warm, and red. The eye itself is not involved, with *acuity and pupillary reaction maintained* and *full ocular motility preserved*. The majority of cases occurring in children and adults are the result of inoculation secondary to skin infection or trauma (see Chap. 117, "Skin and Soft Tissue Infections"). The offending agent is usually *Staph. aureus*. These patients can frequently be treated with oral antibiotics, but if orbital involvement becomes evident, then intravenous antibiotics, CT scanning, and possible admission should be considered.

Preseptal cellulitis in children under 5 years of age is a special circumstance due to the association with bacteremia, septicemia, and meningitis and warrants a complete workup, including blood cultures and intravenous antibiotics. Although *Staph. aureus* is still the most common organism, often these children will have bacteremic spread of *H. influenzae* from otitis media or pneumonia. The incidence of *H. influenzae* preseptal cellulitis has been decreasing with the advent of the *H. influenzae* type b vaccine. Consultation with a pediatrician is recommended for consideration of admission.

Treatment:

1. Ascertain no restriction of ocular motility, no proptosis, no pain with eye movement, and preserved pupillary response and acuity.
2. Regarding those above 5 years of age:
   Children: Augmentin 20 to 40 mg/kg per day PO divided tid.
   Adults: Augmentin 500 mg PO tid.
3. Regarding those below 5 years of age or in severe cases, admit for intravenous antibiotics and systemic workup.
   Children: Ceftriaxone 100 mg/kg per day IV divided bid plus vancomycin 40 mg/kg per day IV divided tid.
   Adults: Ceftriaxone 1 to 2 g IV q 12 h plus vancomycin 0.5 to 1.0 g IV q 12 h.

Orbital Cellulitis (Postseptal Cellulitis)

Orbital cellulitis is an *orbital* infection; therefore it is deep to the orbital septum. This is a serious ocular infection that has the potential to be life-threatening. *Staph. aureus* is the most common pathogen; however, *H. influenzae* flu should be considered in young children and mucormycosis in diabetics and immunocompromised patients. Polymicrobial infection is common. Orbital extension of paranasal sinus infection (especially ethmoid sinusitis) is the most frequent source. Orbital and sinus computed tomography (CT) scans should be performed in the ED. If the CT is negative, an enhanced CT should be performed looking for a subperiosteal abscess. Diagnostic clinical findings that help distinguish this infection from preseptal cellulitis include EOM motility impairment, pain, fever, and occasionally proptosis. Decreased visual acuity is a late finding. Cavernous sinus thrombosis can also occur. These patients require a full workup, admission, and intravenous antibiotics.

Treatment:

1. Intravenous cefuroxime alone, or intravenous penicillin plus nafcillin, or chloramphenicol plus nafcillin. In penicillin-allergic patients vancomycin or a cephalosporin can be substituted.
2. CT scanning of orbits and paranasal sinuses; if CT is negative, then CT with contrast should be ordered to identify subperiosteal abscess.
3. Admission

Corneal Ulcer

A corneal ulcer is a serious infection involving multiple layers of the cornea. Corneal ulcers develop secondary to breaks in the epithelial barrier, allowing infectious agents to gain access to the underlying corneal stroma. The initial disruption of the epithelial layer can be due to desquamation, trauma, or direct microbial invasion. Exposure keratitis from incomplete lid closure secondary to Bell palsy can cause corneal desiccation and sloughing of the epithelium, allowing bacteria to gain access to the underlying stroma and create an ulcer. Trauma can also breach the epithelium and inoculate the cornea. Wearing of soft contact lenses is a very common cause of corneal ulcers, and the incidence increases dramatically in those who use extended-wear lenses and wearers who sleep with them in place.

Typically the patient will have a painful red eye, with tearing and occasionally photophobia. Examination reveals a staining epithelial defect and a white, hazy infiltrate underlying the defect and spreading into adjacent stroma. Occasionally a hypopyon is also present on slit-lamp examination (see Fig. 230-7), signifying an intraocular inflammatory response. Corneal ulcers need to be treated aggressively with topical antibiotics. A fluoroquinolone such as ciprofloxacin (Ciloxan) or ofloxacin (Ocuflox), one drop every hour in the affected eye, is the recommended treatment. A topical cycloplegic agent such as cyclopentolate 1% (Cyclogyl), one drop tid, can also help with pain control. The eye *should not be patched* because of risk of *Pseudomonas* infection, which can cause rapid, aggressive ulceration, with corneal melting and perforation. All corneal ulcers should be referred to an ophthalmologist to be seen within 12 to 24 h.

Treatment:

1. Ciloxan or Ocuflox, one drop every hour.
2. No patching.
3. Topical cycloplegic (1% cyclopentolate or 0.25% scopolamine tid).
4. Ophthalmology referral within 24 h.

TRAUMA

Superficial Trauma

SUBCONJUNCTIVAL HEMORRHAGE   The fragile conjunctival vessels can rupture from trauma, sudden Valsalva pressure spikes (sneezing, coughing, vomiting, straining), hypertension, or spontaneously with no discernible etiology. No treatment is necessary, and the hemorrhage usually resolves within 2 weeks. If multiple recurrent episodes occur, coagulation studies and further investigation are warranted.

CONJUNCTIVAL ABRASION   Superficial conjunctival abrasions without any other associated ocular injury only requires erythromycin ointment bid for 2 to 3 days or

no treatment if very small. The lid should be everted and the fornix inspected under magnification for any residual particulate matter or organic debris.

CORNEAL ABRASION   Abrasions of the cornea are associated with pain, photophobia, and tearing. They can be the result of trauma or contact-lens wear. Visual acuity assessment can be difficult because of the patient's extreme discomfort. A drop of a topical anesthetic will often reduce the discomfort temporarily and facilitate visual acuity testing. A corneal epithelial defect will be present and is best seen with fluorescein staining and examination with a cobalt-blue light. The eyelid should be everted and inspected for foreign bodies. Examine the cornea for possible full-thickness injury (optical sectioning) and assess the anterior chamber with the slit lamp, looking for any associated injury. Adequate and persistent cycloplegia is essential to controlling pain. Reduction of ciliary spasm contributes significantly to pain relief and in most cases eliminates the need for narcotic pain medication. By the same token, inadequate cycloplegia almost mandates the need for oral analgesics. If an abrasion is larger than 2 mm or very painful, consider having the patient instill a cycloplegic agent (cyclopentolate 1%, homatropine 5%, or scopolamine 0.25%), one drop every 6 to 8 h at home to help control discomfort. Scopolamine dilates the pupil for several days and is usually reserved for very large, painful abrasions. Cyclopentolate 1% (Cyclogyl) one drop tid does an excellent job of providing cycloplegia and wears off within 24 h of discontinuation. Erythromycin ophthalmic ointment should be instilled and an eye patch may be placed, if desired, provided that the abrasion was not from an organic source or from the wearing of soft contact lenses. Abrasions will heal with or without a patch and ophthalmologists will treat patients either way. Some patients appear to be more comfortable with an eye patch for the first 12 to 18 h, but this is not uniform and the physician can make an individual decision with the patient. Abrasions from organic sources have fungal potential and should not be patched. Abrasions related to the wearing of soft contact lenses pose a risk of *Pseudomonas* infection and likewise should not be patched. These patients should be treated with tobramycin ointment qid, followed by a fluoroquinolone (Ciloxan, Ocuflox) drop or tobramycin drop qid once the epithelial defect starts to close. Do not prescribe a topical anesthetic for pain relief, most anesthetics cause corneal toxicity when recurrently dosed and can lead to blinding complications.

Documenting the Dimensions of a Corneal Abrasion   Some slit lamps (Haag-Streit) have a measuring dial attached to the mechanism that varies the length of the slit beam (Fig. 230-11, Plate 13). If your slit lamp is equipped with this feature, you can vary the length of the slit beam on the cornea until it corresponds to the length or width of the abrasion. The reading on the wheel equals the length of the slit beam in millimeters. This additional feature allows you to document the dimensions of the abrasion precisely, thereby enabling subsequent examiners to evaluate the wound's healing response objectively.
FIG. 230-11. (Plate 13). Slit-lamp measuring wheel. The length of the light beam on the cornea can be varied and the reading on the dial represents the length in millimeters. Useful in measuring corneal abrasion dimensions.

Treatment:

1. Identify source of abrasion if possible.
2. Cycloplegia (cyclopentolate 1%, or homatropine 5%) one drop now and repeat q 6–8 h as needed for pain. Warn patient that the pupil will dilate, lose its ability to focus at near, and that the drop will burn for 10 to 15 s when placed in the eye.
3. Not related to contact-lens wear: Erythryomycin ophthalmic ointment and eye patch, or no patch and erythromycin ointment qid.
4. Related to contact-lens wear: Tobramycin ophthalmic ointment qid. *No patch.*
5. Organic source: Erythromycin ophthalmic ointment qid. *No patch.*
6. Ophthalmology referral or reexamine next day.

CONJUNCTIVAL FOREIGN BODIES   Conjunctival foreign bodies can usually be removed with a moistened, cotton-tipped applicator after anesthetizing the eye with a topical anesthetic. The upper eyelid should be everted and inspected under the highest magnification available to avoid missing any additional foreign bodies. Frequently small wooden particles such as sawdust will blend into the conjunctiva when moistened by the tears and be difficult to find without slit-lamp magnification. Small, fine vertical corneal abrasions seen only with fluorescein staining will often alert the physician to the presence of a foreign body embedded in the tarsal conjunctiva of the upper lid.

CORNEAL FOREIGN BODIES   Foreign bodies should be removed carefully under the best magnification available. The slit lamp provides sufficient magnification and allows both hands to be free for use. A history consistent with high-velocity ocular impact (i.e., hammering metal on metal) should alert you to the possibility of a penetrating injury. The cornea should be inspected using "optical sectioning" (see Fig. 230-11) to assess depth of penetration *prior* to removal. Full-thickness foreign bodies should not be removed in the ED and require an ophthalmology consult. Fortunately most corneal foreign bodies are superficial and can be removed easily and safely. A "golf-club spud" is a handy tool for this task, but a small 30- to 25-gauge needle under slit lamp magnification, or moistened, cotton-tipped applicator will work most of the time. A topical anesthetic should be instilled prior to removal, and it is helpful to also instill an anesthetic drop in the unaffected eye to suppress reflex blinking during removal. Many slit lamps have an attached "fixation light" that is mobile and can be moved in front of the unaffected eye to give the patient a steady target to concentrate on. This reduces the random movements that can occur when you are trying to remove the foreign body. The eyelids can be held open with your fingers, or a wire eyelid speculum can provide excellent support during the procedure. Metallic foreign bodies can create rust rings that are toxic to the corneal tissue. If a rust ring is present, the spud or an ophthalmic burr can be used to remove most of the rust. Even if a thorough job is done initially, the next day more rust can often be seen, requiring additional burring. It is therefore not necessary to go after all the rust aggressively in the ED if the patient can be seen by an ophthalmologist the next day. The rust-ring area can soften overnight and be removed in the office the next day. The deeper the stromal involvement, the higher the risk of corneal scarring; therefore, only a superficial burring should take place in the ED. No ED drill burring should take place if the rust ring is located in the visual axis (pupil) owing to the risk of causing visually significant scarring. These patients should have an ophthalmologist remove the stromal rust in the office within 24 h. As with any foreign body of the eye, the lid should be everted and inspected under magnification to ensure that no additional foreign bodies are present. The corneal abrasion that will be present after the removal of a foreign body should be treated as previously discussed, with adequate cycloplegia, antibiotic ointment, and optional patching.

Treatment:

1. Instill topical anesthetic in both eyes to suppress the blink reflex.
2. Test visual acuity (sometimes easier after an anesthetic drop is administered).
3. Assess if this is a full-thickness or penetrating injury.
4. Remove the foreign body under slit-lamp magnification and remove superficial rust if possible. Use burr if available, but avoid burring in visual axis.
5. Evert lid to rule out additional foreign bodies.
6. Treat resultant corneal abrasion with topical cycloplegia, erythromycin ointment, and optional patching (see "Conjunctival Abrasion," above).
7. Referral to ophthalmologist, to be seen the next day.

Lid Lacerations

Full-thickness lid lacerations should be repaired by an ophthalmologist, if at all possible, within 24 h. Proper alignment of the lid margin during repair under magnification (loupes or microscope) is essential to preserve proper lid function and even corneal wetting with each blink. Improper lid closure can result in notching of the lid and create a functional deformity. If there is no opportunity for the patient to see an ophthalmologist, repair should be performed as in Fig. 230-12. One 6-0 silk vertical mattress suture, using the meibomian gland orifices as a landmark, or two 6-0 silk sutures (one approximating the anterior and the other the posterior lamella) are used to repair the lid margin. The ends of the silk sutures should be left long enough to tuck under the more distal skin sutures to avoid corneal irritation.

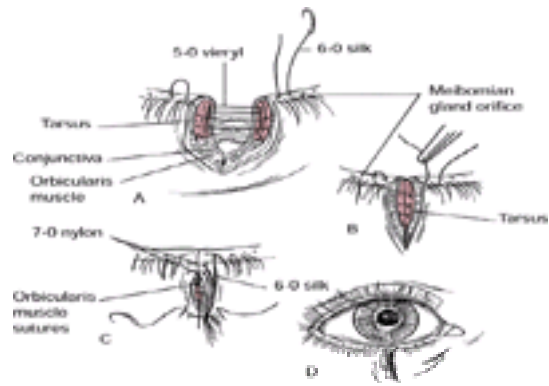
The tarsus should be repaired with 5-0 Vicryl from the external side so as to approximate the wound without the need for sutures on the conjunctival side of the lid (which would abrade the cornea with each blink). Skin closure can be performed with 6-0 or 7-0 monofilament or silk suture. Deep lacerations medial to the punctum can potentially transect the canalicular system. These patients need to be seen by an ophthalmologist for evaluation of the nasolacrimal duct system's integrity. If a canalicular laceration is discovered, the patient will need to go to the operating room within 24 to 36 h for repair and Silastic tube stenting (Fig. 230-13, Plate 14). Because a meticulous repair by an experienced eye surgery team is preferable, it is not unreasonable for the ophthalmologist to discharge a patient seen late in the evening or on the weekend with arrangements for surgical repair to take place within the next 36 h. Patients discharged pending repair should be placed on oral and topical antibiotics and told to use cold compresses. Oral cephalexin (Keflex) 500 mg bid or qid and topical erythromycin ophthalmic ointment qid are reasonable choices.


FIG. 230-12. Full-thickness lid repair. 6-0 silk used for lid margin. 5-0 Vicryl used to approximate tarsal plate. The Vicryl sutures should not pass through the conjunctiva on the inside of the eyelid to avoid mechanical abrasion of the cornea during blinking. 7-0 nylon is used for skin closure, and the lid margin silk suture tail can be incorporated into these sutures to avoid corneal irritation.
FIG. 230-13. (Plate 14). Traumatic canalicular laceration repair requires microsurgical stenting to reestablish patency.

Partial-thickness lid lacerations can usually be repaired in the ED with referral for ophthalmologic evaluation in 2 to 3 days. It is important to have the suture ends closest to the cornea tucked under more distal sutures to avoid corneal irritation (see Fig. 230-12).

Blunt Trauma

After sustaining blunt trauma, the eyelids are frequently swollen shut and the globe is difficult to visualize. Trying to pry the eyelids open with your fingers can be frustrating; it increases the intraocular pressure and usually results in obtaining an unsatisfactory view of the globe. A wire or adjustable eyelid speculum can help tremendously. Insertion of the eyelid speculum provides a significantly improved view of the cornea and anterior chamber and allows your hands to remain free for examination of the globe at the slit lamp. If a speculum is not available, try your best to assess the patient's visual acuity and the integrity of the globe and anterior chamber. If the anterior chamber is flat, a ruptured globe is certain and no further attempts to assess the eye should be made. A metal shield should be placed and an ophthalmologist consulted. A hyphema is also evidence of significant ocular trauma and necessitates an ophthalmology consult. If the globe appears intact and vision is preserved, next check ocular motility. Restricted upgaze or lateral gaze suggests a blowout fracture with entrapment (see " Blowout Fractures," below). Feel the orbital rim above and below for step-off deformities. Test for cutaneous sensation along the distribution of the inferior orbital nerve (below the eye and ipsilateral side of the nose). Perform a slit-lamp examination with fluorescein staining to check for abrasions, lacerations, foreign bodies, hyphema, iritis, and lens dislocation. Traumatic iritis is common, causing cell and flare to be seen on slit-lamp examination. If no corneal epithelial defect is seen, iritis can be treated with one drop of Pred Forte four to five times a day. The pupil can be constricted or dilated after sustaining trauma. It is important to look for pupillary irregularity, because the pupil will often peak toward the site of a penetration or rupture. If the anterior chamber is of normal depth and not shallow, one drop of Mydriacyl 1% will dilate the pupil and allow an easier funduscopic view. Non-Caucasian brown-eyed individuals will frequently require an additional drop of phenylephrine 2.5% to achieve adequate dilation. If vision as well as ocular anatomy and function are preserved, outpatient follow-up by an ophthalmologist in the next 48 h should be planned. If a ruptured globe is suspected (blind eye, flat anterior chamber, obvious full-thickness laceration, intraocular foreign body), no attempts at eye manipulation or IOP measurements should take place and an ophthalmologist should be consulted.

Treatment:

1. Assess globe integrity and vision.
2. If ruptured globe is suspected, do not attempt to check IOP; place a protective metal eye shield, check tetanus status, administer intravenous cephalosporin, let the patient take nothing by mouth, and call ophthalmology.
3. If ruptured globe is not suspected, proceed with the following.
4. Check eye motility and cutaneous sensation.
5. Obtain Waters view and/or orbital CT if blowout fracture or orbital/intraocular foreign body is suspected. Treat accordingly.
6. Slit-lamp examination of corneal, conjunctival, scleral, and anterior chamber structures.
7. Dilate if anterior chamber depth is normal for funduscopic view.
   Caucasians: Mydriacyl 1%, one drop.
   All others: Mydriacyl 1%, one drop, plus phenylephrine 2.5%, one drop.
8. Ophthalmology referral within 48 h if no injuries are found.

HYPHEMA   Blood in the anterior chamber is referred to as a hyphema (see Fig. 230-8). Hyphemas generally can be classified as either traumatic or spontaneous. Traumatic hyphemas are usually the result of bleeding from a ruptured iris root vessel. Both blunt and penetrating trauma can cause hyphemas. Spontaneous hyphemas are frequently associated with sickle cell disease. All hyphemas, regardless of etiology, should be seen by an ophthalmologist. ED management consists of assessing concomitant injury (ruptured globe, intraocular foreign body) and managing rises in intraocular pressure. The patient's head should be elevated to promote settling of suspended red blood cells inferiorly, so as not to clog the entire 360° of trabecular meshwork. The pupil should be dilated to avoid "pupillary play" (constriction and dilation movements of the iris in response to changing lighting conditions). Because an iris vessel is usually involved, pupillary activity can put the vessel on stretch, promoting additional bleeding. Pupillary dilation *does not* compromise the angle and aqueous outflow in normal individuals, and many ophthalmologists choose to dilate hyphemas for the above reasons. Intraocular pressure control is important and consists of topical b blockers, intravenous mannitol, topical a-adrenergic agonists (apraclonidine), and oral, topical, or intravenous carbonic anhydrase inhibitors (CAIs) such as Diamox, Trusopt, and Neptazane. In patients suspected of having sickle cell disease (either by history or if the hyphema was spontaneous), carbonic anhydrase inhibitors should be strictly avoided. CAIs will lower the aqueous pH in the anterior chamber, causing the red blood cells to sickle and become less flexible, thereby clogging outflow through the trabecular meshwork and increasing intraocular pressure. Rebleeding can occur 3 to 5 days later in up to 30 percent of cases, sometimes causing potentially blinding elevations

of IOP and necessitating surgical anterior chamber "washouts." Because of this risk, some ophthalmologists believe in admitting all patients with hyphemas, while others will choose to follow them closely as outpatients. Generally those with hyphemas occupying one-third or less of the anterior chamber can be followed closely as outpatients. Because of the variance in treatment philosophy, the ED physician should not take the responsibility of deciding to discharge a patient with a hyphema. This decision should be made by the ophthalmologist on call after he or she has examined the patient.

Treatment:

1. Elevate the patient's head.
2. Administer atropine 1% one drop tid.
3. Administer prednisolone acetate 1% (Pred Forte) one drop qid.
4. If globe is intact, measure IOP.
5. If IOP is greater than 30 mmHg, administer topical b blocker (Timoptic 0.5%), one drop. Give PO or IV acetazolamide (Diamox) 500 mg and add mannitol 1 to 2 g/kg IV if there is no response to the above.
6. If IOP is greater than 24 mmHg and the patient is sickle cell trait–positive, treat as above *except avoid Diamox.*
7. Arrange for ophthalmology consult.

BLOWOUT FRACTURES   The most frequent sites of orbital blowout fractures are the inferior wall (maxillary sinus) and medial wall (ethmoid sinus). A Waters view x-ray will frequently show a cloudy maxillary sinus on the side of the trauma. This represents blood and fluid in the maxillary sinus from fracture of the orbital floor. Fractures of the medial wall can be associated with subcutaneous emphysema, sometimes exacerbated by sneezing or blowing the nose. Fractures of the inferior wall with entrapment of the inferior rectus muscle can cause restriction of upgaze and diplopia (Fig. 230-14, Plate 15). Isolated blowout fractures with or without entrapment do not require immediate surgery and can be referred to ophthalmology, plastic surgery, oral maxillofacial (OMF) surgery or an ear/nose/throat specialist (depending on the local referral patterns) for repair within the next 3 to 10 days. CT scanning with 1.5-mm cuts of the orbit should take place, and oral antibiotics (Keflex 250 to 500 mg qid for 10 days) are often recommended because of the presence of sinus wall fractures. All blowout fractures with normal initial eye examination in the ED should be referred to an ophthalmologist for an outpatient full dilated examination to rule out any unidentified retinal tears or detachments. Some 32 percent of blowout fractures are associated with ocular trauma (abrasion, traumatic iritis, hyphema, lens dislocation/subluxation, retinal tear or detachment); therefore a careful eye examination in the ED and referral to an ophthalmologist are essential.

FIG. 230-14. (Plate 15). Inferior wall blowout fracture of the left eye with entrapment of the inferior rectus muscle. The patient's left eye is unable to look upward, causing diplopia on upgaze.

Penetrating Trauma/Ruptured Globe

Penetrating ocular trauma can occur from numerous sources (BB pellets, lawn mower projectiles, hammering, knife and gunshot wounds). Any projectile injury has the potential for penetrating the eye. Any lid laceration from a sharp object, especially if it involves the upper and lower eyelid has the potential to have lacerated the globe and requires a slit-lamp examination. Clues to a ruptured globe or intraocular foreign body include shallow anterior chamber, hyphema, irregular pupil, significant reduction in preinjury visual acuity, and poor view of the optic nerve and posterior pole on direct ophthalmoscopy. It is not unreasonable to dilate the eye with Mydriacyl 1% and phenylephrine 2.5% to obtain a better view of the posterior segment of the eye, facilitating identification of an intraocular foreign body or retinal detachment. A modified Seidel test is helpful in identifying wound leaks (see Fig. 230-7). Any penetrating injury is considered a ruptured globe and mandates an eye shield and ophthalmology consultation. Tetanus status should be determined and intravenous cephalosporin administered. Do not attempt to measure IOP if a ruptured globe is suspected. A Waters view x-ray and orbital CT scans can be helpful in locating and confirming the presence of orbital and intraocular foreign bodies.

Treatment:

1. If ruptured globe suspected, do not attempt to check IOP, place a protective metal eye shield, check tetanus status, administer intravenous cephalosporin, caution the patient to take nothing by mouth, and call ophthalmology.
2. Obtain a Waters view x-ray and/or orbital CT scans if foreign bodies are suspected.

Chemical Trauma

CHEMICAL OCULAR INJURY   A chemical injury to the eye is a true ocular emergency. The potential for chemical injury requires immediate recognition and treatment in the field and by the triage nurse. Immediate intervention consists of copious irrigation with at least 1 to 2 L of saline. Topical anesthesia and placement of a Morgan lens allows the irrigation to be delivered effectively and directly to the corneal surface. This is one situation where a delay even to assess visual acuity is inappropriate. Litmus paper or the pH portion of a urine dipstick can be used to assess the pH of the tears in the lower cul-de-sac. Irrigation should continue until pH testing improves to the range of 6 to 8. Both acid and alkali burns can be blinding; however, the majority of acid burns tend to coagulate proteins, thereby limiting the depth of penetration. Alkali burns (lye, ammonia) can rapidly penetrate the cornea, and aqueous pH can rise within minutes of exposure, causing damage to intraocular structures such as the iris and lens. After copious irrigation has been administered and the pH of the tears is close to normal, the eye should be inspected for any particulate matter and visual acuity should be assessed. A topical cycloplegic agent such as 0.25% scopolamine or 1% cyclopentolate should be used tid for pain reduction if an epithelial defect is present. Erythromycin ophthalmic ointment should be instilled qid if both eyes are affected. If only one eye is affected and an epithelial defect is present, adding a pressure patch for the first 12 to 24 h will sometimes make the eye more comfortable. Any patient with corneal clouding or epithelial defect after irrigation should receive prompt ophthalmology referral.

Patients with chemosis (edema of the bulbar conjunctiva overlying the white sclera) and no corneal or anterior chamber findings should be treated after irrigation with erythromycin ointment qid and referred for an ophthalmologic exam in the next 48 h. These patients are considered to have "chemical conjunctivitis."

Treatment:

1. Immediate copious irrigation with a minimum of 1 to 2 L of saline or until tear pH is 6 to 8.
2. If there is no corneal epithelial defect and the anterior segment is normal, administer erythromycin ointment qid.
3. If there is a corneal epithelial defect or there is clouding, administer erythromycin ointment, cycloplegia (cyclopentolate 1% or scopolamine 0.25%), and optional eye patching. Provide for ophthalmology referral within 24 h.

CYANOACRYLATE ("SUPER GLUE/CRAZY GLUE")   Cyanoacrylate adhesives are commonplace and often easily accessible to children. Accidental instillation into the eye and adnexa can cause the lids to adhere and adhesive clumps to form on the cornea. Most of the time these accidental instillations are not permanently harmful to the eye. Medicinal-grade cyanoacrylates are used occasionally directly on the cornea to seal corneal perforations and are not considered toxic to the cornea. The only concern is the mechanical abrasive effect of hard, irregular glue aggregates rubbing against the cornea with eye movement and blinking. Erythromycin is instilled heavily into the eye and on the surface of the eyelids to moisten, lubricate, and provide antibiotic coverage. Initial debridement of the surface

glue clump should be limited to easily removable pieces. The glue will loosen and become easier to remove in a few days. Referral to an ophthalmologist should take place within 24 to 48 h.

Treatment:

1. Moisten glue with erythromycin ointment and remove as much as can be removed easily without causing damage to underlying tissue.
2. Apply erythromycin ointment heavily into eye (if not glued completely shut) and eyelids five or six times a day.
3. Refer to ophthalmologist in next 24 to 48 h.

ULTRAVIOLET KERATITIS ("WELDER'S FLASH")   Pain, tearing, photophobia, and foreign-body sensation typically occur 6 to 12 h after unprotected ocular exposure to welding or sun-tanning lights. The history is diagnostic in these cases. Slit-lamp examination with fluorescein staining shows superficial punctate keratitis (SPK); this appears as numerous small microdots of staining on the corneal surface seen under high magnification using the cobalt-blue light. Treatment consists of cycloplegia, erythromycin ointment, and pressure patching overnight. Oral narcotic analgesia is sometimes necessary.

Treatment:

1. Instill cycloplegic agent: 1% cyclopentolate or 0.25% scopolamine, one drop in each eye; this may be repeated by the patient q 6 to 8 h if needed for pain reduction.
2. Erythromycin ophthalmic ointment now, then qid once the patch is removed.
3. Pressure patching for comfort for the first 24 h; bilateral is preferable but seldom practical.
4. Consider oral narcotic analgesia if pain is severe.
5. Ophthalmology referral within 48 h (this condition is usually self-limited, with complete recovery).

ACUTE VISUAL REDUCTION/LOSS

Painful Visual Reduction/Loss

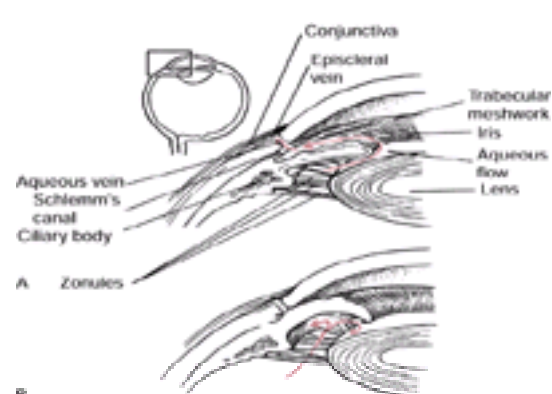
ACUTE ANGLE-CLOSURE GLAUCOMA   Acute angle-closure glaucoma presents with cloudy vision, eye ache and/or headache, increased intraocular pressure, and frequently nausea and vomiting. Abdominal symptoms can sometimes be misleading and delay the diagnosis. Acute angle closure typically occurs in a patient with *no* previous history of glaucoma. These patients generally have narrow anterior chamber angles and suddenly develop "pupillary block" when the pupil becomes middilated and the iris leaflet touches the lens. This prevents circulation of the aqueous humor from the posterior chamber (where it is produced by the ciliary body) through the pupil and into the anterior chamber (where it is filtered out of the eye through the trabecular meshwork located in the angle). The continuous production of aqueous in the posterior chamber is trapped and the increasing hydrostatic pressure bows the iris forward, further compromising the angle and inhibiting outflow (Fig. 230-15). Intraocular pressure rises and eventually exceeds the capacity of the corneal pump mechanism, causing the cornea to become edematous and less transparent. This explains the foggy vision or halos patients complain of and the hazy appearance of the cornea on physical examination. The pupil is *middilated and nonreactive* (Fig. 230-16, Plate 16). Pressures of 50 mmHg and greater are not uncommon. Treatment, aimed at pressure reduction, consists of using suppressants of aqueous production such as topical b blockers, a-adrenergic agonists (apraclonidine), and oral or intravenous CAIs (Diamox). Because patients are frequently nauseated, intravenous CAIs are preferable to oral ones. Intravenous mannitol is very good at quickly lowering intraocular pressure and should be considered an adjunct to treatment if there are no contraindications. Pilocarpine frequently will not cause the iris to constrict during the acute attack until the pressure is reduced. This is due to pressure-induced ischemic paralysis of the iris. Pilocarpine 1 or 2% should be added once the pressure is reduced to make the pupil miotic, thereby pulling the peripheral iris away from the angle. This maneuver will help protect against recurrence until an ophthalmologist can perform the definitive treatment procedure of creating a peripheral laser iridectomy.


FIG. 230-15. A. Normal flow of aqueous from ciliary body, through the pupil and out through the trabecular meshwork and Schlemm's canal located in the anterior chamber angle. **B.** Angle-closure glaucoma with pupillary block. Iris leaflet bows forward, blocking the chamber angle and prohibiting aqueous outflow. Meanwhile aqueous production continues and IOP rises.
FIG. 230-16. (Plate 16). Acute angle-closure glaucoma. Pupil is middilated and nonreactive. The cornea is hazy due to stromal edema.

Treatment:

1. Identify middilated, nonreactive pupil with increased IOP.
2. Topical b blocker (Timoptic 0.5%), one drop.
3. Topical a agonist (Iopidine 0.1%), one drop.
4. Topical steroid (Pred Forte 1%), one drop q 15 min for four doses, then hourly.
5. CAI (acetazolamide) 500 mg IV or PO.
6. Mannitol 1 to 2 g/kg IV.
7. Recheck IOP hourly.
8. Topical pilocarpine 1 to 2%, one drop qid once IOP is below 40 mmHg.
9. Consult ophthalmology.

OPTIC NEURITIS   Optic neuritis is the most common cause of acute reduction of vision due to optic nerve dysfunction in patients 20 to 40 years of age. Women are

more frequently affected. Reduction of vision is rapid and frequently painful (especially with eye movement). Color vision is commonly more affected than visual acuity. The red desaturation test is helpful in identifying optic neuropathies (have the patient look with one eye at a dark red object, then test the other eye to see if the object looks the same color. The affected eye will often see the red object as pink or lighter red). An afferent pupillary defect is commonly present. Visual acuity can range from mildly reduced to no light perception (NLP). If the optic disk is swollen and edematous on the affected side (papillitis), the patient is said to have anterior optic neuritis. If the head of the optic nerve is normal in appearance, the patient is said to have retrobulbar neuritis. The Optic Neuritis Treatment Trial (ONTT) showed that 1 year after an attack of optic neuritis, there was no difference in visual outcome between the patients treated with intravenous steroids and those given a placebo. Treatment with intravenous steroids, however, was associated with a slightly lower 2-year risk of subsequent development of multiple sclerosis, especially in patients whose MRI showed periventricular white matter lesions. For this reason, some physicians will consider intravenous steroids for any attack of optic neuritis, although no treatment is also acceptable. *Initial treatment with oral steroids is contraindicated* and, for unexplained reasons, had the least favorable outcome in the ONTT. Children can develop optic neuritis with similar initial findings except that the majority of them tend to have bilateral optic nerve swelling (simulating papilledema), and a viral illness is frequently associated with an attack. Subsequent development of multiple sclerosis occurs less frequently in children.

Treatment:

1. Check visual acuity, do red desaturation test, APD, eye pain with movement.
2. Check optic nerve head for papillitis (usually unilateral), may be bilateral in children or normal in retrobulbar neuritis.
3. Discuss with ophthalmologist or neurologist whether to treat with IV steroids * or discharge without treatment.

Painless Visual Reduction/Loss

CENTRAL RETINAL ARTERY OCCLUSION   Sudden, profound, painless, monocular loss of vision is characteristic of a central retinal artery occlusion (CRAO). The event is often preceded by episodes of amaurosis fugax. The first branch off the internal carotid artery is the ophthalmic artery, which supplies the central retinal artery, which, in turn, provides the blood supply to the inner retina. If the central retinal artery becomes occluded, the retina will infarct and become pale, less transparent, and edematous. The macula is the thinnest portion of the retina and the intact underlying choroidal circulation remains visible through this section of retina, creating the illusion of a "cherry-red spot." In fact, the macular area tends to maintain its normal color while the surrounding ischemic retina turns pale, thus causing this classic finding on funduscopy (Fig. 230-17, Plate 17). An APD is a common finding associated with a CRAO. Causes include embolus (carotid and cardiac), thrombosis, giant-cell arteritis, vasculitis (lupus), sickle cell disease, and trauma. Often the patient will have atrial fibrillation. The retina will sustain irreversible damage within 90 min of total occlusion, so treatment should begin immediately. Unfortunately these patients rarely respond to therapy, but because the visual loss is usually so profound, every attempt should be made to reestablish circulation to the retina. Treatment in embolic cases (the majority) is aimed at trying to convert a CRAO into a branch retinal artery occlusion (BRAO). In the attempt to dislodge the embolus from the central artery and into one of its retinal branches, the other retinal branches may become reperfused, thereby reducing the size of the infarct. Maneuvers include digital massage, IOP-lowering drugs, and vasodilation techniques (breathing into a paper bag to increase Pa$_{CO_2}$). An ophthalmologist should be consulted immediately to evaluate the patient and decide whether performing an IOP-lowering anterior chamber paracentesis is indicated.
FIG. 230-17. (**Plate 17**). Central retinal artery occlusion. Note macular "cherry-red spot" and retinal pallor between macula and disk. The retinal veins appear normal size, but the arteries are barely visible and attenuated.

Treatment:

1. Consult ophthalmology the moment the diagnosis is made.
2. Administer ocular massage: Firm, steady digital pressure on the globe through closed lids for about 15 s, followed by sudden release of pressure. This may be repeated several times.
3. Administer topical b blocker (Timoptic 0.5%), one drop.
4. Give Diamox 500 mg IV or PO.
5. Consider having the patient breathe into a paper bag for 5 to 10 min if there are no respiratory contraindications.

CENTRAL RETINAL VEIN OCCLUSION   Thrombosis of the central retinal vein causes retinal venous stasis, edema, and hemorrhage. Loss of vision is variable, painless, monocular, and rapid. Funduscopic examination typically reveals optic disk edema and diffuse retinal hemorrhages in all quadrants ("blood-and-thunder fundus," Fig. 230-18, Plate 18). The contralateral optic nerve and fundus are generally normal, which helps distinguish central retinal vein occlusion (CRVO) from papilledema, and the diffuse retinal hemorrhages help distinguish it from optic neuritis (the peripheral retina is normal in optic neuritis). Typically these patients have a history of hypertension, although hypercoagulable disorders, vasculitis, and glaucoma may also be associated. No specific treatment is available, although the addition of aspirin 60 to 325 mg daily is reasonable. These patients should be referred to an ophthalmologist for confirmation of the diagnosis and monitoring of ischemia-induced neovascularization.
FIG. 230-18. (**Plate 18**). Central retinal vein occlusion "blood and thunder fundus." Note diffuse retinal hemorrhages in all retina quadrants and blurred disk margins.

Treatment:

1. Ophthalmology referral.
2. Consider aspirin 60 to 325 mg/day PO.

GIANT-CELL ARTERITIS (TEMPORAL ARTERITIS)   Giant-cell arteritis (GCA) is a systemic vasculitis involving medium-sized arteries in the carotid circulation and can include the aorta and its primary branches. GCA can cause a painless ischemic optic neuropathy with devastating visual consequences and rapid contralateral involvement if not diagnosed and treated promptly. Patients are generally over 50 years of age and frequently have a history of polymyalgia rheumatica. Women are more commonly affected than men. Symptoms may include headache, jaw claudication, myalgias, fatigue, fever, anorexia, and temporal artery tenderness. Up to 33 percent may have associated neurologic symptoms such as transient ischemic attacks or stroke. The patient can develop rapid and profound visual loss, with the contralateral eye becoming involved within days to weeks. The physical examination will frequently reveal an APD if the optic nerve circulation is involved. An elevated Westergren sedimentation rate is usually present, with the majority of biopsy-proven cases in the range of 70 to 110. The added presence of an elevated C-reactive protein also suggests the diagnosis. Treatment consists of several doses of intravenous steroids, followed by oral steroids. Steroids should not be delayed while waiting for a temporal artery biopsy to be performed. Biopsies will still be positive a week after initiation of steroid therapy.

Treatment:

1. Order sedimentation rate and C-reactive protein.
2. Consult patient's personal physician.
3. If highly suspicious or any visual loss: Admit for methylprednisolone 250 mg q 6 h IV for 3 days and temporal artery biopsy.
4. If not suspicious and no visual involvement: prednisone 80 to 100 mg PO per day and close outpatient monitoring.

NEURO-OPHTHALMOLOGY

Approximately 38 percent of all the neurons in the brain have some association with the visual system; therefore an understanding of neuro-ophthalmology is essential.

Bell's Palsy

Bell's palsy is a dysfunction of peripheral cranial nerve (CN) VII commonly of viral origin. The orbicularis muscles are involved, frequently resulting in incomplete closure of the eyelids on the affected side. If the eye rolls up under the upper lid on attempted blinking (*Bell's phenomenon*), the cornea will be moistened and the risk of corneal exposure keratitis and subsequent ulceration will be less. These patients should still use viscous topical wetting agents, such as Celluvisc or Lacrilube, to keep the corneal epithelium from breaking down. Ophthalmology referral for outpatient monitoring of the cornea is warranted. The patient's medical doctor or neurologist should follow the patient for the dysfunction of CN VII and be involved in the decision to institute or forego oral steroid treatment, since this remains an area of controversy.

Treatment:

1. Test ipsilateral abduction [rule out genu VII Bell's palsy *]
2. Have patient use eye lubricants every 2 h (Celluvisc or artificial tears) and ointment at bedtime.
3. Consider oral steroids
4. Refer to ophthalmology for outpatient monitoring of cornea.

Diabetic/Hypertensive Cranial Nerve Palsies

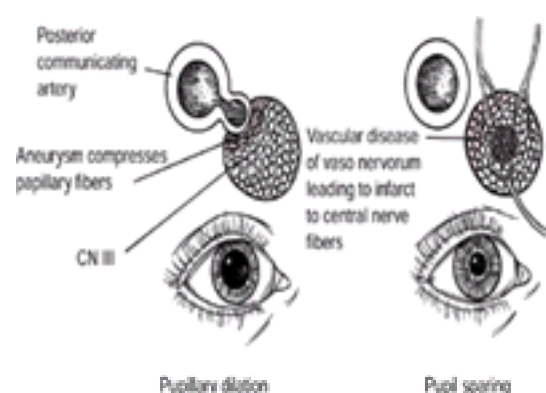
Chronic diabetes and hypertension can eventually create vascular compromise to the vasa nervorum of any CN. Frequently the patient will present with new-onset diplopia and an isolated CN III or VI palsy will be found on physical examination. The CN palsy is often painful, but it can be painless. The *pupil is spared* in acute diabetic CN III palsy due to vascular compromise of the central nerve fibers (the efferent pupillomotor fibers run in the periphery of the nerve—see Fig. 230-19). Extraocular muscle testing will reveal an inhibition of ipsilateral medial gaze, upward gaze, and downward gaze as well as ptosis in an acute CN III palsy. Lateral gaze (abduction) will be preserved, and diplopia will be worse when the patient attempts to look toward the contralateral side due to inability to adduct the eye (medial rectus dysfunction). In an acute CN VI palsy, lateral gaze will be diminished (abduction) on the ipsilateral side and diplopia will be worse when the patient is trying to look to the affected side (lateral rectus dysfunction). If no other associated neurologic symptoms or findings are present and the blood sugar and blood pressure are under control, the patient can be discharged with ophthalmology and/or neurology follow-up. Many of these palsies will resolve or improve over the following 3 months. Imaging is indicated if the history or physical suggests an intracranial lesion or if the palsy fails to improve over the next 6 to 12 weeks.


FIG. 230-19. PCA aneurysm compresses the peripherally located pupillomotor fibers of cranial nerve III, causing a nerve palsy and pupillary dilation. Diabetes and hypertension can cause microvascular compromise of the central nerve fibers causing a nerve palsy with pupil sparing.

Posterior Communicating Artery (PCA) Aneurysm

Acute cranial nerve III palsy with *ipsilateral pupillary dilation* is a PCA aneurysm until proven otherwise. Concomitant headache is a frequent but not absolute finding. Expansion of an aneurysm of the posterior communicating artery frequently causes compression of the outer fibers of CN III. The pupillomotor fibers are located in the outer portion of CN III; therefore the pupil becomes dilated on the affected side (see Fig. 230-19). These patients require emergent blood pressure reduction, neuroimaging, and neurosurgical consultation.

Internuclear Ophthalmoplegia (INO)

A stroke or demyelinating disease involving the medial longitudinal fasciculus (MLF) will cause the patient to experience diplopia, most noticeable when he or she attempts to look to the side opposite the lesion. EOM testing reveals an ipsilateral adduction weakness (medial rectus muscle only—not a CN III palsy).

EXAMPLE   If a patient has experienced a right (MLF) stroke, the right medial rectus muscle will not function when he or she attempts a leftward gaze and the patient will not be able to adduct the right eye. The left eye will abduct but may experience some nystagmus on leftward gaze. The patient will be able to look to the right without difficulty unless there is bilateral involvement. The patient will also be able to look up and down, revealing that the superior and inferior rectus muscles are functioning and that this is not a CN III palsy.

Treatment:

1. Same as with any newly diagnosed CVA.

2. Consider demyelinating disease if the patient is young.

Horner's Syndrome

The physical findings of ipsilateral ptosis and miosis are characteristic of Horner's syndrome (Fig. 230-20, Plate 19). Interruption of the sympathetic nerve impulses controlling the Mueller muscle in the upper eyelid and the iris dilators cause these classic findings. Interruption can occur anywhere along the pathway from the brain stem to the sympathetic plexus surrounding the carotid artery (Fig. 230-21). It is very important to determine whether this syndrome is acute or chronic. Patients with chronic disease can be evaluated on an outpatient basis, but all cases of acute disease require a full emergent evaluation. Workup includes a chest x-ray, CT of the brain and cervical region, and a carotid angiogram if a carotid dissection is suspected (acute Horner's syndrome with neck pain).

FIG. 230-20. (Plate 19). Horner's syndrome. Note ptosis and miosis of the right eye. This patient sustained an acute right carotid artery dissection after being hit in the neck with a football.
FIG. 230-21. Sympathetic nerve pathway of the eye. An interruption anywhere along this pathway can cause Horner's syndrome.

Causes of Horner's syndrome include, in adults, CVA, tumors, internal carotid dissection, herpes zoster, and trauma. In children, the causes include neuroblastoma, lymphoma, and metastasis.

Treatment:

1. Determine whether the condition is chronic or acute.
2. Chronic: outpatient workup by personal physician.
3. Acute: Evaluate for CVA, tumor, or carotid dissection. *

Papilledema

Papilledema is generally defined as bilateral edema of the head of the optic nerve due to increased intracranial pressure. It is a common finding in malignant hypertension, pseudotumor cerebri, intracranial tumors, and hydrocephalus. Any disease process that increases the ICP and thereby inhibits vascular or axoplasmic flow in the optic nerve causes congestion and edema of the nerve head. When only one nerve head is involved, it generally is not related to increased ICP. Monocular optic nerve edema or binocular involvement not associated with increased ICP is usually referred to as *optic nerve edema* or, if inflammatory in origin, *papillitis* (i.e., optic neuritis). Frequently the term *papilledema* has been used interchangeably in the literature to refer to monocular or binocular nerve head edema; however, most neuro-ophthalmologists reserve the term *papilledema* for bilateral nerve involvement due to increased ICP. Regardless of the etiology, the clinical findings on ophthalmoscopy of papilledema and papillitis are identical: the disk margins are blurred, the cup is diminished or absent, and the nerve head is elevated with vascular congestion (Fig. 230-22, Plate 20). Frequently flame-shaped hemorrhages are seen on or adjacent to the nerve head. A distinguishing feature of papilledema is prolonged preservation of visual acuity (frequently patients are visually asymptomatic). In this respect they differ markedly from patients with optic neuritis, who generally present with decreased visual acuity.
FIG. 230-22. (Plate 20). Optic nerve head edema. Vascular congestion, elevation of the nerve head, and blurred disk margins are characteristically seen in papilledema, papillitis, and compressive lesions of the optic nerve.

Pseudotumor Cerebri (Idiopathic Intracranial Hypertension)

Increased ICP, papilledema, normal cerebrospinal fluid, and normal CT/MRI characterize pseudotumor cerebri. Most patients are 20- to 30-year-old obese women, although this condition can occur at any age. Patients complain of nausea, vomiting, headaches, and transient visual obscurations. They can develop CN VI paresis, causing horizontal diplopia (double vision on lateral gaze). A variety of conditions (pregnancy) and exogenous agents (oral contraceptives, vitamin A, tetracycline, nalidixic acid, and corticosteroid withdrawal or prolonged use) have been associated with this poorly understood disease. It can be self-limited, but the recurrence rate can be as high as 40 percent and permanent loss of visual field can occur. Treatment is aimed at weight reduction and use of diuretics. Serial lumbar punctures are

sometimes performed to reduce ICP.

Treatment:

1. Identify papilledema.
2. Perform neuroimaging of brain (CT/MRI).
3. If CT/MRI normal, perform lumbar puncture and record opening pressure, send CSF for routine diagnostics.
4. If ICP is elevated and scans and CSF are normal, discuss with ophthalmologist/neurologist institution of diuretics (Diamox 500 mg PO bid) and outpatient visual field monitoring.

---

*Steroid regimen: methylprednisolone 250 mg IV qid for 3 days, followed by oral prednisone 1 mg/kg per day for 11 days.
*Genu VII Bell's palsy is a CVA masquerading as a peripheral seventh-nerve Bell's palsy. It is a stroke involving CN VI and the ipsilateral CN VII as it genuflects around the sixth-nerve nucleus. This results in a CN VII palsy identical to a typical Bell's palsy (affecting the upper and lower face ipsilaterally) but with the added finding of the patient's inability to abduct the ipsilateral eye (CN VI palsy). This underscores the importance of EOM testing in all Bell's palsy patients to avoid misdiagnosis of a CVA.].
*Neck pain and acute Horner's syndrome suggests carotid dissection and can occur spontaneously (usually at above age 30) or traumatically (see Fig. 230-21).

231 COMMON DISORDERS OF THE EXTERNAL, MIDDLE, AND INNER EAR

Anne Urdaneta
Michael Lucchesi

NORMAL ANATOMY

External Ear

The auricle, or pinna, is the visibly external portion of the ear, whose trumpet shape enables it to collect air vibrations. It consists of a thin plate of elastic cartilage with a tightly adherent covering of skin. The external auditory canal (EAC) is an S-shaped skin-lined tube that extends from the auricle to the tympanic membrane. The outer one-third of the EAC is composed of an incomplete cartilaginous tube; its thick skin contains hair follicles and apocrine and sebaceous glands. The inner two-thirds of the canal is composed of bone covered by a thin layer of tightly adherent skin, which is easily torn by minimal trauma.

The blood supply to the external ear is derived from the posterior auricular, superficial temporal, and deep auricular arteries. Venous drainage of the external ear is into the superficial temporal and posterior auricular veins and then into the external jugular vein. The posterior auricular vein frequently connects to the sigmoid sinus, providing a route for extension of infection into the intracranial cavity.

Middle Ear

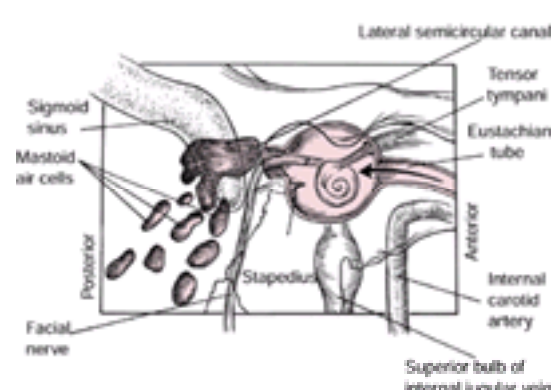
The middle ear is an air-containing cavity in the petrous temporal bone. It contains the auditory ossicles, which function to transmit vibrations of the tympanic membrane (TM) to the perilymph of the internal ear. It communicates with the nasopharynx anteriorly by the eustachian tube and with the mastoid air spaces posteriorly by the aditus ad antrum (Fig. 231-1).


FIG. 231-1. Sagittal section of the middle ear and related structures.

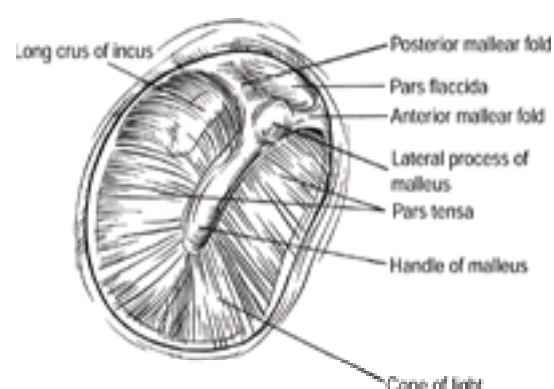
The TM is a thin, pearly gray, fibrous membrane, which, when illuminated, produces a cone-shaped light reflex anteroinferiorly. Superiorly, the pars flaccida is a relatively slack portion of the membrane lying between the malleolar folds; the remainder of the membrane is tense and is called the pars tensa. The auditory ossicles are the malleus, incus, and stapes. Both the incus and the handle and lateral processes of the malleus are typically visible through the TM (Fig. 231-2). The relationships of the facial nerve, sigmoid sinus, and internal carotid artery to the tympanic cavity are shown in Fig. 231-1.


FIG. 231-2. Right tympanic membrane as seen through the otoscope.

Inner Ear

The inner ear consists of the cochlea, which contains the auditory sensory receptors, and the vestibular labyrinth, which contains balance receptors. Cristae in the

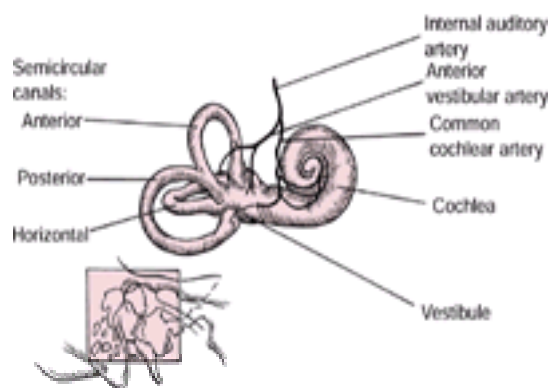
semicircular canals detect angular acceleration and macules detect linear acceleration. Afferent nerves from the vestibular labyrinth connect to brain stem nuclei to maintain smooth movement of the eyes during head movement and to the cerebellum to control oculomotor and postural functions. Blood supply is from the vertebrobasilar system. A branch of the anteroinferior cerebellar artery, the internal auditory artery, supplies the vestibular labyrinth. (See Fig. 231-3).


FIG. 231-3. Schematic drawing of the bony labyrinth containing the vestibular and auditory sensory organs. The otolithic organs (utricle and saccule) lie in the vestibule. The internal auditory artery divides into the common cochlear artery and the anterior vestibular artery. The anterior vestibular artery provides the blood supply to the anterior and horizontal semicircular canals but not to the cochlea. Isolated occlusion of the anterior vestibular artery may therefore cause acute vestibular syndrome without hearing loss.

COMMON EAR COMPLAINTS

Otalgia

Primary otalgia is caused by auricular and periauricular disease, while referred otalgia is caused by disease originating from remote structures. Referred otalgia is common because of the multiple cranial nerves and branches of the cervical plexus that supply sensory innervation to both the ear and other structures of the head and neck. The sensory innervation of the ear is mediated by the fifth, seventh, ninth, and tenth cranial nerves as well as the cervical plexus, with much overlapping and variability. Common causes of primary and referred otalgia are listed in Table 231-1.

Primary	Referred	Neuralgias
Trauma	Dental	Trigeminal
Infection	TMJ disease	(Tic douloureux)
Otitis externa	Abscessed teeth	Herpetic geniculate
Otitis media	Malocclusion	(Ramsay Hunt)
Mastoiditis	Bruxism	
Bullous myringitis	Trauma	
Foreign bodies	Retro- and oropharyngeal	
Cerumen impaction	Tonsillitis	
Cholesteatoma	Abscess	
Neoplasms	Neoplasm	
	Nasal cavity	
	Sinusitis	
	Deviated septum	
	Throat and neck	
	Foreign body	
	Thyroid disease	
	Cervical strain	
	Neoplasm	

TABLE 231-1   Causes of Otalgia

PRIMARY OTALGIA   The mandibular division of the trigeminal nerve mediates sensory innervation from the anterior outer ear: the auricle, tragus, EAC, and external surface of the TM. The facial nerve carries sensory innervation from the EAC and the skin behind the auricle. The glossopharyngeal nerve and the auricular branch of the vagus nerve (the Arnold nerve) carry sensory input from the medial ear structures. Branches of the second and third cervical nerves form the greater auricular and lesser occipital nerves, which receive input from the skin over the parotid gland and behind the ear, respectively.

Disease from any portion of the ear or its surrounding skin and structures may result in primary otalgia. A history and physical examination of the external ear, EAC, and TM will usually identify the cause of primary otalgia, with specific therapy as appropriate.

REFERRED OTALGIA   The maxillary and mandibular divisions of the trigeminal nerve receive sensory input from the nasopharynx, paranasal sinuses, teeth, parotid gland, and muscles of mastication. The facial nerve carries sensory innervation from the nasal mucosa and the ethmoid and sphenoid sinuses. The glossopharyngeal nerve carries sensory innervation from the nasopharynx, eustachian tube, soft palate, posterior pharynx, and tonsils. The vagus nerve mediates sensation from the valleculae and piriform sinuses, from the larynx via the superior laryngeal nerve, and from the cervical esophagus and trachea via the recurrent laryngeal nerve.

Abscessed and impacted teeth, usually mandibular molars, frequently cause ear pain. Malocclusion, bruxism, mandibular trauma, temporomandibular joint (TMJ) disorders, and ill-fitting dentures are frequent causes of otalgia.[1] Trigeminal neuralgia, or tic douloureux, causes severe unilateral facial pain. Herpetic geniculate neuralgia, or Ramsay Hunt syndrome, is herpes simplex of the EAC and auricle with facial palsy which may persist long after the disappearance of the vesicles (postherpetic neuralgia).

The diagnosis of the source of referred otalgia requires a history and physical examination that encompasses the nasal and oral cavities, nasopharynx, oropharynx, throat, and neck. Again, further evaluation and treatment depend upon diagnosis.

Tinnitus

Tinnitus is the perception of sound without external stimulation. It may be constant, pulsatile, high- or low-pitched, hissing, clicking, or ringing. It is most prevalent between the ages of 40 and 70 and has no gender predominance.[2]

Tinnitus is divided into two types: objective and subjective. Objective tinnitus may be heard by the examiner. Subjective tinnitus is more common. Its exact mechanism is unknown, although it is believed to result from damage to cochlear hair cells. Causes are outlined in Table 231-2.[2]

Objective	Subjective
Vascular	Sensorineural hearing loss
AV malformations	Hypertension
Arterial bruits	Conductive hearing loss
Mechanical	Head trauma
Enlarged eustachian tube	Medication
Palatomyoclonus	TMJ disorders
Stapedial muscle spasm	Depression, stress
	Neurologic
	Acoustic neuroma
	Multiple sclerosis
	Benign intracranial hypertension
	Meniere's disease
	Cogan syndrome

TABLE 231-2   Common Causes of Tinnitus

Pharmacologic side effects are the cause of tinnitus in at least 10 percent of cases.[2] The most commonly implicated drugs are aspirin (which may produce tinnitus in doses as low as 1.5 g/day) and aspirin-containing compounds, nonsteroidal anti-inflammatory drugs, and antibiotics, particularly aminoglycosides. (See Table 231-3 for a list of common ototoxic agents.)

Loop diuretics	Topical agents
Ethacrynic acid	Solvents
Furosemide	Propylene glycol
Bumetanide	Antiseptics
Salicylates	Ethanol
NSAIDs	Antibiotics
Quinine	Polymyxin B
Antibiotics	Neomycin
Aminoglycosides	
Erythromycin	
Vancomycin	
Chemotherapeutic agents	
Cisplatin	
Carboplatin	
Vinblastine	
Vincristine	

TABLE 231-3   Ototoxic Agents

Accurate diagnosis usually requires referral to an otolaryngologist. Many medications have been suggested as therapies, but antidepressants are currently the only class of drug found to be useful in alleviating tinnitus in which no correctable cause can be found.

Vertigo

Vertigo is the sensation of motion, either internal ("I feel myself turning") or external ("things seem to spin around me"). It may also be a sensation of linear movement, such as tilting. A careful history and physical examination should distinguish vertigo from other symptoms that cause light-headedness, such as postural hypotension, leg weakness, or peripheral neuropathy.

The history should identify the onset, duration, and frequency of the symptom as well as the presence of crucial movements or positions that precipitate it. Ask about accompanying symptoms such as nausea, vomiting, otalgia, tinnitus, hearing loss, or a sensation of aural fullness. Finally, any clearly precipitating events such as head trauma or recent upper respiratory tract infections should be identified.

In addition to a general physical exam, the Dix-Hallpike maneuver[3] may be performed to check for benign positional vertigo. The maneuver is performed by starting with the patient sitting up, with the patient's head held firmly in the examiner's hands. The patient is quickly laid supine while turning his or her head to one side and extending the neck. After a latent period of about 2 s, a rotatory nystagmus may appear, generally toward the downward-facing ear (clockwise when the patient's head is to the left, counterclockwise when it is to the right). When the patient is again seated upright, a reverse rotatory nystagmus may be observed. The maneuver should be repeated in each direction a number of times to determine whether the nystagmus is extinguishable.

The differential diagnosis of vertigo is large and may be divided into central and peripheral types (Table 231-4).[3,4 and 5] Acoustic neuroma should be considered if there is a concomitant unilateral sensorineural hearing loss. Vertigo may be a symptom of a vertebrobasilar insufficiency or stroke. While classic teaching has stated that vertebrobasilar insufficiency should be accompanied by brain stem findings such as diplopia, dysarthria, dysphagia, or focal deficits, isolated vertigo in a patient with risk factors for stroke is becoming more commonly recognized.[6] Peripheral causes of vertigo, or vestibular vertigo, include benign positional vertigo (BPV), labyrinthitis, Meniere's disease, and perilymphatic fistula. Common causes of peripheral vertigo are discussed below. See Chap. 223 for further discussion.

Systemic	Central	Peripheral
Autoimmune disorders	Acoustic neuroma	Benign positional
Hypo- and hyperthyroidism	Multiple sclerosis	Labyrinthitis
Diabetes mellitus	Vascular insufficiency	Meniere's disease
Anemia	Vertebrobasilar stroke or insufficiency	Cogan syndrome
Leukemia		Perilymphatic fistula
Otosyphilis		

TABLE 231-4   Causes of Vertigo

BENIGN POSITIONAL VERTIGO   BPV is the most common form of peripheral vertigo. Generally, the patient will complain that the vertigo occurs with head movement, typically while turning over in bed or quickly turning the head to one side; it usually lasts seconds to minutes. It is most often idiopathic in nature but is also common secondary to head trauma or viral infections. The peak age of onset is during the sixth decade in the idiopathic group, with a 2:1 female predominance, and in the fourth and fifth decades in the posttraumatic group, with no gender predominance. The pathophysiology of BPV is disputed, but it has been thought to result from lesions of the otolith organs of the inner ear or from deposits in the semicircular canals. BPV is by definition paroxysmal and positional and is reproducible using the Dix-Hallpike maneuver. The nystagmus elicited is usually but not always extinguishable. [3]

LABYRINTHITIS   Labyrinthitis, or vestibular neuronitis, is characterized by the acute onset of a severe vertiginous episode, often accompanied by nausea or vomiting but usually without tinnitus or hearing loss. Typically the symptom develops over a period of hours and peaks the first day, with a gradual and complete recovery in days. It is usually caused by a viral infection from an upper respiratory tract pathogen.

MENIERE'S DISEASE   Meniere's disease, or endolymphatic hydrops, is a diagnosis of exclusion. The classic presentation is of episodic vertigo, hearing loss, tinnitus, and a sensation of aural fullness, although not all symptoms may be present and they may not all occur simultaneously. The symptoms may last seconds to hours, and episodes typically occur in clusters followed by periods of remission. The pathophysiology is thought to be a dilatation of the endolymph-containing spaces of the inner ear, although the primary causative factor is unknown.

PERILYMPHATIC FISTULA   Perilymphatic fistula is another cause of vestibular vertigo lasting minutes to hours and involves rupture of the cochlear membranes with leakage of perilymph from the middle to the inner ear. It may result from surgery, from strenuous physical activity such as weight lifting, or from excessive pressure changes such as may occur during scuba diving or flying.

Primary treatment of vestibular vertigo is often medical and aimed at suppression of the vestibular system. Antihistamines such as meclizine, phenothiazines such as

prochlorperazine, and scopolamine have all been used in the treatment of peripheral vertigo. Specific treatment for Meniere's disease may also include salt restriction and diuretics. Surgery may be necessary for cases refractory to medical therapy.

For those patients in whom BPV may be diagnosed with reasonable certainty, an appropriate plan is a course of medical therapy with otolaryngologic follow-up if symptoms persist more than 1 week. All others should have prompt neurologic or otolaryngologic referral to rule out a central origin of the symptom.

Hearing Loss

Hearing loss may be divided into conductive and sensorineural types; the Weber and Rinne tests may be performed to differentiate between the two. The term *sudden hearing loss* refers only to the sensorineural type.

SUDDEN HEARING LOSS Sudden hearing loss (SHL) is a sensorineural hearing loss occurring over 3 days or less. The incidence increases with increasing age, and there is no gender predominance. Indicators of poor prognosis include more severe hearing loss on presentation and the presence of vertigo. Although most cases of SHL are idiopathic, implicated etiologies include infection, vascular causes, and trauma as well as metabolic disturbances and ototoxic drugs (Table 231-5).[7]

Infection	Rheumatologic
Mumps	Temporal arteritis
Epstein-Barr virus	Polyarteritis nodosa
Herpes	Wegener granulomatosis
Cytomegalovirus	Other
Syphilis	Meniere's disease
Labyrinthitis	Cogan syndrome
Hematologic and vascular	Acoustic neuroma
Leukemia	Pharmacologic
Sickle cell anemia	Cochlear rupture
Polycythemia	Conductive
Berger disease	Otitis externa
Cerebral aneurysm	Otitis media
Metabolic	Ruptured tympanic membrane
Diabetes mellitus	Neoplasms
Hyperlipidemia	Otosclerosis

TABLE 231-5   Causes of Sudden Hearing Loss

Viral infections, most typically mumps, have long been associated with SHL. Because of the terminal branches and interosseous location of the blood supply to the inner ear, the ear is uniquely vulnerable to a variety of vascular and hematologic diseases. Cogan syndrome is an autoimmune disorder that presents with a bilateral hearing loss classically associated with tinnitus and vertigo. SHL may also be caused by mechanical or traumatic rupture of the cochlear membranes.

Many common medications have been implicated in SHL (see Table 231-3).[8,9,10,11,12,13 and 14] Although a variety of mechanisms are responsible for medication-induced SHL, a general rule is that risk of hearing loss increases with increasing dosage and length of use and is further aggravated by factors that impair drug metabolism and excretion, such as renal insufficiency.

The evaluation of SHL begins with a complete history and physical examination. Sudden conductive hearing loss results from obstruction of the EAC or from disturbances of the TM or ossicles. An evaluation of all current medications for possible ototoxic agents is necessary. A history of trauma or recollection of a "popping" noise preceding the hearing loss is a helpful diagnostic clue. Coexistent tinnitus or vertigo may point to Meniere's disease. Systemic illness should be considered.

The differential diagnosis includes both potentially reversible and potentially ominous causes. If the physical examination does not identify the cause, emergency otolaryngologic consultation is necessary.

INFECTIONS

Otitis Externa

Otitis externa includes infections and inflammation of the external auditory canal (EAC) and auricle. It may be divided into acute diffuse and malignant types.

ACUTE DIFFUSE OTITIS EXTERNA **Definition and Diagnosis** Also known simply as otitis externa (OE) or swimmer's ear, this infection is characterized by pruritus, pain, and tenderness of the external ear. Physical signs include erythema and edema of the EAC, which may spread to the tragus and auricle. Other signs are clear or purulent otorrhea and crusting of the EAC. As the disease progresses, the pain becomes intolerable and is present with mastication or any movement of the periauricular skin. Increasing edema eventually narrows the EAC lumen and may cause hearing impairment. In severe cases, infection may spread to the periauricular soft tissues and lymph nodes, and there may be lateral protrusion of the auricle secondary to inflammation.

Pathophysiology Predisposing factors for the development of OE are trauma to the skin of the EAC and elevation of the local pH. Constant contact with water, from swimming, bathing, or a humid environment both elevate the pH of the EAC skin and may cause maceration. Trauma is most commonly caused by scratching or by overzealous disimpaction of cerumen. Cerumen is an acidic mixture of sebaceous and apocrine gland secretions and desquamated epithelial cells. It forms a physical barrier that protects the EAC skin from violation, while the acidic pH has antimicrobial properties.

Microbiology The most common organisms implicated in OE are *Pseudomonas aeruginosa* and *Staphylococcus aureus*,[15] although one study found a polymicrobial etiology in one-third of patients and an anaerobic bacterial etiology in one-quarter, with *Bacteroides* species predominating.[16]

Otomycosis, or fungal OE, accounts for approximately 10 percent of cases, with a high percentage found in tropical climates.[17] A history may reveal the presence of diabetes or other immunocompromised states or previous long-term therapy with antibiotics. Most (80 to 90 percent) of otomycosis is due to *Aspergillus* species, and physical examination may reveal a black, blue-green, or yellow discoloration of the EAC. The second most common fungal pathogen is *Candida*.[17]

Noninfectious causes include contact dermatitis from topical medications or resins in hearing aids, seborrhea, and psoriasis.

Treatment The treatment of OE involves analgesia, cleansing of the EAC, acidifying agents, topical antimicrobials, and sometimes steroids. Cleansing may be done with gentle irrigation using hydrogen peroxide, and gentle debridement by the physician with a suction aspirator such as a Frasier suction.

A variety of topical agents exist that combine an antimicrobial agent with either an acid and/or a steroid. Table 231-6 lists the components of many otic preparations. No single agent has been shown to be more effective than the others, although the lower-pH preparations are thought to be better.[15] The burning associated with the acidic preparations may reduce compliance, however, and patients unable to tolerate the low pH of otic preparations may instead use the slightly more alkaline ophthalmic drops. Also, if there is suspected TM perforation or the TM cannot be visualized, antibiotic drops should be prescribed. Cortisporin Otic *Suspension* should only be used; the solution is toxic to the middle ear. The medication should be instilled into a cleansed ear while it is facing up, with this position held for 3 min. This should be done four times daily for at least 10 days or until after the resolution of symptoms. If edema of the EAC obstructs the lumen, a commercial wick or piece of gauze may be inserted into the EAC and kept moist with the otic drops.

Preparation	Constituents	Comments
CiproHC Otic	Ciprofloxacin Hydrocortisone	Not safe with perforation
Cortisporin Otic	Neomycin Polymixin B Hydrocortisone	Use suspension* only Theoretic potential for ototoxicity; no longer widely used.
Floxin Otic	Ofloxacin	Safe with perforations; 5 drops bid
Otic Domeboro	2% Acetic acid solution	pH 4.5–6.0
VoSol HC Otic	Acetic acid Hydrocortisone	pH 3.0

*Solution is thinner and more easily absorbed through the round window or a perforation.

TABLE 231-6   Some Common Topical Otic Preparations

Bacterial and fungal cultures may guide treatment of nonresponsive cases. Oral antibiotic therapy should be reserved for febrile patients and those with periauricular extension. All patients with OE should be taught to avoid predisposing factors in order to eliminate recurrences. Strategies include ear plugs while swimming or bathing (cotton wool impregnated with Vaseline or commercial ear plugs), occasional, brief use of a hair dryer to remove EAC water, and avoidance of cotton-tipped applicators or other devices to remove cerumen.

Specific treatment of otomycosis consists of antifungal agents such as clotrimazole. *Aspergillus* is not sensitive to most oral antifungals with the exception of itraconazole.[17] With noninfectious OE, removal of the offending agent is the first step in treatment. Topical steroid drops may be used for seborrhea and psoriasis.

Finally, all patients should be instructed to follow up with their primary physician or an otolaryngologist if the condition worsens at any time or does not respond to treatment in 1 week; these patients must be evaluated for the more serious disease of malignant otitis externa.

MALIGNANT OTITIS EXTERNA   Definitions   Malignant otitis externa (MOE) is a potentially life-threatening infection of the EAC with variable extension to the skull base. It is almost always caused by *P. aeruginosa*. The term *MOE* actually refers to a spectrum of disease. When it is limited to the soft tissues and cartilage, it is called necrotizing otitis externa (NOE). When there is involvement of the temporal bone or skull base it is called skull-base osteomyelitis (SBO).

Pathophysiology   MOE begins as a simple otitis externa that then spreads to the deeper tissues of the EAC and infects cartilage, periosteum, and bone, with the normal anatomy of the ear serving as the conduit for the spread of infection. The cartilaginous floor of the EAC has clefts, known as the fissures of Santorini, through which the infection may spread to deeper structures. The parotid gland and TMJ are anterior, the mastoid air cells are posterior, and the skull base, carotid artery, jugular bulb, and sigmoid sinus are inferomedial. Infection may spread to any of these structures as well as to the seventh cranial nerve as it exits the stylomastoid foramen and the ninth, tenth, and eleventh cranial nerves at the jugular foramen.

The typical patient with MOE is the elderly diabetic. The impaired immune response of the diabetic, which is further compromised in the elderly, may predispose to the onset of pseudomonal infection. Furthermore, the cerumen of diabetic patients has been found to have a higher pH than that of normal controls; this represents an additional breakdown in local defense mechanisms. Finally, the small blood vessel disease of diabetics may lead to cartilaginous degeneration, further promoting the spread of infection.

Microbiology   The most common causative organism of MOE is *P. aeruginosa. Aspergillus* has been reported to cause SBO, usually in patients who are immunosupressed due to AIDS or other causes. *Aspergillus* SBO also has a different presentation than typical pseudomonal SBO in that the infection generally begins in the middle ear rather than in the EAC.

Diagnosis   Any elderly, diabetic, or immunocompromised patient presenting with OE or any person with persistent OE despite 2 to 3 weeks of topical antimicrobial therapy should be suspected of having MOE. The typical presentation is similar to that of OE: otalgia and edema of the EAC with or without otorrhea. The otalgia may be out of proportion for routine OE. Granulation tissue may be evident on the floor of the EAC near the bone-cartilage junction.

The history and physical examination should also be directed toward determining the extent of progression of the disease by identifying involvement of nearby structures. Parotitis may be present, and trismus indicates involvement of the masseter muscle or TMJ. Cranial nerve involvement is a serious sign; the history and examination should specifically rule out facial palsy and hoarseness or dysphagia. The seventh cranial nerve is usually the first affected, and the presence of dysfunction of the ninth, tenth, or eleventh cranial nerve implies even more extensive disease. Lateral or sigmoid sinus thrombosis and meningitis are also possible complications.

Certain patients may have an atypical clinical presentation and require special mention. MOE in children tends to to be rapidly progressive; thus children may be more ill appearing upon presentation, with fever, leukocytosis, and even bacteremia. Also, the TM, middle ear, and facial nerve are more likely to be involved in children than in adults. AIDS patients with MOE tend to be younger, have etiologic organisms other than *Pseudomonas,* and tend to have a worse prognosis than patients without AIDS.

Diagnosing MOE depends first on having a high index of suspicion; emergent otolaryngologic consultation is necessary. The next step involves radiographic confirmation and staging of the disease with CT of the head, focusing on the EAC and temporal bone (Table 231-7).[17]

RADIOLOGIC STAGING	
Stage I	Soft tissue involvement only (NOE)
Stage II	Bony involvement limited to mastoid (Early SBO)
Stage III	Extensive SBO (May involve occipital, facial or contralateral temporal bone)
CLINICAL STAGING	
Stage I	Involvement limited to EAC and mastoid
Stage II	SBO with cranial nerve involvement
Stage III	Extension to brain and meninges

Key: NOE, necrotizing otitis externa; SBO, skull-base osteomyelitis; EAC, external auditory canal.

TABLE 231-7   Staging of Malignant Otitis Externa

Treatment   Once the diagnosis of MOE has been made, the patient must be admitted to the hospital for parenteral antibiotics. Therapy with an aminoglycoside and antipseudomonal penicillin, or cephalosporin, or quinolone is standard, and should be initiated in the emergency department. Selected cases may be managed with oral quinolones, depending on the otolaryngologist's preference.

The ultimate prognosis of MOE is primarily based on the stage of disease at presentation. Earlier stages are likely to completely resolve with a single course of antibiotic therapy, while more advanced stages may require surgical debridement and may ultimately prove fatal.

Otitis Media

EPIDEMIOLOGY   Otitis media (OM) is primarily a disease of infancy and childhood. Although adults may present with OM, its incidence and prevalence peak in the preschool years and then decrease with increasing age. There is little or no literature to suggest that the diagnosis or management of OM in adults differs from that in children. The decrease in incidence of OM from childhood through adolescence is thought to be due to the changing anatomy of the eustachian tube; between infancy and adulthood the eustachian tube angle and length both increase, promoting drainage of the middle ear and offering a greater physical barrier to the migration of bacteria from the nasopharynx to the middle ear.

MICROBIOLOGY   The most common bacterial pathogens in acute OM are *Streptococcus pneumoniae, Haemophilus influenzae,* and *Moraxella catarrhalis.* The predominant organisms involved in chronic OM are *Staphylococcus aureus, P. aeruginosa,* and anaerobic bacteria.[18] Viruses probably play a role in the pathogenesis of OM in that they may promote bacterial superinfection by impairing eustachian tube function and other host defense mechanisms; they may also interfere with host response to antimicrobial drugs.

DIAGNOSIS   The patient with OM will present with otalgia with or without fever. Otorrhea and hearing loss are variably present, while tinnitus, vertigo, and nystagmus are uncommon. The TM may be retracted or bulging. It may be red in color, indicating inflammation, or it may be yellow or white, due to middle ear secretions. Pneumatic otoscopy demonstrates impaired mobility. The facial nerve should always be assessed because of its proximity to the middle ear.

TREATMENT   Oral antimicrobial agents are the therapy of choice for acute OM. Initial treatment should be with one of the following, for 7 to 10 days: amoxicillin, trimethoprim-sulfamethoxazole, or erythromycin plus sulfamethoxazole. OM unresponsive to initial therapy should be treated with one of the alternate drugs for the same period of time; this method will generally eradicate organisms that are resistant to one of the drugs. Topical therapy should be avoided in cases with an associated TM rupture. Since pain usually continues for 8 to 24 h after the initiation of antibiotics, the addition of acetaminophen or ibuprofen analgesia is appropriate. OM with effusion requires treatment with the same antimicrobials, but for 3 weeks, and prednisone may be added.[18]

Adults with simple acute OM should receive follow-up to assess treatment efficacy and to ensure that there is no anatomic obstruction to the eustachian tube, as for example, from occult carcinoma. Any patient who presents with complications of OM or who appears septic should have urgent consultation for diagnostic and therapeutic tympanocentesis and possible admission for intravenous antibiotics.

Complications

Complications of OM can be divided into intratemporal and intracranial types. Perforation of the TM is a common intratemporal complication and most often occurs in the pars tensa from the increased pressure of middle ear secretions, with resultant otorrhea. Healing usually occurs in 1 week, although a chronic perforation may result. A temporary conductive hearing loss may occur with OM secondary to fluid in the middle ear; the hearing loss resolves as the fluid is resorbed. Acute serous labyrinthitis may occur when bacterial toxins enter the inner ear via the round window. Facial nerve paralysis is an uncommon complication but requires emergent otolaryngology consultation.

ACUTE MASTOIDITIS   One of the most serious complications of acute OM is acute mastoiditis. This occurs as infection spreads from the middle ear to the mastoid air cells via the aditus ad antrum. When this opening becomes blocked, the mastoid cavity becomes a closed space, and the mastoid air cells become filled with fluid and inflamed. Spread through venous channels to the overlying periosteum is referred to as *acute mastoiditis with periostitis.* In addition to otalgia and fever, patients with mastoiditis will have postauricular erythema, swelling, and tenderness, with protrusion of the auricle and obliteration of the postauricular crease. Although the diagnosis can usually be made based on the history and physical examination, certain radiographic tests are indicated. Mastoid radiographs will demonstrate mastoid clouding due to fluid accumulation, and CT may delineate the extent of bony involvement. Mastoiditis requires admission for intravenous antibiotics, tympanocentesis, and myringotomy. Cefuroxime is frequently chosen as an initial empiric agent.[19] Incision and drainage of subperiosteal abscess or mastoidectomy may ultimately be indicated.

CHRONIC MASTOIDITIS   Chronic mastoiditis presents with chronic otorrhea and has an increased incidence in patients with nasopharyngeal tumors, Down syndrome, or craniofacial abnormalities. Each of these predisposing factors can cause obstruction of the eustachian tube. *P. aeruginosa* is the most common cause of chronic mastoiditis. Tuberculosis may also present as chronic mastoiditis.[19]

INTRACRANIAL COMPLICATIONS   Intracranial complications of OM are more likely with chronic than with acute OM and are, in general, decreasing with the widespread use of antibiotics in the treatment of OM. However, suppurative intracranial extension is a severe complication, and suggestive signs and symptoms should be investigated appropriately. Meningitis is the most common intracranial complication of OM; the most prevalent causative organisms are *Strep. pneumoniae* and *H. influenzae* type b. Extradural abscess and subdural empyema are also potential complications.

LATERAL SINUS THROMBOSIS   Lateral sinus thrombosis (LST) is another ominous complication of acute OM. It arises from extension of infection and inflammation in the mastoid, with eventual inflammation of the adjacent lateral or sigmoid sinus. Reactive thrombophlebitis with mural clot formation, intraluminal empyema, or perforation of the venous wall may occur. A high index of suspicion is necessary to diagnose LST because the common clinical findings are similar to those found in acute OM or mastoiditis.

Headache is the most common symptom, with papilledema, sixth-nerve palsy, and vertigo being less frequently present.[20] Angiography with venous phase and magnetic resonance imaging (MRI) are more sensitive than computed tomography (CT) in diagnosing LST. Although in the majority of cases of LST no bacterial isolates are recovered, antibiotic therapy is the initial treatment of choice. The agent should cover *Staphylococcus, Streptococcus,* and upper respiratory anaerobes and have good penetration of the blood-brain barrier. A combination of intravenous penicillin or nafcillin, ceftriaxone, and metronidazole has been recommended as an initial empiric regimen.[20] Most patients will also require surgical intervention.

CHOLESTEATOMA   A serious complication associated with chronic OM is cholesteatoma. Aural cholesteatoma is composed of epidermis and exfoliated keratin within pneumatized spaces of the temporal bone. It is an erosive, expanding lesion originating within the middle ear or mastoid air cells. As the cholesteatoma expands, it may erode the ossicular chain, bony labyrinth, or facial nerve canal. Cholesteatomas are often infected and their intracranial extensions may be life-threatening.

Bullous Myringitis

DEFINITION   Bullous myringitis is a painful condition of the ear characterized by bulla formation on the TM and deep EAC. Its epidemiology, etiology, and pathology are poorly understood. It may occur at any age, frequently after an upper respiratory tract infection.

PATHOPHYSIOLOGY   The blisters are believed to occur between the highly innervated outer epithelium and the inner fibrous layer of the TM, explaining the severe otalgia. The blisters may be blood-filled, serous, or serosanguinous. Middle ear effusions may be present, either sympathetic in origin or as a result of medial rupture of bullae. Otorrhea as a result of ruptured bullae is short-lived. A reversible hearing loss is commonly associated with the condition and may be conductive, sensorineural, or mixed.

MICROBIOLOGY   Although bullous myringitis was originally associated with influenza epidemics, since then numerous pathogens have been implicated in its etiology, including *Mycoplasma pneumoniae, Chlamydia psittaci,* and numerous viral pathogens. Herpes simplex has not been implicated as a causative agent.[21]

DIAGNOSIS   Patients with bullous myringitis typically present with severe, throbbing otalgia, often with hearing loss. Otoscopy reveals multiple fluid-filled blisters, which may be yellow to red in color. There may be bloody otorrhea or hemotympanum.

TREATMENT   As the etiologic agent of bullous myringitis remains elusive, treatment of the condition consists of warm compresses and systemic analgesia with acetaminophen or nonsteroidal anti-inflammatory drugs (NSAIDs). Oral antibiotics may be added in cases with an associated middle ear effusion, since some of these may represent a concomitant otitis media.

TRAUMA TO THE EAR

Although trauma to the ear is rarely life-threatening, its associated morbidity is significant and includes hearing loss and poor cosmetic outcome.

Abrasions can cause partial loss of the covering epidermis. Abrasions that do not penetrate to the underlying perichondrium should be thoroughly irrigated with normal saline. If there are any embedded foreign bodies, they should be meticulously removed to prevent infection and "tattooing" of the wound. A topical antimicrobial ointment with a contoured nonpressure dressing should be applied. The wound should be reevaluated in 24 h. Lacerations of the auricle require delicate closure with careful realignment to maintain the natural contour. (See Chap. 38.) Prior to closure, a thorough examination is required to determine the magnitude of the injury, followed by cleansing and irrigation with normal saline. Further exploration can be done with a sterile cotton swab to determine the actual extent of the injury and explore for any remaining foreign bodies. In simple lacerations not involving the perichondrium or cartilage, the skin can be approximated with everting nylon sutures. In lacerations involving the cartilage, the perichondrium should be sutured using 5-0 or 6-0 absorbable sutures. If debridement is necessary, the otolaryngologist may be consulted. After skin closure, an antimicrobial ointment and a firm, contoured, nonpressure dressing should be applied. Complete or partial avulsion injuries, especially those involving tissue loss exposing large areas of cartilage, should be referred to an otolaryngologist or plastic surgeon. [22,23,24 and 25]

Thermal Injuries

FROSTBITE   With its position of prominence and large surface area, the auricle is extremely susceptible to extremes in temperature. The thin subcutaneous tissue makes the auricle particularly susceptible to cold-induced injury. In frostbite, the ear will initially appear pale. In superficial frostbite injuries, the underlying tissue remains soft and pliable. In deep injuries, the underlying tissue is very hard. With rewarming, the ear may become painful, with edema and blister formation. If blisters do form, they should be allowed to reabsorb spontaneously. The ear should be aseptically and quickly rewarmed with saline-soaked gauze that has been warmed to 38 to 40°C (100.4 to 104°F). The rewarming process may be very painful and conscious sedation may be necessary.

BURNS   Burns of the upper body occur frequently, with burns of the face and neck representing about 30 percent of all burn injuries. In one study of patients sustaining significant facial burns, 42 percent suffered burns to the ears. [26] Direct thermal burns may be severe enough to cause necrosis and sloughing of the entire external ear. Even with lesser injury, disruption of the auricular skin can lead to damage of the underlying cartilage, which, once damaged, is particularly susceptible to infection. Factors that affect the healing of burn injuries include the depth of the burn, development of infection, and external pressure or friction on the burned auricle. [23] Otochondritis is a potentially disfiguring complication of otic burns. Chondritis may occur in up to 20 percent of significant otic burns and may appear anywhere from 2 to 5 weeks after the injury. The hallmarks of chondritis consist of helical dull pain followed by erythema, edema, exquisite tenderness to palpation, and an increase in the auriculocephalic angle (lateral protrusion of the ear from the head). [26] Once chondritis is present, treatment must be aggressive to preserve ear architecture; it usually consists of surgical debridement. Systemic antibiotics alone are generally considered ineffective.

First-degree burns involve only the superficial layers. Vascular congestion and dilation occur in the intradermal vessels. First-degree burns can be gently cleaned, and the patient can be discharged with mild analgesics as needed. Second-degree burns exhibit destruction of varying depths of epidermis, with coagulation necrosis. Third-degree burns involve destruction of all skin elements with coagulation of the subdermal plexus.

Burns more severe than first-degree should be seen in consultation with a burn unit or an otolaryngologist. If the burn is an isolated injury and a mild second-degree type, treatment in the emergency department should consist of meticulous cleaning and irrigation with normal saline, application of a non-sulfa-containing antimicrobial ointment, and a nonpressure dressing. Silvasulfadiazine ointment can cause skin pigmentation changes and should not be used above the clavicles. Referral should be made within 24 h. Substantial second-degree burns with blistering or any third-degree burns should be referred to a burn center for further management.

Hematoma

A hematoma can develop from almost any type of trauma to the ear. As a result of the lack of subcutaneous fat on the anterior surface of the auricle, blunt force applied to this area tends to shear the perichondrium from the underlying cartilage and tear the adjoining blood vessels. The cartilage depends on the perichondrial blood vessels for viability. Any separation can result in necrosis. In addition, a subperichondral collection can lead to stimulation of the overlying perichondrium, which can result in an asymmetrical formation of new cartilage and deformity of the auricle. The resultant deformed auricle has been referred to as "cauliflower ear," which was fairly common in wrestlers and boxers of the past. The auricular hematoma itself presents as a painful swelling after trauma, which obscures the normal contour of the ear. The hematoma may accumulate immediately or several hours after the insult; if it is large enough, it may have an ecchymotic hue. In the past, the advised treatment was aspiration of the hematoma. More current literature suggests that aspiration alone does not completely evacuate the clot and therefore leads to deformity and increased morbidity. The goal of treatment is to remove the fluid collection and maintain pressure in the area for several days to prevent reaccumulation of fluid. [24,25] After local anesthesia, and using sterile technique, a circular incision should be made through the skin with caution not to violate the underlying perichondrium. The incision should be the minimal necessary to drain the underlying hematoma and positioned in an area with the least exposure (the inner curvature of the helix or anthelix). The hematoma can then be removed by gentle suction or curettage. [24,25,26,27 and 28]

A dental roll or a firm sterile pledget can then be placed over the resutured site with through-and-through sutures connected to a similar bolster on the opposite side. [22] A nonpressure dressing with antibiotic ointment should then be applied and the patient given instructions as to reevaluation within 24 h to assure there has been no reaccumulation. Prophylactic antibiotics can be reserved for immunocompromised patients and should cover *P. aeruginosa* and *Staphylococcus aureus,* the two likely participants in posttraumatic chondritis.

Foreign Bodies

Foreign bodies in the external canal are commonly seen in the emergency department. The variations can include anything from cotton, pencil erasers, or pieces of toys to illicit drugs and insects. Organic materials such as beans, seeds, and vegetable matter may conform to the contour of the canal or expand if moistened, complicating the dilemma of removal. Insects that crawl into the ear can actually survive for a long period of time, causing a local inflammation and a great deal of distress to the patient.

The evaluation of a patient with a foreign body in the ear should begin with calming the patient and placing him or her in the reclined position. Occasionally the complaint may be sudden pain while in the recumbent position, as in the case of an embedded insect. Most of the time, the history will reveal the type of material in the ear. A thorough examination and visualization of the complete tympanic membrane is mandatory. Inability to visualize the entire canal, contact of the foreign body with the tympanic membrane, or the presence of a perforation mandates the use of an operative microscope and speculum, with obvious consultation. Foreign bodies in children medial to the bony isthmus often require conscious sedation or even general anesthesia for safe extraction. [29] Cerumen loops, a right-angle hook, and alligator forceps are the instruments of choice for the removal. Live objects should be drowned with a 2% lidocaine solution or viscous lidocaine, which immediately paralyzes the bug and provides modest topical anesthesia to the cutaneous area. The liquid can then be suctioned out with butterfly tubing and the insect removed with gentle suction or forceps under direct visualization. Care must be taken to assure that no debris of the insect remains in the canal. Irrigation with room-temperature water is adequate for small particles such as hard sand or cerumen and can mobilize distally positioned objects. Irrigation should not be used unless the tympanic membrane is completely visualized and free of perforation, and it can be utilized only for nonorganic matter, which will not expand when moistened.

Complete inspection of the ear canal after removal of the foreign body is important to exclude more significant injury to the canal skin, tympanic membrane, and ossicles caused by the foreign body or its extraction. Small abrasions heal spontaneously. Topical antibiotics should be considered in cases where there was more serious cutaneous damage or where the foreign body consisted of organic material (see Table 231-6). [29]

Cerumen Impaction

Occasionally the diagnosis is made as patients present with unrelated complaints, but more often, patients complain of decreased hearing, a sensation of pressure or fullness in the ear, dizziness, tinnitus, or pain. The symptoms are often precipitated by the use of cotton-tipped applicators. Most of the time, cerumen loops can be used. In the particularly difficult cases or where cerumen is completely occluding the canal, softening of the cerumen can be accomplished with half-strength hydrogen peroxide, sodium bicarbonate drops, mineral oil, or over-the-counter preparations such as Debrox or Cerumenex for 30 min. If irrigation is the treatment of choice, it can usually be accomplished with a metal ear syringe, a flexible 18-gauge intravenous catheter, or a syringe attached to the tubing of a butterfly infusion catheter. Body-temperature irrigant is the solution of choice. The catheter should be inserted into the cartilaginous canal (distal third) and a pulsatile flow should be inserted

along the superior portion of the external auditory canal. Irrigation of the canal when the middle ear is not infected often causes a temporary redness of the tympanic membrane; therefore, the subsequent diagnosis of otitis media should be made with caution.

Tympanic Membrane Perforation

Tympanic membrane perforations can occur as a result of blunt, penetrating, or noise trauma. When it is secondary to blunt or noise trauma, the perforation almost always occurs in the pars tensa, usually anteriorly or inferiorly. The pars tensa, the largest area of the tympanic membrane, is only a few cell layers thick.

The patient usually complains of an acute onset of pain and hearing loss, with or without bloody otorrhea. There may also be associated vertigo and tinnitus, but this is usually transient unless there has been injury to the inner ear or rupture of the round or oval windows. [30] In evaluating these injuries, the canal must be cleared of blood and debris. The tympanic membrane should be completely visualized. Greater than 90 percent of tympanic membrane perforations heal spontaneously. Those occurring secondary to blunt or noise trauma can be safely discharged and referred to a specialist for further evaluation and a formal audiogram as soon after the injury as possible. Patients should be instructed not to allow water to enter the canal of the ear. They do not need topical or systemic antibiotics. Perforations in the posterosuperior quadrant or those secondary to penetrating trauma have a greater likelihood of damaging the ossicular chain or, in the case of the latter, a retained foreign body and should be referred to an otolaryngologist within 24 h. [30,31]

Lightning fatally strikes approximately 600 persons annually in the United States and leaves thousands more survivors with permanent sequelae. Although the blast effect associated with a lightning strike plays a part in perforations, conducted electrical current from cutaneous sites via the external auditory canal and into the middle or inner ear structures is another hypothesized mechanism for lightning-induced otologic injuries. [29] Tympanic membrane perforation is the most common sequela.

Barotrauma

Barotrauma to the middle ear, also called barotitis media, is discussed in Chap. 192.

FACIAL CELLULITIS

Facial cellulitis represents a group of diseases requiring individualized diagnosis and treatment. Periorbital and orbital cellulitis are covered in Chap. 117.

Pathophysiology

A bacterial infection may enter the soft tissues from virtually any skin violation. Patient risk is increased by immunosuppression, alterations in vascularity (e.g., previous radiation treatment), underlying systemic disease (e.g., diabetes), and the presence of foreign bodies or appliances precluding normal host defenses. A remote history of silicone injections may predispose to recurrent episodes of cellulitis. [1]

The most likely pathogens causing facial cellulitis include *Haemophilus influenzae* type b, *Streptococcus pneumoniae*, *Strep. pyogenes*, *Strep. viridans*, *Staphylococcus aureus*, *Bacteroides fragilis*, *B. melaninogenicus*, and other pathogens found in deep neck abscesses. [2]

Clinical Features

The history should examine recent prodromal events (e.g., insect bites, trauma), allergen exposure, chronic dental caries, painful mastication, previous treatments with radiation, or silicone injections. The presence of dental or cosmetic appliances, nasal discharge, or vision changes should be ascertained. Systemic signs of infection should be excluded, such as fever and vomiting. A thorough head and neck exam is required. Occult infection, with extension from other head and neck structures, should be excluded.

Diagnosis

Cellulitis is classically defined by pain, erythema, edema, increased tactile temperature, and dysfunction of the involved structure. The diagnosis is usually based upon these clinical findings. When there is a focus with purulent drainage, such as an abscess, cultures may yield the organism.

The differential diagnosis includes insect envenomation or other traumatic event, dental caries with abscess formation, occult head and neck infection, orbital or periorbital cellulitis, sinusitis with erosion of the bony cortex, otitis externa, erysipelas, viral exanthems (e.g., erythema infectiosum), parotitis, impetigo, systemic lupus erythematosus, herpes zoster, dermatitides, angioneurotic edema, and allergy. [3,4]

Treatment

Analgesics and antipyretics should be administered as indicated. Broad-spectrum antibiotic therapy, ensuring coverage of staphylococcal and streptococcal species, is indicated. When possible, all foreign bodies and appliances should be removed. Initially recommended antibiotics are amoxicillin/clavulanate or ampicillin/sulbactam. Alternatives include vancomycin plus aztreonam. [2] If cellulitis is secondary to underlying abscess or osteomyelitis, diagnostic evaluation and treatment for the underlying source is necessary.

Disposition

Hospitalization, with antibiotic therapy initiated in the emergency department (ED), is required for patients with facial cellulitis and the following associated conditions:

1. Systemic signs of sepsis
2. Antibiotic intolerance for any reason (e.g., emesis)
3. Immunosuppressive therapies or illness
4. Extensive areas of erythema or induration
5. Unremovable head/neck appliances or foreign bodies
6. Inability to comply with outpatient therapy

Outpatient therapy is appropriate in selected cases. Patients should be instructed to return to the ED for fever, difficulty swallowing or breathing, inability to take their antibiotics for any reason, or if there is worsening of their condition. The patient should be seen the following day for evaluation. If there is continued progression, admission for inpatient antibiotics is warranted. Patients at the extremes of age should have a lower admission threshold.

TEMPOROMANDIBULAR JOINT DYSFUNCTION

The temporomandibular joint (TMJ) combines both a hinge and gliding action. The articular surfaces are separated by the articular disk (also known as the meniscus), which assists in the hinge action between the mandibular condyle and the disk and the gliding action between the disk and temporal bone. Part of the lateral pterygoid

muscle inserts into the anterior portion of the disk. Closure of the mandible is by the powerful muscles of mastication, which include the masseter, temporalis, and medial pterygoid. The jaw is opened by forward traction on the mandibular neck by the lower portion of the lateral pterygoid, with assistance from the digastric, mylohyoid, and geniohyoid muscles. Lateral movement of the jaw is by unopposed contraction of one of the lateral pterygoids. Protrusion occurs by the combined action of the medial and lateral pterygoids, and retrusion occurs by contraction of the posterior temporalis with the suprahyoid muscles.

In population studies, TMJ dysfunction is estimated to have a prevalence of 6 to 12 percent, with a 2:1 female preponderance.[5] However, in most treatment samples, women of about age 38 constitute 85 to 90 percent of patients.[5]

Pathophysiology

There is no single clear explanation for all manifestations of TMJ pain. Chronic TMJ dysfunction probably results from a variety of causes, either singly or in combination, and includes neuromuscular disturbance, anatomic deviations as a result of trauma or congenital formation, dental abnormalities, TMJ manifestations of systemic disease, and psychic tension.

Classification[6] is initially based upon whether the primary pathologic event is intracapsular (e.g., disk pathology) or extracapsular (e.g., myositis). This may be difficult to determine.

Myofascial disorders are characterized by pain and spasm of the muscles around the joint; there may be inflammation, tendinitis, or trismus. The patient may report associated bruxism or jaw clenching. Dental malocclusion is felt to play only an indirect role. Most studies have found no significant correlation between occlusal parameters and signs or symptoms of temporomandibular disorders.[7]

Anatomic internal derangement may occur as the result of disk displacement. This may be the result of single major traumatic event (motor vehicle accident, whiplash, direct blow) or secondary to chronic microtrauma (bruxism, jaw hypermobility with chronic injury).

Degenerative joint disease may result from chronic internal derangement or secondarily as the result of systemic disease [e.g., rheumatoid arthritis, systemic lupus erythematosus (SLE)]. At the extreme end of the spectrum, joint ankylosis can occur.

Clinical Features

The patient's chief complaint is usually of pain localized to one of the muscles of mastication. The masseter is the most frequently identified painful area, followed by the temporalis, sternocleidomastoid, trapezius, splenius capitis, and cervical spine musculature.[5] One-third of patients complain of earache.[5] There may be unilateral headache, or pain about the TMJ. Discomfort may be exacerbated by yawning, chewing, jaw clenching, or bruxism. Eighty percent report their discomfort as unilateral.[5]

The onset of discomfort is insidious in 75 percent of patients, with the remainder attributing their onset to a trauma (injury, surgery, bruxism, stress event).[5] In the absence of an acute trauma (e.g., fracture), acuity of onset is not related to ultimate outcome.[5]

Physical findings may include limitation in the range of motion of the mandible, defined as restricted if the distance between the upper and lower incisors is less than 35 mm.[5] With clicking, there may be irregular jaw motion with opening of the mouth.[5] Because the pain is frequently unilateral, there may be jaw deviation. Clicking or popping at the TMJ may be audible or palpable by the physician.

Palpation should be performed at the muscles of mastication to assess for areas of sensitivity, induration, rigidity, size, and swelling. The condylar heads may be palpated just anterior to the tragus with the teeth together and then with the teeth apart.

A careful head and neck exam is warranted to exclude other more malignant causes of facial pain.

Diagnosis

The ED diagnosis of TMJ dysfunction is predominately based upon the history and physical findings. In the absence of acute trauma without the suggestion of an infectious or neoplastic lesion, there is little necessity for x-rays. It is rare to find abnormalities of the joint with plain radiography unless there is degenerative joint disease.

If acute trauma is the etiology, the initial radiographic evaluation of the TMJ is usually a panoramic view of the mandible. The principal advantage of the panoramic view is the ability to demonstrate pathology causing discomfort from sites other than the TMJ. Other imaging modalities include computed tomography (CT) scanning and magnetic resonance imaging (MRI), but these are not relevant in the ED setting.[6]

Since patients with TMJ are frequently women in their thirties, men of any age and older women presenting with their first onset of pain should prompt concern. An expanded differential, including other etiologies of facial pain, should be considered but can usually be excluded by history and physical exam. Jaw pain secondary to angina, sinusitis, toothache, otitis, septic TMJ, alternative diagnoses of headache (e.g., temporal arteritis), neoplastic lesions, and trigeminal neuralgia[5] may be considered.

Treatment

Recommendations to the patient may include the following:

1. Use ice or hot packs to the reduce pain and muscle spasm.
2. Eat soft foods to reduce chewing stress (no chewing gum or ice).
3. As much as possible, disengage the teeth by keeping them slightly apart.
4. Control body position: do not sit with the chin resting on the hand and do not sleep with the pillow pushing against the TMJ.

The physician may prescribe nonsteroidal anti-inflammatory drugs as indicated by the patient's discomfort. Muscle relaxants may be helpful. If narcotic use is necessary, it should be of limited duration.[8,9]

Many patients with chronic TMJ have been treated with oral appliances; however, controlled studies have shown no benefit for these over placebo.[5]

DISLOCATION OF THE MANDIBLE

Epidemiology

Mandibular dislocation is a common problem in emergency medicine.[10] Dislocations are usually preceded by a preexisting risk factor. These include general joint laxity, neurologic disease resulting in increased muscular activity, and extrapyramidal side effects of neuroleptic medication.[11] In a population study of 400 patients with symptomatic TMJ dysfunction, only 1.8 percent sustained recurrent mandibular dislocation.[11]

Pathophysiology

The mandible can be dislocated in an anterior, posterior, lateral, or superior plane. Anterior dislocation is most common and occurs when the mandibular condyle is forced in front of the articular eminence. The jaw is then kept in this position by muscular spasm. Anterior subluxation occurs in up to 70 percent of normal individuals but can be spontaneously reduced by the patient.[12] A predisposition to symptomatic anterior dislocation includes anatomic predilection (a shallow glenoid fossa), loss

of joint capsule integrity (previous trauma), or increased muscle tone. Once the jaw is dislocated, muscular spasm, particularly from the temporalis and lateral pterygoid muscles, tends to prevent reduction. Dislocations are most frequently bilateral, but they also occur unilaterally. [12]

Anterior dislocations are classified as acute, chronic recurrent, or chronic. [12] Acute dislocations usually present shortly after their occurrence, owing to severe discomfort. In chronic recurrent dislocations, precipitating factors should be considered. This includes dystonic reactions and hypermobile syndromes (e.g., Marfan, Ehlers-Danlos).[12] Chronic dislocations, where the condyle is displaced from the fossa for an extended time, occur in patients unable or unwilling to obtain prompt medical treatment (e.g., severe mental illness, alcoholism, etc.).

Posterior dislocations are rare. They follow a direct blow to the chin that does not break the condylar neck. In this dislocation, the mandibular condyle is thrust against the mastoid. As a result, the condylar head may prolapse into the external auditory canal. [12]

Lateral dislocations are always associated with jaw fracture. With a lateral dislocation, the condylar head is forced laterally and then superiorly into the temporal space.

Superior dislocations occur from a blow to the partially open mouth that forces the condylar head upward. Associated injuries include cerebral contusions, facial nerve palsy, and deafness. Mandibular fractures are not always present. [12]

Clinical Features

Patients with acute dislocation usually present with severe pain, difficulty in speaking or swallowing, or malocclusion. There may be loose or missing teeth and areas of sensory deficit at the chin or mouth.

With anterior dislocation, pain is localized anterior to the tragus. The symptoms are frequently reported to have begun acutely following extreme mouth opening. Anterior dislocation has been reported to have occurred after laughing, yawning, vomiting, taking a large bite, trauma, oral sex, dental extraction, overstretching of the mouth during general anesthesia, or tonsillectomy. [11,12] As opposed to anterior dislocation, all other types of mandibular dislocation tend to require significant trauma.

All patients with a history of possible mandibular dislocation should have a good head, neck, and dental examination. With anterior dislocations, there is a visible and palpable preauricular depression from the displacement of the mandibular condyle. There will also be difficulty with jaw movement. If the dislocation is unilateral, there is deviation of the jaw away from the dislocation.

When a posterior dislocation is considered, the external auditory canal should be visualized. Baseline hearing function should be verified. With lateral dislocations, the condylar head is palpable in the temporal space and there are always signs of a jaw fracture (e.g., malocclusion). When a superior dislocation is suspected, a thorough exam is needed, especially focusing on the head, neck, and neurologic systems.

Diagnosis

In the cooperative patient with a spontaneous nontraumatic anterior dislocation, the diagnosis is based upon clinical grounds. In other dislocations, radiographs may be needed to confirm clinical suspicion. In the setting of significant trauma, radiographs should be obtained to exclude fracture. The panoramic view usually demonstrates the pathology and excludes other mandibular injury. Specific jaw or TMJ films may be helpful. In the patient with more serious trauma, where there may be a superior dislocation or intracranial injury, a CT scan will provide more information.

The differential diagnosis of jaw dislocation includes mandibular fracture, traumatic hemarthrosis, acute closed locking of the TMJ meniscus, and TMJ dysfunction. [12]

Treatment

Reduction may be attempted in closed anterior dislocations without fracture. Most attempts are made easier with analgesia. A short-acting intravenous muscle relaxant (e.g., midazolam) helps to decrease muscle spasm.[11] Appropriate airway and hemodynamic monitoring is required. A systemic analgesic (e.g., narcotic) may also be considered. Conscious sedation has also been used successfully. [10]

Alternatively, local anesthetic can be placed into the joint capsule. [11] Using aseptic technique, a 21-gauge needle is placed into the preauricular depression just anterior to the tragus and 2 mL of 2% lidocaine is injected. [12] (See Fig. 232-1.)
FIG. 232-1. Site of injection for dislocated mandible local anesthesia.

There are two methods for reducing an anterior mandibular dislocation. [12] The most commonly used technique requires the patient to be firmly seated, with the head against the wall or chair back, positioned so that the examiner's flexed elbow is at the level of the patient's mandible. Facing the patient, the examiner places his or her gloved thumbs in the patient's mouth, over the occlusal surfaces of the mandibular molars, as far back as possible. The fingers should curve beneath the angle and body of the mandible. Using the thumbs, the examiner applies pressure downward and backward. Slightly opening the jaw may help disengage the condyle from the anterior eminence. (See Fig. 232-2). When the dislocation is bilateral, it may be easier to relocate one side at a time. Some suggest that the examiner may wish to wear gauze over the thumbs for protection, should the mandible snap closed after reduction. [12]
FIG. 232-2. The temporomandibular joints in normal and dislocated positions, and positioning for mandibular relocation in a seated patient. Positioning for mandibular

relocation in a recumbent patient.

The second technique requires the examiner, standing behind the recumbent patient, to place the thumbs on the molars and apply downward and backward pressure.[12]

If the reduction is successful, the patient should be able to close his or her mouth immediately. Postreduction radiographs are not usually required unless the procedure was difficult or traumatic or there is significant discomfort postprocedure.

Complications from the reduction itself are unusual but can include iatrogenic fracture or avulsion of the articular cartilage. [10]

Disposition

Patients with dislocations that are open, superior, associated with fracture, that manifest any nerve injury, or that are unreducible by closed technique should be emergently referred to a head and neck or oral surgeon.

Following the successful reduction of an acute dislocation, patients are placed on a soft diet and cautioned against opening their mouths more than 2 cm for the following 2 weeks.[11] They should be instructed to support the mandible with a hand when they yawn. Nonsteroidal analgesics may be required to manage initial discomfort.

In all dislocations, follow-up is recommended. In severe cases, intermaxillary fixation may be required to control jaw motion during healing. Chronic dislocations may require operative intervention.

MASTICATOR SPACE ABSCESS

Pathophysiology

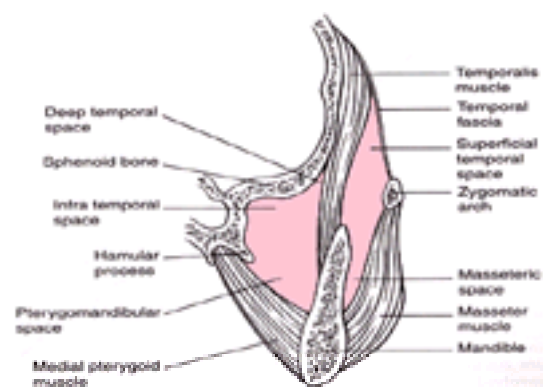
The masticator space consists of four potential spaces bounded by the muscles of mastication. (See Fig. 232-3.) These spaces include the masseteric, superficial temporal, deep temporal, and pterygomandibular spaces.[13] Since they are contiguous, it is rare for a single one to be infected. Secondary infection usually occurs by extension from one of the anterior spaces (buccal, sublingual, or submandibular).


FIG. 232-3. Masticator space.

Infection of the masseteric space most frequently arises via extension from soft tissue infection around the third molar. Rarely, it may follow as a complication to an inferior alveolar nerve block, an open fracture at the angle of the mandible, or as an extension from osteomyelitis of the zygoma or temporal bones. [14]

The temporal spaces are rarely involved. If this occurs, it is usually the result of a serious, overwhelming infection. The pterygomandibular space is usually infected secondarily by extension from the sublingual or submandibular spaces or from infection from around the third molar. Untreated, infection can spread to the adjacent spaces of the head and neck that are contiguous with the mediastinum, resulting in mediastinitis, pericarditis, and death. [15]

Soft tissue infections of the spaces in the perimandibular and parapharyngeal region are frequently caused by oral anaerobes. These include *Peptostreptococcus*, *Fusobacterium* sp., *Bacteroides* sp. (*oralis* and *melaninogenicus*), *Propionibacterium*, and *Clostridium* sp.[2] Masticator space infections are frequently mixed, with at least two organisms present.[15]

Clinical Features

The most frequent acute clinical findings are facial swelling, pain, erythema, and trismus. [15] In chronic infection the patient may be afebrile but may complain of progressive trismus.[15]

Constitutional signs include fever, malaise, dehydration, dysphagia, nausea, or vomiting. In more advanced cases, systemic signs of sepsis are present.

History and physical exam features are variable. When infection occurs in the masseteric space, there is posteroinferior facial swelling with mild to moderate trismus. If the temporal space is infected, there is soft tissue swelling over the temporalis and significant trismus. Trismus without swelling suggests pterygomandibular space abscess.

Diagnosis

The diagnosis of masticator space infection is clinical. Radiographs occasionally demonstrate osteomyelitis of the mandible. CT may define the extent of an abscess but is not required in the management of those well enough to be treated as outpatients. CT may be needed in more ill-appearing patients. Abscess culture usually yields *Streptococcus* and oral anaerobes but is unnecessary in uncomplicated immunocompetent patients.

Because the parotid gland overlies the masseter, diagnostic confusion with parotitis can result when there is swelling over these structures. Useful distinctions are that the symptoms of parotitis are cyclically related to eating, whereas the pain of an abscess is constant, [14] and parotitis is not associated with the significant trismus that accompanies infection of the masticator space.[15] Other diagnoses to consider with lateral jaw pain include jaw discomfort of angina, masticator space neoplasm, TMJ dysfunction, referred dental pain, pharyngeal infection, tonsillitis or peritonsillar abscess, and otitis media or externa. History and physical exam are usually sufficient to exclude these other considerations.

Treatment

Therapy is determined by the patient's condition. In unilateral masticator space infections, airway compromise is rare; however, the possibility should always be considered. Emergent ear, nose, and throat (ENT) consultation is required in patients with airway compromise, severe trismus, vomiting, palpable abscess, large or

diffuse areas of cellulitis, large areas of induration, or systemic signs of sepsis.

For patients requiring hospitalization, intravenous antibiotics should be started in the ED. Large doses of penicillin, 20 million units daily, are appropriate. In penicillin-allergic patients, clindamycin is a good alternative. [2,16] Analgesics should be administered as needed.

In candidates for outpatient management, antibiotic selection is as follows: penicillin as a first choice, erythromycin, or clindamycin may be selected. Antibiotics should be continued for 10 to 14 days.

Disposition

Stable afebrile patients with minimal symptoms, only slight trismus, no palpable abscess or induration, and without vomiting or systemic signs of infection may be considered for discharge on oral antibiotics and analgesics. They should have follow-up in 24 h and should receive precise discharge instructions to return should they experience difficulty in swallowing or breathing, fever, vomiting, or inability to take their medication for any reason.

SALIVARY GLANDS

The salivary glands are generally considered as comprising two major groups: the parotid and the submandibular. The facial nerve passes through the superficial portion of the parotid gland. The parotid (Stenson) duct opens into the mouth opposite the upper second molar.

The submandibular and sublingual glands lie beneath the tongue. The submandibular ducts open into the mouth at either side of the frenulum of the tongue. The multiple sublingual ducts open into the sublingual fold or directly into the submandibular duct.

Disorders of the salivary glands may have inflammatory, neoplastic, immunologic, or traumatic causes. Only the most common disorders are discussed below. It is important to determine which glands are involved; whether single or multiple glands are affected; whether there is pain, tenderness, or a palpable mass; the acuity of symptoms and their precipitants, whether symptoms are persistent or recurrent; and whether associated problems such as dry mouth or eyes, joint symptoms, or diabetes are present.

MUMPS AND OTHER VIRAL PAROTITIS

Prior to the advent of the vaccine in 1968, mumps caused by the paramyxovirus was the most frequent cause of painful parotid swelling in children between the ages of 5 and 15.[2,17,18] The incubation period is 12 to 21 days.[17] Patients are infective from 3 days prior to 7 days after salivary gland swelling.[19] Repeat episodes of mumps occur but are rare. Viral parotitis can also be caused by influenza, enteroviruses, cytomegalovirus, and the human immunodeficiency virus (HIV).[18]

Symptoms progress from initial fever and malaise to increasing pain and stiffness with chewing.[18] Parotid swelling, bilateral in 70 percent of patients, follows.[17] The angle of the mandible may be obliterated.[16] There may be edema of the surrounding area, but there is no discharge from the Stenson duct. In 10 percent, the submandibular glands are involved.

Usually benign in children, mumps can be severe in adults. Although 25 percent of men suffer orchitis, only 5 percent of women manifest oophoritis.[19] Possible complications include mastitis, pancreatitis, myocarditis, meningoencephalitis, encephalomyelitis, and sensorineural deafness.[17,18]

The diagnosis of mumps can be made solely on clinical grounds.[17] Amylase levels may be elevated.[18] There is no specific therapy. Treatment is supportive. Children with mumps should be excluded from school or day care for 9 days following the onset of parotid swelling.[18]

SUPPURATIVE PAROTITIS

Parotitis can occur in any debilitated or dehydrated patient. About one-third of cases occur postoperatively.[20] Suppurative parotitis is believed to occur from the retrograde migration of oral bacteria.[19] Predisposing conditions are ductal abnormalities (e.g., stricture), drugs or therapies decreasing the flow of saliva (e.g., phenothiazines, antihistamines, parasympathetic inhibitors, radiation treatment), and poor oral hygiene.[17,20]

Suppurative parotitis presents clinically as a tender, erythematous, and swollen parotid gland. It is bilateral in up to 20 to 25 percent of cases.[19] Pain may extend from the ear to above the mandible. Swelling may progress over the face and neck. The angle of the mandible may be obliterated.[18] Fever and trismus may be present, and pus (which should be cultured) may be expressed from the Stenson duct.[20] Abscesses can occur, although the fluctuance may be difficult to appreciate on physical exam.

Suppurative sialoadenitis can occur in the other salivary glands, but the expected pathogens and recommended treatment are the same. Usual bacteria are *Staph. aureus* mixed with anaerobes.[17,20] In chronically ill, dehydrated, or hospitalized patients, *Pseudomonas*, *Enterobacter*, *Klebsiella*, enterococci, *Proteus*, and *Candida* spp. can be found.

The diagnosis is strictly clinical.[17] No specific testing is available. Examination will identify the parotid as the source of discomfort. In patients failing to improve after several days of treatment, CT or ultrasound should be considered to identify a possible abscess. Because it may aggravate the condition, sialography is contraindicated during the acute stage.[17]

It may be difficult to differentiate viral and suppurative parotitis. The differential is broad and includes sialolithiasis (Table 232-1). Bacterial parotitis is usually associated with higher fever, greater warmth, and more overlying erythema as compared with viral parotitis. Lymphadenitis can present with similar findings but usually involves an identifiable source of infection, is not localized to the parotid, and will not cause purulent discharge from the Stenson duct.

TABLE 232-1   Causes of Salivary Gland Enlargement

Hydration to ensure salivary flow, massage, local heat, and sialogogues (such as lemon drops) are the mainstays of therapy. The patient should receive antibiotics effective against the expected pathogen. Initially recommended antibiotics are amoxicillin/clavulanate or ampicillin/sulbactam.[2] Alternative choices include clindamycin, antistaphylococcal penicillin, cefoxitin, or vancomycin plus metronidazole.[2] Antibiotics should be continued until culture results are known.

Patients who are clinically stable and able to complete their antibiotic regimen may be discharged for outpatient management. Those with hemodynamic instability,

vomiting, severe complicating disease, or other factors precluding compliance with their antibiotic therapy should be admitted for intravenous antibiotics. When an abscess is identified, ENT consultation for consideration of surgical drainage is necessary.

SIALOLITHIASIS

Salivary calculi can be seen at any age, peak in the third to sixth decades, and have a male predominance. More than 80 percent of stones occur in the submandibular gland; most of the remainder are found in the parotid.[17,19] The sublingual glands are rarely involved. Submandibular sialoliths are more common because of more viscous and alkaline secretions as well as the anatomically "uphill" path of the Wharton (submandibular) duct.[20] Sialoliths are composed mostly of calcium phosphate and organic matrix.[19] Multiple stones are seen in approximately 25 percent of patients who present with an initial stone.[20]

The symptoms of pain, swelling, and tenderness are similar to those of parotitis and the two conditions may be difficult to differentiate. However, ductal obstructive symptoms (pain and swelling) are exacerbated by meals, when salivary secretion is stimulated.[17,20] Sialolithiasis usually presents with unilateral swelling and pain in the affected gland. The stone may be palpated within the duct. If there is superimposed infection, the diagnosis may be difficult.

Diagnosis is usually clinical. Although intraoral radiographs visualize more than 90 percent of calculi, extraoral radiographs demonstrate only about 50 percent. This is despite the fact that 80 percent of submandibular calculi are radiopaque.[19] Only 20 percent of parotid calculi are visualized by plain radiography.[17]

Sialography, diagnostically limited in the detection of small stones and extrinsic masses, is being replaced by ultrasound, CT, and MRI. These diagnostic procedures are rarely indicated emergently.

Diagnosis and therapy may be initiated on the basis of clinical findings. Conservative treatment is usually effective. Initial management consists of analgesics, antibiotics if there is concurrent infection, massage, and sialogogues (e.g., lemon drops).[17,19] Easily located distal calculi may be digitally "milked" from the duct.[19] Alternatively, they may be removed by the specialist by either dilation or incision of the ductal orifice. Most patients with sialolithiasis may be discharged for outpatient management. If there is a concurrent abscess, disposition should be guided by the recommendations for abscess management, as outlined above. Proximal or intraglandular sialoliths should be referred for outpatient ENT evaluation.

Complications of salivary duct obstruction include recurrent or persistent obstruction, sialectasia (irregular dilations of the ductal system resulting in stasis and further stone formation), and superimposed infection.[19]

SALIVARY GLAND ENLARGEMENT

The majority of causes of salivary gland enlargement do not require emergency intervention. However, the patient should be instructed to seek appropriate follow-up for definitive diagnosis and treatment.

Salivary gland enlargement can result from a large number of conditions. (See Table 232-1.) HIV may cause painless gradual enlargement.[17] Other infectious diseases, such as sarcoidosis, cat-scratch disease, tuberculosis, atypical mycobacterial infections, and actinomycoses may present as a chronic form of sialoadenitis.[17,19]

Neoplastic lesions may present with enlarged salivary glands. Less than 3 percent of all head and neck tumors are found in the salivary glands.[17] Although about 70 to 80 percent of salivary tumors arise in the parotid, 75 to 90 percent are benign.[17,20]

ED disposition and outpatient follow-up should be based upon the suspected underlying cause of salivary gland enlargement.

233 NASAL EMERGENCIES AND SINUSITIS

Thomas A. Waters
W. F. Peacock IV

EPISTAXIS

Because the blood supply of the nasal mucosa ultimately originates from the internal and external carotid arteries, acute epistaxis has the potential to be very serious, especially when the patient is frail or elderly. Still, most cases of epistaxis are self-limited and can be managed conservatively. Epistaxis has an increased incidence during the dry, cold winter months, due to abrupt temperature changes and exposure to dry heat.

Pathophysiology

The origin of epistaxis can be broadly divided into two categories: anterior and posterior. Anterior epistaxis is more common in young patients, while posterior is the most common in older patients. Determining the origin of bleeding will help guide treatment. Some common causes are listed in Table 233-1.

Infection
  Rhinitis
  Nasopharyngitis
  Sinusitis
Trauma
  Self-induced (i.e., nose-picking)
  Facial bone fractures
  Nasal foreign body

TABLE 233-1   Common Etiologies of Epistaxis

Anatomy

The nose functions to warm and humidify air and therefore requires a vigorous blood supply (Fig. 233-1). Its blood supply originates from both the internal and external carotid arteries. The posterior and inferior aspects of the nasal cavity are supplied by the sphenopalatine artery, which is a branch of the maxillary artery. The internal carotid artery gives rise to the ophthalmic artery, which supplies the anterior-superior nasal cavity by the anterior and posterior ethmoidal arteries. The nasal septum receives its blood supply from multiple arteries. The superior labial branch of the facial artery supplies the vestibule and inferior-anterior septum. The posterior and superior septum is supplied by branches of the sphenopalatine, anterior ethmoidal, and posterior ethmoidal arteries. These all join to form Kiesselbach's plexus.
FIG. 233-1. Arterial blood supply to the nasal cavity. The most common site of nasal hemorrhage is at Little area, located on the nasal septum. The most common site of posterior epistaxis is at the lateral nasal branch of the sphenopalatine artery, which enters the nasal cavity behind the middle turbinate. AE, anterior ethmoid; GP,

greater palatine; LA, Little area; PE, posterior ethmoid; SL, superior labial; SP, sphenopalatine (lateral nasal branch).

ANTERIOR EPISTAXIS

Anterior epistaxis represents 90 percent of nosebleeds, with the majority originating from Kiesselbach plexus. This area has been referred to as the "picking zone," and is also the area most prone to drying and cracking due to environmental effects. Anterior nose bleeds result from any process that causes mucosal hyperemia.

Hereditary hemorrhagic telangiectasia (HHT), or Osler-Weber-Rendu disease, is an unusual, but severe, cause of recurrent anterior nosebleeds. HHT is an autosomal-dominant disorder, characterized by mucosal telangiectasia throughout the airway and gastrointestinal tract.

Clinical Features

The history can provide valuable insight as to the location of the epistaxis. Questions that are important to ask include:

- Which side is bleeding?
- Do you have a sensation of blood in back of throat?
- Do you have a history of previous epistaxis, trauma, head/neck tumor, radiation therapy, or head/neck surgery?
- Is there a family history of bleeding disorders?
- Are you using anticoagulants, aspirin, or NSAIDs?

Typically, with anterior epistaxis, the bleeding is unilateral and the patient will not report the sensation of blood in the posterior oropharynx.

In anterior epistaxis one can often visualize the area of bleeding. However, proper lighting and suction are essential. Adequate lighting is best achieved by the use of an ENT head lamp or with a head mirror. Universal precautions must be observed by the examiner and the patient's clothing should be protected with a gown. The patient should be seated in a chair leaning forward with the head inclined anteriorly. This helps to visualize the nasal cavity, minimizes backward blood flow, and decreases gagging.[1] The assessment of the patient must include a complete set of vital signs, as well as a thorough exam of the oropharynx and nasopharynx. Additionally, a general physical overview is necessary to evaluate for signs of systemic coagulopathy.

Laboratory investigation is not routinely required. Exceptions to this are in the patient with multiple or prolonged episodes of hemorrhage when there is a clinical suspicion of coexisting anemia or if coagulopathy is suggested by either the history or physical exam.

Treatment

The treatment of anterior epistaxis includes direct pressure, vasoconstrictive agents, nasal packing, and cautery. Despite a frequently elevated blood pressure in the setting of acute epistaxis, initial efforts at stabilization should focus on direct control of hemorrhage. Once the bleeding has been stopped and patient anxiety regarding exsanguination resolved, elevated blood pressure usually spontaneously resolves. Persistent or extremely high elevations of blood pressure can then be addressed.

Most episodes of anterior epistaxis can be managed by direct pressure to the nose. This is achieved by compressing the elastic areas of the nose between the thumb and middle phalanx of the index finger. Pressure must be continuously maintained for 10 to 15 min, and confirmed with a clock, as patients frequently underestimate the amount of time that has elapsed. Release of pressure to see if the bleeding has stopped will not allow adequate clot formation and may result in continued bleeding.

Vasoconstrictive agents may be used in conjunction with all other treatment modalities. Table 233-2 lists common vasoconstrictive agents. These compounds can be instilled into the nasal cavity by a spray bottle, an atomizer, or cotton swab. If the area of bleeding can be visualized, cotton swabs or pledgets are preferred. This provides excellent contact with the mucosa and can provide direct pressure to the site.

Phenylephrine (Neo-Synephrine) 0.5–1.0% concentration mixed with 4% lidocaine*

Oxymetazoline (Afrin) 0.05% concentration mixed with 4% lidocaine*

Epinephrine 0.25 mL of 1:1000 concentration mixed with 20 mL of 4% lidocaine*

* The maximum dose of lidocaine applied to the nasal mucosa should not exceed 4 mg/kg.

TABLE 233-2   Vasoconstrictive and Anesthetic Agents Used in Epistaxis

If the source of bleeding is easily visualized anteriorly, cautery can be attempted with either silver nitrate or electrocautery. Cautery should not be performed indiscriminately. It can lead to septal perforation if used in an overzealous fashion. Silver nitrate sticks can be used as an aid in the management of well-visualized anterior nose bleeds. It should only be attempted after the bleeding has already been stopped and the offending area is well visualized. It is extremely difficult to cauterize an actively bleeding site by chemical means.

Electrical and thermal cautery are best left for the otolaryngologist. It is difficult to control or estimate the depth of cautery achieved with the battery-powered cautery devices available. Significant trauma can occur to the nasal mucosa, septal cartilage, and the skin surrounding the nares.

Anterior Nasal Packing

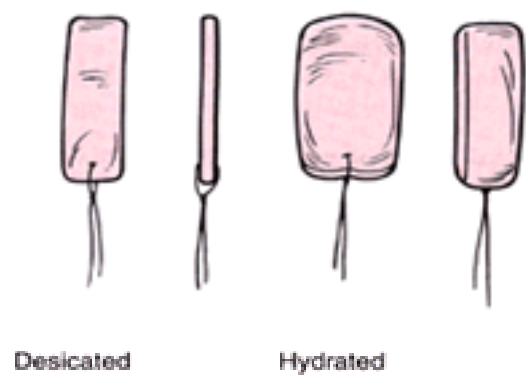
Anterior nasal packing should be performed on any patient in which direct pressure and vasoconstrictors are unsuccessful in controlling epistaxis. The use of nasal tampons, or sponges, is a very quick and effective method for controlling epistaxis. Nasal tampons, which are initially rigid, are inserted along the floor of the nasal cavity against the septum. They are made of synthetic, sponge-like material that expands to many times its original size after installation of saline or the absorption of blood (see Fig. 233-2). Insertion of the device can be facilitated by coating the tampon with water-soluble antibiotic ointment. This ointment will also help delay expansion until after the tampon is in place. Patients report such commercial devices to be significantly more comfortable than traditional gauze or balloon packing. This, coupled with the ease of insertion when compared to gauze packing, has made such devices very popular. Placement of a traditional anterior nasal pack may be considered when the bleeding is difficult to control, or other methods fail (see Fig. 233-3).


FIG. 233-2. The Merocel nasal sponge in its desiccated (left) and hydrated (right) forms.
FIG. 233-3. The key to placement of an anterior nasal pack that will control epistaxis adequately and stay in place is to lay the packing into the nasal cavity in an "accordion" manner, so that part of each layer of packing lies anteriorly, preventing the gauze from falling posteriorly into the nasopharynx. **A.** The first layer of $\frac{1}{4}$-in. petrolatum-impregnated gauze strip is grasped approximately 2 to 3 cm from its end. **B.** The first layer is then placed on the floor of the nose through the nasal speculum (not pictured here). The beyonet forceps and nasal speculum are then withdrawn. **C.** The nasal speculum is reintroduced on top of the first layer of packing, and a second layer is placed in an identical manner. After several layers have been placed, it is often useful to reintroduce the bayonet forceps to push the previously placed packing down onto the floor of the nose, making it tighter and more secure. **D.** A complete anterior nasal pack can tamponade a bleeding point anywhere in the anterior nasal cavities and will stay in place until removed by the physician or patient.

Any patient who has undergone nasal packing may be considered for prophylactic treatment against toxic shock syndrome (TSS) with antistaphylococcal medications. Coating the pack with antibiotic ointment before placement helps decrease the amount of nasal bacteria, as well as decreases the number of episodes of bacteremia. [2] The recommended regimen is either cephalexin (250 or 500 mg qid) or amoxicillin/clavulanate (250 or 500 mg tid). In the patient who cannot tolerate these, clindamycin (150 to 300 mg qid) or trimethoprim/sulfamethoxazole DS (bid) can be used as a second choice. [2]

Approximately 25 percent of properly placed anterior nasal packs fail to control the hemorrhage. [1] In such a case, emergency ENT consultation should be obtained if replacing the pack does not control the bleeding. Patients may also experience reflux of blood through the ocular puncta and need to be warned about this. No specific therapy is indicated if this occurs.

Anterior packing alone is a relatively benign procedure. Complications associated with anterior nasal packing include: dislodgement of the pack, persistent bleeding, sinusitis, septal necrosis, and, rarely, TSS. Any patient presenting after nasal packing with fever, rash, nausea, or vomiting, should be considered suspicious for TSS.

Anterior Packs in Children

Anterior epistaxis is fairly common in children. In a study of 1218 children age 11 to 14, 6 percent had experienced epistaxis. The most common cause is idiopathic or related to upper respiratory infections. Treatment is by direct pressure. In the rare case when packing is required, conscious sedation may be needed.

Removal of Anterior Nasal Packs

Removal of nasal packing should be performed at follow-up, after 2 to 3 days. When nasal tampon removal is planned, the pack should be first rehydrated with 5 cc of normal saline. If a gelfoam packing has been placed, this can be left to be absorbed by the body. Recurrent epistaxis may accompany packing removal.

Disposition

Hospital admission is rarely required for patients when good control of anterior epistaxis has been obtained. If bleeding persists after placement of an anterior pack, the possibility of inadequate packing or a posterior bleed needs to be considered. If epistaxis cannot be controlled, or is posterior in origin, emergency ENT consultation should be requested.

At the time of discharge, patients should be given these instructions:

- Do not manipulate the external nares or insert any foreign object into the nasal cavity. If there is no packing, as an exception, the patient may apply petrolatum jelly or triple-antibiotic ointment to dry mucosa. This is performed gently with a sterile cotton-tipped applicator once or twice daily for 3 to 4 days.
- Do not use aspirin or nonsteroidal anti-inflammatory agents for 3 or 4 days.
- If bleeding recurs from simple anterior epistaxis, where no packing has been inserted, home measures may be tried before returning to the emergency department. Patients may be advised to use an over-the-counter vasoconstrictor nasal spray (such as phenylephrine or oxymetazoline) and pinch their nose, with proper technique, for 10 to 15 min. If the bleeding continues, compression may be repeated twice more. If after three unsuccessful attempts, the bleeding continues, they should return to the emergency department immediately. Patients who have had an anterior pack inserted should return if bleeding occurs around the packing or if there is a sensation of blood trickling down the back of the throat. They should be advised to leave the pack in place and not attempt to remove it themselves.
- The patient should follow-up with a primary care or ENT physician in 2 to 3 days.

POSTERIOR EPISTAXIS

Posterior epistaxis represents only 5 percent of nosebleeds presenting to the ED. [3] It is more common in elderly patients and is believed to be due to arteriosclerosis of the large posterior vessels of the nasal cavity. Hypertension is also a large contributor to posterior epistaxis. One study reported that 64 percent of patients with posterior epistaxis had a previous diagnosis of hypertension. Forty-eight percent were actually hypertensive with a systolic blood pressure (BP) greater than 180 or diastolic greater than 110 at the time of their epistaxis. The most common site of bleeding is posterior to the inferior turbinate, occurring 6 to 7.5 cm posterior to the vestibule, and emanates from branches of the sphenopalatine artery. [4] The actual bleeding site usually cannot be visualized.

Clinical Features

Bleeding is typically more profuse than with anterior epistaxis and may be more difficult to control. Blood can often be seen flowing down the posterior oropharynx, or

from both nares. The latter is thought to be more common with posterior epistaxis because the site of hemorrhage is closer to the choanae and blood is more likely to reflux to the unaffected side. Direct visualization of the bleeding site may require use of a fiberoptic nasopharyngoscope. Anytime an anterior pack has been placed, and the patient continues to feel blood trickle down the posterior pharynx, a posterior bleed must be considered. A complete set of vital signs, and a thorough head, neck, and naso/oropharyngeal exam should be performed. A general physical overview, searching for evidence of systemic coagulopathy is warranted.

Because posterior epistaxis patients are at greater risk for morbidity and mortality, lab evaluation is often appropriate. This should include hemoglobin and hematocrit, blood type and screening for a possible transfusion, INR/PTT, and any other baseline lab as indicated by the patient's underlying comorbidities. Finally, an intravenous line should be established.

Posterior Nasal Packing

The treatment of posterior epistaxis is posterior nasal packing. Direct pressure is ineffective. The use of cautery in posterior epistaxis is best left to an otolaryngologist. Attempts at cauterizing a vigorously bleeding posterior hemorrhage is nearly impossible and often leads to increased bleeding. Severe damage to the posterior nasal cavity can be sustained with blind attempts at chemical, heat, or electrocautery. The use of vasoconstrictors and anesthetic agents in the treatment of posterior epistaxis is the same as for anterior bleeding.

In the past, physicians were taught to construct a posterior nasal pack using a gauze roll and silk ties. In actual practice, this is a time-consuming and difficult procedure. This practice has been superseded by the advent of commercial devices such as nasal sponges, the Nasostat epistaxis balloon (Sparta Surgical Corp., Hayward, CA), and the Storz epistaxis catheter (Storz Instrument., St. Louis, MO). These tools allow for rapid control of epistaxis with minimal preparation. The use and insertion of the nasal tampons in posterior epistaxis is the same as discussed for anterior epistaxis. A longer sponge is utilized to obtain both anterior and posterior tamponade.

The procedure for insertion of a commercial nasal catheter is as follows:

- The nasal cavity is prepared using vasoconstrictors and anesthetic agents.
- A test is performed for leakage by filling the anterior balloon with 25 mL of water and the posterior balloon with 8 mL of water. If no leak is detected, the water is removed.
- The device is lubricated with 4% lidocaine jelly and inserted into the nasopharynx. The patient opens his or her mouth, and the catheter is advanced until the distal balloon tip is visible in the posterior pharynx.
- The posterior balloon is slowly filled with 4 to 8 mL of water, and the device is pulled anteriorly so that it wedges in the posterior nasopharynx.
- While gentle traction is maintained, the anterior balloon is slowly inflated with 10 to 25 mL of water, providing anterior tamponade. Inflation should be stopped immediately if the patient complains of significant pain. However, some discomfort is usually present.
- Bilateral packing may be necessary to control hemorrhage.
- Analgesics are usually required.

If a commercial device is not available, a Foley catheter can be used to construct a posterior pack. The procedure for placement of the Foley catheter is identical to the procedure described above with only slight differences. The tip of the Foley catheter must be trimmed off to avoid stimulation of the posterior pharynx. The Foley catheter must be pulled anteriorly and held in the forward position by a transverse clamp across the catheter, external to the nasal septum. Ensure that alar necrosis does not result by inserting padding between the nasal alae and the clamp. After placement of a Foley catheter, the anterior nasal cavity is packed as previously described.

The procedure of inserting a posterior nasal pack is very uncomfortable and stressful to the patient. After placement, the patient often continues to have significant discomfort and may require sedation.

Posterior nasal packs carry a significant morbidity. Problems include difficulty swallowing; eustachian tube dysfunction; otitis media; sinusitis; nasal synechiae; hypoventilation with resultant hypoxia; cardiac dysrhythmias; cardiac arrest; accidental dislodgement into the airway; or aseptic necrosis of the nasal alae, columella, palate, and nasal mucosa. In patients with severe COPD or CHF, posterior nasal packing can result in hypoxia.

Embolization and Ligation

If epistaxis is refractory to the above treatments, more extensive and specialized techniques may be needed. These include arterial ligation or embolization. These options should only be performed by a specially trained physician.

Surgical ligation can be performed as treatment for posterior epistaxis. The external carotid artery can be ligated distal to the lingual branch. However, this is rarely successful in controlling epistaxis secondary to the extensive collateral circulation. Ligation of the ethmoidal vessels and the maxillary artery have been successful in controlling hemorrhage. Angiographic embolization of the vessels supplying the bleeding site is usually used when bleeding has failed to respond to packing or arterial ligation. A 96 percent success rate has been reported in patients with severe or intractable epistaxis. [5] The risks of embolization include neurologic and ocular complications from accidental embolization of the cerebral or ophthalmic arteries. Despite this, in experienced hands embolization results in low morbidity and negligible mortality. [5]

Disposition

All patients with posterior epistaxis should have emergent consultation with an otolaryngologist. Attempts at controlling bleeding with the appropriate balloon technique should not be delayed pending the arrival of a specialist physician. Because of the potential for serious morbidity and mortality associated with posterior packing, patients are usually admitted for observation. They may need sedation secondary to severe discomfort and require monitoring for hypoxia. Prophylactic antibiotics are generally given (see anterior packing).

NASAL FRACTURE

Pathophysiology

Any significant central midface trauma should be considered highly suspicious for the presence of a nasal bone fracture. A direct impact is most likely to cause a fracture because there is no soft tissue to dissipate the force of the blow. The pathomechanics of the resulting fracture vary according to the site, direction, and intensity of impact, as well as the characteristics of the bone that is struck. In younger patients, bones are denser and more elastic, whereas in older patients, bones are less dense and more brittle.

Clinical Features

A careful history can usually ascertain the severity of trauma incurred. In cases where the forces involved are severe, the physician must be suspicious of cervical spine injury or closed-head injury. These injuries take precedence over any concurrent nasal fracture. Epistaxis may be frequently associated with nasal trauma.

Findings suggestive of a nasal fracture include swelling, tenderness, crepitance, ecchymosis, or nasal deformity. Indirect evidence of nasal fracture include periorbital ecchymosis, epistaxis, and rhinorrhea. A general physical exam, specifically focused on the head, neck, and neurologic system, is necessary to exclude associated injury.

After spraying the nasal mucosa with a vasoconstricting agent, search for defects in the mucosa, septal hematoma, and bony displacement. Finally, palpate the injured nose checking for crepitance, stepoffs, and instability. Severe edema often precludes immediate detection of nasal fractures.

The diagnosis of nasal fracture is predominately based upon historical and physical exam findings. Nasal radiographic studies are usually not required for diagnosis

or management. Radiographic imaging selection depends upon suspicion of other associated facial fractures.

Treatment

A simple, minimally or nondisplaced nasal fracture does not require specific treatment other than analgesia, nasal decongestants, and protection from further injury. If significant epistaxis occurs, nasal packing can be placed as previously discussed, but is usually unnecessary. All patients with suspected nasal bone fractures should be given follow-up for reevaluation with either a plastic surgeon, otolaryngologist, or an oral and maxillofacial surgeon, once the swelling has subsided, usually in 2 to 5 days. Grossly displaced nasal fractures should receive consultation in the ED for correction.

Complications

The complications of a nasal fracture include nasal deformity, deviated nasal septum, septal hematoma, cribiform plate fracture, and associated facial, head, or spinal injuries.

A septal hematoma is a rare complication. It is a collection of blood beneath the septal perichondrium. Easily visualized using an otoscope, it appears as a bluish, fluid-filled sac overlying the septum. Such a hematoma is easily managed by making an incision for drainage, followed by packing the nasal cavity to prevent reaccumulation. If undiagnosed or left untreated, it may progress to an abscess or result in avascular necrosis (AVN) of the cartilaginous septum within three to four days. Septal AVN is associated with the cosmetic complications of saddle nose deformity, retraction, and changes in phonation.

Fracture through the cribiform plate of the ethmoid bone is associated with a cerebrospinal fluid (CSF) leak through torn meninges. It represents a violation in the integrity of the subarachnoid space. Cerebrospinal fluid rhinorrhea is suspected in any patient presenting with a clear nasal discharge following facial injury. CSF rhinorrhea is usually seen within the first week as cerebral edema resolves, but it may be delayed days to weeks following a traumatic event. If untreated, possible sequelae include meningoencephalitis or brain abscess. Fortunately, this is rare.

The identification of CSF rhinorrhea can be difficult in nasal injuries because it is not unusual for there to be a clear transudate from the traumatized nasal mucosa. One method of detecting CSF is to put a drop of the suspected liquid on a piece of filter paper and see if a clear area surrounds a central blood stain. An alternative is that CSF can be detected by using a glucose reagent strip. If the glucose content of suspected fluid is greater than 30 mg/dL, then the presence of CSF is suggested. These tests should not be used to definitively exclude the diagnosis. All patients with suspected CSF rhinorrhea should undergo a head CT and urgent neurosurgical consultation. If a fracture of the cribiform plate is clinically suspected, the patient should be placed in an upright position, intranasal packing avoided, and immediate neurosurgical consultation obtained. Coughing, sneezing, nose blowing, and straining by the patient should be avoided.

Other injuries often seen with nasal trauma are fractures of the orbital wall, sinuses, and zygoma. The emergency physician should also be suspicious of cervical spine damage or closed-head injury in any patient with significant facial trauma.

Disposition

An isolated nasal bone fracture does not itself warrant admission to the hospital. The patient should be advised to initiate measures to reduce swelling immediately. Discharge instructions should instruct intermittent ice application for 24 to 48 h, elevation of the head, even while sleeping, and over-the-counter decongestants as needed. They should also include head-injury instructions and advise the patient to be alert for CSF rhinorrhea. All patients should be given follow-up with an appropriate specialist at 2 to 5 days.[5] Although nondisplaced fractures rarely need further treatment, follow-up should be provided secondary to the cosmetic importance of the injury.

NASAL FOREIGN BODIES

Children frequently insert foreign bodies in their nares that may require removal by a physician. Items that may be found in the nasal cavity are limited only by the child's imagination. Among foreign bodies most often found in children's nostrils are food, paper, and pieces of toys.[6,7] Dried beans and vegetable matter are particularly concerning because they tend to absorb fluid and swell, increasing discomfort and making removal more difficult. Other common foreign bodies include rocks, buttons, and button batteries.

Clinical Features

When obtaining a history, interact with the child in a nonjudgmental manner. Many children are hesitant to admit placing a foreign body in their nose for fear they will elicit displeasure from their parents or the physician. In 73 percent of cases, the insertion of the foreign body is actually observed by the caregiver or the child reported the presence of a foreign body.[8] The treating physician should suspect a nasal foreign body in a child who presents with any of the following:

- Sensation of unilateral nasal obstruction
- Persistent, foul-smelling rhinorrhea despite proper antibiotic treatment
- Persistent unilateral epistaxis

In addition to a nasal examination, a complete head and neck physical exam should also be performed. The ears should be carefully checked for foreign bodies, and the lungs auscultated for wheezing.

Treatment

If the child is cooperative and the foreign body visible, it is possible to remove the object in the emergency department. In small or uncooperative children, a papoose board may be used for patient restraint. The nasal mucosal is generally prepared with vasoconstrictors and anesthetics (1 cc of phenylephrine mixed with 3 cc of 4% xylocaine). In uncooperative children, aerosolized adrenaline (racemic epinephrine) can be used to decongest the nasal mucosa and loosen the foreign body.[9] When administered in the aerosolized form by the parent, it causes little or no distress to the child. Following this, visualization with an appropriate-sized nasal speculum is attempted.

If the object appears loose after vasoconstriction, an attempt to remove it can be made using a number of different techniques including:

- Positive pressure technique.
- Removal by a suction catheter.
- Grasping the object with bayonet or alligator forceps.
- Passing any blunt-hooked instrument beyond the object, rotating the instrument, and pulling the foreign body out.
- Passing a Fogarty vascular catheter past the foreign body, inflating the balloon and removing the catheter and foreign body.

The latter four techniques are all acceptable but require a cooperative child, or conscious sedation, to prevent damage to the nasal mucosa.

Regardless of the technique utilized, the airway must be protected and appropriate material for managing airway obstruction should be immediately available. The examiner should be careful not to advance the foreign body any deeper into the nasopharynx.

Positive Pressure Technique

The successful use of this method is well documented.[9,10 and 11] It can be performed in both cooperative and uncooperative patients, and it is less invasive. After vasoconstrictors, positive pressure can be applied by the patient, if cooperative, or the caregiver. The caregiver is instructed to give a puff of air to the mouth of the child while occluding the unobstructed nare with a finger. The foreign body is usually expressed from the nose onto the cheek of the caregiver. Repeated attempts

may be necessary.

Disposition

Despite anxiety generated in the mind of the parent, most patients with nasal foreign bodies can be discharged home even if removal attempts are unsuccessful. Admission need only be considered if the patient exhibits constitutional symptoms such as fever, malaise, or lethargy. If attempts to remove the foreign body are unsuccessful, the patient should follow-up with an otolaryngologist within one to two days. If foreign body removal was successful, no further follow-up or treatment is required.

SINUSITIS

Acute sinusitis is defined as acute inflammation of the paranasal sinuses of less than three weeks duration. It has been reported to affect 14 percent of the population.[12] In 1992, direct medical costs of sinusitis reached almost $2.4 billion.[12] Despite the frequency of the disease, it often goes unrecognized or misdiagnosed. Once an accurate diagnosis has been made, appropriate treatment is essential to avoid the complications associated with acute sinusitis. Mastoid sinus disease is covered in Chap. 231.

Pathophysiology

There are six distinct nasal sinuses: two maxillary, two frontal, one sphenoidal, and the ethmoidal air cells. The biologic function of the paranasal sinuses remains unknown. Various hypotheses as to their function have been suggested, including humidification of air, pressure equalization, reduction in the weight of the skull, provision of vocal resonance and sound projection, and assisting in olfaction.

Sinusitis occurs when there is an acute obstruction of the normal drainage mechanisms of the sinuses. Efficiency of sinus drainage consists of three elements: ostial patency, ciliary apparatus function, and the quality of the nasal secretions. Although an alteration in any of these components can result in sinusitis, obstruction of the mucociliary drainage at the osteomeatal complex is generally accepted as the major cause.

Viral upper respiratory tract infections and allergic rhinitis are the most common initiating factors in sinusitis.[13] Edema from rhinitis causes obstruction at the osteomeatal complex, followed by reabsorption of the air in the sinus, that results in negative pressure. Negative pressure causes a collection of transudate within the sinus cavity. If bacteria are present, multiplication leads to suppuration. It is most commonly caused by *Streptococcus pneumoniae* in 37 percent, and *Haemophilus influenzae* in 38 percent of cases.[14] Other organisms seen in acute sinusitis include, in decreasing order of frequency, other haemophilus species, *Streptococcus pyogenes, Moraxella catarrhalis,* alpha streptococci, and gram-negative bacilli with mixed anaerobes.[14]

Chronic sinusitis results from unresolved acute sinusitis of more than three weeks duration. In chronic sinusitis, polymicrobial anaerobic species are found in over 50 percent of cases. The anaerobic bacteria of chronic sinusitis consist of peptostreptococcus in 22 percent and prevotella species in 15 percent of cases.[14] Decreasing in order of frequency, other species include bacteroides, *Propionibacterium,* and *Fusobacterium.*[14] A number of aerobic species are found in chronic sinusitis, including streptococci, *Staphylococcus aureus,* haemophilus species, and *M. catarrhalis.*[14] In pediatric cases with chronic sinusitis, bacteria are most likely to represent the pathogens of acute sinusitis.[14]

Nosocomial sinusitis is associated with nasotracheal or nasogasric tubes. It is frequently due to gram-negative bacilli, and is commonly mixed. *Pseudomonas aeruginosa* is seen in 48 percent of cases, followed by *Klebsiella* (28 percent), enterobacter species (28 percent), *Proteus mirabilis* (20 percent), *Escherichia coli* (12 percent), b-hemolytic strep (12 percent), bacteroides species (8 percent), and *S. aureus* (4 percent).[14] Pseudomonas is the predominant pathogen in individuals with cystic fibrosis, and is common in patients with nasal polyps.[14]

As many as 70 percent of HIV patients develop sinusitis. In addition to the usual pathogens, they may be infected with opportunistic bacteria, viruses, or fungi.[14] Consequently, cultures are essential in this subgroup.

Clinical Features

The classic symptoms of acute sinusitis include pain overlying the affected area, decreased sense of smell, fever, headache, and purulent nasal discharge. These symptoms are often difficult to differentiate from upper respiratory infection or allergic rhinitis, and have been found to be poor indicators of sinus infection. The best indicators of bacterial sinusitis are, in decreasing order of predictive value, maxillary toothache, mucopurulent discharge, poor response to nasal decongestants, and abnormal transillumination.[15,16] Although maxillary toothache is a good predictor of acute sinusitis, it is only found in 11 percent of patients with the disease.[15]

The presence of ethmoidal sinusitis usually causes the patient to complain of a dull, aching sensation behind the eye. Infection of the frontal and maxillary sinuses generally causes pain over the affected sinus. Ethmoidal sinusitis can spread to orbit, retroorbital area, and central nervous system. The headache seen in sinusitis is usually aggravated by bending forward, coughing, or sneezing, although these findings have poor sensitivity and specificity.[15]

Typically the physician may find tenderness to palpation and percussion over the involved sinus. Direct visualization of the nasal cavity may show swollen, erythematous mucosa with purulent exudate draining from the ostia. Diminished transillumination of the affected sinus is also seen. However, results regarding the sensitivity of the various techniques is conflicting, and there is a significant amount of interobserver variability.[16] The physical should include comprehensive head, neck, and neurologic system examination. It should be directed to specifically exclude indications of infectious spread beyond the sinus cavity, as well as complications and confounders in the differential diagnosis.

In the emergency department, acute sinusitis is generally a clinical diagnosis based on history and physical exam. Standard radiography can visualize the paranasal sinuses, but there is no consensus role for their use in emergency diagnosis. The most reliable radiographic signs include sinus opacity, air fluid levels, or at least 6 mm of mucosal thickening.

The primary role of CT is to diagnose sinusitis when the differential diagnosis is unclear and to define anatomy before surgery.[17] Only 62 percent of patients with sinus-related symptoms will have CT evidence of abnormality.[18] Interestingly, 16 percent of patients without sinus-related symptoms will have abnormalities on CT scanning.[18] Therefore, CT is not routinely indicated in the emergency department setting. It should be considered in immunosuppressed or toxic patients.

Cultures are not routinely required. However, they should be considered in patients with HIV, chronic immunosuppression (e.g., transplant patients), those who demonstrate any signs of infectious spread external to the sinus cavity, or in those who are systemically toxic.

Differential Diagnosis

The most important points to consider are those diagnoses arising as complications from sinusitis. These include any evidence of infectious extension from the sinus cavity, such as periorbital cellulitis, brain abscess, subdural empyema, meningitis, or cavernous sinus thrombosis. Such patients are febrile, extremely ill, may have unstable vital signs, can demonstrate altered mental status, meningismus, or focal neurologic findings. None of these symptoms are compatible with diagnosis of sinusitis. The history and physical should be structured such as to exclude these diagnoses.

The differential diagnosis of patients with signs and symptoms of facial pain includes tension headache, migraines, and cluster headache. Headache syndromes can usually be excluded based upon limited and historical evidence of an infectious process. Cluster and migraine headache patients usually have a history of similar headache, and sinusitis is never preceded by aura or other prodromal neurologic symptoms. Tension headache may exhibit trigger points and its distribution does not suggest sinusitis. Occasionally, however, the above disorders can coexist with sinusitis, making diagnosis more difficult.

Other diagnoses to consider include nasal polyp or foreign body. While a foreign object or polyp may cause purulent rhinorrhea, a physical exam localizing either can exclude sinusitis as the primary etiology of the discharge. Dental pain is usually localized to a single tooth, exquisitely sensitive to percussion, with little other symptoms to support the diagnosis of sinusitis. Likewise, temporomandibular syndrome may result in facial pain, but it is usually localized to the region of the

temporomandibular joint, exacerbated by jaw movements, and has no associated infectious findings. Trigeminal neuralgia may cause facial pain. However, there is no evidence of infection, the symptoms are intermittent, and the pain character does not suggest sinusitis.

Finally, other diagnoses may mimic bacterial sinusitis. These include viral infection of the upper respiratory tract, nasal congestion, allergic rhinitis, and mucosal engorgement due to rebound following excessive topical decongestant use.

Treatment

Antimicrobial therapy reduces or eliminates bacteria in the maxillary sinus and improves symptoms in acute bacterial sinusitis. [19] Empiric therapy against the typical pathogens seen in acute sinusitis is usually appropriate. Timely treatment helps prevent complications.

Antibiotics usually recommended for the treatment of acute sinusitis in the outpatient environment include amoxicillin, amoxicillin-clavulanate, or erythromycin plus sulfonamide. Alternatives include third-generation cephalosporins, clarithromycin, azithromycin, doxycycline, or trimethoprim sulfamethoxazole. [14] In chronic sinusitis, recommended antibiotics include amoxicillin-clavulanate or ampicillin sulbactam. Alternatives include clindamycin, a cephalosporin plus metronidazole, or doxycycline.[14] When HIV or cystic fibrosis complicates the presentation, the initial choice of antibiotics is clindamycin in addition to ciprofloxacin. Alternatives include augmented penicillin plus ciprofloxacin or gentamicin. [14] The recommended duration of therapy varies. Most authorities recommend either 10-, 14-, or 21-day regimens.[14,20]

Over-the-counter nasal spray decongestants or antihistamines, such as pseudoephedrine, phenylephrine, oxymetazoline, and phenylpropanolamine, are commonly used, but there is scant literature to support the practice. [21,22 and 23] While some authors feel that decongestants are important in treatment, [23] there are unproven theoretical concerns that vasoconstrictors may impede mucociliary transport. [22,24] If topical decongestants are prescribed they should be of limited duration due to rebound mucosal congestion and edema if their use exceeds five to seven days. [23] Oral antihistamines may be of use in allergic rhinosinusitis. [23] However, in suppurative sinusitis, they may result in thickening of secretions, with crust formation, at the osteomeatal complex. [23] No superior therapeutic benefit of the newer nonsedating antihistamines has been documented in comparison to older sedating antihistamines. [23] While soporific side effects can be avoided with newer nonsedating antihistamines, they have the drawback of increased cost, and some have significant drug interactions (e.g., terfenadine or astemizole with macrolides or ketoconazole may cause ventricular dysrhythmias).[23]

Topical steroids have been shown to reduce local inflammation, thus increasing ostial drainage. However, there is inadequate data to justify their use in all patients with acute sinusitis. If allergic rhinitis is a significant contributing factor, corticosteroids may be indicated.

Complications

Persistent sinusitis can result in extension of the infectious process into the surrounding tissues. Bony destruction, originating from the frontal sinus, can extend anteriorly. This leads to the development of a doughy edematous forehead called Potts puffy tumor. If a frontal bone osteomyelitis extends posteriorly, a frontal brain abscess, meningitis, subdural empyema, or epidural abscess can develop. Extension from the ethmoid sinus can result in orbital or periorbital cellulitis. Finally, direct extension from the paranasal sinus to the venous or lymphatic system can cause cavernous sinus thrombosis. All patients suspected of having any infection extension of infection beyond the paranasal sinuses should undergo immediate CT scanning, intravenous antibiotic therapy, and emergent consultation with the appropriate specialist.

Disposition

Most patients with acute sinusitis can be treated as outpatients. Any patient demonstrating evidence of infectious spread beyond the sinus cavity should be admitted to the hospital, including patients who appear toxic, are febrile with neurologic signs, or have orbital/periorbital cellulitis.

Patients who are candidates for discharge should be advised to follow-up with their primary care physician or an otolaryngologist if their symptoms persist longer than 5 to 7 days despite appropriate treatment. Patients with evidence of chronic sinusitis (symptoms greater than three weeks) should follow-up with an otolaryngologist within 5 to 7 days. At discharge, they should be instructed to see their doctor promptly, or return to the emergency department if they develop uncontrolled fever, severe or worsening headache, vision changes, or persistent vomiting.

234 ORAL AND DENTAL EMERGENCIES

Ronald W. Beaudreau

Although few life-threatening dental emergencies occur, oral and dental complaints commonly result in emergency department (ED) visits in the United States. Oral emergencies generally can be divided into three categories: (1) orofacial pain, (2) orofacial trauma, specifically dentoavleolar trauma, and (3) hemorrhage. Early manifestations of many systemic illnesses are evident in the oral environment and may provide clues to the diagnosis of systemic illnesses. Oral lesions may cause pain or anxiety, and it is important that the emergency physician be familiar with common oral pathology and its management. An understanding of dental anatomy and the attachment apparatus is essential for the recognition and management of oral disease.

ORAL AND DENTAL ANATOMY

The normal adult dentition consists of 32 permanent teeth. The adult dentition has four types of teeth: 8 incisors, 4 canines, 8 premolars, and 12 molars. The primary or deciduous dentition consists of 20 teeth of three types: 8 incisors, 4 canines, and 8 molars. Figure 234-1 shows the eruptive pattern of both the primary and permanent dentition. *Agenesis,* or lack of formation of a tooth or teeth, especially maxillary lateral incisors and third molars, is not uncommon. Likewise, extra or *supernumerary teeth* are not uncommon. Each tooth type is designed for a specific function in the process of mastication. Incisors are used for biting and cutting, canines and premolars for ripping, and molars for grinding. Figure 234-2 illustrates one commonly used tooth numbering system; however, description by the emergency physician of the tooth type and location is appropriate. Mastication is an important initial step in the digestive process and thus nutrition. The dentition is also important in the development of the mandible and maxilla and aesthetic development of the midface.

FIG. 234-1. Normal eruptive patterns of the primary and permanent dentition.

FIG. 234-2. Identification of teeth.

Anatomy of the Teeth

A basic understanding of dental anatomy is important in understanding dental disease. Table 234-1 lists commonly used dental nomenclature. A tooth consists largely of *dentin,* which surrounds the *pulp,* or neurovascular supply of the tooth (Fig. 234-3). Dentin is a homogeneous material produced by pulpal odontoblasts throughout life. It is deposited as a system of microtubules filled with odontoblastic processes and extracellular fluid. The *crown,* or portion of the tooth that is visible, consists of a thick *enamel* layer overlying the dentin. Enamel, the hardest substance in the human body, consists largely of hydroxyapatite and is produced by ameloblasts prior to eruption of the tooth into the mouth. The *root* portion of the tooth extends into the alveolar bone and is covered with a thin layer of *cementum.*

Anatomically descriptive terms for tooth surfaces	
Interproximal	The surfaces between two adjacent teeth
Mesial	The interproximal surface facing anteriorly or toward the midline
Distal	The interproximal surface facing posteriorly or away from the midline
Occlusal	The chewing surface
Facial	Toward the face, a general term applicable to all teeth
Labial	Toward the lips, specific to anterior teeth
Buccal	Toward the cheek, specific to posterior teeth
Palatal	Toward the palate, specific to maxillary teeth
Lingual	Toward the tongue, specific to mandibular teeth
Apical	Toward the tip of the root of the tooth
Radicular	Associated with the root, especially the apical region
Coronal	Toward the crown of the tooth
Incisal	Toward the biting edge of incisors
Cervical	Related to the junction of the crown and root of the tooth

TABLE 234-1   Commonly Used Dental Terminology

FIG. 234-3. The dental anatomic unit and attachment apparatus.

The Normal Periodontium

The periodontium, or attachment apparatus, is essential for maintaining the integrity of the dentoalveolar unit. The attachment apparatus consists of a gingival component and a periodontal component. The gingival component includes the junctional epithelium, gingival tissue, and gingival fibers. The periodontal component includes the periodontal ligament, alveolar bone, and cementum of the root of the tooth. The periodontal ligament consists of collagen fibers that extend from the alveolar bone to the root of the tooth, adhering to the cementum via a hemidesmosomal attachment. The latter component forms the majority of the attachment apparatus, and the former aids primarily in maintaining the integrity of the periodontal ligament. Disease states such as gingivitis and periodontal disease weaken and destroy the attachment apparatus, resulting in tooth mobility and tooth loss. [1]

Gingival tissue is keratinized stratified squamous epithelium. It can be divided into the free gingival margin and the attached gingiva. The free gingiva is the portion that forms the 2- to 3-mm-deep *gingival sulcus* in the disease-free state. The attached gingiva adheres firmly to the underlying alveolar bone and extends to the oral vestibule and floor of the mouth. There the tissue becomes nonkeratinized *alveolar mucosa.* This nonkeratinized tissue covers the mucosal surface of the cheeks, lips, and floor of the mouth.[1]

OROFACIAL PAIN

Pain of Odontogenic Origin

TOOTH ERUPTION   Discomfort is commonly associated with the eruption of primary or deciduous teeth in infants. Irritability, drooling, and decreased intake are commonly associated findings. An associated low-grade fever (37.9°C) and diarrhea are more controversial findings. No scientific data support an association of teething, fever, and diarrhea. It is plausible that mild dehydration from excessive salivary production or a decrease in intake may result in a low-grade fever, and changes in feeding habits may result in diarrhea. One must be careful in attributing either to tooth eruption. Other sources for fever must be carefully sought. [2] Other common causes of orofacial pain are listed in Table 234-2.

TABLE 234-2   The Differential Diagnosis of Orofacial Pain

As with the primary dentition, eruption of permanent teeth, especially third molars, or *wisdom teeth,* may result in significant pain. Gingival irritation and inflammation associated with tooth eruption are common and must be distinguished from *pericoronitis.* Pericoronitis, although usually associated with the eruption of third molars,

can be associated with any tooth. Gingival tissue overlying the occlusal surface of an erupting tooth, or *operculum,* progressively becomes inflamed secondary to impaction of food and debris beneath the operculum. Direct trauma from opposing teeth during mastication compounds the inflammatory process. Normal gingival irritation associated with tooth eruption is replaced by a progressive inflammatory process resulting in frank infection. Because of the close proximity of the masseteric space to third molars, associated trismus is common and portends the potential for extension into the communicating parapharyngeal spaces. Treatment consist of appropriate antibiotic therapy with penicillin VK 500 mg qid, erythromycin 250 mg qid, or clindamycin 300 mg qid, local irrigation of food and debri from underneath the operculum, saline mouth rinses, and analgesic therapy with nonsteroidal anti-inflammatory drugs (NSAIDs) and narcotic preparations as appropriate. Referral to a general dentist or an oral and maxillofacial surgeon within 24 to 48 h is essential. If pericoronitis is related to trauma from an opposing tooth, as is frequently the case with third molars, concomitant extraction of the opposing tooth and antibiotic therapy will bring marked relief within 24 h. [3] Definitive treatment is extraction of the associated tooth by a general dentist or oral and maxillofacial surgeon.

DENTAL CARIES AND PULPAL PATHOLOGY   *Dental caries* represents the loss of integrity of the tooth enamel secondary to dissolution of hydroxyapatite from prolonged exposure to the acidic metabolic by-products of plaque bacteria. Caries most commonly occurs in areas where plaque accumulates such as pits and fissures of the occlussal surface, interproximally, and along the gingival margins. When a sufficient breach of enamel integrity has occurred, sensitivity to cold or sweet stimulus may result. With dentinal involvement, caries progression occurs more rapidly, spreading along dentinal microtubules. At this stage, direct communication between the oral environment and the vital dental pulp has been established, and inflammatory changes in the pulpal tissue are evident histologically.

The pulpal inflammatory process is initially reversible, but with continued stimuli, the pulp's ability to respond and repair is jeopardized.   *Irreversible pulpitis* can be distinguished from *reversible pulpitis* by the duration of symptoms. Both require a stimulus to initiate a painful response; however, in reversible pulpitis, the duration of pain is short, lasting seconds, as compared with irreversible pulpitis, in which the pain may last for minutes to hours. The most common stimulus is thermal, although sweet or sour stimulus also can elicit a painful response. Spontaneous odontogenic pain most frequently represents pulpal death or necrosis. Pain elicited with heat stimulus is most commonly associated with pulpal necrosis, but some painful response to heat with irreversible or irreversible pulpitis may occur. Distinguishing where a particular tooth falls on the continuum is impractical for the emergency physician. Treatment focuses on providing adequate analgesia and referral to a general dentist. The definitive treatment for irreversible pulpitis and pulpal necrosis is root canal therapy or dental extraction. [4,5]

PERIRADICULAR PATHOLOGY   The most common cause of severe odontogenic pain is periapical pathology. *Periapical granuloma,* more appropriately termed *periradicular periodontitis,* is the most common periapical lesion. This lesion is not a true granuloma but rather slowly expanding granulation tissue associated with the root apex. Most commonly, periradicular periodontitis is a result of pulpal inflammation or necrosis, but it can be associated with trauma. *Periapical* or *radicular cyst* and *periradicular abscess* are clinically and radiographically identical lesions to periradicular periodontitis. A periapical cyst has an epithelial lining originating embryologically from the rest of Malassez, and a periradicular abscess represents the accumulation of associated inflammatory cell. All three lesions are only associated with the apical region of teeth with severely inflamed or necrotic pulps and may cause significant pain. Radiographically, these periapical lesions appear as a slight widening of the periodontal ligament space, thinning of the lamina dura, or a frank radiolucent area associated with the apex on a periapical dental radiograph (Fig. 234-4). Radiographic evaluation with a panorex is rarely useful for identification of all but the most extensive periradicular lesions but can be important in identifying more significant painful osseous pathology. Erosion of a periradicular abscess through the cortical bone results in subperosteal extension with intraoral or facial swelling and fluctuance. A small swelling of the gingiva with a draining fistula adjacent to the affected tooth is known as a *parulis.*[4,5]
FIG. 234-4. A. The radiographic appearance of a healthy tooth with a normal periodontal ligament space and distinct lamina dura compared with the radiographic appearance of a periapical abscess, periradicular periodontis, and periradicular cyst.   **B.** A frank periapical radiolucency. **C.** Subtle radiographic loss of the periapical lamina dura and widening of the periodontal ligament space. (*Courtesy of Gary M. Beaudreau, D.M.D.*)

Pain of dental origin may be diffuse in nature, presenting as a headache, sinus pain, eye pain, or jaw or neck pain or may be localized to a single tooth. One must remember to consider myocardial infarction as an etiology of jaw pain. Identification of the offending tooth is best accomplished by eliciting pain with percussion of the suspected teeth with a dental mirror handle or similar metallic object. Definitive treatment of periradicular periodontitis, periapical cysts, and abscesses is root canal therapy or extraction of the affected tooth. This, however, is not prudent in the ED. Subperiosteal extension and the resulting fluctuant abscess should be incised and drained orally. The emergency physician should treat dental abscesses or other periapical lesions with oral antibiotics such as penicillin VK 500 mg qid, clindamycin 300 mg qid, or erythromycin 500 mg qid and provide adequate analgesia with an NSAID. Narcotic analgesia may be indicated in the first 24 to 48 h. Prompt referral to a dentist for definitive treatment such as root canal therapy or extraction is indicated. [4,5]

FACIAL CELLULITIS   Spread of odontogenic infections into the various facial tissue spaces is relatively common. Buccal extension of a periapical infection of the mandibular teeth will involve the buccinator space. Maxillary labial extension of infection primarily will involve the infraorbital space. Perforation through the lingual cortical bone of mandibular molars, particularly the second and third molars, usually occurs below the mylohyoid ridge, affecting the submandibular space. Lingual spread of periapical infections associated with mandibular anterior teeth will affect the lingual space. The submandibular space and lingual space communicate with each other at the posterior border of the mylohyoid muscle.

Cellulitis of bilateral submandibular spaces and the lingual space is called *Ludwig's angina* and is potentially life threatening. Clinically, Ludwig's angina is a rapidly spreading cellulitis that results in brawny induration of the suprahyoid region and elevation of the tongue. Involvement of the floor of the mouth pushes the tongue posteriorly. Epiglottic involvement is not uncommon. As a result, airway compromise is the immediate primary concern. The primary focus of initial management is maintenance of a patent airway. Timely administration of high-dose penicillin and metronidazole or cefoxitin is essential. An aminoglycoside may be added to extend coverage, and in the penicillin-sensitive person, clindamycin may be substituted. Immediate oral and maxillofacial surgical consultation and hospitalization for incision and drainage and intubation as indicated are necessary. [6]

Infection of the infraorbital space may have a potentially devastating outcome if retrograde spread via the ophthalmic veins occurs, and the cavernous sinus becomes involved. *Cavernous sinus thrombosis* presents as an infraorbital or periorbital cellulitis with rapidly developing meningeal signs, sepsis, and coma. Early recognition and treatment with high-dose intravenous antibiotic as above are essential in decreasing morbidity and mortality.

POSTEXTRACTION ALVEOLAR OSTEITIS   Pain in the initial 24 to 48 h after dental extraction, termed *periosteitis,* is common and responds well to analgesics. Depending on the tooth removed, density of the bone, and amount of associated trauma that occurred during extraction, significant discomfort can occur. *Postextraction alveolar osteitis,* or *dry socket,* usually occurs on the second or third postoperative day and is associated with exquisite oral pain. Dislodgment of the clot from the socket or fibrinolytic dissolution of the clot results in exposure of the alveolar bone to the oral environment. This initiates an inflammatory response resulting in a localized osteomyelitis of the exposed bone. A higher incidence of dry sockets has been identified in females on hormone replacement therapy probably secondary to increased plasmin fibrinolytic activity as a result of exogenous estrogens. Other risk factors for developing postextraction alveolar osteitis include smoking, preexisting pericoronitis or periodontal disease, traumatic extractions, and a prior history of alveolar osteitis. [7,8]

The incidence of postextraction alveolar osteitis is 2 to 5 percent of all extractions but is considerably higher (20–35 percent) among impacted third molar extractions. Many studies have shown that topical antibiotic placement such as tetracycline or clindamycin at the time of surgery or chlorhexidine mouth rinses after extraction reduce by nearly tenfold the incidence of dry sockets. Dental radiographs should be taken to ensure the absence of a retained root tip or other foreign body. Thorough irrigation of the dental socket with sterile normal saline and packing it with oil of cloves– or eugenol-impregnated gauze results in an almost

immediate improvement in level of comfort. Dental anesthesia may be necessary to adequately irrigate and pack a dry socket. Antibiotic therapy is indicated in the most severe cases, and daily packing changes are important. Thus referral to a dentist within 24 h is indicated. [7,8]

Managing postoperative dentoalveolar sequelae is in the realm of emergency medicine. Postoperative pain is a common presentation. Pain immediately postoperative is most commonly related to the trauma of surgery. Providing adequate analgesia is important in these patients. Postoperative edema such as with extraction of third molars is best managed with ice packs and elevation of the head of the bed to 30°. Most oral and maxillofacial surgeons premedicate patients with Decadron in complex cases to minimize swelling. Swelling normally peaks in the first 24 to 48 h. Trismus is common postoperatively and can result from infection, direct injury to the temporomandibular joint, injury to the muscles of mastication during administration of the inferior alveolar nerve block or during the surgery, and most commonly, normal perioperative inflammation. Trismus peaks in the first 24 h and usually decreases thereafter unless an infective process is the etiology. Postoperative trismus should resolve entirely by 1 week. If trismus persists, stretching exercises usually are initiated by the oral and maxillofacial surgeon. [9]

DENTINAL SENSITIVITY   Improper tooth brushing techniques may result in cervical erosion and abrasion, recession of the gingival tissue, and exposure of the root surface to the oral environment. In this setting, teeth may be very sensitive to cold stimulus. Microscopic or macroscopic fractures of the enamel also will result in pain on cold stimulus or mastication. Avoidance of the inciting stimulus is recommended. There are several therapies available to a dentist such as topical flouride application or restorative repair of areas of significant toothbrush abrasion that may be helpful. [3]

POSTRESTORATIVE PAIN   Pain may occur after a dental restorative procedure. Trauma from mechanical instrumentation of the tooth or direct exposure of the pulpal tissue during instrumentation may result in pain. Pain associated primarily with mastication may be a result of improper occlusion of the new restoration. Analgesia and referral to the patient's general dentist are the treatment of choice. After endodontic therapy, patients may experience exquisite pain secondary to instrumentation or a buildup of gaseous pressure in the pulp chamber and may require a dentist to reopen the tooth because analgesics may be ineffective.

Periodontal Pathology

PERIODONTAL DISEASE   Gingival inflammation and bleeding, or *gingivitis*, results from the accumulation of plaque along the gingival margins. Hormonal variations of puberty, adolescence, and pregnancy, as well as many medications such as phenytoin, also may result in gingival inflammation. As the inflammatory process progresses, destruction of the attachment apparatus occurs, and the gingival sulcus deepens, resulting in periodontal pockets and *periodontitis.* Periodontal pockets create a favorable environment for plaque accumulation, maturation, and mineralization into *calculus.* Further destruction of the periodontal attachment results. Eventually, sufficient bone loss causes tooth mobility and tooth loss. [1,10]

The pathogenesis of periodontal disease is uncertain, but there is a very strong association between adult periodontitis and *Bacteroides gingivalis.* Many other specific bacteria have been shown to have a role in periodontitis. Destruction of tissue collagens, proteoglycans, and the connective tissue matrix is a major feature of gingivitis and periodontitis. Three theories for the etiology of this destruction have been proposed. Tissue destruction may occur as a result of the direct effects of bacterial plaque and their metabolic products, an accelerated host immune response, or immune deficiencies involving neutrophil function or the autologous mixed lymphocyte response. [1,10]

Four distinctive types of periodontal disease have been identified. These include adult, rapidly progressing, juvenile, and prepubertal periodontitis. [10] Etiology, age and sex predilection, and clinical course of disease vary by type. A definite association between juvenile periodontitis and *Actinobacillus actinomycetemcomitans* exists. More severe and rapidly progressing periodontitis, especially those types affecting a younger population such as the prepubertal and juvenile periodontitis, appears to be associated with decreased neutrophil chemotaxis or phagocytosis. Systemic illnesses such as human immunodeficiency virus (HIV) infection, diabetes, lazy leukocyte syndrome, Down syndrome, and cyclic neutropenia are associated with severe periodontal disease. [1]

Periodontal disease is the most common cause of tooth loss today. It usually progresses painlessly but may present as gingival bleeding or tender, swollen ginigval tissue. Treatment is directed at slowing or arresting the progression of disease primarily by the removal of plaque and its by-products. [1] Antibiotics may play a role in treatment. Referral to a dentist for definitive treatment is indicated because the treatment involves extensive dental cleaning, instruction and improvement in oral hygiene, and periodontal surgery in some cases.

PERIODONTAL ABSCESS   When plaque and debris are entrapped in the periodontal pocket, a periodontal abscess may form, resulting in severe pain. Small periodontal abscesses respond to local therapy with warm saline rinses and antibiotics such as penicillin VK 500 mg PO qid or erythromycin 250 mg PO qid. Larger periodontal abscesses require incision and drainage. Saline mouth rinses four times a day are useful. Analgesics are essential.

ACUTE NECROTIZING ULCERATIVE GINGIVITIS   Acute necrotizing ulcerative gingivitis (ANUG) is an aggressively destructive process (Fig. 234-5). Also known as *Vincent's disease* or *trench mouth,* it is part of a spectrum of disease ranging from localized ulceration of the gingiva to often fatal noma, in which localized ulceration and necrosis spread to the adjacent tissues of the cheeks, lips, and underlying facial bones. [11,12] ANUG is also related to Vincent's angina or tonsilar ulceration and necrosis. The diagnostic triad includes pain, ulcerated or "punched out" interdental papillae, and gingival bleeding. Secondary signs include fetid breath, pseudomembrane formation, "wooden teeth" feeling, foul metallic taste, tooth mobility, lymphadenopathy, fever, and malaise. [12,13]

FIG. 234-5. Acute necrotizing ulcerative gingivitis. (*Courtesy of Philip J. Hanes, D.D.S.*)

The differential diagnosis for ANUG is quite extensive, but herpes gingivostomatitis is most difficult to differentiate. Herpes gingivostomatitis usually has smaller vesicular eruptions, less bleeding, more systemic signs, and lack of interdental papilla involvement. [12,13]

The etiology of ANUG is still poorly understood, but three patterns of disease have been clearly identified: the malnourished child pattern, the young adult stress pattern, and the HIV-positive adult pattern. It appears to be an opportunistic infection in a host with lowered resistence. It is believed that suppression of the humoral and cell-mediated immune response in HIV infection, severe malnourishment, and perhaps stress are responsible for this lowered host resistence. Anaerobic bacteria such as *Treponema, Selenomonas, Fusobacterium,* and *Prevotella* are uniformly identified. These bacteria appear to invade otherwise healthy tissue, resulting in an aggressively destructive disease process. [12,13]

The most important predisposing factor is HIV infection. Previous necrotizing gingivitis infection is the second most important predisposer. Other contributing factors include poor oral hygiene, unusual emotional stress, poor diet, inadequate sleep, Caucasian heritage, age less than 21 years, poor socioeconomic status, recent illness, alcohol use, tobacco use, acatalasia, and various infections such as malaria, measles, and intestinal parasites. [12,13]

The treatment is threefold. Primarily, identification and resolution of the predisposing factors are essential. Bacterial control using chlorhexidine oral rinses twice daily, professional debridement and scaling by a dentist, and adjunctive antibiotic therapy with metronidazole 250 mg tid are the mainstay of treatment. [12] A significant reduction in pain can be expected within 24 h of institution of this regimen. [3] Finally, supportive therapy with a soft diet rich in protein and vitamins and plenty of fluids

is important in establishing and maintaining a disease-free state. [12]

Cranial Neuralgias

Trigeminal neuralgia is the most common of the cranial neuralgias. Others include postherpetic neuralgia, glossopharyngeal and vagal neuralgia, and superior laryngeal neuralgia. All these are far less common. Trigeminal neuralgia is undoubtedly one of the most painful presentations involving the face. [14]

Trigeminal neuralgia affects adults 30 to 60 years of age most commonly. Females constitute 60 percent of the patients. Patients report recurrent episodes of excruciating paroxysmal pain of short duration separated by pain-free periods. Painful episodes have been described as stabbing in nature resembling a severe electric shock. Contraction of the facial and masticatory muscles during an episode is characteristic, resulting in the term *tic douloureux*. Physical stimulation of a trigger point is the usual inciting event. Trigeminal neuralgia is almost always unilateral, following the anatomic distribution of the involved cranial nerve. The maxillary branch of the fifth cranial nerve is most commonly affected. [14]

The pathogenesis of trigeminal neuralgia is still unknown. The two prevailing theories include the vascular compression theory and the demyelination theory. Neither adequately explains the disease. Diagnosis is based on clinical presentation. Since 3 percent of patients with trigeminal neuralgia have multiple sclerosis, referral to a neurologist is essential. Comprehensive examination of the head and neck is required to eliminate organic pathology such as acoustic neuroma or a nasopharyngeal carcinoma. [14]

Trigeminal neuralgia may respond well to the administration of carbamazepine (100 mg/bid initially and gradually increasing as needed to a maximum dose of 1200 mg daily). Surgery is reserved for patients who do not respond to medications. [14]

Nonparoxysmal pain of neuropathic origin may develop (1) in patients who have had long-standing neuralgias, (2) secondary to surgical trauma along the distribution of the affected nerve branch, and (3) in association with viral infections, drugs, or heavy metal intoxication. Other neuropathies such as alcoholic and diabetic sensory neuropathies also may affect the oral cavity.

SOFT TISSUE LESIONS OF THE ORAL CAVITY

Lesions of the oral mucosa are common and, when symptomatic or noticed by patients, may require identification and treatment by the emergency physician. Treatment depends on the appropriate diagnosis. Thus familiarization with common oral pathology is important.

Oral Candidiasis

Candidiasis commonly affects the oral cavity. Nearly 60 percent of healthy adults harbor candidal microorganisms. Concurrent histologic evidence of tissue invasion and clinical manifestations of candidal infections are the primary means for diagnosing oral candidiasis. Many predisposing factors influence the development of oral candidiasis. These include the extremes of age, intraoral prosthetic devices such as dentures, malnourished states, associated mucosal disorders, concurrent infections, antibiotics, and immunocompromised conditions such as acquired immunodeficiency syndrome (AIDS), transplant recipients, radiation therapy, and chronic immunosuppressive therapy. Three oral clinical types have been described. The most common type is the psuedomembranous type with white, curdlike plaques. These plaques can be easily scraped off to reveal an underlying erythematous mucosal base. The second type is atrophic or erythematous and usually involves the dorsum of the tongue. Atrophy of the filiform papillae is seen. Finally, the lesions of hyperplastic candidiasis are raised white plaques that can only be partially removed with scraping due to deeper infiltration into the underlying tissue. Perioral candidiasis also may occur and is commonly seen as angular cheiltis or scaling patches of the perioral facial tissues. Treatment is with topical oral antifungal agents such as nystatin oral suspension 500,000 units qid or systemic agents such as fluconizole 200 mg bid. [11,15,16]

Aphthous Stomatitis

Aphthous stomatitis or ulceration is one of the most common oral lesions, affecting 20 percent of the normal population (Fig. 234-6). Although uncertain, significant evidence suggests that the etiology appears to be a cell-mediated immune response to a yet unidentified triggering agent. Three etiologic factors are known to predispose aphthous ulcer formation: an immune imbalance, a breach in the mucosal barrier, and an allergic response. Aphthous ulceration involves the nonkeratinized epithelium, especially the labial and buccal mucosa, and begins as an erythematous macule that ulcerates and forms a central fibropurulent eschar. Lesions measure from 2 to 3 mm to several centimeters in diameter, are painful, and frequently are multiple. They usually resolve spontaneously in 10 to 14 days. Aphthous stomatitis occurs in a major and minor form. The major form has larger, deeper ulcers that take up to 6 weeks to heal. A third form called *herpetiforme apthae* have up to 100 ulcers each 1 to 2 mm in diameter and take 7 to 10 days to heal. Treatment consist of topical corticosteroids such as betamethasone syrup or 0.01% dexamethasone elixir as a mouth rinse. Fluocinonide 0.05% gel applied topically to isolated lesions is acceptable. Resolution typically occurs 2 days after therapy. Aphthous major is more resistant to therapy and may require intralesional steroid injection or systemic steroid therapy. [16,17]

Herpes Simplex

Herpes simplex type 1 most commonly affects the oral cavity. Herpes simplex type 2 can occur orally and will be discussed later. The primary infection, herpes gingivostomatitis, causes acute painful ulcerations on the gingiva and mucosal surfaces. Fever and lymphadenopathy are commonly associated findings and may occur up to 3 days prior to the appearance of oral lesions. Vesicular lesions appear and rupture after 1 to 2 days, leaving painful ulcers that heal gradually over 1 to 2 weeks. Secondary infection affects mostly the lips but may affect the hard palate and attached gingiva. By adulthood, most of the population has been exposed to herpes simplex type 1. The virus is harbored in sensory ganglion such as the gasserian ganglion of the trigeminal nerve. Periodic stresses activate the virus from its normally dormant state and allow for infection along the sensory distribution of the affected nerve. A prodrome of burning or tingling frequently occurs 1 to 2 days preceding outbreak of the characteristic vesicular lesion. Vesicles rupture within 2 to 3 days, forming small, shallow ulcers that heal in 6 to 10 days. Treatment is usually palliative; however, antiviral therapy with acyclovir 400 mg tid or valacyclovir 500 mg bid for 5 days initiated during the prodromal phase lessens the severity and duration of the ulceration. [11,16]

Varicella-Zoster

The varicella-zoster virus causes chickenpox in its primary infection, resulting in the typical vesicular eruption. It occurs most commonly in childhood but may affect patients at any age. The rash begins on the face and trunk, spreading to involve the entire body over the course of several days. Fever, malaise, pharyngitis, and rhinitis are associated. Vesicular involvement of the oropharynx is common and may precede skin involvement. Treatment is palliative, although special care in

maintaining adequate hydration is important when oral lesions are present.

Herpes zoster, a latent infection of varicella, typically begins with a 1- to 4-day prodrome of exquisite pain in the area innervated by the affected nerve. Although more commonly found on the trunk, herpes zoster may occur in the distribution of the trigeminal nerve 15 to 20 percent of the time. During it prodomal stage, herpes zoster may present only as oral or facial pain, a headache, or a toothache. Vesicular eruptions characteristically occur unilaterally, not crossing the midline, and last 7 to 10 days. Intraoral lesions are most commonly associated with a facial outbreak but can occur alone. Treatment is largely palliative, although early treatment with acyclovir 800 mg 5 times per day for 7 to 10 days or valacyclovir 1 g tid for 7 days reportedly will lessen the outbreak and the likelihood or severity of postherpetic neuropathy.[11],[16]

Herpangina

Herpangina is caused by coxsackievirus group A, types 1–6, 8, 10, and 22 most commonly. Most commonly occurring in the summer and autumn, herpangina presents with a sudden onset of high fever, sore throat, headache, and malaise followed by eruption of oral vesicles 1 to 2 mm in size within 24 to 48 h. The vesicles quickly rupture, leaving numerous shallow, painful ulcers. The soft palate, uvula, posterior pharynx, and tonsilar pillars are usually affected, sparing the buccal mucosa, tongue, and gingiva. The disease lasts 7 to 10 days and can be distinguished from herpetic gingivostomatitis by the lack of gingival involvement. [11]

Hand, Foot, and Mouth Disease

Coxsackievirus type A16, and occasionally types A4, A5, A9, and A10, are associated with hand, foot, and mouth disease. This entity is characterized by the development of a few small vesicles on the tongue, gingiva, soft palate, and buccal mucosa. These vesicles rupture, resulting in painful, shallow ulcers with a surrounding red halo. The lateral and dorsal aspects of the fingers and toes are frequently involved and aid the diagnosis. The buttocks, palms, and plantar surfaces of the feet may be affected. Fever is usually of short duration, and the disease lasts 5 to 8 days. Treatment is palliative. [11]

Traumatic Ulceration

Traumatic ulcers are a result of direct trauma to epithelial tissue causing in a painful area of erythema with a central fibropurulent eschar. They most commonly occur on the tongue, lips, and buccal mucosa. Common sources of trauma include rough or jagged edges on teeth or restorations, ill-fitting dentures, or mishaps during oral hygiene. Trauma from dental injection may result in ulceration. Removal of persistent sources of trauma is essential; otherwise, treatment is palliative. [16]

Lesions of the Tongue

Many systemic conditions and local stimuli affect the appearance of the tongue. Asymptomatic deep fissuring of the dorsal surface is common and probably represents a developmental phenomenon. Many systemic conditions, various vitamins deficiencies, and iron-deficiency anemia cause atrophy of the filiform papillae, resulting in a smooth erythematous appearance. Excessive intake of hot, spicy foods also can result in a smooth appearance. Occurrence of ectopic thyroid tissue on the midline posterior portion of the tongue is called a *lingual thyroia* and is a common finding. Some of the common conditions affecting the tongue not discussed elsewhere will be mentioned here.

ERYTHEMA MIGRANS   Erythema migrans, geographic tongue, or benign migratory glossitis is a common benign finding on oral examination, occurring in 1 to 3 percent of the population. Females are affected twice as often as males. The typically multiple, well-demarcated zones of erythema on the tongue are due to atrophy of the filiform papillae. The lesions concentrate on the tip and lateral borders of the tongue and heal in several days, only to quickly reappear in other areas. Lesions can occur on any oral mucosa site. These lesions usually are asymptomatic; however, a burning sensation or sensitivity to hot or spicy foods has been described. Etiology is yet unknown; however, fluctuations with stress and menstrual cycle occur. Generally, treatment is not indicated because this entity is benign. Reassurance of patients is usually sufficient. In patients in whom discomfort is a major factor, oral topical steroids such as fluocinonide gel applied several times daily may provide relief.[18],[19] and [20]

MEDIAN RHOMBOID GLOSSITIS   Median rhomboid glossitis is believed to be a developmental defect of the dorsal surface of the tongue. It appears as a small 1 by 2 cm ovoid erythematous area just anterior to the circumvallate papillae. The area is devoid of papillae and usually asymptomatic. Recently, it has been suggested that this lesion represents an area of erythematous candidiasis. No treatment is necessary. [20]

BLACK HAIRY TONGUE   First reported by Lusitanus in 1557, black hairy tongue represents yellow to brown discoloration of elongated filiform papillae. This entity is rare, affecting 0.15 percent of the population. Normal papillae are 1 to 2 mm in length, but these elongate up to 12 to 18 mm, taking on the characteristic hairlike appearance. Only the dorum of the tongue anterior to the circumvallate papillae is affected. The condition is usually asymptomatic but of significant concern to the patient. The etiology remains obscure. Treatment consist of frequent brushing of the tongue and avoidance of predisposing factors such as tobacco, strong mouthwashes, and antibiotics. Resolution usually occurs spontaneously, and surgical clipping is rarely needed. [20]

STRAWBERRY TONGUE   Strawberry tongue is associated with erythrogenic, toxin-producing *Streptococcus pyogenes.* Clinically, the tongue has prominent red spots on a white-coated background. Microscopically, the fungiform papillae are hyperemic with a smooth glossy surface. Treatment is with antibiotics directed at group A streptococci.[20]

Leukoplakia and Erythroplakia

Leukoplakia is defined by the World Health Organization as a white patch or plaque that cannot be scraped off or characterized clinically or histopathologically as any other disease.[21] Leukoplakia is the most common oral precancer; however, only 2 to 4 percent of leukoplakic lesions are carcinoma. [22] The prevalence is approximately 20 to 39 per 1000 persons, affecting males twice as frequently as females. Etiology is unknown, but tobacco, alcohol, ultraviolet radiation, candidiasis, human papillomavirus, tertiary syphilis, and trauma have all been implicated. The most common intraoral site involved is the buccal mucosa. Other sites of involvement include the hard and soft palates, maxillary gingiva, and lip mucosa. Biopsy is mandatory for all persistent leukoplakic lesions, yet most demonstrate no dysplastic changes histologically. Leukoplakic lesions of the floor of the mouth, tongue, and vermilion border are most likely associated with malignancy. Lesions demonstrating dysplastic changes warrant removal.[21]

Erythroplakia is defined as a red patch that similarly cannot be clinically or pathologically characterized as any other disease. Although erythroplakia is far less common than leukoplakia, it has a far greater potential for dysplastic findings histologically. [22]

Oral Cancer

Oral cancer accounts for 2 to 4 percent of the cancers in the United States. [23] More than 90 percent of all oral malignancies are squamous cell carcinoma. [22] Lymphomas (both Hodgkin's and non-Hodgkin's), Kaposi's sarcoma, and melanoma comprise most of the remainder. Several intrinsic and extrinsic etiologic factors for oral squamous cell carcinoma have been identified. Extrinsic factors include tobacco use, especially chewing tobacco or snuff; excessive alcohol consumption; and sunlight exposure (Fig. 234-7). Intrinsic factors include general malnutrition and iron-deficiency anemia, especially chronic forms such as Plummer-Vinson syndrome.
FIG. 234-7. Oral squamous cell carcinoma. **A.** Squamous cell carcinoma of the lip secondary to sun exposure. **B.** Squamous cell carcinoma of the hard palate. **C.** Verrucous carcinoma secondary to dipping snuff. (*Courtesy of H. Anthony Neil, D.D.S.*)

Specific etiologic factors play varying roles in oncogenesis. Oral candidiasis, especially in its hyperplastic form, promotes the development of oral squamous cell carcinoma. Immunosuppressive states such as HIV infection slightly increase one's risk of oral cancer, and oncogenic viruses such as human papillomavirus, herpes simplex virus, and various adenoviruses and retroviruses may play some role in the etiology of oral cancer. [19,22]

Oral squamous cell carcinoma has four common morphologic presentations. It can be exophytic, or mass-forming, with an irregular or papillary surface. Endophytic, or ulcerative, cancers usually present as depressed irregular ulcers with rolled borders. Leukoplakic and erythroplakic lesions, when malignant, are felt to represent squamous cell carcinomas that have yet to form a mass or ulcerate. [19]

The most common site involved in oral cancer is the tongue, particularly the posterolateral border, accounting for approximately 50 percent of oral cancers in the United States. Cancer of the floor of the mouth accounts for nearly 35 percent. [19] Cancer of the lips is common and usually secondary to sunlight exposure. Table 234-3 lists the common signs and symptoms of oral cancer; unfortunately, oral cancer is generally painless, and patients are often unaware of the presence of a mass until it is advanced. Early diagnosis is the key to successful treatment of oral squamous cell carcinoma. Careful oral screening by emergency physicians through methodical examination of the oral cavity should reveal most oral carcinomas. All ulcers, erythroplakic lesions, and leukoplakic lesions of the oral cavity that do not respond to palliative treatment in 10 to 14 days warrant biopsy.

Signs
Nonhealing ulcer: can be in form of crater with elevated, indurated margins
Bleeding: resulting from ulceration
Lymphadenopathy
Rigidity: lesion fixed to surrounding tissue
Induration: hardness of the lesion
Functional interference: such as speech and mastication

Symptoms
Pain
   Secondary to ulceration
   Secondary to trauma related to functional interferences
Paresthesias
Drooling: secondary to functional interferences

Source: From Marder.[34] Used with permission.

TABLE 234-3   Signs and Symptoms of Oral Cancer

Treatment depends on site of involvement and staging of disease. It consists primarily of wide radical excision, radiation therapy, or a combination of the two. Adjunctive chemotherapy has been used to aid in tumor debulking. The prognosis depends on site and tumor stage, but an overall 5-year survival rate for patients with lesions that have not metastasized is 76 percent, 41 percent when cervical nodes are involved, and 9 percent when metastasis below the clavicle has occurred. [19]

Other

Fordyce granules that are slightly elevated, cream-colored spots seen frequently on the vermilon border of the lips and buccal mucosa represent ectopic sebaceous glands.[25] *Linea alba* is a white line on the buccal mucosa at the level of the occlusal surface. It is caused by normal friction from the facial surfaces of the teeth during mastication. *Leukedema*, which is a normal variant, is a grayish white appearance to the mucosal surfaces secondary to thickening of the mucosa and edema of the spinosal layer. It usually affects the buccal musosa bilaterally and can be diagnosed by its disappearance on eversion or stretching of the mucosal surface. [19] Firm exophytic enlargement along the lingual surface of the mandible (*torus mandibularis*) or of the hard palate (*torus palatinus*) represents benign exostoses of the associated bone. The etiology is unknown, but no therapeutic intervention is required. [26] Other entities that cause oral lesions such as pemphigoid, pemphigus, lichen planus, and erythema multiforme are discussed later as manifestations of systemic disease.

OROFACIAL TRAUMA

Dentoalveolar Trauma

Dentoalveolar trauma is a very common reason for ED visits. Approximately 20 percent of all school-age children will experience oral trauma. The most common mechanism of injury is falls. Sporting injuries, fights, and motor vehicle collisions account for most of the remainder. Injury to the maxillary central incisors accounts for 70 percent of dental injuries.[27] The management of dentoalveolar trauma depends on the extent of tooth and alveolar involvement, the degree of development of the apex of the tooth, and the age of the patient. In isolated fractures of a tooth, treatment decisions are based on the vitality of the tooth and, in a vital tooth, the proximity to the pulpal tissue. Involvement of the root of the tooth compromises the attachment apparatus and thus the ability of a dentist to adequately restore the tooth to function. Isolated alveolar bone trauma rarely occurs.

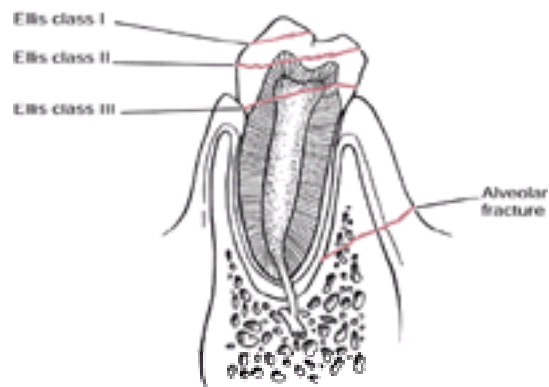
DENTAL FRACTURES   A simple classification of dental fractures is the Ellis classification shown in Fig. 234-8. The goal of the emergency treatment of a fractured tooth is maintaining pulpal vitality. The proximity of the fracture to the pulp and the length of time before treatment are most important in determining outcome. Treatment is aimed at sealing the dentinal tubules and creating a barrier between the dental pulp and the oral environment. In properly treated uncomplicated dental fractures, 1 to 2 percent of the affected pulps undergoes necrosis. Since pulpal necrosis is a process, it can occur at any time after trauma, and serial follow-up with a dentist is recommended.[4,29]


FIG. 234-8. Ellis classification for fractures of anterior teeth.

Ellis class I fractures involve the enamel portion of the tooth only. Generally, no emergent treatment of these fractures is indicated, except to smooth sharp corners that may irritate the tongue or mucosa. An emory board or similar instrument is sufficient. Referral to a general dentist for aesthetic repair depends on the degree of cosmetic concern of the patient.[4,28,29]

Ellis class II fractures involve the dentin of the tooth and require intervention by the emergency physician. These fractures account for 70 percent of tooth fractures. Generally, patients express sensitivity to hot or cold stimuli as well as air passing over the expose surface during breathing. The Ellis class II fracture can be identified both by the patient's symptomatology and visualization of exposed dentin, which is a creamy yellow color compared with the whiter enamel. One may need to use gauze to wipe blood from the fractured tooth surface to determine the classification. Because dentin is microtubular in structure, communication between the oral environment and the dental pulp is established with exposure of the dentin. The thickness of remaining dentin determines the rate of pulpal contamination. Greater than 2 mm of remaining dentin is felt to offer some protection to the pulpal tissue. Microorganism contamination of the pulp, oral irritants, or desiccation from mouth breathing initiates an inflammatory process in the pulpal tissue. A delay in treatment increases the likelihood of pulpal necrosis. Thus it is the responsibility of the emergency physician not only to identify such a fracture but also to cover the exposed dentin to decrease pulpal contamination. This is best achieved using a glass ionomer cement that is easily mixed according to the manufacturer's instructions and carefully applied to the dried exposed dentin. A calcium hydroxide dental base such as Dycal historically has been recommended. It is now felt that this provides a less effective dentinal seal. Although calcium hydroxide is acceptable, glass ionomer is recommended in the recent literature because it is hydrophilic and fluid from the dentinal tubules does not weaken the seal. Referral to a dentist within 24 h is mandatory to best ensure tooth vitality.[4,28,29]

In Ellis class III fractures, exposure of the pulp has occurred. On wiping the fractured surface dry with sterile gauze, blood originating from the pulp of the tooth is easily identified. A class III fracture is a true dental emergency, and immediate attention by a dentist or oral and maxillofacial surgeon is indicated. One should attempt to cover the exposed dentin with a glass ionomer cement or calcium hydroxide base as in class II fractures until urgent dental evaluation can occur. If this is not possible because of the size of exposure, then maintaining a sterile environment by isolating the tooth with moist sterile gauze is important. If the pulpal exposure is extremely small, placing a glass ionomer or calcium hydroxide base is adequate until dental evaluation within 24 h. Prompt appropriate treatment lessens the likelihood of pulpal necrosis by minimizing pulpal contamination. For all but the most minuscule pulpal exposures, definitive treatment is endodontic or root canal therapy. Oral analgesics should be prescribed and topical analgesics avoided. [4,28,29]

Crown root fractures account for 5 percent of all injuries of the permanent dentition. Extraction of the coronal segment is required. If less than one-third of the root is involved, root canal therapy can be performed by a dentist, and restoration of the tooth may be possible. Careful attention must be paid to identifying fractures of the root because they can be clinically obscure.[29]

The age of the patient becomes important in dental trauma for several reasons. As indicated earlier, dentin is formed throughout the life of a tooth. Thus, in younger patients, especially those less than 12 years of age, the pulp of anterior teeth is quite large and the dentinal layer is thin. Dental fractures in this age group more commonly involve the pulp of the tooth. Even when the pulp is not exposed directly, the dentinal layer separating the pulp from the oral environment is thin, so contamination is more likely. Fortunately, in this age group the apex of the root also is usually incompletely formed, allowing for a greater pulpal regenerative capability. In this age group, a blush of the pulp underneath a thin translucent dentinal layer in a class II fracture should be treated like a class III fracture. As one ages, more dentin is formed. Thus, in older patients, the pulpal chamber may be very small and pulpal exposure highly unlikely. Understanding the effects of age on the dentin layer is important for treatment of Ellis fractures.[28,29]

CONCUSSIONS, LUXATIONS AND AVULSIONS The same forces that cause dental fractures may result in loosening of a tooth from the attachment apparatus. Careful evaluation of the teeth for tenderness, malpositioning or mobility must be performed. Luxations account for nearly 50 percent of injuries to teeth. [27] Five distinct types of luxations have been described. (1) *Concussion* injuries are defined as injury to the supporting structures of a tooth with clinical tenderness to percussion but no mobility. (2) *Subluxation* is defined as an injury to the attachment apparatus resulting in mobility without clinical or radiographic evidence of dislodgment of the tooth. (3) *Extrusive luxation* is defined as partial avulsion or dislodgment of a tooth from the alveolar bone. (4) *Lateral luxation* is defined as dislodgment of a tooth laterally with concomitant fracture of the alveolar bone. (5) *Intrusive luxation* is defined as displacement of a tooth into its socket with associated alveolar fracture. Treatment of luxations depends on identifying and assessing tooth involvement, permanent or primary tooth involvement, and presence of root fracture and/or significant associated alveolar fracture. [4,27,28]

A concussive injury to a tooth represents a minor injury. The degree of tenderness to percussion determines the treatment. Stabilizing the tooth by splinting it to adjacent teeth is not indicated. Management of pain with NSAIDs, soft diet, and referral to a dentist to confirm the diagnosis and exclude more severe injury, are the most appropriate courses of action for the emergency physician. Removal of the occlusal forces from the tooth by a dentist may aid in comfort and healing. Similarly, a subluxed tooth generally does not require splinting. Again, removal from occlusion by a general dentist may be beneficial. Subluxation represents a more significant injury and is associated with a higher incidence of subsequent pulpal necrosis. Clinically, bleeding around the tooth is common. [4,27]

Extrusive luxation requires repositioning the tooth in its original position and splinting to stabilize the tooth during healing. Repositioning the tooth may require local anethesia. Firm, gentle pressure usually will reposition the tooth. If a clot has formed apical to the tooth, then more aggressive manipulation may be required. Stabilization is ideally obtained with a flexible wire splint place by a dentist. In the ED, a temporary splint with Coe-Pak (Fig. 234-9) as described by Medford[30] is acceptable until the patient can see a dentist or oral and maxillofacial surgeon within 24 h. Care must be taken to avoid excess material placement, especially on the occlusal surface, because interference in occlusion will place stresses on the tooth during mastication. Splinting should be maintained for 1 to 2 weeks. Close follow-up by a dentist is necessary to identify early occurrence of any of the potential postluxation sequelae such as internal and external root resorption, ankylosis, and pulpal necrosis.[4,27]
FIG. 234-9. Reimplantation and stabilization of an avulsed tooth. **A.** Tooth is rinsed. **B.** Tooth is placed back into socket. **C.** Splint material is ready for application. **D.**

Packing is molded over reimplanted tooth and two adjacent teeth to each side.

A lateral luxation represents a more extensive injury with associated crazing or fracture of the surrounding alveolar bone. Repositioning of the tooth is generally more difficult. It usually can be accomplished by manipulating the displaced tooth with thumb and forefinger. Once the apex has been dislodged from its locked-in position labially, apically directed axial pressure will reposition the tooth. Intraarch stabilization is necessary for a minimum of 2 weeks. Temporary splinting with Coe-Pak is acceptable if a minimal associated alveolar fractured occurred. Otherwise, splinting by an oral and maxillofacial surgeon or general dentist in the ED is mandatory. [4,27]

Intrusive luxations are the most serious because significant damage to the alveolar socket and periodontal ligament occurs. Root resorption is common as a result of damage to the periodontal ligament. Recommended treatment is allowing the tooth to reerupt on its own or to orthodontically extrude the tooth over 3 to 4 weeks. [27]

Total displacement of a tooth from its socket, or *avulsion,* accounts for up to 16 percent of all injuries to teeth. It is necessary to reimplant avulsed permanent teeth as soon as possible. Reimplantation is possible if performed within 2 to 3 h. Ideally, the tooth should be reimplanted by the patient or health care provider at the scene to minimize this time. The tooth should be rinsed with sterile normal saline or tap water to remove debris. Care should be taken to handle only the crown portion of the tooth, and it should be reimplanted immediately into the socket. If this is not possible, or if the risk of aspiration is high, such as in a young child or a patient with a decreased level of consciousness, then the tooth should be transported with the patient to the ED. Acceptable transport media include isotonic solutions such as Hank's solution, sterile saline, and milk. Commercial preparations of Hank's solution such as Save-A-Tooth (TPS, Biologic Rescue Products, Inc.) are available and come with a useful transport container as part of the system. If the avulsed tooth was not recovered, radiographs to ensure that the tooth was not aspirated are indicated.[31,32 and 33]

Survival of the periodontal ligament fibers that remain attached to the root of an avulsed tooth is key to successful reimplantation. Milk is an acceptable storage medium due to its osmolarity and essential concentration of calcium and magnesium ions. Hank's solution, a pH-balanced cell culture medium, is the best transport medium and has been found to maintain periodontal ligament cell viability for up to 4 to 6 h. It also has been found that Hank's solution can help to restore cell viability in a tooth that has been avulsed longer than 20 and 60 min. [32,33]

In the ED, prior to reimplantation, the tooth should be thoroughly rinsed clean of dirt and debris with sterile saline or preferably Hank's solution. The root of the tooth should not be scrubbed, and care should be taken not to disrupt existing periodontal fibers. If an avulsed tooth with an open apex has been dry for less than 20 min, then the prognosis for reestablishing a vital pulp is good. If the apex is completely closed, then revitalization is not possible. If the tooth has been dry from 20 to 60 min regardless of apices, it is recommended that the tooth be soaked in Hank's balanced salt solution for 30 min. This has been found to decrease the chance of ankylosis. For an avulsed tooth that has been dry for greater than 60 min, the periodontal cells are dead, and the goal is to reduce root resorption. It is recommended that the tooth be soaked in citric acid for 5 min, then 2% stannous flouride, and finally doxycycline for 5 min prior to reimplantation. [31]

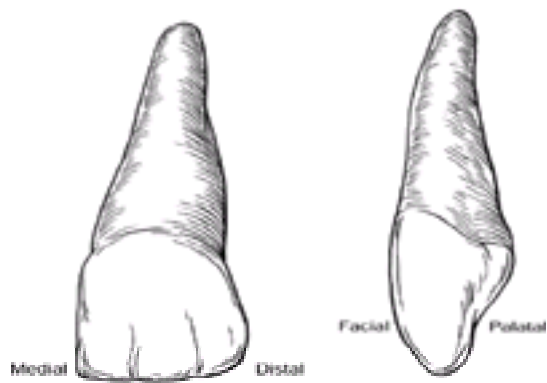
Preparation of the dental socket plays little role in the success or failure of the reimplanted tooth. The socket is prepared by carefully removing the clot and irrigating gently with sterile normal saline. As little manipulation as possible of the socket should occur. Local anesthesia is usually required. Reimplantation is accomplished with firm pressure and having the patient bite on gauze until more permanent stabilization can be arranged. Anterior teeth are most commonly affected, and Fig. 234-10 illustrates the morphology of the maxillary central incisor to assist reimplantation in the proper orientation. Early improper reimplantation holds a higher success rate for tooth salvage than delayed reimplantation resulting from waiting for an oral and maxillofacial surgeon. Stabilization by an oral and maxillofacial surgeon or using a temporary method such as Coe-Pak is necessary.[31,32 and 33]


FIG. 234-10. Illustration of a maxillary left central incisor. Note that the part of the tooth facing medially comes to more of a right angle at the incisal edge than occurs distally. The facial portion of the tooth is more convex.

Avulsion or luxation of primary teeth is treated differently from that of permanent teeth. Thus identification of primary teeth in patients aged 6 to 12 years when the dentition is mixed is essential. Avulsed primary teeth are not reimplanted. More severe luxations in primary teeth generally require extraction of the tooth. Repositioning or reimplanting primary teeth risks injuring the underlying permanent teeth and thus is avoided. Intruded primary teeth are an exception and generally are left alone to reerupt into normal position. Primary teeth maintain space and allow for adequate growth of the mandible and maxilla to accommodate their permanent successors. Thus postavulsion orthodontic space maintenance may be important. Referral to a general dentist for follow-up is essential to ensure optimal long-term outcome.[28,31]

Posttraumatic sequelae are variable. Pulp canal obliteration, pulpal necrosis, internal resorption and external resorption of the root, and ankylosis may occur. The severity of luxation or avulsion is the most important determining factor in sequela occurrence. Transient apical breakdown occurs with all type of luxations but is especially common with extrusive and lateral luxations. More than 50 percent of extrusively luxated teeth undergo pulpal necrosis within 1.5 years or the traumatic event.[27]

Significant force must occur to dislodge or fracture teeth, and associated alveolar ridge fracture is common. Care to ensure the integrity of the maxilla and mandible is also important. Stabilization of repositioned or reimplanted teeth is essential for optimal results. This is best accomplished with semirigid fixation by a general dentist or oral surgeon. Stabilization is maintained for 1 to 2 weeks depending on the involvement of alveolar bone. Early placement back into function is felt to improve the success rate by decreasing ankylosis and resorption of the root. Decisions concerning when to remove the stabilization should be left to the consultant. With significant alveolar ridge fracture, segments may require intermaxillary stabilization. Oral and maxillofacial surgical consultation is necessary. Stabilization in these patients is usually maintained for up to 6 weeks in order to ensure adequate healing. [28,31]

Soft Tissue Trauma

Repair of associated injuries of gingival, lip, mucosal, and facial soft tissues should occur after stabilization of hard tissue in the oral cavity. Otherwise, intricate repairs may be damaged and torn during the manipulation required to reduce, reimplant, and stabilize subluxed or avulsed teeth or associated bony fractures.

Oral lacerations can involve any of the soft tissues of the mouth. Large intraoral lacerations (>1 cm) are susceptible to ulceration and secondary infection and tend to heal in a fibrotic mass. Intraoral lacerations should be inspected carefully for foreign material, including tooth fragments, and irrigated well with sterile normal saline. Retained foreign bodies serve as a nidus for infection and can result in need for later surgical removal and poor aesthetic outcome. Crushed and nonviable tissue should be debrided. Close approximation of the wound edges rather than a tissue seal is desired to allow drainage. Resorbable suture material such as 4-0 chromic is generally used. Black silk (4-0) is easier to use but requires removal in 7 to 10 days. When resorbable sutures are used, care should be taken to place the sutures so that the knots are buried. Prophylactic antibiotics generally are not indicated except with the most extensive lacerations. Forty-eight-hour follow-up is necessary to

monitor healing.

Lacerations of the lips and tongue require special consideration. Care should be taken in wound-edge approximation of lacerations on the dorsum of the tongue because reepithelialization across the wound edge is important. If the edges are not well approximated, the epithelia will migrate downward and will result in an epithelial cleft and a bifid appearance. This is both a cosmetic and a functional problem requiring revision. Small tongue lacerations in children, where the edges remain approximated, need not be sutured. Bleeding can be controlled with pressure using gauzes or moistened tea bags (see below). Extensive tongue lacerations in children require conscious sedation and may be best referred for repair.

Lip lacerations are a potential cosmetic problem, so careful closure is essential. In lacerations involving the vermilion border, alignment of the border is important and should be completed first. The portion of the laceration extraoral to the wet-dry line of the lip and involving the skin of the face should be closed with 6-0 nylon monofilament or Prolene. The intraoral portion of the laceration is repaired in the same manner as any oral laceration. Because of the musculature of the lips, any deep laceration requires closure of the deep layers using a 4-0 resorbable suture material such as Polyvicryl to decrease the likelihood of the wound edges opening on removal of the suture. With any laceration involving the face or other aesthetic areas, sutures should be removed as early as possible, generally in 5 days, so as to decrease scarring from the suture material. Careful daily cleansing of the wound with dilute hydrogen peroxide and application of a triple-antibiotic ointment makes suture removal easier and improves the aesthetic results.

Controversy concerning closure of through-and-through lip laceration exists. Some advocate leaving the intraoral portion of the laceration open; however, it is my recommendation that mucosal lacerations larger than 1 cm be repaired. Generally, the intraoral component should be repaired first, and then, from an extraoral approach, the laceration should be cleansed and irrigated aggressively. A deep layer of sutures may be necessary in large lacerations. The skin then should be closed aesthetically. Prophylactic antibiotics such as penicillin VK or erythromycin 250 mg PO qid for about 5 days, are indicated.

Laceration of the maxillary labial frenulum, unless unusually large, does not require repair. These lacerations can be very painful, so adequate analgesia must be prescribed. Because of the vascularity of adjacent tissue, lacerations to the lingual frenulum usually do need to be repaired. Resorbable suture such as 4.0 chromic is appropriate.

Other soft tissue injuries commonly occur. Intraoral contusions and ecchymoses are prevalent with facial trauma. Ecchymoses and petechial hemorrhages to the soft palate, uvula, and pharynx from direct trauma or from the negative pressure created from suction are frequently associated with fellatio. Treatment is mainly palliative, with reassurance to the patient and NSAIDs for discomfort.

HEMORRHAGE

Spontaneous Hemorrhage

Spontaneous gingival hemorrhage is not uncommon. A history of recent dental therapy such as periodontal scaling or curettage is important because resulting hemorrhage after scaling is easily controlled with peroxide mouth rinses or direct gingival pressure A careful medical history must be obtained because systemic diseases such as clotting factor deficiencies, leukemia, and end-stage liver disease that result in a hypocoagulable state may first manifest as spontaneous gingival hemorrhage. Overanticoagulation with oral agents may present as spontaneous gingival bleeding. The need for laboratory evaluation depends on a careful history and physical examination. Treatment depends on the specific cause of bleeding in the event that local measures are unsuccessful.

Postoperative Bleeding

Postextraction bleeding is not uncommon. Dislodgment of the clot may result in recurrent or continued bleeding. Generally, firm pressure applied to the extraction site is adequate to control bleeding. This is best accomplished by neatly folding a 2 × 2 gauze pad and placing it over the extraction site, applying firm pressure by clenching firmly with the opposing teeth. This pressure must be held firmly, not a chewing action, for 20 min or until hemostasis is complete. Also, pressure with a used tea bag aids hemostasis because the tannic acid is a natural hemostatic agent. If direct pressure is not successful, then application of Gel-Foam, Avitene, or Instat to the socket may provide a matrix for clot formation. Sutures should be used for holding such agents in place or to close the gingiva over the socket. The gingiva should not be closed under pressure, especially along the suture line, since this may result in necrosis of the gingival flap. If these methods are unsuccessful, the vasoconstrictive effect of direct instillation of lidocaine with epinephrine may aid hemostasis. Finally, if hemostasis still cannot be obtained, then oral and maxillofacial surgical consultation becomes necessary.

Bleeding may occur after periodontal surgery secondary to underlying clotting abnormalities or from dislodgment or instability of the periodontal packing. It is important that the practitioner who performed the surgical procedure be contacted to direct care because positioning of the periodontal flap is critical for successful therapy.

ORAL MANIFESTATIONS OF SYSTEMIC DISEASE

Vitamin Deficiencies

In the developed world today, significant vitamin deficiency is uncommon. Patients with malabsorption syndrome and eating disorders, fad dieters, and alcoholics are notable exceptions. Most significant vitamin deficiencies have characteristic oral manifestations.

RIBOFLAVIN   A diet deficient in riboflavin causes many abnormalities. Oral manifestations include glossitis and angular cheilitis, sore throat, and swelling and erythema of the oral mucosa. Seborrheic dermatitis is seen commonly in chronic riboflavin deficiency. A normocyctic normochromic anemia is also common. [19]

NIACIN   Severe niacin deficiency results in a condition known as *pellagra*. Once common in the southeastern United States, it manifests as a dermatitis (especially on sun-exposed areas), dementia, and diarrhea. Oral manifestations include angular cheilitis, stomatitis, and glossitis. The tongue typically appears smooth and fiery red. Untreated severe deficiencies ultimately may result in death. [19]

PYRIDOXINE   Pyridoxine deficiency is extremely uncommon because pyridoxine occurs almost universally in foods. Deficiency states occur not uncommonly in patients taking a number of drugs such as isoniazid that are pyridoxine antagonists. Deficiency states result in weakness, dizziness, and seizure activity. The oral manifestations are similar to those of pellagra, with glossitis and angular cheilitis. [19]

VITAMIN C   A deficiency of vitamin C is known as *scurvy* and is limited to people with diets deficient in fresh fruits and vegetables such as inner-city infants and the edentulous elderly. The clinical symptoms are related to the vitamin's role in collagen synthesis. Typically, wound healing is impaired, and decreased vascular wall integrity results in widespread petechial hemorrhages or ecchymoses. Oral manifestations include the typical gingival lesion, or scorbutic gingivitis, with gingival swelling and ulceration. Spontaneous gingival hemorrhage, tooth mobility, and increased severity of periodontal disease are also common. Severe deficiency can result in death secondary to spontaneous intracranial hemorrhage. [19]

VITAMIN D   A deficiency of vitamin D historically was quite common and in children is called *rickets* and in adults *osteomalacia.* Essential in the absorption of calcium from the small intestines and, in conjunction with parathyroid hormone, reabsorption from the distal tubule of the kidney, manifestations of a deficiency state are related to problems with calcium homeostasis. This is manifested primarily as inadequate calcification of the bones. Otherwise, there are no specific oral manifestation of vitamin D deficiency. [19,34]

VITAMIN K   Seen most commonly in patients with a malabsorption syndrome or whose gastrointestinal flora have been irradicated by long-term antibiotic use, vitamin K deficiency results in coagulation abnormalities. A deficiency in vitamin K results in inadequate synthesis of prothrombin and other clotting factors. Spontaneous gingival hemorrhage is not uncommon in severe vitamin K deficiency. [19]

Anemia

IRON-DEFICIENCY ANEMIA   Iron-deficiency anemia is the most common cause of anemia in the world today. In severe deficiencies, patients may complain of

fatigue, palpitations, light-headedness, and lack of energy. Oral manifestations include angular cheilitis, diffuse or patchy atrophic glossitis, and mucosal atrophy. Associated oral candidiasis is common. Such oral changes are rarely seen in the developed world because iron-deficiency anemia is identified relatively early. [19]

MEGALOBLASTIC ANEMIA   Dietary deficiency of cobalamin (vitamin B_{12}) or folate is uncommon. A deficiency state leads to megaloblastic anemia. Pernicious anemia is a result of poor absorption of cobalamin or extrinsic factor. Intrinsic factor is produced by the parietal cells of the stomach and combines with cobalamin in the duodenum, enabling its absorption in the small intestine. Pernicious anemia is a result of a lack of intrinsic factor secondary to an autoimmune destruction of the parietal cells of the stomach. Gastric bypass and severe gastrointestinal disease also may result in a decreased production of intrinsic factor and thus absorption of cobalamin. Cobalamin is essential for the production of nucleic acids. Consequently, rapidly dividing cells such as the hematopoetic cells and mucosal lining are affected most. The most common systemic complaints associated with pernicious anemia are fatigue, weakness, shortness of breath, headache, parathesias, and diminished vibratory and positional sense. Oral manifestations reportedly affect up to 50 percent of patients and include atrophic glossitis and erythematous mucositis. A frequent complaint is a painful or burning sensation of the tongue, lips, and buccal mucosa. Angular cheilitis and hyperkeratosis are also common. Biopsies of unaffected mucosal surfaces reveal atrophy, inflammatory changes, loss of melanin pigments, and glycogen depletion. Treatment involves parenteral supplementation of the deficient vitamin. [19,35]

Endocrine Abnormalities

THYROID HORMONE   The most common findings of hypothyroidism include lethargy, fatigue, dry coarse skin, facial and extremity swelling, hoarseness, constipation, and weakness. Oral manifestations are related to the accumulation of glycosaminoglycans in the oral tissues, causing macroglossia and thickened lips. If hypothyroidism occurs in childhood, teeth may fail to erupt, although tooth formation is unimpaired. [19]

Grave's disease is the most common type of hyperthyroidism and is associated with an increased metabolic rate, tachycardia, nervousness, weight loss, heat intolerance, emotional lability, and muscle weakness. The most prominent feature of hyperthyroidism, however, is exopthalamus. No characteristic oral findings are associated with hyperthyroidism. [19]

PARATHYROID HORMONE   Findings of hypoparathyroidism are related to the resulting serum hypocalcemia. Common oral findings include Chvostek's sign, or twitching of the upper lip secondary to tapping the facial nerve just below the zygomatic arch. This is indicative of latent tetany associated with hypocalcemia. If hypoparathyroidism occurs during childhood, odontogenesis may be affected, and pitting enamel hypoplasia, widened pulp chamber, short roots, hypodontia, and failure of teeth eruption may occur. [19,36]

Uncontrolled production of parathyroid hormone may result from a pituitary adenoma or primary hyperparathyroidism or from a chronically low serum calcium level secondary to the renal failure of secondary hyperparathyroidism. Primary hyperparathyrodism occurs most commonly over the age of 60 years and is four times more prevalent in females. The classic findings of hyperparathyroidism include "stones, bones, and abdominal groans." Stones refer to an increased incidence of kidney stones. Abdominal groans refer to the tendency to develop duodenal ulcers. Bones refer to a variety of osseous lesions such as the radiographic subperiosteal resorption of the phalanges of the index and middle fingers. Generalized loss of the lamina dura surrounding the roots of teeth is an early finding. With disease progression, loss of trabeculation results in a ground glass radiographic appearance of the mandible and maxilla. Persistent disease results in the development of other osseous lesions such as the brown tumor of hyperparathyroidism. These lesions occur most commonly in the mandible, clavicle, ribs, and pelvis and appear radiographically as well-demarcated unilocular or multilocular radiolucencies. [19]

GROWTH HORMONE   Pituitary dwarfism is caused by a lack of growth hormone production by the anterior pituitary gland. Characteristic features include the remarkably short stature of the patient with normal body proportions. The maxilla and mandible of affected persons are smaller than usual. Tooth eruption is typically delayed from 1 to 3 years. Root formation is often delayed, and third molars ageneisis is common. Also, tooth size is usually smaller. [19]

Gigantism is a result of overproduction of growth hormone prior to closure of the bony epiphyses and, if untreated, results in extreme heights. Acromegaly is a result of overproduction of growth hormone in an adult patient, resulting in renewed growth in the small bones of the hand as well as the membranous bones of the skull and mandible. Similar oral findings occur in both cases. True macrodontia is a characteristic finding of gigantism. Mandibular prognathia with an anterior open bite is seen characteristically in acromegaly. Abnormal growth of the mandible and maxilla may result in diastema formation between the teeth. Soft tissue growth may result in thickening of the soft palate and a uniform macroglossia. [19]

ADRENAL CORTICOSTEROIDS   Addison's disease is due to insufficient production of adrenal corticosteroids and results in gastrointestinal upset, fatigue, anorexia and weight loss, and salt craving. A characteristic bronzing of the skin is evident, and orally, brown macular pigmented lesions are common. The hyperpigmentation of the oral mucosal is caused by excessive melanin production and may be the first manifestation of Addison's disease. [19]

Hypercortisolism results in slow weight gain, particularly in the central areas of the body. No characteristic oral findings are noted; however, "moon facies" from deposition of fat in the facial region is characteristic. [19]

INSULIN   Most of the systemic complications of diabetes are related to the microangiopathy caused by the disease. [19] Oral manifestations are associated more commonly with insulin-dependent diabetes mellitus but may be associated with non-insulin-dependent diabetes mellitus. Periodontal disease is more common and more aggressive in the diabetic patient. Wound healing postoperatively is delayed, and diabetics are prone to infections secondary to impairment of neutrophil function. In the poorly controlled diabetic patient, gingival erythema and proliferation are common. [37] The poorly controlled diabetic patient is more susceptible to oral candidiasis. Erythematous candidiasis with its central papillary atrophy of the tongue is reported in up to 30 percent of diabetic patients. An increased incidence in benign migratory glossitis is seen in insulin-dependent diabetes. Diabetic sialadenosis, or diffuse nontender enlargement of the parotid salivary glands, is not uncommon. Xerostomia is a common complaint of diabetic patients, yet no conclusive studies demonstrating an actual decrease in saliva production exists. Oral complaints in diabetic patients are extremely common and may lead to a new diagnosis of diabetes. [19,37]

Renal Failure

Findings associated with chronic hypocalcemia and secondary hyperparathyroidism of renal failure are common. These findings were described previously. Uremic stomatitis is an uncommon finding of renal failure. When present, it is commonly associated with acute renal failure and a blood urea nitrogen level of greater than 30 mmol/L. The characteristic manifestation is an erythematous, pseudomembranous stomatitis. This presents as white mucoid plaques or crusts on the gingiva, buccal mucosa, tongue, and floor of the mouth, possibly extending into the pharynx. Ulcerative lesions are less common. Patients usually complain of oral pain or a burning sensation. The etiology is uncertain, but it is felt that the urease in oral flora metabolizes salivary urea to ammonia. It is this free ammonia that damages the oral mucosa. An astute clinician may be able to detect an odor of ammonia. [38]

Medication-Related Soft Tissue Abnormalities

Gingival hyperplasia is associated with many commonly used medications (Fig. 234-11). Historically, phenytoin-related gingival hyperplasia has been described. Approximately 50 percent of patients on phenytoin will develop significant gingival hyperplasia. Many other medications are known to cause gingival hyperplasia, such as calcium channel blockers, especially nifedipine, and cyclosporine. Concomitant use of two agents known to cause gingival hyperplasia results in accelerated gingival proliferation. With phenytoin hyperplasia, enlargement begins in the interdental papillae. Characteristics of the gingival tissue depend on oral hygiene and secondary inflammation. In the absence of inflammation, gingival proliferation results in dense tissue, normal in coloration, with a smooth, stippled, or granular texture. Inflammation results in edematous changes and erythematous coloration. Inflamed tissue bleeds readily. Histologically, an increase in collagen fibers, in fibroblasts, and in glycosaminoglycans is seen. Epithelial acanthosis also occurs. The characteristics of gingival hyperplasia related to cyclosporine and calcium channel blockers appear to be identical to those of phenytoin hyperplasia. The etiology of drug-related gingival hyperplasia remains unclear, but clearly, poor oral hygiene increases its likelihood and severity. Treatment includes fastidious oral hygiene to slow the hyperplasia and gingivectomy in advance cases. [39]

FIG. 234-11. Gingival hyperplasia secondary to cyclosporine. (*Courtesy of Philip J. Hanes, D.D.S., M.S.*)

Many other medications are known to cause abnormalities of the oral mucosa or dental structures. Allergic mucositis, erythema multiforme, and fixed drug type reactions are examples. Xerostomia and associated mucosal alterations are a side effect of many medications such as anticholinergics, antidepressants, and antihistamines.[1] Tetracycline taken systemically during tooth formation results in a characteristic gray-brown discloration of the dental enamel. Systemic flouride ingestion, although significantly reducing caries rates, in higher than the recommended 1 ppm may result in significant enamel defects called *flourosis.* Flourosis is dose-dependent and is primarily an aesthetic concern, with the most common abnormality being lusterless, opaque white discolored areas on the teeth.

Heavy Metal Intoxication

Ingestions of one of several heavy metals can lead to systemic manifestations. Lead poisoning, or *plumbism,* is the most common heavy metal poisoning. Systemic signs of lead poisoning are highly variable depending on the age of the patient and the amount of lead ingested. Symptoms range from colic, iritability, fatigue, and anemia to encephalopathy. Intraorally, lead poisoning presents as an ulcerative stomatitis or a bluish hue to the buccal mucosa. The classic bluish lead line on the ginigiva, secondary to subepithelial deposits of lead sulfide, also may be seen. In addition, a tremor on tongue thrusting, excessive saliva production, metallic taste, and severe periodontal disease may occur. Treatment is chelation therapy.[40]

Granulomatous Disease

SARCOIDOSIS   Sarcoidosis is a multisystem granulomatous disease with an uncertain etiology. The lungs, lymph nodes, skin, and eyes are affected most commonly. Skin lesions are common and include classic painless erythematous nodules, erythema nodosum, on the extremities. Oral involvement is primarily limited to enlargement of major and minor salivary glands, and xerostomia is a common complaint. Mucoceles of the minor salivary glands are common, and biopsy of these lesions may result in the diagnosis of sarcoidosis.[19]

WEGENER'S GRANULOMATOSIS   Wegener's granulomatosis causes necrotizing lesions of the upper and lower respiratory tracts, kidney, and small arteries and veins. Any organ system can be involved. Orally, a distinctive form of gingivitis called *strawberry gingivitis* is seen. Originating from the interdental gingiva, strawberry gingivitis is characterized by a hyperemic granular hypertrophy of the gingival tissue. Eventually involving the entire gingiva and periodontal tissue, tooth mobility and loss are common. Poor healing at the site of tooth loss also occurs. Oral ulceration, jaw claudication, and temporomandibular joint arthralgia also may occur. Oral lesions are frequently the first manifestation of Wegener's granulomatosis. Since the disease is uniformly fatal without early detection and treatment, familiarity with this entity is important.[19,41]

MYCOBACTERIAL INFECTIONS   Most oral lesions of tuberculosis represent secondary infection from a primary pulmonary infection, but primary oral tubercular lesions can occur. Discovery of oral lesions prior to diagnosis of pulmonary tuberculosis is rare. Prior to effective antitubercular therapeutic regimens, oral lesions were considered a poor prognostic indicator. Secondary oral tubercular lesions are usually painful, irregular, nodular ulcers surrounded by an area of erythema affecting the tongue, lips, and palate most commonly. Lesions also may be leukoplakic. Primary lesions more commonly affect the gingiva. Tubercular osteomyelitis of the mandible is uncommon but has been reported.[19,42]

Oral lesions of lepromatous leprosy occur most commonly in the first 5 years of disease and are reported to affect up to 60 percent of patients. This is in contrast to tuberculoid leprosy, in which the oral cavity is rarely involved. The most commonly affected oral sites are the anterior maxillary gingiva, hard and soft palates, uvula, and tongue. In most patients, intranasal lesions precede oral involvement. Mucosal lesions may appear as yellowish sessile, enlarging nodules that may ulcerate and necrose with time. A pink or red discoloration of the maxillary incisors is the only specific dental finding. However, involvement of the maxilla in children can affect the development of teeth. Specific gingival involvement is limited to the premaxillary gingiva and is associated with underlying bony destruction and eventual loss of teeth.[43]

CROHN'S DISEASE   Crohn's disease is an inflammatory disease that may affect the entire gastrointestinal tract from mouth to anus. A wide variety of oral lesions may be associated with Crohn's disease. The most common lesions are diffuse or nodular swelling of the oral and perioral tissue, a cobblestone appearance to the mucosa, and deep granulamatous ulcers surrounded by hyperplastic margins, fissuring on the midline of the lower lip. Oral lesions may be asymptomatic or painful. Additionally, angular cheilitis and submandibular lymphadenopathy can occur. Metallic dysguesia and gingival and buccal mucosal bleeding have been reported. Although these findings may be associated with any orofacial granulomatosis, it is important to note that the oral manifestations of Crohn's disease precede the gastrointestinal lesion in 30 percent of patients.[44]

PYOGENIC GRANULOMA   A pyogenic granuloma is a common, benign proliferation of connective tissue in a sessile or pedunculated manner in response to local trauma or irritation. It occurs primarily on the gingiva. Despite its name, this lesion is not a true granuloma but rather an accumulation of granulation tissue. A specific pyogenic granuloma occurring in pregnancy is referred to as a *pregnancy tumor* (Fig. 234-12). This tumor is benign and usually recurs if removed during pregnancy. If the tumor does not regress 2 to 3 months postpartum, definitive removal is indicated.[45]

FIG. 234-12. Pyogenic granuloma.

Collagen Vascular Disease

Collagen vascular diseases are a group of disorders that includes systemic lupus erythematosus and systemic sclerosis or scleroderma. They are immunologically mediated. Nearly a quarter of systemic lupus patients develop oral lesion affecting the palate, buccal mucosa, or gingiva. These lesions may be lichenoid in

appearance with associated ulceration, pain, erythema, and hyperkeratosis.

Systemic sclerosis patients characteristically have microstomia secondary to perioral contractures as a result of the deposition of collagen in the perioral tissue. Limited mobility of the tongue and crenations of the buccal mucosa are common in severe disease. Trigeminal paresthesias and hyperesthesia are found in 4 percent of systemic sclerosis patients. Dental radiographs reveal a diffuse widening of the periodontal ligament space, and a panorex view in up to 70 percent of patients shows varying degrees of resorption of the posterior ramus, coronoid process, and mandibular condyles. [46]

Leukemia

Patients with leukemia frequently experience easy bruising and spontaneous gingival hemorrhage secondary to thrombocytopenia. Common oral findings include petechial hemorrhage of the soft palate. Leukemic patients are more prone to oral candidiasis and oral herpetic infections. Ulceration of the oral mucosa as a result of severe neutropenia, or neutropenic ulcers, occurs in leukemia due to the host's inability to combat normal oral flora. These ulcers are typically deep, punched-out lesions with a gray-white necrotic base. They occur most commonly after mucosal trauma, herpes infection, or chemotherapeutics. Acute leukemias, particularly acute monocytic forms, cause infiltration of leukemic cells into oral soft tissue, especially gingival tissue, resulting in swollen, boggy hyperplastic gingivitis. Gingival lesions can be a result of direct infiltration, as shown in Fig. 234-13, due to drug toxicity, from graft-versus-host disease, or secondary to marrow or lymphoid tissue depression. [47] Infiltration of leukemic cells into the periapical tissue clinically and radiographically resembles periapical inflammatory disease. [48]

FIG. 234-13. Oral manifestations of leukemia.

Chronic Vesiculoulcerative Disease

PEMPHIGUS VULGARIS   Pemphigus vulgaris is a rare disease with an incidence of 0.5 to 3.2 per 100,000 persons annually. It is important, though, because without treatment, its mortality rate is high. Oral manifestations occur in up to 70 percent of patients and are frequently the first sign of disease, preceding cutaneous lesions by up to a year. Oral lesions are also the most difficult to treat. Ulceration results from autoantibodies attacking the deeper layer of the stratum spinosum of the epidermis, resulting in an intraepithelial split. Females are affected slightly more commonly, with a female-to-male ratio of 2:3. Pemphigus vulgaris most commonly affects people in their sixth decade of life. Typical lesions are superficial erosions with ragged edges found on any oral mucosal surface. Involvement of the soft palate is most common, occurring 80 percent of the time. The buccal mucosa is the next most common site of involvement (46 percent), followed by the tongue (20 percent). Cutaneous lesions appear as fluid-filled vesicles and bullae. Lesions can be induced by firm lateral pressure on apparently normal skin (Nikolsky's sign). Treatment includes systemic corticosteroids as well as other immunosuppressive agents and is beyond the realm of emergency medicine. Referral to an appropriate consultant is necessary. [16,49]

CICATRICIAL PEMPHIGOID   Cicatricial pemphigoid is a chronic vesiculobullous mucocutaneous disorder with an autoimmune etiology. Autoantibodies against the basement membrane result in subepithelial cleft formation. Cicatricial pemphigoid affects people in the seventh decade of life, with no race predilection. The ratio of males to females 1:2.27. Oral lesions are seen in approximately 85 percent of patients, but any mucosal or cutaneous site can be affected. Oral lesions may begin as a desquamative gingivitis or vesiculobullous lesions. Oral lesions eventually become denuded, leaving a painful, erythematous, irregularly bordered erosion or ulcer. Lesions may persist for weeks. Significantly, ocular involvement occurs in 65 percent of cicatricial pemphigoid patients and, if untreated, may lead to blindness. Referral to an ophthalmologist is essential. Diagnosis is by biopsy and immunofluorescent staining of perilesional mucosa. Histologically, the lesions show inflammatory infiltrates surrounding subepithelial bullae. Treatment must be individualized. Treatment of isolated oral lesions with topical steroids is acceptable. Intralesional steroid injections may be useful. Systemic involvement or persistent oral lesions require systemic steroid therapy. [16,50]

ERYTHEMA MULTIFORME   Erythema multiforme most commonly affects men in the third or fourth decade of life. Early cutaneous lesions are concentric erythematous circular rings resembling a target (target lesion). Oral lesions are painful erythematous patches that undergo necrosis, forming large ulcerations with irregular borders. They occur most commonly on the lips, labial mucosa, buccal mucosa, tongue, floor of the mouth, and soft palate, sparing the hard palate and gingiva. Erythema multiforme is a spectrum of diseases that includes toxic epidermal necrosis in its most severe form. Stevens-Johnson syndrome includes ocular and genital involvement accompanying oral lesions. Treatment is with systemic steroids in all patients except those with isolated oral lesions. In such patients, topical steroids may be adequate. [16,51]

LICHEN PLANUS   Lichen planus is one of a group of chronic cutaneous vesiculoerosive diseases affecting approximately 1 percent of the population. Females are affected three times as often as males. Certain drugs such as ACE inhibitors have been shown to cause lichenoid-type reactions, and these must be differentiated from lichen planus. Lichen planus is a result of T-lymphocyte attack on the basal cell layer. Approximately, 50 percent of patients with cutaneous lesions have oral lesions, but only 25 percent of patients have isolated oral lesions. Lichen planus can affect any mucosal surface; however, orally, the buccal mucosa is most common (Fig. 234-14). In its reticular form, lichen planus appears as multiple scattered white papules interconnected via white lines called   *Wickham's striae.* Definitive diagnosis is via biopsy and immunofluorescent staining. The reticular and papular patterns are usually asymptomatic and require no treatment. Symptomatic erosive and atrophic forms of lichen planus, especially those involving the tongue, can be treated successfully with topical corticosteroids. Some question concerning the premalignant potential of lichen planus, especially the erosive form, exists, but less than 1 percent of oral lichen planus undergoes malignant transformation. [16,52]

FIG. 234-14. Lichen planus. (*Courtesy of Baldev Singh, B.D.S., Ph.D.*)

Graft-versus-Host Disease

Graft-versus-host disease occurs in up to 50 percent of allogeneic bone marrow transplants despite HLA matching and immunosuppressive therapy. In graft-versus-host disease, the transplanted bone marrow cells recognize the host as foreign, and transplanted hematopoetic cells attack the host. Systemic manifestations of the disease vary by the severity of disease, organ system affected, and acute versus chronic disease. Oral manifestations include lesions in a fine white papular pattern, interlacing white striae in a lichenoid or reticular pattern, and a desquamative pattern occurring commonly on the tongue and labial and buccal mucosa. Posttransplant ulcerations related to the induced neutropenic state occur in the first 2 weeks. Ulcerations that persist longer must be attributed to graft-versus-host disease. Xerostomia and a burning oral sensation are common. The oral lesions and xerostomia as a result of chronic graft-versus-host disease may persist for years. An increased incidence of periodontal disease and dental caries is associated with decreased salivary flow. The principal approach to treatment is to prevent disease with the addition of other immunosuppressive agents. Oral topical steroids improve healing of oral ulceration and psoralen and ultraviolet A (PUVA) therapy may be used on cutaneous oral lesions. [47,53]

Sexually Transmitted Diseases

GONORRHEA   Oral gonococcal infection with *Neisseria gonorrhoeae* is not uncommon. The most frequent mode of transmission is fellatio. Consequently, it is seen more commonly in females and homosexual males. A stomatitis may occur with fiery red and inflamed oral mucosa. More commonly, a pharyngitis involving the uvula and tonsils occurs. Gonococcal pharyngitis may present with or without pustules or exudate. In the carrier state, a normal pharyngeal appearance may be present. Treatment is the same as with genital involvement. [11,54]

SYPHILIS   The primary chancre of syphilis can occur orally and may affect the lips, gingiva, hard and soft palates, buccal mucosa, pharynx, and tongue. Chancre of the lip is the most common oral site involved. Tongue involvement is next in frequency, followed closely by the tonsils. An oral chancre is similar in appearance to the genital counterpart. Initially, the lesion may be an erythematous papule that erodes into the classic painless, punched-out ulcer that becomes firm and indurated. [11,54]

Secondary syphilis follows the onset of the primary lesion by 9 to 90 days. Systemic symptoms such as fever, malaise, generalized lymphadenopathy, weight loss, and arthralgia are common during the secondary stage. Oral lesions are common and frequently accompany cutaneous lesions but may occur alone. They are usually multiple, oval-shaped, slightly raised ulcers or erosions covered with a gray membrane. They occur most commonly on the tip and sides of the tongue. Condyloma lata rarely occur intraorally. [11,54]

Tertiary syphilis can occur many years after the initial infection. Intraorally, the tongue is enlarged in a lobulated or irregular pattern with atrophic and hypertrophic areas. A single gumma is unusual. Chronic interstitial glossitis may result in fissuring of the tongue. In late syphilis, the tongue atrophies secondary to ischemia associated with chronic interstitial glossitis, resulting in balding of the tongue with thinning and wrinkling of the mucosal surface. Gummatous infiltration of the hard palate also may occur. [11,54]

Congenital syphilis affects the formation of both the anterior and posterior teeth. The permanent maxillary incisors are most affected. These *Hutchinson incisors* are usually shorter than the lateral incisors and barrel-shaped, resembling a screwdriver. The central portion of the incisal edge may be notched. The posterior molars, or *mulberry molars,* are narrower at the oclussal surface, and the normally occurring four cusps are replaced by many more, resulting in the characteristic mulberry appearance. [11,19,54]

Diagnosis of syphilis is with serology or dark-field examination of the primary and secondary lesions. Benzathine penicillin G 2.4 million units intramuscularly is used to treat primary, secondary, and latent syphilis of less than 1 year duration. VDRL at 3, 6, 12, and 24 months is necessary. Weekly injections for 3 weeks are necessary for the treatment of infections of greater than 1 year duration. Daily ceftriaxone injections for 10 days in the penicillin-allergic patient are an alternative. [11,54]

HERPES TYPE 2   Ninety percent of all herpes type 2 occurs in the anogenital region, but with oral-genital contact, oral lesions may occur. Oral herpes type 1 and type 2 infections are clinically indistinguishable, with primary infection frequently causing a gingivostomatitis and associated fever and malaise. Lesions may last up to 2 weeks. Secondary or recurrent lesions occur as a result of the same predisposing factors as type 1. Definitive diagnosis is made in the laboratory by viral cultures or DNA probe. Treatment of primary genital lesions with acyclovir 400 mg PO tid or Valtrex 1g PO/bid for 10 days is recommended. Acyclovir 400 mg PO tid or valacyclovir 500 mg PO bid for 5 days shortens the course of disease, and prophylactic therapy reduces recurrences and subclinical shedding of herpes simplex type 2. [11,16,54]

HUMAN PAPILLOMAVIRUS   Human papillomavirus is probably the most common sexually transmitted disease today. HPV-6, -11, and -45 are most commonly associated with *condyloma acuminatum,* or *venereal warts.* Although most commonly affecting the anogenital region, oral lesions can occur. Intraorally, the labial and buccal mucosa, palate, tongue, and gingiva are most commonly affected, although any site can be involved. Lesions many be solitary or multiple and are sessile or pedunculated nodules. Treatment is with electrosurgical or laser therapy. [11,54]

Acquired Immunodeficiency Syndrome

There are numerous oral manifestations of HIV infection. Primary HIV infection, occurring from 1 to 6 weeks after contact, is an acute viral syndrome but may have associated intraoral findings such as a sore throat, mucosal erythema, and focal ulceration. Persistent generalized lymphadenopathy, particularly of the cervical lymph nodes, is present in 70 percent of otherwise asymptomatic HIV-infected patients. The presentation of acquired immunodeficiency syndrome (AIDS) is highly variable, and numerous oral manifestations can occur. Oropharyngeal candidiasis is the most common oral finding and may lead to the initial diagnosis of AIDS. HIV-related gingivitis is distinctive, presenting as a 2- to 3-mm linear band of erythema along the gingival free margin. Periodontitis among the HIV-infected population is common and usually more aggressive and painful in its presentation. Such necrotizing periodontitis is distinguished from acute necrotizing ulcerative gingivitis, which is also a common finding, by it distribution and microbiology. Viruses such as herpes simplex virus, varicella-zoster virus, and Epstein-Barr virus are fairly common and produce more significant disease when present in the immunocompromised patient. Hairy leukoplakia, somewhat distinctive hyperkeratotic and epithelial hyperplastic lesions on the lateral borders of the tongue, strongly suggests HIV infection. Kaposi's sarcoma is the most common malignancy associated with AIDS and appears orally as a nonblanching brown to purplish macule or papule affecting most commonly the gingiva or hard palate. Lymphoma, primarily non-Hodgkin's lymphoma, is the second most commonly associated cancer. Many less common findings occur such as aphthous-like ulcerations, mulloscum contagiosum, verruca vulgaris, thrombocytopenia, salivary gland enlargement, and mucosal hyperpigmentation. With the concurrent use of newer therapeutic agents such as the nonnucleoside inhibitors, protease inhibitors, and the nucleoside inhibitors, significantly fewer opportunistic infections are seen. [19,55]

Other

Many other diseases have intraoral manifestations. Of note, mucopolysaccharidosis and amyloidosis show some degree of magroglossia. Ectodermal dysplasia results in varying degrees of xerostomia and oligodontia. Several other diseases such as amelogenesis imperfecta, dentinogenesis imperfecta, and osteogenesis imperfecta cause significant defects of the enamel and dentin.

Rudolph J. Triana, Jr.

This chapter discusses common infections and the most important conditions that can obstruct the upper airway. The upper airway infections are pharyngitis, epiglottitis, peritonsillar abscess, and retropharyngeal abscess. Noninfectious conditions that can obstruct the airway are posttonsillectomy bleeding, caustic ingestion, foreign bodies, and laryngeal trauma.

PHARYNGITIS

Pharyngitis is an infection or irritation of the pharynx and tonsils. It rarely occurs in infants younger than 1 year and is uncommon in infants younger than 2 years. It peaks between the ages of 4 to 7 years but recurs throughout life. Seasonal variation occurs, with a higher incidence in winter. [1]

Causal agents of pharyngitis include viruses, bacteria, fungi, and parasites (Table 235-1). Most often, viruses are the culprits. Rhinovirus and adenovirus are the most common, but Epstein-Barr virus, herpes simplex virus, influenzavirus, parainfluenzavirus, and coronavirus are responsible for about 5 percent of the infections. [2] Fungal and, very rarely, parasitic infection occurs in an immunocompromised host, but such infections are rarely found in immunocompetent patients. The most common bacteria causing pharyngitis include *Streptococcus pyogenes* [group A b-hemolytic streptococcus (GABHS)], *Mycoplasma, Chlamydia, Neisseria,* and *Corynebacterium.* GABHS is responsible for 15 percent of all pharyngitis and is associated with significant nonsuppurative sequelae in the form of acute rheumatic fever (ARF) or acute glomerulonephritis (AGN). [2] Because of the sequelae associated with GABHS, there is a greater emphasis placed on early diagnosis and treatment of this causal agent. This organism produces three extracellular pyrogenic exotoxins (A, B, and C) that facilitate tissue penetration. Almost every body tissue is subject to infection, but the skin and throat are favorite targets because of host-dependent surface receptor sites. [2]

TABLE 235-1   Causes of Pharyngitis

Endemic year-round GABHS pharyngitis has its peak occurrence in the late winter and early spring. [1] After an incubation period of 2 to 5 days, patients develop the sudden onset of sore throat, painful swallowing, chills, and fever. Headache, nausea, vomiting, and abdominal pain are common associated symptoms.

On physical examination of patients with typical GABHS, there are erythematous tonsils, discrete tonsillar exudate; enlarged, tender anterior cervical lymph nodes; and uvula edema. Often, palatal petechiae accompany the marked erythema of the throat and tonsils. Viral and bacterial agents often present with a more vesicular and petechial pattern on the soft palate and tonsils of the pharynx and no exudate. Clinical differentiation between viral and bacterial infection can be difficult.

Throat culture remains the most effective method for diagnosis. A single throat swab cultured correctly on a blood agar plate has a sensitivity of 90 to 95 percent in detecting the presence of a GABHS.[3] A disadvantage of culturing a throat swab is the delay in obtaining the culture results. Rapid antigen detection tests (RADTs) have been developed for the identification of GABHS directly from throat swabs. Most of the RADTs currently available have an excellent specificity (>95 percent) compared to blood agar plate cultures.[4] Either a positive throat culture or RADT result provides adequate confirmation of the presence of GABHS in the pharynx, but a negative RADT result should be confirmed with a throat culture.

All patients with pharyngitis should receive symptomatic treatment. Gargling with warm saltwater, drinking warm liquids, and rest are important. Patients unable to tolerate oral fluids or who become dehydrated should be given intravenous fluids. Young children and geriatric patients should be carefully assessed for their ability to remain well hydrated.

A number of antibiotics are effective against GABHS. These agents include penicillin and its congeners (e.g., ampicillin and amoxicillin), as well as numerous cephalosporins, macrolides, and clindamycin. However, penicillin remains the drug of choice because of its proven efficacy, safety, narrow spectrum, and low cost. Erythromycin is a suitable alternative for patients allergic to penicillin. First- or second-generation cephalosporins are also acceptable for penicillin-allergic patients who do not manifest immediate hypersensitivity. Most oral antibiotics, except the newer macrolides, must be administered for 10 days to achieve maximal pharyngeal eradication of GABHS. It has been reported that azithromycin, cefuroxime, cefixime, and cefpodoxime can be used to achieve comparable bacteriologic and clinical cure rates among patients with streptococcal pharyngitis when given for less than 5 days. [3] Close contacts and family members should be cultured, and those whose results are positive should be treated.

All types of pharyngitis can lead to suppurative complications, including cervical lymphadenitis, peritonsillar abscess, retropharyngeal abscess, sinusitis, and otitis media.

EPIGLOTTITIS

Epliglottitis is a potentially life-threatening disease that can lead to rapid, unpredictable airway obstruction resulting in hypoxia and respiratory arrest. It is an inflammatory condition, usually infectious, primarily of the epiglottis but often including the aeryepiglottic folds and the loose connective tissue in the pre-epiglottic and paraglottic spaces. Some clinicians prefer the term *supraglottitis* because the process rarely involves just the epiglottis.

Epiglottitis is traditionally reported to affect children between the ages of 2 and 8 years. [5] Epiglottitis and meningitis are the most common life-threatening diseases caused by *Haemophilus influenzae* type b (Hib). With the introduction of the Hib vaccine, the incidence of epiglottitis in children has been reduced, while the incidence in adults appears to be increasing. [6] Epiglottitis is more common in African Americans than in whites or Hispanics. [7] Incidence peaks in the spring and the fall and in during the summer months.[8]

Epiglottitis can be caused by bacteria, viruses, and fungi (Table 235-2), but the commonest cause is Hib.[9,10] Other pathogens that have been isolated include *Streptococcus* species, *Staphylococcus* species, *Moraxella catarrhalis, Klebsiella, Mycobacterium tuberculosis, Candida* species, respiratory syncytial virus, varicella virus, adenovirus, and herpesvirus.

BACTERIA
Haemophilus influenzae
Streptococcus species
Staphylococcus species
Moraxella catarrhalis
Klebsiella pneumoniae

FUNGI
Mycobacterium tuberculosis
Candida albicans

VIRUSES
Varicella virus
Adenovirus
Herpesvirus
Respiratory syncytial virus

TABLE 235-2   Causes of Epiglottitis

Patients with epiglottitis caused by Hib typically experience a 1- to 2-day prodrome that resembles a benign upper respiratory tract infection. The symptom constellation associated with epiglottitis is listed in Table 235-3.

Fever
Dysphagia
Stridor
Apprehension
Drooling
Pooling of secretions
Labored breathing
Protrusion of the tongue
Tender larynx
Erect position
Panting

TABLE 235-3   Signs and Symptoms of Epiglottitis

Physical examination of a patient with epiglottitis may reveal an appearance of apprehension, drooling, and difficulty lying supine. Stridor and protrusion of the tongue are frequently noted. The stridor associated with epiglottitis is primarily inspiratory and is softer and lower pitched than in children with croup. [11] Fever is initially absent in 30 to 50 percent of cases and may develop later.[11] Patients often position themselves sitting up, leaning forward, mouth open, head extended, and panting. Thick oral pharyngeal secretions are commonly present, with little or no cough. Movement of the upper trachea or thyroid cartilage is often quite painful and is a marker for supraglottic infection.

Diagnosis is made by history, clinical examination, radiographs, and laryngoscopy. Lateral cervical soft tissue radiographs demonstrate obliteration of the vallecula, swelling of the aryepiglottic folds, edema of the prevertebral and retropharyngeal soft tissues, and ballooning of the hypopharynx (Fig. 235-1).[12] The edematous epiglottis appears enlarged and thumb-shaped. Blood and surface cultures of the epiglottis are useful to confirm the presence of Hib but should be postponed until an artificial airway has been established.
FIG. 235-1. Lateral radiograph demonstrating thumbprinting of the epiglottis and ballooning of the parapharyngeal space consistent with epiglottitis.

Patients should be treated with extreme care because of the possibility of unpredictable sudden airway obstruction. While severe cases of epiglottitis are easily recognized, as many as 36 percent of less severe cases are initially misdiagnosed as pharyngitis. [9] Therefore, clinicians must maintain heightened suspicion for this disease. All patients with suspected epiglottitis require immediate otolaryngologic consultation, and the emergency physician must be prepared to establish a definitive airway at all times. Patients should never be left unattended. Initial treatment consists of supplemental humidified oxygen, intravenous hydration, monitoring, and intravenous antibiotics. Heliox can be given to temporarily decrease airway resistance. In cases of airway obstruction in the emergency department, endotracheal intubation must be attempted, but the physician should be prepared for a very difficult intubation secondary to the swollen, distorted anatomy. In the case of intubation failure, the last resorts for preserving the airway in adult and pediatric patients are cricothyrotomy and needle cricothyrotomy, respectively. Current antibiotic recommendations include cefuroxime, cefotaxime, or ceftriaxone as first-line drugs. [10] Alternative antibiotics include ampicillin-sulbactam and trimethoprim-sulfamethoxazole. The use of steroids to decrease inflammation and edema remains controversial, but they are used empirically by many otolaryngologists.

PERITONSILLAR ABSCESS

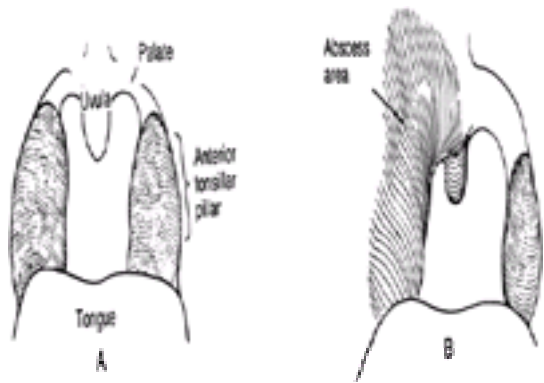
Peritonsillar abscess (PTA) is the most frequently occurring deep-space infection of the head and neck. [13,14] It is an acute, usually infectious, accumulation of purulent material between the tonsillar capsule and the superior constrictor muscle of the pharynx (Fig. 235-2). It is thought to be a complication of follicular tonsillitis that progresses from local cellulitis to abscess. A secondary mechanism of abscess development may occur through seeding of bacteria throughout the tonsil via the bloodstream or lymphatics.[15]


FIG. 235-2. A. In tonsillitis, the tonsils are enlarged. They may be covered by white exudate. The margin between the tonsil and the anterior tonsillar pillar is well defined. **B.** In peritonsillar abscess, the tonsil, palate, and anterior tonsillar pillar may be bulging medially in one unit. The margin between the tonsil, palate, and anterior tonsillar pillar is somewhat effaced. The uvula is usually edematous and may be pointing toward the opposite tonsil. The safest area to aspirate a peritonsillar abscess is usually just above the tonsil in the soft palate. This location will serve to guard the deep vessels of the neck from inadvertent injury. (From Abelson TI, Witt WJ, in Roberts JR, Hedges JR, eds: *Clinical Procedures in Emergency Medicine,* 2d ed. Philadelphia, Saunders, 1991, with permission.)

PTAs are more common during the second and third decades.[13] The incidence of PTAs corresponds to the incidence of streptococcal pharyngitis and tonsillitis, occurring with greatest frequency from November to December and from April to May.

Cultures of aspirates from PTAs characteristically produce a mixture of aerobic and anaerobic flora.[16] The most predominant infective organisms in PTAs are *S. pyogenes, Bacteroides, Peptostreptococcus,* and *Staphylococcus aureus.*[14,16] b-lactamase producing organisms are present in up to one half of all culture specimens.[14]

Symptoms of a PTA include fever, malaise, "hot-potato voice," sore throat, odynophagia, dysphagia, and otalgia. Signs of a PTA include dehydration, unilateral tonsillar hypertrophy, palatal edema, contralateral deflection of the swollen uvula, inferior and medial displacement of the infected tonsil, tender cervical lymphadenopathy, drooling, rancid breadth, and trismus (Fig. 235-3).

FIG. 235-3. Open-mouth view with mouthgag present in a patient demonstrating tonsillar hypertrophy, palatal edema, and uvula deviation consistent with a peritonsillar abscess.

The differential diagnosis of a PTA includes cellulitis, infectious mononucleosis, herpes simplex tonsillitis, retropharyngeal abscess, neoplasm, foreign body, and internal artery carotid aneurysm.

The diagnostic gold standard of a PTA is aspiration of pus through an 18-gauge needle. This should be done by individuals trained in the technique who can manage complications of the procedure. Prior to aspiration lidocaine spray or gel is used to anesthetize the overlying mucosa topically. Then, 1 to 2 mL lidocaine with epinephrine, using a 25-gauge needle, can be injected into the mucosa of the anterior tonsillar pillar. Once adequate anesthesia is achieved, an 18-gauge needle should be directed medially and superiorly within the abscess cavity. The needle should penetrate no more than 1 cm. A needle guard can be made by cutting the distal tip of a needle cover and replacing it over the needle so that less than 1 cm of the needle is exposed. Note that the carotid artery lies laterally and inferiorly, and care should be taken to avoid this area. Often, multiple aspirations may be required to find the abscess. Attempts should first begin on the superior aspect of the anterior tonsillar pillar and then progress inferiorly. Any pus aspirated should be sent for Gram stain, aerobic cultures, and anaerobic cultures. Children with trismus in whom adequate examination is not possible should be brought to the operating room and examined under anesthesia. When the airway is not in jeopardy and either a complete examination or aspiration is not possible, a computed tomography (CT) scan of the neck may be required to better evaluate this area.

The majority of PTAs can be treated effectively with outpatient needle aspiration, antibiotics, and pain medication. Incision and drainage or tonsillectomy can be performed when needle aspiration fails. A contrast CT scan of the neck is recommended when the results of needle aspiration are negative and a parapharyngeal- or retropharyngeal-space process is suspected. A PTA in a child requires hospitalization, intravenous hydration, antibiotics, and removal of the abscessed tonsil under general anesthesia. High-dose penicillin is the drug of choice, although, in light of current microbiologic findings of penicillin-resistant organisms, treatment with penicillin alone may be ineffective. Ampicillin-sulbactam, clindamycin, cefotaxime, and metronidazole should be considered. Ten days of antibiotics after aspiration is usual. Previous antibiotic treatment does not always prevent the development of peritonsillar abscess. Many patients presenting with peritonsillar abscess have been treated with antibiotics at the time of presentation.

Complications of a PTA include airway obstruction, rupture of the abscess with aspiration of the contents, thrombophlebitis, ulceration of the large submaxillary arteries, epiglottitis, septicemia, endocarditis, retropharyngeal abscess, and mediastinitis.

RETROPHARYNGEAL ABSCESS

A retropharyngeal abscess is an infection of the deep neck spaces resulting from suppuration and necrosis of the lymph nodes in those spaces. The retropharyngeal space is a connective tissue pocket that extends from the base of the skull to the level of the tracheal bifurcation. The two paramedial chains of lymph nodes (nodes of Rouvier), which drain the nasopharynx, adenoids, and posterior nasal sinuses, can be found within this space.

Although a retropharyngeal abscess is relatively uncommon, it occurs most frequently in very young children. The majority of children treated for this infection are younger than 12 months of age, and almost one-third of cases occur in children less than 6 months of age.[17] There is a higher incidence of retropharyngeal abscess in young children because of the prominence of several lymph nodes in the space between the posterior pharyngeal wall and the prevertebral fascia. By 3 to 4 years of age, these lymph nodes atrophy and are no longer functional.[17] Predisposing factors for the development of a retropharyngeal abscess include a penetrating foreign body, such as a nasogastric tube or nasotracheal tube; trauma; pharyngitis; tonsillitis; otitis media; nasal or dental procedures; and tonsillectomy or adenoidectomy.

Signs and symptoms include fever, dysphagia, neck pain, limitation of cervical motion, cervical lymphadenopathy, sore throat, poor feeding, muffled voice, and difficulty breathing. Symptoms in children less than 1 year of age are more likely to include stridor and neck swelling. The intense inflammation and swelling associated with a retropharyngeal abscess can lead to inflammatory torticollis, which is unilateral spasm of the sternocleidomastoid muscle, causing posturing of

the head with the occiput rotated toward the affected side.

Cultures from retropharyngeal abscesses have revealed a polymicrobial milieu including aerobes and anaerobes. The most common aerobic species isolated are *Streptococcus viridans* and *S. pyogenes.* Most of the staphylococcal species isolated are b-lactamase producing. *Bacteroides* and *Peptostreptococcus* are the most commonly isolated anaerobes.[18],[19] Aerobes and anaerobes work synergistically to increase the severity of the disease.

Radiographs and CT scans are helpful diagnostic tools. A lateral soft-tissue radiograph of the neck taken during inspiration with moderate cervical extension demonstrates thickening and protrusion of the retropharyngeal wall. However, even a small degree of flexion in children normally causes a marked forward bulge of the posterior pharyngeal wall that can be misleading. In adults, the posterior pharyngeal tissue is more constant appearing in flexion and extension, and the width of the soft tissue should not exceed the width of the adjacent vertebral body. A CT scan from the skull base to the clavicles with intravenous contrast is the gold standard for diagnosing deep neck space infections if there is suspicion on radiographs because CT differentiates abscess formation from other causes of retropharyngeal thickening.

All patients suspected of having a retropharyngeal abscess should have immediate otolaryngologic consultation and be admitted to the hospital. Close observation for airway obstruction is the highest priority. Procedures to relieve acute airway obstruction include endotracheal intubation, tracheostomy, cricothyrotomy, and fiberoptic endotracheal intubation. Intravenous hydration and antibiotic treatment should be started in the emergency department until the patient can be brought to the operating room for transoral or transcervical incision and drainage. Antibiotics effective against normal oropharyngeal flora, penicillin-resistant *S. aureus,* and *Bacteroides* should be used. Clindamycin combined with an aminoglycoside, or penicillinase-resistant penicillin combined with a third-generation cephalosporin and metronidazole, is a reasonable antibiotic choice.[18],[19]

Catastophic complications from retropharyngeal abscess include extension of the infection into the mediastinum, and upper airway asphyxia from direct pressure or sudden rupture of the abscess.[20]

POSTTONSILLECTOMY AND ADENOIDECTOMY BLEEDING

Tonsillectomy with and without adenoidectomy is one of the most common surgical procedures performed in the United States.[21] It is estimated that 750,000 tonsillectomies with or without adenoidectomies are performed annually.[22] Since this surgery has become an outpatient procedure, complications that were previously evident in the hospital are now presenting to the emergency department. Postoperative bleeding is a well-known complication that can lead to death from airway obstruction or hemorrhagic shock. Estimates of the incidence of posttonsillectomy hemorrhage range from 1 to 10 percent.[21],[23]

Classically, hemorrhage occurs between 5 and 10 days postoperatively, but it has been seen as late as 6 weeks postoperatively.[24] There is a significantly higher of incidence of bleeding in the age group between 16 and 25 years of age, with males having a slightly higher predominance than females.[25],[26] Hemhorrhage is rare in children under 3 years of age.[27]

Emergency management of posttonsillectomy bleeding consists of ensuring an adequate airway and controlling the bleeding. Otolaryngologic consultation is necessary. Massive bleeding is rare. However, when it occurs, intubation may be the only means of protecting the airway. Each patient should be placed on a monitor, intravenous access should be obtained, blood should be typed and crossmatched, and direct pressure should be applied to the bleeding tonsillar bed while otolaryngologic consultation is obtained. Significant bleeding typically comes from a specific vessel, while generalized oozing comes from the tonsillar bed. More commonly, patients present with bleeding that can be controlled by silver nitrate, electric cautery, or direct pressure with ringed forceps, oxidized cellulose, thrombin packs, or gauze moistened with an equivolume solution of 1:1000 epinephrine and 1% lidocaine. If direct pressure fails, local infiltration of 1 to 3 mL 1% lidocaine with 1:1000 epinephrine may be attempted until the otolaryngologist arrives.

CAUSTIC INGESTION

Esophageal, pharyngeal, and tracheolaryngeal injury can occur from ingestion of bases (alkalis or caustics), acids, and bleaches. Children represent the largest group of caustic injuries, resulting mostly from accidental ingestion. Most adult caustic injuries are suicide attempts.

Ingestion of base-containing substances produces the most significant injury because bases cause liquefactive necrosis, which allows deep penetration of the caustic material.[28] Such substances include lye (NaOH and KOH), ammonia (NH_4OH), hair relaxers, hair straighteners, and electric dishwasher soaps. Small amounts of caustic materials can cause significant injury.[28] The injury associated with alkaline substances is completed almost immediately on mucosal contact. Acidic substances cause less severe injury because they cause a coagulation necrosis, which tends to limit extension into the muscular layer.[28]

Patients presenting with caustic injuries of the upper aerodigestive tract display a wide variety of symptoms and physical findings, depending on the anatomic area of involvement (Table 235-4). Studies have failed to show a consistent relationship between symptoms and signs and the ability to predict the severity of injury.[28],[29] and [30] Absence of oropharyngeal lesions does not exclude esophageal, gastric, or tracheal injury. Eight to 20 percent of patients without oropharyngeal lesions have esophageal burns.[30] Conversely, the presence of oropharyngeal lesions does not necessarily mean that the esophagus or trachea is involved.

Pharynx, larynx	Pain, odynophagia, mucosal ulceration, tongue edema, drooling, stridor, hoarseness, refusal to eat or drink
Esophagus	Dysphagia, odynophagia, chest pain, back pain
Stomach	Thoracoabdominal pain, abdominal tenderness, vomiting, hematemesis

TABLE 235-4 Symptoms of Caustic Ingestion

The essence of the physical examination is to try to determine the extent of the injury. The examination begins with a careful history, including the type, amount, and brand name of the ingested product. The precise location and extent of the burn in the oropharynx and pharynx should be noted. Complete examination, including the extremities, groin, and chest, is necessary to detect caustic spills to those areas. Patients with oral mucosal burns and tongue edema should be monitored closely for developing airway obstruction, which may be heralded by dyspnea, hoarseness, and stridor. Because symptoms can develop as early as 1 h postingestion or as late as 5 h postingestion, emergency departments should observe children who have ingested caustic substances for at least 5 h.[28] The patient should be given nothing by mouth. Gastric lavage and emesis are contraindicated.

Fiberoptic laryngoscopy is a valuable adjunct in the assessment of the larynx and hypopharynx for injury. Blind nasotracheal or nasogastric intubation may lead to obstructive bleeding or esophageal or pharyngeal perforation, and should not be performed. In a patient with rapid airway deterioration and poor visualization of the larynx, emergency cricothyrotomy or tracheotomy may be necessary. Intravenous steroids are used by many otolaryngologists, but the issue remains very controversial.

Chest and neck radiographs may reveal airway edema, free air, aspiration, mediastinal air, or obstruction. Immediate esophagoscopy and laryngoscopy should be performed in any caustic or acidic ingestion in a symptomatic patient.[31] Asymptomatic patients observed for 5 h may be safely discharged as long as home

observation can be provided, the patient is close to medical care, and follow-up can be provided the next day. [31]

Bleach ingestion is the one exception to the general rule of performing immediate endoscopy and bronchcospy. [31] Bleaches are chlorides that are oxygenating compounds. Sodium hypochlorite is the most common component in such products as Clorox and Comet. In the United States, bleaches typically are only 2.5 percent acid, which produces a superficial ulceration that does not result in stricture or residual sequelae. Management of chlorine bleach ingestion includes careful oropharyngeal examination. If no burns are present and the patient is tolerating fluids by mouth, the patient may be safely discharged with follow-up scheduled in 12 h.[31]

FOREIGN BODIES OF THE AERODIGESTIVE TRACT

Foreign bodies in the aerodigestive tract can be life threatening if not detected early. It is estimated that approximately 1500 people die annually from complications related to foreign-body ingestion and aspiration, with children being the commonest victims. [32] Although a history of solid-particle ingestion is important, this information is often missing for children. The most common foreign body ingested by children is a coin, the second most common is food (e.g., peanuts and popcorn).[33] Because many of the symptoms may be subtle in children, a high index of suspicion is required to arrive at the correct diagnosis before several days have passed. In all children with choking, stridor, wheezing, or unexplained cough, foreign-body aspiration should be suspected. The symptoms in adults are more obvious because adults recognize the symptoms and seek help early. The most common foreign bodies in adults are fishbones, dentures, meat, and meat bones (Fig. 235-4).[34]

FIG. 235-4. Lateral radiograph demonstrating a fishbone in the soft tissues of the pharynx.

Symptoms of laryngeal or tracheal foreign-body aspiration classically follow sudden onset of choking or coughing. Symptoms are listed in Table 235-5. The stridor resembles croup, with a high-pitched inspiratory quality usually associated with a barking cough. Wheezing may be heard throughout the lung fields but is usually loudest over the involved area. [35] Chronic cough or wheezing that fails to respond to medical management, especially in a child without a history of previous reactive airway disease, should raise suspicions of an airway foreign body. In contrast to patients with foreign-body aspiration, patients with foreign-body ingestion usually complain of dysphagia, chest pain, or nausea, which may be accompanied by drooling and vomiting. Cough is uncommon, since most symptoms are related to the pharynx, esophagus, and stomach.

FOREIGN BODY ASPIRATION
Cough
Shortness of breath
Wheezing
Stridor
Dysphonia
Recurrent pneumonia
FOREIGN BODY INGESTION
Dysphagia
Drooling
Vomiting
Chest pain

TABLE 235-5   Signs and Symptoms of Foreign-Body Aspiration versus Ingestion

It is crucial to obtain a careful history and a precise description of the foreign body ingested or aspirated. Careful questioning of the parents may uncover an episode of choking or vomiting that was dismissed at the time as insignificant. Although they are not always diagnostic, routine chest radiographs should be obtained. Because some foreign bodies may be very thin and poorly seen in one dimension, both anteroposterior and lateral radiographs are essential. Both inspiratory and expiratory films should be obtained. Changes related to inspiration and expiration are the most common abnormal findings, consisting of differential inflation or a shift of the mediastinum toward the object with inspiration. Atelectasis, hyperinflation, and aerophagia are radiographic findings consistent with foreign-body aspiration. [35]

In contrast to foreign-body ingestions, all suspected foreign-body aspirations require bronchoscopic evaluation by a consulting otolaryngologist. See Chap. 72 and Chap. 129 and for discussions of foreign-body ingestion and aspiration.

LARYNGEAL TRAUMA

External laryngeal trauma is reportedly rare, occurring in approximately 1 in every 30,000 emergency room visits. [36] However, the actual number of laryngeal injuries is probably underestimated, since many cases go unrecognized, and the victims of the most severe laryngeal trauma frequently die at the scene of the accident. Several authors suggest that an increase in the incidence of laryngotracheal injury patients reaching the emergency room alive is a result of improved prehospital care and the development of specialized regional trauma units. [36,37]

Blunt trauma to the larynx occurs primarily as the result of motor vehicle accidents (dashboard), personal assaults, or sports injuries. The basic mechanism for blunt external injury to the laryngotracheal skeleton is compression of the larynx on the anterior cervical bodies. The varying densities of the hard and soft tissues of the larynx and the rotation of these elements around fixed points cause tearing of the cartilage and mucosa. Injuries range from mucosal tears, to cartilaginous fractures of the hyoid, cricoid, or thyroid, to dislocation of the cricoarytenoid joints or vocal cords. The so-called clothesline injury is a form of blunt laryngeal trauma that deserves special attention due to its severity. This typically occurs when the victim is riding a motorcycle or snowmobile and the neck strikes a stationary object, such as a wire fence or tree limb. The transfer of such a large amount of force to the neck crushes the laryngeal cartilage and may cause laryngotracheal separation. Asphyxiation often occurs at the scene, and survivors of such injuries may have an airway held together precariously by mucous membranes bridging the cartilage.

The larynx of a child responds to blunt trauma differently than does that of an adult. The pediatric larynx is situated higher in the neck and is protected by the mandible. Although the larynx of a child has relatively smaller dimensions, fractures are less common due to the elasticity of the pediatric cartilaginous skeleton. However, the lack of fibrous tissue support and the loose attachments of the mucous membranes increase the likelihood of soft-tissue damage in children. [38]

An upper airway injury should be suspected in any patient with anterior neck trauma. The classic symptoms associated with laryngeal trauma are listed in Table 235-6. With the exception of a subtle change in voice, injuries may be initially asymptomatic. With more significant or worsening injury, the patient may become increasingly aware of pain. Dyspnea, cough, and hemoptysis are common symptoms of tracheobronchial injury. Subcutaneous emphysema of varying degrees is a

common finding. When the laryngeal lumen is severely compromised, aphonia and apnea may occur, signaling the need for immediate establishment of an alternative airway.[36]

Hoarseness
Laryngeal pain
Dyspnea
Dysphagia
Cough
Hemoptysis
Aphonia

TABLE 235-6 Classic Signs and Symptoms of Blunt Laryngeal Trauma

If the airway is stable, a thorough physical examination of the neck and larynx is required. Bleeding, expanding hematomas, bruits, and loss of pulses are signs associated with vascular injury.[37,38] Other signs of laryngeal trauma include stridor, hemoptysis, subcutaneous emphysema, and tenderness or deformity of the laryngeal skeleton. The type of stridor may suggest the location of the lesion. Inspiratory stridor is typically indicative of partial supraglottic airway obstruction, as might occur from edema, hematoma, foreign body, soft-tissue injury, or cartilaginous fractures. Expiratory stridor may portend lower airway pathologic conditions in the trachea. Inspiratory and expiratory stridor suggest partial obstruction at the level of the glottis.

Flexible fiberoptic nasopharyngolaryngoscopy is the examination of choice, since it allows immediate assessment of airway integrity while maintaining cervical spine immobilization. In stable patients, CT is helpful in defining the extent of injury and need for structural repair. [36] In cases of massive blunt trauma, CT scanning is not indicated, since patients require immediate tracheostomy, direct laryngoscopy, and open exploration. Cervical spine radiographs should be performed to rule out vertebral injury, and soft-tissue anteroposterior and lateral radiographs of the neck should be obtained. Deep cervical and prevertebral air is the most common finding on radiographs of the cervical spine and on CT (Fig. 235-5 and Fig. 235-6).
FIG. 235-5. Lateral radiograph demonstrating air in the retropharyngeal space after blunt laryngeal trauma.
FIG. 235-6. Two axial computed tomographic (CT) cuts demonstrating air in the retropharynx after blunt laryngeal trauma.

The two primary goals in the management of acute laryngeal trauma are preservation of life by maintaining the airway and restoration of function. There is controversy regarding the best way to establish an alternative airway in blunt laryngeal trauma. Some authors believe that intubation following laryngeal trauma is hazardous, since the endotracheal intubation of a traumatized larynx may cause iatrogenic injury as well as the loss of an already precarious airway. [36,37,38] Other authors suggest that orotracheal intubation is a safe method of establishing an airway in this setting if it is done with a small tube under direct visualization. [40] If the lumen of the laryngeal airway is compromised by ecchymosis and edema but there is no gross disruption of the laryngeal mucosa or displacement of the arytenoids and the tracheal lumen can be identified, then the airway may be secured with an endotracheal tube advanced over the bronchscope. [40] When the laryngeal lumen cannot be visualized because of gross anatomic disruption or edema and hemorrhage, urgent tracheostomy is the preferred method of controlling the airway and avoiding further injury to the larynx.[41] An emergent tracheotomy is performed through a midline vertical skin incision, and the trachea should be entered at a level lower than usual (fourth or fifth tracheal ring.) Cricothyrotomy may be difficult because of cervical emphysema and swelling, and should be avoided if possible in suspected laryngeal trauma, since it may further injure the subglottis. [39] Retrograde intubation should not be attempted.

NECK MASSES

Neck masses may be due to congenital disorders, infection, or neoplastic lesions. With careful attention to the history and physical examination and selected imaging tests, the physician can arrive at a correct diagnosis.

The patient's age may give a clue to the diagnosis (Table 235-7). Neck masses in children represent benign conditions in 90 percent of cases.[42] Neck masses in infants and children commonly include branchial cleft abnormalities, thyroglossal duct cysts, lymphangiomas, hemangiomas, or benign lymphadenopathy. [43] Branchial cysts are round, smooth, and movable, but they are not tender unless they become infected. They are located along the anterior border of the lower sternocleidomastoid muscle (Fig. 235-7). In contrast, thyroglossal duct cysts are found in a subhyoid position, either midline or just to the left of midline (Fig. 235-8). These cysts commonly enlarge after an upper respiratory illness. Lymphangiomas are most commonly found in the lateral cervical region along the jugular chain of lymphatics as a result of sequestration of lymphatic channels and failure to communicate with the internal jugular system. Sixty-five percent of these soft, painless, compressible lymphangiomas are present at birth, and 90 percent are clinically detectable by the end of the second year of life. [44] Large lesions may result in airway and feeding problems. Hemangiomas are congenital vascular malformations that on physical

TABLE 235-7   Neck Masses by Age

FIG. 235-7. Lateral neck mass in an adolescent demonstrates an infected branchial cleft cyst. It can be found anatomically along the sternocleidomastoid muscle.

FIG. 235-8. Midline mass in an adolescent demonstrating a thyroglossal duct cyst.

examination are soft, mobile, and frequently have a bluish hue. They undergo a proliferative phase soon after birth, followed by an involutional phase, which is usually complete by age 2 to 3. Almost 90 percent of hemangiomas resolve spontaneously.[45] General lymphadenopathy is also common in infants and children and usually is infectious in origin.[46]

Neck masses in adolescents and young adults represent either infection or tumor. Significant cervical lymphadenopathy, malaise, and pharyngitis are the symptom complex for mononucleosis. A single, large, inflamed anterolateral neck mass in this age group that develops after an upper respiratory infection suggests a branchial cleft cyst. Young adults with multiple, rubbery low-neck masses, night sweats, fever, and malaise may have Hodgkin disease or lymphoma.

In adults, 80 percent of neck masses are neoplastic.[47] The most common cause of a unilateral neck mass in a middle-aged person with a history of tobacco use is squamous cell carcinoma of the upper aerodigestive tract metastatic to the cervical lymph nodes. Other common neoplasms that present in the neck include tumors of the parotid, submandibular, and minor salivary glands, and Hodgkin and non-Hodgkin lymphomas. Neoplastic lymph nodes usually feel firm, and, although initially mobile, they become fixed to surrounding structures as the cancer invades their capsules. Infectious neck masses can be seen in adults, but these nodes can be differentiated from their malignant counterparts by their soft and sometimes fluctuant appearance. Untreated suppurative lymphadenopathy can lead to deep neck infections and should be treated aggressively.

Other common neck masses seen in all age groups include prominent normal structures, such as the pulsatile carotid bulb or the hard transverse process of the first cervical vertebra.[45] Carotid aneurysm, while uncommon, should be suspected if a patient has an expanding neck mass or a history of cervical trauma. Thyroid masses are common. Diffuse nodular thyroid enlargement that is present for many years suggests a simple goiter, whereas a solitary thyroid nodule, although usually benign, may represent thyroid cancer. Epidermal and dermal inclusion cysts are very superficial and result from recurrent cutaneous inflammation.

In addition to age, the history often helps to limit the differential diagnosis. Infectious processes usually develop over hours to days and have associated pain, redness, warmth, and fever. Patients often have a preceding upper respiratory tract or dental infection. Infected congenital cysts may have enlarged on earlier occasions and resolved with antibiotics. Submandibular gland infections (sialadenitis) often wax and wane, are exacerbated by eating, and may cause a foul taste in the mouth as the gland decompresses. Hodgkin disease and lymphomas are associated with night sweats, malaise, itching, and/or fever. Neoplastic disease usually occurs in patients with a history of heavy smoking and alcohol abuse. Such patients often present with dysphagia, otalgia, dyspnea, voice change, or weight loss.

The head and neck examination should include thorough visualization of the ears, nose, oral cavity, oropharynx, nasopharynx, hypopharynx, and larynx. Factors critical in the neck examination include mass consistency and location, as described above. A variety of laboratory studies may prove useful. A heterophil antibody test may reveal mononucleosis in a young patient with pharyngitis and cervical lymphadenopathy. Serologic tests for HIV infection may help in the evaluation of an at-risk patient with multiple enlarged cervical lymph nodes. Intradermal antigen testing for tuberculosis and a control substance, thyroid function tests, and a complete blood cell count with differential counts can each provide useful data in appropriate situations. Several imaging studies can yield helpful information. Chest radiographs may show a primary lung carcinoma or findings consistent with tuberculosis or lymphoma. CT can delineate cervical anatomic relationships and reveal such pathologic conditions as primary aerodigestive tract cancer.

All patients with neck masses must be assessed for airway patency and protection. Patients with any airway concerns, such as stridor or difficulty breathing, or patients with signs of infection, should be evaluated immediately by an otolaryngologist. All other patients may be referred on an outpatient basis.

236 COMPLICATIONS OF AIRWAY DEVICES

Rudolph J. Triana, Jr.
Theresa A. Hackeling

Even with expertise and meticulous planning, complications of airway management are bound to occur. Most complications are due to many factors, including inadequate preparedness, inadequate assessment, failure to anticipate or recognize the complication, and inadequate skill during the airway crises. [1] This chapter focuses on complications of airway devices, including endotracheal tubes, tracheostomy tubes, laryngeal stents, and alternative speech devices.

ENDOTRACHEAL TUBES

Acute complications of endotracheal intubation range from minor to catastrophic. Minor complications, such as lip lacerations, corneal abrasions, tooth fractures, or tongue injuries, occur in 5 percent of patients with normal airways. [2] The blades of the laryngoscopes and the use of adjuvant airway devices and malleable stylets are well known to contribute to lip lacerations. Some patients present with dry lips, and merely opening their mouth or stretching their lips may lead to a lip laceration. Application of petroleum jelly or an antibiotic ointment to the lips before manipulating the oral cavity may reduce the extent of injury. In most cases, eye damage is an avoidable complication of securing an airway. The physician preparing to intubate the patient should remove any objects hanging from scrub clothes or gowns. Anesthesia masks, syringes hanging from endotracheal tubes, and stylets must be carefully watched, since they may also cause corneal abrasions. After the induction of anesthesia and before manipulation of the airway, a lubricant and tape or occlusive dressing should be applied to the eyes. Another relatively common complication of securing the airway is dental damage. Facial trauma increases the risk of damage. Proper techniques and avoidance of rocking the laryngoscope back can help to avoid tooth fracture. Tongue laceration, ischemia, or lingual nerve injury may occur as a result of oropharyngeal airway misplacement, use of an inappropriately sized airway device, pressure on the orotracheal tube, or injudicious use of a laryngoscope. [3]

More serious complications of endotracheal intubation include damage to the soft tissues of the pharynx, formation of a false passage, aspiration of particulate matter, and dislocation of the arytenoid cartilage or vocal cords. [4] Repetitive intubation or "blind stabs" are more likely to result in such problems. [5] Unfortunately, many such complications go unnoticed in the emergency department. Formation of a false passage is one injury that will become evident early in the emergency department because the patient will not be adequately oxygenated or ventilated (Fig. 236-1). In the case of placement of the endotracheal tube into a false passage, the tube should be removed immediately and replaced under fiberoptic guidance.
FIG. 236-1. Anteroposterior radiograph demonstrating creation of a false passage by the tracheostomy tube and subcutaneous air in the soft tissues of the neck.

The emergency physician should be well prepared to deal with common complications of intubation, such as laryngospasm, endotracheal tube obstruction, and pnuemothorax. Laryngospasm is a serious complication of securing a difficult airway. In addition to the problem of hypoxia and its sequelae, acute pulmonary edema is a well documented phenomenon that often accompanies laryngospasm and makes the problem more difficult to handle. [1] The best approach to relieving laryngospasm is to try continuous positive-pressure bag-mask ventilation. If this technique is unsuccessful, more neuromuscular blockade should be administered to the patient. If the first two maneuvers fail, 1 to 2 mL lidocaine on a 25-gauge needle can be injected into the cricothyroid membrane. The advantage of this technique is that it anesthetizes the vocal cords and immediately results in coughing and subsequent passage of air.

Endotracheal tube obstruction is a known complication that occurs frequently while the patient is in the emergency department. The tube is often plugged with friable tissue, thick mucous secretions, or granulation tissue. Options of treatment include suction techniques using saline solution or *N*-acetyl cysteine (Mucomyst), or removal and placement of a larger endotracheal tube.

Pneumothorax can also result when securing an airway by overzealous initial ventilation with high volumes and pressures. Clinical assessment and a chest radiograph should thus be performed after each endotracheal intubation to confirm tube placement and to look for evidence of a pneumothorax. All intubated patients with a pneumothorax require immediate chest tube placement and reassessment of the ventilation parameters.

TRACHEOSTOMY TUBES

The emergency department care of a patient with a tracheostomy tube can be problematic due to difficulty with patient communication, urgency of airway control, and unfamiliarity with tracheal equipment. An understanding of tracheal anatomy, tracheal equipment, and the complications and management of tracheostomies can assist the emergency physician in managing such patients.

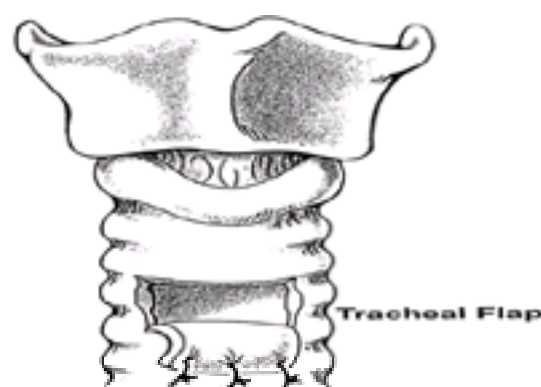
A standard tracheostomy is a surgical procedure that creates an opening between cartilaginous rings in the airway by suturing the skin to the anterior tracheal wall (Fig. 236-2). Current indications for tracheostomy tube placement include the maintenance of airway patency in patients with functional or mechanical airway obstruction, the provision of airway access for suctioning retained airway secretions, the prevention of aspiration in a patient with glottic dysfunction, significant obstructive sleep apnea, and the management of patients who require long-term access for ventilatory support.


FIG. 236-2. Creation of a tracheal flap.

There are many tracheostomy tubes available, including those made of plastic, silicone, nylon, and metal. They vary in luminal diameter, length, angle of the curvature, presence of an inner cannula, obturators, locking mechanisms at the hub, cuffs, valves, and fenestrations (Fig. 236-3). The size of the tracheostomy tube is defined by the size of the inner diameter. Adult tracheostomy tubes range from 4.0 to 10.0 mm, and pediatric tracheostomy tubes range from 0.0 to 4.0 mm. Some tubes are designed to work with an artificial voice through an airport above the tracheostomy, with a tracheoesophageal prosthesis, and with other voice devices. Obturators fit through the tracheal tube to create a smooth surface during insertion. Inner cannulas provide a mechanism for clearing the artificial airway without losing patency. It should be noted that pediatric tracheostomy tubes never have an inner cannula due to the small size of the inner diameter. Most pediatric and adult tracheostomy tubes have a 15-mm standard respiratory connection that may be used with ventilator tubing and a bag-valve device. Tracheostomy tubes with balloon cuffs are used in the first postoperative week to prevent aspiration of blood or secretions. To prevent tracheomalacia and stenosis, cuffless tracheostomy tubes are used after 1 week if the patient is not ventilator dependent.
FIG. 236-3. Contents of a tracheostomy tube.

The most common complications of tracheostomy tubes include accidental decannulation, tube obstruction, infection, development of a bleeding tracheoinnominate fistula, and tracheal stenosis (Fig. 236-4). Accidental decannulation can occur in the early or late period after tracheostomy tube placement, particularly when patients cough or extend their neck. To replace the tube, hyperextend the patient's neck and, using the curve of the tube, gently direct the tube into the opening (Fig. 236-5). Hyperextension of the neck places the larynx and trachea in a very anterior position, thereby facilitating placement of the tube. If a tracheostomy tube is not readily available, an endotracheal tube may be quickly inserted into the stoma in order to maintain airway security. In cases of extreme airway compromise, the patient may be endotracheally intubated from above in order to secure the airway and allow time to assess the tracheostomy site. The only time the patient may not be endotracheally intubated orally is in the case of a laryngectomy. Patients who have had a laryngectomy will have a tracheal stoma and sometimes a tracheostomy tube in place but will not have an accessible airway passage from their mouth. The only access to the tracheal bronchial tree in laryngectomy patients is through the neck.

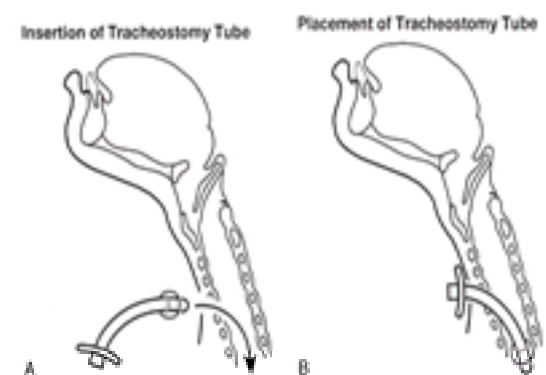
FIG. 236-4. Algorithm for evaluation of the tracheostomy patient.


FIG. 236-5. Insertion and placement of the tracheostomy tube.

Tracheostomy tube obstruction with mucous plugging is a common complication of this airway device. Secretions may act by a ball-valve mechanism, allowing air in but restricting outward ventilation. Dried crusts and secretions and other obstructing lesions should be manually removed. The inner cannula of the tracheostomy tube must be removed, and often the entire tracheostomy tube must be removed and cleaned with sterile saline water. If profuse, thick secretions are seen in the trachea, they should be suctioned after preoxygenation and placement of sterile saline solution to aid in loosening the secretions. Prolonged use of large suction catheters without preoxygenation will cause hypoxemia.

All indwelling tracheostomy tubes are contaminated with normal and sometimes pathogenic flora. Stomal skin infection, tracheitis, and bronchitis can be a recurring problem.[6] *Staphylococcus aureus, Pseudomonas,* and *Candida* are often identified.[6] Broad-spectrum antibiotics are indicated in the setting of clinical disease.

Bleeding is one of the most common complications in the early period after tracheostomy tube placement. Hemorrhage most commonly occurs between the first and third week postoperatively.[7] Sources of hemorrhage include granulation tissue, thyroid arteries, the thyroid gland, the tracheal wall, or the innominate artery. [7] If bleeding is slow, the tube may be removed, and the stoma and tracheal wall should be examined. Local bleeding can be controlled with silver nitrate or electrocautery. With more brisk bleeding, the tracheostomy tube should be kept in place until an airway is placed below the bleeding site. Maneuvers to control bleeding include local digital pressure, hyperinflation of the cuff, and mild traction of the tube with manual pressure. These maneuvers are particularly essential in cases of tracheoinnominate fistula. Tracheoinnominate artery fistula is a rare but life-threatening complication occurring in approximately less than 1 percent of all

tracheostomies.[8] Bleeding results from direct pressure of the tip of the tracheal cannula against the innominate artery (Fig. 236-6). Some patients may present with premonitory tracheal stomal bleeding (a sentinel bleed) or hemoptysis. Such bleeding may be mild to severe and should not be taken lightly, since the potential exists for sudden massive hemorrhage. Immediate otolaryngologic consultation is required, and operative intervention is lifesaving.

FIG. 236-6. The arrow points to the position of the tracheostomy tube in relation to the innominate artery. This close approximation facilitates creation of a tracheoinnominate fistula.

Less commonly seen is the presentation of tracheal or stomal stenosis. Tracheal stenosis results from necrosis at the pressure points of the cuff that become scar and result in airway narrowing. Signs and symptoms include dyspnea, wheezing, stridor, or inability to clear secretions. Treatment includes humidified oxygen, nebulized racemic epinephrine, and early administration of steroids. Radiographs may be helpful in demonstrating narrowing of the trachea, but flexible bronchoscopy is the diagnostic modality of choice. Immediate otolaryngologic consultation is warranted.

LARYNGEAL STENTS

The surgical management of laryngotracheal stenosis often employs techniques that utilize tracheal stents for various periods of time. Placement of an endolaryngeal stent renders a patient tracheostomy dependent until the stent is removed, due to blockage of the airway at the laryngeal level by the solid stent (Fig. 236-7). There are many different endolaryngeal stent designs and materials, including silastic endolaryngeal molds secured by cutaneous buttons, a stent secured by a strap that comes out the tracheal stoma and is attached to the skin, the Abouker stent complex (used in pediatric airway surgery), and the Montgomery T-tube stent. Although endolaryngeal stents are secured by buttons or straps, a known complication of these devices is dislodgement. If a stent becomes dislodged but the tracheostomy tube remains in position, airway security is not an issue. The operating surgeon should be notified when extrusion or dislodgment of any stent occurs.
FIG. 236-7. Relation of the tracheostomy tube to the laryngeal stent. The stent lies superior within the lumen of the trachea.

The Abouker stent, which is commonly used in pediatric laryngotracheal reconstruction, consists of a metal tracheostomy tube wired to a silastic stent that remains in the tracheal lumen (Fig. 236-8).[9] Removing the inner cannula of the trachesotomy tube should relieve airway obstruction in patients with Abouker stents. Only the inner cannula can be removed. The tracheostomy tube cannot be removed because it is wired to the stent.
FIG. 236-8. The Abouker stent, which is commonly used in pediatric laryngotracheal reconstruction, involves a metal tracheostomy tube that is wired to a silastic stent that remains in the tracheal lumen.

The Montgomery T-tube configuration is commonly used in adult laryngotracheal reconstruction. [10] It is a modification of a tracheostomy tube that does not have an inner cannula. Humidification and suctioning of the T tube is essential to prevent mucous plugging. Airway obstruction should be addressed by first suctioning both the upper and lower limbs of the T tube (Fig. 236-9). If suctioning both limbs of the T tube does not relieve the obstruction, the T tube should be removed and the trachea should be cannulated with an appropriately sized tracheostomy tube or an endotracheal tube.
FIG. 236-9. Suctioning is required of both the upper and lower limbs of the Montgomery T tube. If necessary the entire T tube can be removed.

SPEECH DEVICES

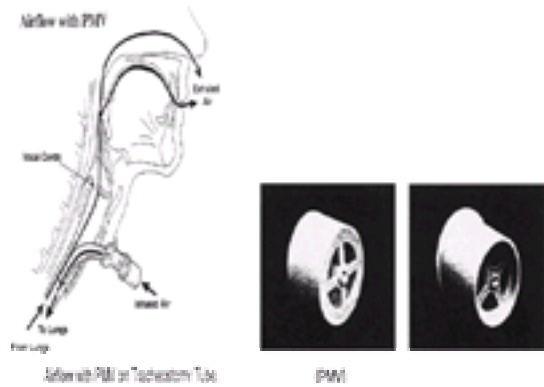
Speech in patients who are tracheostomy-tube dependent was nonexistent prior to the late 1980s. The development of the Passy-Muir valve has enabled patients to produce lung-powered speech. The Passy-Muir valve is a one-way valve that fits directly over the opening of the tracheostomy tube. The patient may breathe freely through the tracheostomy tube. Speech is created when the patient exhales hard enough to close the Passy-Muir valve and the air is thus directed up through the vocal cords and out the mouth (Fig. 236-10).[11]


FIG. 236-10. The Passy-Muir valve is a one-way valve that fits directly on the opening of the tracheostomy tube. Speech is created when the patient exhales as air is passed up through the vocal cords and out the mouth.

Complications with the Passy-Muir valve may initially present as airway obstruction or an inability to speak. In such cases, the speaking device should be removed from the tracheostomy tube so that air can pass freely during both inhalation and exhalation. If this does not improve the situation, the physician should assess the tracheostomy tube for evidence of obstruction.

Speech in postlaryngectomy patients has also improved dramatically with the use of the Blom-Singer voice prosthesis. This one-way valve is surgically placed between the posterior wall of the trachea through the anterior wall of the cervical esophagus. To speak, patients exhale while occluding the tracheal stoma with their thumb, thus forcing the exhaled air into the esophagus. The air vibrates the esophagus (as a belch does) and the resultant tone is used to provide speech. [11] Two common complications with the Blom-Singer speech devices are aspiration of the valve and dislodgment. Patients with aspiration are likely to present with persistent cough and respiratory distress. Initial evaluation may include passing a flexible scope into the tracheal stoma to see if the prosthesis has been dislodged. In addition, a chest radiograph may show the valve. If there is suspicion of aspiration, an otolaryngologic consultation is indicated for further bronchoscopic evaluation.

A more common problem is dislodgment or extrusion of the prosthesis. If the prosthesis has just fallen out, recannulate the tracheoesophageal fistula as soon as possible using a small Foley catheter (10 or 12 French). Many times, a stiffer tube, such as a red rubber catheter, facilitates cannulation of the fistula. Sterile surgical lubricant or lidocaine jelly may be applied to the tube or on a cotton swab applicator, which can identify the fistula prior to placement of the tube. If the fistula can be cannulated, the tube should be secured to the neck or chest, and the patient should follow up with a speech pathologist or otolaryngologist the next day. If recannulation is not easily achieved, repeated attempts are not recommended because they may result in formation of a false tract. If recannulation is unsuccessful, an otolaryngologist should be consulted immediately.

237 APPROACH TO THE DERMATOLOGIC PATIENT IN THE EMERGENCY DEPARTMENT

William J. Brady
Marcus L. Martin

The chief complaint "rash" is encountered in approximately 5 percent of ED visits nationwide; additionally, cutaneous findings are felt to contribute significantly toward the correct diagnosis and management in another 5 percent. In children, rashes are encountered even more often. A medical record survey of pediatric patients presenting to an academic ED revealed that 31 percent of cases primarily involved a dermatologic aspect; an additional 9 percent of ED patients demonstrated various skin findings that did not relate to the chief complaint, yet may have contributed to the final diagnosis and management plan. [1] The dermatologic syndromes seen in the ED span the spectrum of cutaneous disease. The majority of skin lesions involve infections, irritants, and allergies. [2] Fortunately, few presentations represent life- or limb-threatening skin disorders. Visual diagnosis using pattern recognition is the key to cutaneous diagnosis. The recommended approach to the patient with skin disease in the ED is (assuming resuscitation or stabilization is not required):

- Determine the chief complaint.
- Obtain a brief history (duration, rate of progression, location of lesions).
- Perform the dermatologic examination (morphology, distribution).
- Formulate the differential diagnosis based upon lesion morphology and distribution.
- Elicit additional issues from the history (associated complaints, comorbidity, medications, exposures) and include/exclude syndromes in the differential based upon this information.
- Perform ancillary investigations, if necessary.
- Obtain dermatologic consultation if necessary and/or arrange for appropriate referral (primary care or dermatologic).

DIAGNOSTIC APPROACH

The History

The emergency physician should determine the chief complaint and obtain a brief history (discomfort, duration, rate of progression, and location of lesions). The secondary history should include issues relating to the lesion—morphology, evolutionary nature, rate of progression, and distribution. Associated systemic complaints and mucosal systems must be identified. Ask about exposures to medications (over-the-counter, prescription, and illicit), immunizations, toxins, chemicals, foods, animals, insects, plants, and ill contacts. Sexual history, if appropriate, as well as medical and family histories, should be reviewed. Asking about medication use, sun exposure, or particular food ingestion may also yield helpful information.

The Examination

The dermatologic physical examination must be performed on the disrobed patient in a room with adequate lighting. All skin and mucosal surfaces must be inspected, including hair, nails, scalp, and mucous membranes. Then, the specific skin lesions must be inspected. A magnifying lens and a portable lamp are helpful for conducting the examination.

The skin should be examined in a systematic, methodical, orderly process. The distribution, pattern, arrangement, morphology, extent, and evolutionary changes of the lesions must be determined. Distribution is the location of the skin findings while the pattern is the anatomic, functional, and physiologic arrangement of the lesions. For example, the patient with a unilateral band-like arrangement of lesions on the thorax suggest varicella-zoster infection (Fig. 241-5). Skin diseases often present with a predilection for certain body areas; as such, location will assist in narrowing the diagnostic possibilities (Table 237-1). From the anatomic perspective, the skin surfaces that are usually considered as separate areas of distribution include scalp, hair, face, eyelids, mouth, trunk, axilla, perineum, extremities, and nails; the extremities may be further subdivided into upper versus lower and proximal versus distal, as well as wrists/ankles and hands/feet (Fig. 239-5). Rashes on exposed portions of the skin should prompt inquiries about sun exposure, jewelry, or topical agents. Refer to Table 237-2 for a differential diagnosis of skin lesions as a function of location.

DISTRIBUTION		
Scalp	Trunk	Further subdivision of
Hair	Axilla	Extremities:
Face	Perineum	Upper vs. Lower
Eyelids	Extremities	Proximal vs. Distal
Mucosa (eyes, lips)	Nails	Wrists/Ankles
Mouth		Hands/Feet
	PATTERN	
Sun-, clothing-, jewelry-, or agent-exposed	Hair-bearing	Apocrine
Intertriginous	Palmar/plantar	Acneiform
Flexor/extensor	Pityriasis rosea	Acrodermatitis

TABLE 237-1   Distribution and Pattern Descriptors

Pattern	Differential Diagnosis
Flexor areas of skin	Atopic dermatitis, candidiasis, eczema, ichthyosis
Sun-exposed (face, upper thorax, distal extremities)	Sunburn, photosensitive drug eruption, photosensitive dermatitis, systemic lupus erythematosus, viral exanthem, porphyria
Acrodermatitis (distal extremities)	Viral exanthem, atopic/contact dermatitides, eczema, Rocky Mountain spotted fever, gonococcemia
Pityriasis rosea (anterior and posterior thorax)	Pityriasis rosea, secondary syphilis, drug eruption, atopic/contact dermatitis, psoriasis
Clothing-covered (thorax and distal lower extremities)	Contact dermatitis, psoriasis, folliculitis
Acneiform (face and upper thorax)	Acne, drug-induced acne, irritant dermatitides

TABLE 237-2   Differential Diagnosis Relative to Lesion Distribution/Pattern

Lesion arrangement refers to both the symmetry and configuration. Bilateral symmetry suggests either a systemic internal event or symmetric external exposure, as seen in erythema multiforme, with plaque-like lesions on the flexor surfaces of the extremities (Fig. 241-1A) or in the patient with contact dermatitis related to a lotion application. An asymmetric arrangement supports a localized process. Configuration may apply to a single lesion with reference to its individual features or, alternatively, to multiple lesions and their relationship to one another. For instance, internal configuration is illustrated by the relationship between the central papule relative to the erythematous ring in the target lesion of erythema multiforme (Fig. 241-1B); on the total-body scale, configuration is demonstrated by clustering of lesions in a herpes virus infection (Fig. 241-5) or by a linear arrangement in poison ivy or oak. Other terms used to describe the lesion configuration are listed in Table 237-3.

Descriptor	Configuration
Annular	ring-like or pertaining to the outer edge
Arcuate	curved or pertaining to the curve
Circinate	circular
Confluent	blending together
Dermatomal	belt-like or limited to one side of body in anatomic dermatome
Discoid	solid, round, slightly raised or pertaining to a disk
Discrete	separate or individual
Grouped	clustered
Guttate	scattered or droplike
Gyrate	coiled or winding
Herpetiform	creeping
Iris	concentric circles
Linear	in a line
Polycyclic	overlapping circles or borders of irregular curves
Retiform	net-like
Serpiginous	snake-like

TABLE 237-3   Lesion Configuration Descriptors

Recognition of the primary lesion is vital in establishing the diagnosis. The primary lesion is the lesion which has not been altered by secondary issues, including healing, complicating infection, medication application, or scratching. Examples of primary skin lesions include macules, papules, nodules, tumors, cysts, plaques, wheals, vesicles, bullae, and pustules. Secondary lesions have had their appearance altered due to disease evolution or various external factors as noted above, and include crusts, scales, fissures, erosions, ulcerations, excoriations, atrophy, scarring, and lichenification. See Table 237-4 for a listing with description of the various morphologic descriptors of dermatologic lesions; refer to Table 237-5 and Table 237-6 for a differential diagnosis of the various skin disorders relative to primary and secondary lesion morphologies that can use the "Burn rule of 9's" (Chap. 194, "Thermal Burns") to estimate the degree of skin involvement.

TABLE 237-4   Lesion Morphology

TABLE 237-5   Differential Diagnosis of Selected Skin Disorders Relative to Primary Lesion Morphology

Lesion Morphology	Differential Considerations
Scales	Psoriasis; pityriasis rosea; toxic-infectious erythema; secondary syphilis; dermatophytic infection (tinea); tinea versicolor; xerosis (dry skin); thermal burn (first degree)
Crusts	Eczema; dermatophytic infection (tinea); impetigo; contact dermatitis; insect bite
Erosions	Candidiasis; dermatophytic infection (tinea); eczema; toxic epidermal necrolysis; toxic-infectious erythemas; erythema multiforme; primary blistering disorders (bullous pemphigoid and pemphigus vulgaris); brown recluse spider bite
Ulcers	Aphthous lesions; chancroid; decubitus ulcer; thermal or friction injury; subacute/chronic ischemia; malignancy; chancre (primary syphilis); primary blistering disorders (bullous pemphigoid and pemphigus vulgaris); brown recluse spider bite; pyoderma gangrenosum; stasis ulcer; factitial

Please note that this list is not exhaustive; it represents the more common syndromes that are likely to be encountered in the ED.

TABLE 237-6   Differential Diagnosis of Selected Skin Disorders Relative to Secondary Lesion Morphology

Diagnostic Techniques

The potassium hydroxide preparation is used in patients with suspected molluscum contagiosum and dermatophytic infections. The test is performed on loose skin scales, nail pairings, subungual debris, short residual hairs, or small pearly globules (from a molluscum body). The material is placed on the microscope slide, gently crushed, and mixed with two drops of a 20% KOH solution. The specimen is then warmed; boiling will produce artifactual change. Excess solution may be removed by placing a paper towel at the corner of the slide. A coverslip may be applied for especially thick specimens; gentle pressure on the coverslip will compress the material adequately for viewing. Thick skin scrapings may also be allowed to set in the potassium hydroxide solution for 20 min, which should allow additional dissolving. The material is then viewed under a microscope at low power with the condenser and light at low levels. As the slide is scanned, rapidly focus up and down. True hyphae

are long, branching, green rods of constant width that cross the borders of epithelial cells. Molluscum bodies are oval discs with homogeneous cytoplasm. In hair fragments, the organisms appear as small round spores packed closely within the hair shaft.

Scabies and lice preparations are useful in patients with possible infestation. In scabies infestations, the rash itself may resemble other dermatologic syndromes; microscopic analysis will confirm the diagnosis. The donor site for skin specimen selection is very important. The best sites include burrows (10-mm elongated papule with a pustule or vesicle) and papules located on the fingers, wrists, and elbows. Within the vesicle or pustule, a small black dot is noted, which is the mite. The point of the scalpel is scraped across the lesion while holding the skin taut; the mite is then removed. A single drop of mineral oil may be applied to the blade to ensure that the scrapings adhere to the instrument. The material is then placed on the microscope slide with an additional drop of mineral oil; gentle pressure on the coverslip will flatten thick specimens. Using low power, the slide is scanned for presence of the mite, eggs, or feces. Mites are eight-legged creatures that are easily identified on thin smears; thick specimens may require additional viewing to look for the mite. Additional findings supportive of the diagnosis include eggs (smooth ovals) and feces (clusters of red-brown pellets). Lice are usually found on the scalp, eyelashes, and pubic areas, and may be visible to the unaided eye. Moving objects in the area should be grasped with forceps and placed on a slide and viewed under low power. Head lice are long and thin while pubic lice are shorter and broad.

The Tzanck smear, useful in blistering disorders, assists in establishing the diagnosis of a herpes infection—herpes simplex, herpes zoster, and varicella. The choice material for examination is obtained from the base of a recently unroofed lesion; purulent fluid at the base of the lesion is removed with a scalpel and placed on a microscope slide. The material is allowed to air dry and then is stained with either Giemsa or Wright's stain. Using low power, the slide is scanned for epithelial cells. Multinucleated giant cells, indicative of a herpes infection, are a syncytium of epidermal cells with multiple overlapping nuclei. The presence of the multinucleated giant cell does not distinguish herpes simplex, herpes zoster, and varicella syndromes. Wood's light examination is helpful in several different situations, including erythrasma (a superficial *Corynebacterium* infection of moist skin in the groin, axilla, and web spaces), tinea versicolor (a superficial fungal infection), certain pseudomonal skin infections, and porphyria cutanea tarda. Wood's light is an ultraviolet source that emits light at a wavelength of 365 nm. The following fluorescent findings are noted in these conditions: erythrasma—red or pink; tinea versicolor—green or yellow; pseudomonas—yellow or green; and porphyria cutanea—orange or yellow (urine only). Other laboratory investigations are of limited value; selected tests are listed in Table 237-7 with the respective dermatologic disease.

Laboratory Test	Dermatologic Disease
Sedimentation rate	Leukocytoclastic vasculitis
Urinalysis (active sediment)	Leukocytoclastic vasculitis
Microbiologic studies	Infectious syndromes (toxic-infections erythemas, tick-borne illnesses, STDs, etc.)
Platelet count/coagulation studies	Purpuric/petechial states

TABLE 237-7   Selected Laboratory Investigations Useful in the Diagnosis of Dermatologic Disease

TOPICAL THERAPIES

In general, the maxim "if it's dry, wet it, and if it's wet, dry it" applies to the initial therapy of many rashes. Water, protein, and lipid losses characterize dry skin diseases. Emollient creams and lotions restore water and lipids to the epidermis, hasten the healing process, and reduce pruritus and pain. Emollients are moisturizers that reduce skin dryness and decrease skin friction and the sensation of tightness. In patients with chronic drying dermatitides, ointments are best used, particularly in the winter months; in warm weather climates, less viscous, less oily preparations, such as a cream, are better tolerated by the patient. Open wet dressings using tap water or normal saline not only reduce discomfort due to the drying but also cleanses the skin by painlessly loosening crusts and exudates. The various wet cutaneous syndromes involve similar protein and lipid losses due to excessive flow of transudative or exudative fluid from the diseased skin with leaching of the complex macromolecules of the epithelial cells. Drying agents retard this flow of fluid and associated biologic materials from the body, assisting in the curative process.

Corticosteroids

Urticaria, angioedema, and toxicodendron and other contact/allergic dermatitides are potential indications for systemic corticosteroids. Other dermatologic syndromes, such as erythema multiforme, toxic epidermal necrolysis, and vasculitis, are best treated with systemic steroids only after consultation with a dermatologist. Eczema and psoriasis, both of which are chronic dermatologic conditions, are likely to rapidly improve after systemic steroid therapy. Both will also rebound as rapidly with discontinuation of treatment; further, such management increases the possibility of development of pustular psoriasis. Oral prednisone has been used successfully in urticaria patients. In a recent small study, the addition of prednisone burst therapy (40 mg daily for 4 days) markedly reduced the pruritus and hastened the clinical improvement. The authors of this study felt that the patients' conditions improved more rapidly and more completely, and without apparent adverse effects, when prednisone was administered.[3] Patients with poison ivy or oak who require systemic steroids should be treated with oral prednisone (1 mg/kg body weight) with a slow two- to three-week taper. Other contact or allergic dermatitides may benefit from an abbreviated course (four days) of oral prednisone.

Topical corticosteroids are a powerful tool in the management of dermatologic disease. Numerous agents are available for use. They differ in concentration, base components, and cost. Familiarity with a single agent in each potency class is sufficient to safely and effectively treat any steroid-responsive skin ailment. Corticosteroid potency or strength, i.e., the anti-inflammatory property, is measured by the agent's ability to induce vasoconstriction. Agents' strengths are rated using the vasoconstricting ability on a scale of one to seven with lower scale numbers correlating with more potent corticosteroids—group I agents are the most powerful corticosteroids while group VII medications are the least potent. Marked variation in potency is seen among various corticosteroids while much less difference in strength is encountered for individual agents at varying concentrations. Many corticosteroids are fluorinated. Fluorination greatly increases the potency but also increases the risk of adverse reactions and should not be used in pregnancy.

Use of the appropriate-strength steroid is strongly encouraged at the start of therapy. The use of a less powerful agent is not likely to either spare the patient from potential adverse effect or produce adequate control of the disease. Hydrocortisone, perhaps the most frequently used topical corticosteroid in the outpatient setting, is available over-the-counter in strengths up to 1% and by prescription to a maximum of 2.5%. Hydrocortisone is safe and may be used on most body surfaces, including the face, genitalia, flexure creases, and intertriginous zones; it also is safe for use in infants and children. For the treatment of diseases involving the palms and soles, hydrocortisone is a poor choice in that the thickened skin does not allow adequate penetration of this relatively low-potency steroid. Corticosteroids of moderate potency, including triamcinolone acetonide and fluocinolone acetonide, are useful in severely inflamed skin and on the thicker skin of the scalp, trunk, extensor surfaces, and palms/soles; these agents should not be applied to the face or genitals nor used in the infant. Fluorinated steroids should not be prescribed to pregnant women. See Table 237-8 for recommendations of corticosteroid potency relative to dermatologic disease.

Groups I and II	Groups III, IV, and V	Groups VI and VII
Psoriasis	Atopic dermatitis	Nonspecific dermatitis, of face, eyelids, and perineum
Eczema, of hand (severe)	Stasis dermatitis	
Poison ivy (severe)	Seborrheic dermatitis	
Atopic dermatitis (severe)	Tinea	
	Scabies	
	Nonspecific dermatitis, of face (severe)	

*Group I, highest potency; Group VII, lowest potency.

TABLE 237-8 Recommendations of Corticosteroid Potency Relative to Dermatologic Disease*

Different skin surfaces respond differently to topical corticosteroid therapy; this different response rate varies relative to the absorption of the steroid into the deeper tissues. The relatively thin skin surfaces of the face respond very rapidly to the use of group VII agents, whereas the thicker skin of the palms and soles requires a highly potent steroid. Issues that result in an effective higher potency application when using a low-potency agent include: raw, inflamed skin (such skin more rapidly and readily absorbs medication); treatment regions involving skin surfaces in frequent contact, such as intertriginous areas (the apposition of two skin surfaces produces enhanced absorption of drug similar to the effect to an occlusive dressing); and areas of skin surfaces enclosed under tight clothing, such as the diaper area (once again, enhanced absorption of the agent due to the occlusive effect of the garment). In general, lower potency agents are acceptable in these situations.

The application of creams, ointments, gels, and lotions is relatively straightforward. The medication, applied in thin layers, should be massaged into the skin as directed daily. Prewashing the skin prior to corticosteroid application is unnecessary. Patients should be advised to follow directions closely, both early and late in the treatment course. Early application with either extra medication per dose or more frequent medication administrations is not desired; likewise, both a reduced frequency of application or a decreased amount of medication as the disease process responds to therapy can cause relapse. Optimum application regimens have not been determined for topical corticosteroids in most dermatologic syndromes. The more potent agents are best applied two to three times daily for 1 to 2 weeks followed by a drug-free week; additional therapy may be required as determined by the disease as well as by the particular patient's response to the initial therapy. Agents from the less potent steroid groups may be applied three times daily for 2 to 4 weeks followed by a seven day steroid-free period.

The prescription of the correct amount of topical steroid is at times difficult. The burn rule of nines may be used to estimate the amount of topical corticosteroid to prescribe. Calculate the percentage of body surface area requiring therapy; then, multiply the percentage by a correction factor of 30. This calculation will provide the amount of topical corticosteroid in grams for a single application. Next, determine the number of administration required in the treatment course. For example, a tid regimen for a duration of 10 days ultimately requires 30 applications. The number of applications is multiplied by the amount required for a single use. In general, 9 g of topical steroid will cover 9 percent of the body surface area in a tid application for a single day.

Tachyphylaxis refers to the decrease in responsiveness to a drug as a result of enzyme-mediated events. The term is used in relation to topical corticosteroids in reference to acute tolerance to the vasoconstricting ability. In general, vasoconstriction has been demonstrated to decrease progressively over time when a topical steroid is applied. Such reductions in strength due to tolerance are encountered as early as four days into the treatment course in all potency groups yet are felt to be more important in groups I and II. A reasonable strategy to employ to counter the development of tachyphylaxis is the use of interrupted application schedules; such an interrupted treatment course might include an initial tid application for two weeks followed by a single week of drug holiday followed by a repeat of the cycle.

Antihistamine Agents

Antihistamines (H_1 antagonists) are frequently used in the management of dermatologic disease, particularly in the control of pruritus. These agents include diphenhydramine and hydroxyzine and are dosed using these guidelines: for diphenhydramine, adult: 25 to 50 mg po q6h; children: 4 to 6 mg/kg/24 h po given q6 to 8h not to exceed 200 mg in 24 h; and for hydroxyzine, adult: 25 to 100 milligrams po q8h; children: 2 to 4 mg/kg/24 h po q8 to 12h not to exceed 200 mg in 24 h. Parenteral H_1 antagonists may also be used intramuscularly or intravenously. H_2 antagonists (e.g., ranitidine or famotidine) have also demonstrated some benefit in the patient with an allergic-mediated event, particularly urticaria. The second-generation antihistamine agents, including astemizole, cetirizine, fexofenadine, and loratadine, are newer agents that may be used in certain circumstances. In general, the newer antihistamines offer the advantages of reduced dosing frequency and less sedative effect, but they are more costly. Comparisons of these new medications to hydroxyzine are generally favorable; comparisons among these second-generation agents do not demonstrate significant differences.[4,5] The use of topical antihistamine preparations is discouraged. Topical antihistamine agents are readily absorbed; dosing is therefore difficult to predict. Accidental overdosage may result in the patient who aggressively applies the preparation and/or is also using similar oral agents. Numerous other antipruritic therapies are recommended including Domeboro solution (diluted 1:10 aluminum sulfate) soaks, potassium permanganate baths, and oatmeal baths.

Antimicrobial Agents

Topical antibacterial agents are used primarily as adjuncts to wound dressings; these agents rarely are useful as primary therapy for superficial bacterial infections of the skin. The exception to this statement is topical mupirocin, which is reportedly as effective as oral antimicrobial agents in the management of impetigo. Concerning wound dressings, the agents commonly used include polymyxin B, bacitracin, neomycin, and silver sulfadiazine. Suggested benefits of these medications include reduced adherence of bandaging material to the wound, as well as less coagulum and decreased bacterial colonization. The impact on the rate of wound healing and the prevention of wound infection are less well characterized. Another use of topical antibacterial agents is the treatment of aphthous stomatitis with oral tetracycline rinses. Systemic antibiotic therapy is of use in certain dermatologic syndromes and is discussed in those areas.

Various topical antifungal agents are available for the treatment of candida and the dermatophytic infections. The imidazole and polyene classes of agents are the most commonly used in outpatient medicine. Members of the imidazole class include clotrimazole, miconazole, and ketoconazole, while the polyenes are represented by nystatin and amphotericin B. Generally, the imidazoles are effective against yeasts and dermatophytes, whereas the polyenes are useful only in the treatment of candidal infections. In that diagnostic confusion that may arise in the fungal etiology of the superficial infection, polyene agents are best avoided; imidazole agents will treat all such superficial fungal infections. Dermatophytic and yeast infections should be treated for prolonged periods to reduce the possibility of recurrence; in general, a two- to four-week period of therapy is advised. In cases involving significant discomfort, combination agents composed of imidazole and corticosteroid agents reduce discomfort and eradicate the organism. Selenium sulfide shampoo is effective against tinea versicolor when applied for 30 min daily for 14 days.

Acyclovir has been used extensively in patients with various herpes virus infections, including acute varicella, varicella zoster virus infections ("shingles"), and herpes simplex infections. Valacyclovir[6] and famciclovir[7] are acceptable therapies.[8] In general, these agents do not offer significant advantage over acyclovir with the exception of reduced dosing frequency—perhaps increasing compliance and, therefore, the possibility of an improved outcome.

Infestations with lice are treated with topical lindane, permethrin 1%, or pyrethrins. These agents are reasonably effective against adult lice but are less useful against the unhatched eggs—the nit. Consequently, a second application 5 to 10 days after the initial treatment should clear the new generation of lice, which was not affected by the first use. Central nervous system toxicity has been reported in small infants treated with lindane; as such, permethrin or pyrethrins should be used in children less than one year of age. Scabies may also be treated with a single overnight application of lindane or permethrin 5% covering the entire nonhair-bearing skin surface.

Topical Agent Vehicle Considerations

The vehicle, or medication base, is the substance in which the active ingredient is dispersed. The base determines the rate at which the active ingredient is absorbed through the skin. Components of some bases may cause irritation or allergy. Creams, a mixture of oils, water, and preservative, are white in color and greasy in texture. Creams are the most versatile vehicle and can be applied to any body surface area; they are particularly useful in the intertriginous areas. Creams are best used for acute therapy only; chronic application may cause excessive drying. Ointments are composed of greases such as petroleum jelly and are preservative-free; little water is added to this vehicle. This vehicle is translucent and, when applied to the skin, remains greasy. This greasy consistency may aid in the lubrication in particularly dry lesions. In general, ointment vehicles allow deeper tissue penetration when compared to the cream base. Ointments are too occlusive, providing very thorough coverage with deep tissue penetration while allowing little movement in moisture and other material into and out of the skin. Acute exudative syndromes, as well as intertriginous areas of the body, should not be treated with topical steroids using the ointment vehicle. Gels are greaseless mixtures of propylene glycol and water at times with alcohol. Gels have a translucent appearance and are described as "sticky." Alcohol-containing gels are best used for acute exudative lesions such as poison ivy dermatitis, whereas alcohol-free combinations should be applied to dry, scaling conditions. In denuded areas, the alcohol component may cause discomfort. Gels are of particular use in the scalp area; their presence does not alter the arrangement of the hair and therefore more tolerable for the patient from the cosmetic perspective. Solutions or lotions may contain water or alcohols in addition to other agents. They are clear or milky in appearance; with their liquid consistency, they are best applied to the scalp and other dense hair-bearing areas without leaving significant residue on the hair. In denuded areas, the alcohol component may cause discomfort. Guidelines for specialty consultation or hospital admission are similar. First, extensive skin involvement by erythroderma, bullae, or a palpable purpura suggests the need for rapid ED consultation followed by hospital admission. However, certain dermatologic syndromes typically present with

generalized involvement and do not require specialty care; classic examples include urticaria and angioedema, acute varicella, and toxicodendron dermatitis. If the diagnosis is in question in the patient with a generalized rash consider the need for dermatologic consultation.

General medical concerns that might prompt consultation and admission include cardiorespiratory instability, the systemic signs and symptoms, multisystem involvement, significant comorbidity, patient age, poor home environment, or the need for the initiation of aggressive medical therapy.

238 DISORDERS OF THE FACE AND SCALP

Lisa May

The list of cutaneous disorders affecting the face and scalp is quite long. This chapter focuses on those disorders that are more specific to this distribution and likely to be encountered in an acute care setting.

ACNEIFORM ERUPTIONS

Although acne vulgaris is a common chronic problem that likely would not be encountered as a chief complaint in the emergency department setting, several acneiform eruptions may develop with alarming clinical presentations prompting a patient to seek immediate attention. As these disorders are uncommon and require a dermatologic consultation, they are discussed only briefly. These disorders include acne fulminans, pyoderma faciale, dissecting cellulitis of the scalp, and acne keloidalis.

Acne fulminans is a severe form of cystic acne with ulcerating cysts. It most commonly affects the chest and back of young males. Severe scarring may result. It may have systemic associations including fever, myalgias, arthralgias, malaise, and anorexia. Treatment includes systemic corticosteroids and isotretinoin (Accutane). As isotretinoin has potentially severe side effects, including devastating teratogenicity in women who become pregnant while on this medication, it should be administered only by those familiar with the use of Accutane and able to follow the patient during the entire course of therapy.

Pyoderma faciale is an inflammatory cystic acneiform eruption on the central face of young women. Comedones are absent. Scarring is likely to result and thus treatment should be instituted rapidly. Treatment consists of systemic corticosteroids and isotretinoin (Accutane). Again, a dermatology consultation is recommended.

Dissecting cellulitis of the scalp is an inflammatory and scarring disease of the scalp and neck. It is most commonly seen in young African-American males. Clinically, the disease begins with boggy tender nodules on the scalp and neck. The nodules suppurate and develop sinus tracts. Hair loss develops over these nodules, and with time, a permanent scarring alopecia results. The etiology is unknown. It may be seen in association with acne conglobata and hidradenitis suppurativa, where together these three diseases are referred to as the follicular occlusion triad. Treatment is difficult and often unsuccessful. Therapy includes topical and systemic antibiotics; topical, intralesional, or oral corticosteroids; isotretinoin; and excision. Therapy is best managed by a dermatologist.

Acne keloidalis is a perifollicular inflammatory process of the scalp resulting in hypertrophic and keloid scarring. The exact etiology is unknown. It is most common in African-Americans, and it is more common in males than females. The primary lesions are follicular-based papules and pustules on the occipital scalp. The individual keloidal papules enlarge and coalesce to form keloidal plaques with an associated scarring alopecia. Treatment includes topical antibiotics such as clindamycin solution (Cleocin-T solution), topical corticosteroids such as flucinonide (Lidex) solution, and oral antibiotics such as tetracycline. Repeated intralesional corticosteroids may help relieve pruritus and pain, and soften keloidal plaques. Surgical excision and Laser excision are often unsatisfactory.

SEBORRHEIC DERMATITIS

Because seborrheic dermatitis is such a common disorder, its recognition and management are important in any clinical setting including the emergency department. Although the exact etiology is unclear, the yeast, *Piytrosporum ovale,* may play a role in the pathogenesis of this disease.

Clinical Features

Clinically, one sees erythema and waxy scale in the skin folds and hair-bearing areas of the face, scalp, chest, and groin. Common sites of involvement include the scalp, the pinna of the ear, the posterior auricular sulcus, the eyebrows, and the alar grooves of the nose. Itching is quite variable but usually mild. Any age may be affected but the elderly and debilitated are more likely to have extensive involvement. In newborns, seborrheic dermatitis is often referred to as cradle cap. Extensive seborrheic dermatitis that is poorly responsive to treatment may be seen in association with HIV.

Diagnosis

Diagnosis is based on clinical examination. A skin biopsy is rarely necessary. The differential diagnosis includes tinea capitis, psoriasis of the scalp, rosacea, and cutaneous lupus erythematosus. Seborrheic dermatitis is diffuse and rarely associated with hair loss; thus if hair loss is present or the eruption is focal, fungal cultures should be obtained to rule out tinea capitis. As seborrheic dermatitis is uncommon between infancy and puberty, tinea capitis should always be excluded in this age group. Rosacea and seborrheic dermatitis may overlap, but if the predominant features are inflammatory papules and pustules, the patient should be treated for rosacea.

Treatment

Therapy is aimed at controlling the disease; treatment is not curative. Initial treatment should consist of an antidandruff shampoo containing zinc pyrethrin (Head and Shoulders), selenium sulfide (Selsun Blue), salicylic acid (Neutrogena T-Sal), or tar (Polytar or Neutrogena T-Gel). Nizoral shampoo can also be used and is now available over the counter. The shampoo should be lathered into the scalp and left on for 5 to 10 min before rinsing. Shampooing should be performed three times a week. A topical corticosteroid such as flucinonide solution may be applied to the scalp in severe cases. For the face, hydrocortisone 1% or 2.5% applied bid should be the initial management. The use of higher-potency topical corticosteroids on the face can lead to the development of perioral dermatitis and should be avoided.

Patients should treat the seborrheic dermatitis until clear and then on a prn basis.

ERYSIPELAS AND FACIAL CELLULITIS

Erysipelas and cellulitis are infections of the dermis and subcutis with erysipelas being more superficial than cellulitis. The distinction between the two is subtle and therapeutically irrelevant. Erysipelas is more likely to occur in the young and in the elderly.

Pathophysiology

Cellulitis may be a primary process or it may complicate another dermatosis. On the face, it may begin at a site of minor trauma that is often inapparent. A group A streptococcus is the most likely cause of erysipelas. *Haemophilus influenzae* may be a causative organism in children; although this is not as common because of the widespread use of the *H. influenzae* vaccine. *Staphylococcal spp* and *Streptococcal spp* are the most likely pathogens of cellulitis.

Clinical Features

Erysipelas and cellulitis of the face presents as a hot, bright red, tender, indurated plaque (Fig. 238-1). The area of involvement is sharply demarcated and expands peripherally. They do not clear centrally. Vesicles or bullae may be present. They may be unilateral or bilateral. When unilateral, erysipelas and cellulitis need to be distinguished from early herpes zoster infection. When bilateral, they may be mistaken for the malar eruption of systemic lupus erythematosus.

FIG. 238-1. Facial cellulitis. Erythema and edema involve the cheek, nasal bridge, and the upper and lower eyelids.

Fever and lymphadenopathy are often present. Periorbital cellulitis can be associated with orbital cellulitis and has the risk of developing an orbital abscess, cerebral abscess or meningitis.

Diagnosis

Diagnosis is based on clinical presentation. A biopsy is rarely necessary and often not helpful. Needle aspiration of the leading edge for culture has a low yield. A complete blood count and blood cultures should be performed to exclude bacteremia. An imaging study and an ophthalmologic consultation should evaluate periorbital cellulitis.

Treatment

Cellulitis or erysipelas of the face warrants parenteral therapy in an inpatient setting. Unless history is suggestive of an unusual organism, therapy should be directed toward *Staphylococcal spp* and *Streptococcal spp* in adults. Coverage should include these organisms and *H. influenzae* in children. Again, an immediate ophthalmology consultation should be obtained if there is any question of orbital involvement.

HERPES ZOSTER INFECTION

Herpes zoster infections ("shingles") can occur anywhere on the body but most commonly involve the thoracic dermatomes. Involvement of the trigeminal nerve occurs in about 10 percent of herpes zoster infections. Involvement of the face and scalp has the most potentially serious sequelae and thus is discussed here.

Clinical Features

Herpes zoster results from reactivation of latent varicella-zoster virus (VZV). The initial eruption of varicella-zoster virus is chickenpox. Pain or dysesthesia precedes the eruption by 3 to 5 days. Erythematous papules progress to clusters of vesicles with an erythematous base. The vesicles crust in about 1 week. Generalized eruptions may occur in immunocompromised patients.

Any of three branches of the trigeminal nerve may be involved on the face. Involvement of the ophthalmic branch (V1), especially with vesicles on the tip of the nose indicative of involvement of the nasociliary branch, is of serious concern. Involvement of this area raises the possibility of developing keratitis. Therefore, an ophthalmology consult should be obtained.

The virus may spread to motor root ganglia, resulting in motor weakness or paralysis. Ramsay-Hunt syndrome results from facial and auditory nerve involvement. The cutaneous eruption consists of zoster lesions in the external auditory canal (Fig. 238-2) and on tympanic membrane. Bell's palsy and possible deafness or vertigo may result.

FIG. 238-2. Herpes zoster infection. This example demonstrates clustered intact vesicles and crusts of the pinna and external auditory canal. Patients with this distribution are at risk of developing Ramsay-Hunt syndrome with facial nerve involvement resulting in Bell's palsy.

Diagnosis

The differential diagnosis includes herpes simplex infections, impetigo, and contact dermatitis. A Tzanck preparation and a viral culture can confirm the diagnosis. The yield is higher when the tests are performed on early intact vesicles. A Tzanck preparation allows for visualization of multinucleated giant cells. It is useful to determine if an eruption is viral in origin; however it is unable to distinguish between herpes simplex and varicella zoster viruses. Viral culture should be obtained by opening a vesicle and scraping the base of a vesicle onto a synthetic (not cotton) swab to be placed in viral culture media. Growth may take as long as one week.

Again, ophthalmic nerve involvement requires an ophthalmology consultation to rule out ocular complications.

Treatment

Antiviral medications are helpful if given within the first 72 h after the eruption begins. Antiviral therapy can shorten the time to healing, decrease new lesion formation, and possibly decrease the pain and duration of postherpetic neuralgia. Acyclovir (800 mg po five times per day for 7 days), famciclovir (500 mg po tid for 7 days), and valacyclovir (1 g po tid for seven days) are recommended outpatient regimens.

Symptomatic treatment includes Domeboro's solution compresses 1:40 dilution for 15 min qid followed by Polysporin ointment or Silvadene cream. Analgesics are often necessary as well.

HERPES SIMPLEX VIRUS INFECTIONS

Herpes simplex virus (HSV) type I most commonly occurs on the face. Initial infection occurs during childhood or adolescence and varies in its presentation. Many individuals experience mild symptoms while a few experience a debilitating eruption. Recurrences tend to be mild and occur primarily on the lips, in the nose, and in the oral cavity.

The typical lesions of HSV are painful, grouped vesicles with an erythematous base. The primary eruption may be preceded by constitutional symptoms. The characteristic primary eruption is a gingivostomatitis with herpetic lesions on the lips and in the oral cavity. It may persist for weeks. The differential diagnosis includes erythema multiforme, Coxsackie virus, varicella zoster virus, idiopathic aphthae, and, rarely, Behçcet's disease and pemphigus vulgaris.

Recurrent HSV is typically seen as herpes labialis ("fever blisters" or "cold sores"). The individual often experiences a prodrome of localized tingling or burning several hours before the onset of the eruption. The herpetic lesion usually occurs along the lip margin and completely heals within 10 days. Ultraviolet light, fever, or local trauma can induce these eruptions.

The diagnosis is established in the same manner as that for herpes zoster with a positive Tzanck preparation and viral culture.

Treatment for primary HSV gingivostomatitis includes symptomatic treatment, as mentioned previously for herpes zoster infections, including compresses and topical antibiotics. If mild, oral antiviral medications are not necessary; in more severe cases, use acyclovir (200 mg po five times per day for 5 days). Immunocompromised patients with severe involvement require hospitalization for intravenous acyclovir. Treatment can continue for up to 10 days if lesions have not crusted. Recurrent HSV does not require oral antiviral therapy. Patients with recurrent disease should be instructed to avoid triggers, especially the sun, by using sunscreen and a lip balm with ultraviolet light protection.

ECZEMA HERPETICUM

In individuals with cutaneous diseases, most commonly atopic dermatitis, HSV or VZV can infect the dermatitic skin. This disorder is referred to as eczema herpeticum or Kaposi's varicelliform eruption. Initially, the infection may be mistaken as an exacerbation or impetiginization of the dermatitis. Pustules or confluent areas of pus develop. Constitutional symptoms and adenopathy are usually present. Dissemination of the virus is possible; mortality reports in this disorder are as high as 10 percent. Furthermore, scarring may be extensive if the viral infection is not treated early and aggressively.

An immediate dermatology consultation is warranted if this diagnosis is entertained. Depending on the extent of involvement, oral or intravenous acyclovir should be used. The underlying cutaneous disease requires aggressive treatment as well.

OTHER INFECTIOUS DISEASES OF THE FACE

In addition to the infections mentioned above, numerous other infections can occur on the face. In children, impetigo on the face is common, as is dermatophyte infections (tinea faciei and tinea barbae). Staphylococcal folliculitis is also seen on the face. The face and scalp are also a common site of involvement in secondary syphilis in which individuals develop "moth-eaten" alopecia, scaly or moist papules around the nose and at the angles of the mouth. Flat warts are frequently seen in males as a result of spreading the virus by shaving. Numerous molluscum contagiosum on the face of an adolescent or adult are suggestive of HIV. Patients with this disorder should be tested for HIV.

Uncommon infectious diseases on the face include blastomycosis, histoplasmosis, leishmaniasis, leprosy, tuberculosis, sporotrichosis, actinomycosis, and atypical mycobacterium infections.

CUTANEOUS LUPUS ERYTHEMATOSUS

Lupus erythematosus is a connective tissue disease of uncertain etiology. It may be a systemic disease with many organ systems involved or confined exclusively to the skin. Cutaneous lupus erythematosus can be divided into three major types: acute cutaneous lupus, subacute cutaneous lupus, and chronic cutaneous lupus. All three types may occur on the face. This section focuses on the malar rash of acute cutaneous lupus and the discoid lesions of chronic cutaneous lupus erythematosus.

Acute Cutaneous Lupus Erythematosus

The classic eruption of acute cutaneous lupus is the malar or butterfly rash. In most cases, this eruption is associated with systemic disease. It usually occurs simultaneously with the onset or flare of SLE. This eruption is induced by ultraviolet radiation. The malar rash is more common in whites than in African-Americans.

Clinically, the malar rash consists of erythema on the medial cheeks and across the bridge of the nose. Induration, scale, or telangiectasias may be present. Occasionally, the eyelids may be involved which makes the eruption difficult to distinguish from heliotrope rash of dermatomyositis.

Diagnosis is based on clinical examination and the presence of other systemic symptoms suggestive of SLE. This eruption is by no means specific for lupus erythematosus. The differential diagnosis includes rosacea, erysipelas, dermatomyositis, seborrheic dermatitis, medication-induced photosensitivity, polymorphous light eruption, and allergic contact dermatitis. Skin biopsy may be helpful especially if the diagnosis is in question. Initial laboratory evaluation includes a complete blood count, chemistry profile to include BUN and creatinine, urinalysis with evaluation of urine sediment, antinuclear antibodies, double-stranded DNA, and complement.

If the diagnosis of SLE is likely, a rheumatology consultation should be obtained for further evaluation and management. The urgency of this consultation is dependent on the patient's systemic complaints. If other signs or symptoms of SLE are not present, the other entities in the differential diagnosis should be explored. A nonemergent consultation with a dermatologist is recommended.

Chronic Cutaneous Lupus Erythematosus

Chronic cutaneous lupus erythematosus is referred to as discoid lupus erythematosus (DLE). It is an eruption that results in scarring and pigmentary changes in the skin. DLE is most commonly seen in African-Americans. Only 10 percent of patients with this type of lupus develop systemic disease.

Clinically, the lesions of DLE occur in a photodistributed area, especially on the face, ears, scalp, and neck. The lesions begin as erythematous or hyperpigmented papules or plaques that enlarge leaving central depigmentation (Fig. 238-3). Follicular plugging may be visible, especially in ear lesions. On the scalp, a scarring alopecia with typical discoid lesions may occur. More extensive involvement of the trunk and extremities is more likely to be associated with systemic disease.
FIG. 238-3. Discoid lupus erythematosus. The external ear and preauricular cheek is a common site of involvement. Central depigmentation with surrounding erythema and hyperpigmentation is typical of discoid lupus erythematosus.

The lesions of DLE are quite characteristic and the diagnosis can often be made clinically. A skin biopsy is performed to confirm the diagnosis or to make a diagnosis in atypical clinical presentations. As DLE is a chronic disease and individuals suspected of having this disorder should be referred to a dermatologist for long-term management.

PHOTOSENSITIVITY

The types of reactions to ultraviolet light are varied. In many disorders, ultraviolet light aggravates, but does not cause, the disease. Examples of this type of reaction include lupus erythematosus, porphyria cutanea tarda, dermatitis associated with niacin deficiency (pellagra), and recurrence of HSV. Other disorders are caused primarily by the sun. The most common is a sunburn reaction. Sunburn reaction, exogenously induced photosensitivity, and polymorphous light eruption are discussed here.

Sunburn

A sunburn reaction is the inflammatory response to skin injury as a result of ultraviolet radiation. It may be minimal with little discomfort to the patient, or it may be severe with extensive blistering. Individuals with fair skin, light eyes, and naturally light hair color are more susceptible to sunburns; however, even darker pigmented skin can develop skin injury with large enough ultraviolet light exposure.

The sunburn reaction begins 2 to 6 hours after exposure and peaks in one to three days. Erythema and warmth in sun-exposed areas occurs. Vesiculation may result that is equivalent to a second-degree burn.

The most important part of treatment is to stress prevention. Education includes counseling the patient to avoid the midday sun, to apply liberally and frequently a broad-spectrum sunscreen (UVA and UVB protection with SPF 15 to 30), to wear protective clothing, and to seek shade. Sunburns can be treated symptomatically with NSAIDs, with tepid baths, and by applying topical antibiotics to areas of vesiculation. Emollients may be soothing but will not prevent eventual exfoliation. Individuals should also be advised to avoid the sun until the eruption resolves.

Exogenous Photosensitivity Disorders

These disorders result from topical application or ingestion of an agent that causes the skin to be more sensitive to ultraviolet light. Photosensitivity disorders may be phototoxic or photoallergic. The clinical differences are subtle and do not impact on acute management of a patient; therefore, the reader is referred to a reference or dermatology textbook for further information.

Topical photosensitizers usually result in a cutaneous eruption at their sites of application. Ultraviolet exposure is necessary for the eruption to occur. Furocoumarins are the most common group of agents causing topical photoeruptions. Lime juice applied to the skin, fragrances, figs, celery, and parsnips are examples of furocoumarins. Other topically applied agents causing photosensitivity include PABA esters, topical psoralens, musk ambrette, and salicylanilide antibacterials. The typical clinical eruption is a severe sunburn-like reaction, often with vesiculation. Often a linear appearance suggests that an externally applied substance is the culprit.

Numerous ingested substances can result in a photosensitivity eruption as well. Table 238-1 lists the most common offending agents. Because these agents are ingested and distributed throughout the body, the eruption involves all sun-exposed areas. The characteristic distribution of a photosensitivity eruption is the face, posterior neck, dorsal hands, and extensor arms. Certain areas including the creases of the eyelids, the upper lip, the V of the anterior neck, and the posterior auricular neck are spared.

Aminodarone
Chlorpromazine
Chloroquine/hydroxychloroquine
Furosemide
NSAIDs
Psoralen
Sulfonamides
Sulfonylreas
Tetracyclines
Thiazides

TABLE 238-1   Medications Commonly Causing Photosensitivity Eruptions

The diagnosis is based on identifying the offending agent. If the diagnosis is unclear, other photosensitivity disorders, such as lupus erythematosus and polymorphous light eruption, should be excluded. Photopatch testing performed by a dermatologist or allergist may be helpful in identifying the photosensitizing agent.

The causative agent should be discontinued, if possible. Initial management includes topical corticosteroids and management similar to a sunburn reaction. The

patient should avoid the sun until the eruption has cleared completely.

CONTACT DERMATITIS OF THE FACE

Two types of contact allergies are likely to result on the face. The first is the result of an aerosolized allergen. The second is direct physical contact that is most prominent on the sensitive skin of the face.

Clinically, allergic contact dermatitis resulting from an aerosolized allergen presents as erythema or scale with or without vesiculation. The involvement is diffuse with upper and lower eyelids affected. This distribution is in contrast with photosensitive eruptions in which nonsun-exposed areas, such as the upper eyelids and the upper lip, are spared. Direct allergic contact dermatitis tends to be most prominent on the most sensitive skin, such as the eyelids. Examples of aerosolized contactants include rhus (poison ivy, oak) when the plant has been burned. Examples of common contactants affecting the face include nickel, nail polishes, toothpaste, preservatives in make-up, contact lens solutions, eyeglasses, and hair care products. Chemical-splash injuries are a common cause of facial-irritant contact dermatitis. A thorough history is necessary to uncover the offending agent. Referral to a dermatologist or allergist may be necessary if the history is unrevealing.

Avoiding the offending agent is the most crucial part of treatment. Medical treatment will be of little value if the offending agent is not removed from the patient's environment. Depending on the severity, topical or oral corticosteroids and oral antihistamines are used in medical management. Domeboro's compresses can be beneficial as well. Only low-potency topical corticosteroids should be used on the face. Hydrocortisone 2.5%; cream or ointment should be tried initially. Careful application around the eyes is important because topical corticosteroid use has been implicated in causing cataracts and glaucoma. Oftentimes, extensive and severe periocular involvement requires oral prednisone.

HAIR LOSS

Hair loss can be a very alarming event leading to visits to an emergency department. The causes of hair loss are numerous and are typically divided into scarring and nonscarring alopecia. Nonscarring alopecia may be reversible where as scarring alopecia is rarely reversible. The differential diagnoses for alopecia are listed in Table 238-2. Several of the more common types are discussed here.

Nonscarring	Scarring
Alopecia areata	Kerion tinea capitis
Secondary syphilis	Herpes zoster infection
Traumatic alopecia	Dissecting cellulitis of the scalp
Trichotillomania	Folliculitis decalvans
Traction alopecia	Acne keloidalis
Contact dermatitis	Discoid lupus erythematosus
Androgenic alopecia	Lichen planopilaris
Thyroid disorders	Morphea
Telogen effluvium	Sarcoidosis
Medications	Scleroderma
Hair shaft abnormalities	Tumors (squamous cell carcinoma, basal cell carcinoma, melanoma, metastatic disease, cylindroma, lymphoma)

TABLE 238-2   The Differential Diagnosis of Alopecia

Tinea Capitis

Tinea capitis is a dermatophyte infection of the scalp. It is most commonly seen in children, particularly African-American children.

CLINICAL FEATURES   Clinically one sees areas of alopecia with broken-off hairs and scale at the periphery. The alopecia is patchy and usually nonscarring (Fig. 238-4). Occasionally, tinea capitis is associated with an intense inflammatory response. This is manifested as a boggy, tender, indurated plaque with superficial pustules and overlying alopecia. This is referred to as a kerion, and it may result in permanent scarring and alopecia.
FIG. 238-4. Tinea capitis. Patchy areas of hair loss with broken-off hairs and scale is characteristic of tinea capitis.

DIAGNOSIS   Diagnosis is based on a positive potassium hydroxide preparation or positive fungal culture. A potassium hydroxide preparation of the hair is necessary; scraping only the scalp rarely gives a positive KOH exam. Culture is often necessary to establish or confirm the diagnosis. Wood's light examination may be helpful as certain types of dermatophytes fluoresce under Wood's light examination.

TREATMENT   After a diagnosis is established, the current first-line therapy is griseofulvin. Topical treatment alone is not affective. Ultramicrosized griseofulvin at doses of 15 mg/kg/day given bid with meals is recommended. Individuals should be treated for six weeks, at which time the patient should be reevaluated to determine whether therapy should be continued longer. Nizoral shampoo at least three times per week is recommended in addition to griseofulvin.

DISPOSITION   Other family members, especially children, and other close contacts, such as classmates at school or day care, should be evaluated as well. Other affected members should be treated simultaneously to prevent reinfection. Follow-up is crucial and should be stressed as persistent infection may only manifest as scale and go unrecognized by caregivers. Follow-up should be with a primary care provider or a dermatologist.

Alopecia Areata

Alopecia areata (Fig. 238-5) is disease of unknown etiology that results in nonscarring alopecia. Clinically, one will loose round patches of hair leaving behind smooth bald skin. Inflammation or scale is not present. Any hair-bearing area may be affected, but the scalp is the most common site of involvement. Rarely, patients loose all of their scalp or body hair; these are referred to as alopecia totalis and alopecia universalis, respectively. Diagnosis is based on clinical examination. "Exclamation point" hairs may be noted at the periphery. Alopecia areata may be associated with hyperthyroidism; thus, checking a TSH is warranted. Secondary syphilis may result in patchy alopecia described as "moth-eaten" alopecia. Often, scale is present. If secondary syphilis is suspected by history, a screening test, such as an RPR or VDRL, should be performed.

FIG. 238-5. Alopecia areata. This patient's hair loss results in areas of complete balding. The etiology is unknown.

Patients should be counseled that localized alopecia areata usually resolves spontaneously within two to six months. Extensive disease is less likely to resolve. If the disease is extensive, rapidly progressive, or of significant cosmetic concern, the patient should be referred to a dermatologist for treatment. Multiple therapies have been reported including topical, intralesional, and, rarely, systemic corticosteroids; anthralin; contact sensitizers such as dichloronitrobenzene; and photochemotherapy. None is universally successful, and all have potential complications; thus, only those health care providers who can follow the patient long-term to monitor for potential benefit and complications should administer therapy.

Telogen Effluvium

Telogen effluvium is hair loss resulting from a major stressful event. This may include pregnancy and delivery, major surgery, major illness usually requiring hospitalization, or crash diets. The event causes hair to arrest in the telogen growth phase of the hair. Two to three months after the event, when new hairs are growing, the telogen hairs are shed. The patient often notices hair clogging the shower drain or numerous hairs on the pillow upon rising in the morning. The patient and the patient's family notice appreciable thinning that is sudden and often quite alarming. Diagnosis is based on diffuse hair loss in the appropriate clinical setting. A related disorder is anagen effluvium, which is secondary to systemic chemotherapeutic agents. Patients should be reassured that complete hair loss is unlikely and actually heralds new hair growth.

239 DISORDERS OF THE HANDS, FEET, AND EXTREMITIES

Lisa May

Dermatological conditions affecting the hands, feet, and extremities encompass a great majority of skin diseases. This chapter focuses on the disorders that are most likely encountered in an acute care setting. This is by no means a comprehensive review of the subject. The reader is referred to the suggested reading section at the end of this section for a more in-depth coverage of this topic.

ACUTE PARONYCHIA

Paronychia is inflammation of the nail folds. It may be acute or chronic in nature, is seen more often in women than in men, and is associated with frequent wetting of the hands.

Pathophysiology

Acute paronychia results from trauma to the cuticle or nail fold allowing bacteria or yeast to enter. Aggressive manicuring can contribute to this process in adults while nail biting and thumb sucking contribute in children. Excessive water exposure also softens the cuticle allowing for easier entry of organisms. Continued water exposure prevents the reforming of the cuticle, thus providing an environment for colonization of the area with bacteria or yeast. This process results in a chronic paronychia. The most common organisms found in acute paronychia include *Staphylococcal* and group A *Streptococcal* species. The organisms most likely involved in chronic cases are *Candida, Staphylococcus,* and *pseudomonas*.

Clinical Features

Acute paronychia presents as a rapid onset of swelling, tenderness, and redness of the nail fold. A pustule or abscess may develop and pus can often be expressed from the space between the nail fold and the nail. Erythematous streaks may extend proximally from this area and may be associated with fever. Chronic paronychia has a less abrupt onset, and swelling, tenderness, and redness will wax and wane. Retraction of the cuticle is prominent in chronic paronychia, and the nail plate usually has horizontal ridging [Fig. 239-1 (Plate 21)].
FIG. 239-1 (Plate 21). Chronic *candida paronychia*. The cuticle is absent. Erythema and edema are prominent at the proximal and lateral nail folds. The dystrophic

ridged nail is a sign of chronic disease.

Other noninfectious causes of paronychia include psoriasis, dermatitis, and even certain medications including Accutane. Because of injury to the proximal nail fold and cuticles, these patients are at risk of developing secondary infection as well. A clue to the diagnosis is sudden exacerbation of the nail disease without exacerbation of other cutaneous disease.

Diagnosis

The diagnosis of paronychia is based primarily on clinical examination and history. In chronic cases, differentiating between bacterial and *Candida* paronychia may be difficult clinically. Therefore, a fungal culture should be obtained in addition to a bacterial culture.

Treatment

If an abscess or fluctuance is present, immediate treatment includes drainage of the affected area. To perform this procedure, a no. 15 scalpel blade is inserted between the nail plate and the cuticle. The nail fold is then gently massaged to aid in drainage. An incision does not need to be made through the nail fold. Cultures should be obtained in recurrent or chronic cases. Drainage should be followed with warm tap water soaks for 10 to 15 minutes three times a day for one to two days in acute cases. In chronic cases, the area should be kept as dry as possible. In mild acute cases, topical antibiotics like mupirocin (Bactroban) can be applied twice a day for seven days. In more severe acute cases, oral antibiotics such as cephalexin or dicloxacillin (250 mg po qid for 10 days) should be started until culture results and sensitivities have returned.

In chronic paronychia, the hands should be kept dry. Avoiding prolonged water exposure is imperative. In occupations where this is not feasible, such as bar tending, janitorial services, or dish washing, the patient should wear a pair of thin cotton gloves underneath rubber or vinyl gloves. The cotton gloves should be changed frequently as sweating can lead to maceration and further contribute to the problem. All manicuring should be stopped. Drying agents are the treatment of choice. A 2% to 4% thymol in absolute alcohol can be compounded by a pharmacist and applied to the area four times a day. Topical antifungal solutions, such as clotrimazole solution, can be used twice a day as well. Acute flares should be treated like acute paronychia with drainage and antibiotics. Occasionally, severe or recalcitrant candidal paronychia may require oral antifungal therapy with fluconazole or itraconazole. Such cases should be referred to a dermatologist.

Disposition

The patient should be told to avoid water exposure, wear gloves, and avoid manicuring nails as mentioned above. If the patient has not improved in 10 to 14 days in cases of acute paronychia, refer the patient to a dermatologist. Chronic paronychia may take weeks to months to improve; however, lack of response to the above-mentioned treatments or frequent relapses are indications for referral to a dermatologist.

TINEA PEDIS AND TINEA MANUUM

Tinea pedis is a fungal infection of the feet and is often referred to as athlete's foot. Tinea manuum is a dermatophyte infection of the hand. It is often unilateral and associated with tinea pedis. Tinea pedis is very common and usually begins in early adulthood. It is rare in children. Men are more often affected than women. Predisposing factors include hot, humid weather, excessive sweating, and occlusive footwear.

Pathophysiology

Dermatophyte infections result from invasion of the stratum corneum by dermatophytes. *Trichophyton rubrum, Trichophyton mentagrophytes,* and *Epidermophyton floccosum* are the most common organisms causing tinea pedis/manuum. *T. mentagrophytes* is most likely to cause inflammatory bullous tinea pedis. Dermatophyte infections are transmitted from person-to-person or from animal-to-person via fomites or direct contact.

Clinical Features

There are three main types of tinea pedis. The most common type of tinea pedis is the interdigital type. This type manifests as maceration and scale in the web spaces between the toes. Ulceration may even be present in severe cases with secondary bacterial and candidal infection (Fig. 239-2).

FIG. 239-2. Ulcerative interdigital tinea pedis. Secondary bacterial and/or *candida* infection complicate this case of interdigital tinea pedis. This eruption is quite painful and debilitating.

The second type, which is seen in tinea manuum as well, presents as chronic, dry scales with little, if any, inflammation on the palmar or plantar surfaces. It often extends to the medial and lateral aspects of the feet but not the dorsal surface. When present on the feet in this distribution, it is often described as a moccasin distribution. Polycyclic or annular patterns may be seen. Maceration between the toes is common. Onychomycosis may be present with numerous, but usually not all, nails having onycholysis (separation of the nail from the nail bed), and thick subungual debris. Oftentimes, if one hand is involved, both feet are involved as well. It is unclear why the other hand is spared in this "two foot, one hand" type of fungal infection (Fig. 239-3).

FIG. 239-3. Tinea manuum. The right hand has a markedly scaly palm while the left hand is uninvolved. This presentation is typical of tinea manuum. The feet would

likely be involved as well.

The third type of fungal infection presents as an acute, painful, pruritic vesicular eruption on the palms or soles. Erythema is a prominent feature. Toenails and web spaces are usually not involved.

Diagnosis

Diagnosis is based on clinical examination and identification of fungal elements on a potassium hydroxide preparation or with fungal culture. Involvement between the toes and dystrophic toenails support the diagnosis of a fungal infection. Remember, however, that psoriasis, and even chronic hand and foot dermatitis, can involve the web spaces and can cause dystrophic nails.

Although a KOH examination appears to be a simple test, it is often difficult to perform and interpret by inexperienced clinicians. Even in experienced hands, the KOH exam may have a low yield in the noninflammatory type of tinea pedis/manuum. To perform a KOH exam, the area to be scraped (the peripheral scaling margin or vesicle roof) is cleaned with an alcohol swab. With a no. 15 scalpel blade, the scale is scraped onto a glass slide. A coverslip is then placed over the specimen and a drop of 10% potassium hydroxide solution is placed at the edge of the coverslip and allowed to diffuse under the coverslip. The specimen is then heated gently under an alcohol flame to aid in dissolving the keratin of the squamous cells. The specimen is then viewed under 10× magnification. Hyphae appear as light-green, thin strands that cross over cells and have branches (Fig. 239-4).
FIG. 239-4. Positive KOH exam. As viewed under 10× magnification, long, thin branching hyphae are seen.

If a positive KOH exam cannot be obtained, scraping of scale can be sent to the laboratory for KOH exam and fungal culture.

Treatment

If a positive KOH exam is obtained, nonbullous tinea pedis and manuum can be treated with topical antifungal agents. Imidazole antifungal agents such as clotrimazole (Lotrimin and Mycelex), miconazole (Micatin and Monistat), ketoconazole (Nizoral), or econazole (Spectazole) cream should be used twice a day. Treatment should be continued for one week after clearing has occurred. Although econazole cream is more expensive, it is preferred for interdigital tinea pedis as it has antibacterial properties to treat secondary bacterial (often corynebacterium) infection. Topical terbinafine (Lamisil) cream is a fungicidal agent. It is nonprescription and is used once a day. It is currently used in cases that have not responded to other topical agents. Patients should be warned that tinea pedis is often a chronic disease and that recurrences are common. Recurrences or failure to clear with topical medications may warrant treatment with oral agents. Such patients should follow up with a primary care provider or dermatologist.

Furthermore, patients and physicians should be aware that these topical agents do not treat nail infections. Thus, if a patient desires treatment of onychomycosis as well, an oral agent such as itraconazole, fluconazole, or terbinafine is needed. Because onychomycosis does not require emergent attention, such patients should see their primary care provider or dermatologist should they wish to pursue treatment of onychomycosis.

If a positive KOH cannot be obtained, but the clinical examination is highly suspicious for a fungal infection, empiric therapy is not unreasonable. Prior to starting therapy, obtaining scrapings for fungal culture is suggested. As positive KOH exams are difficult to obtain after treatment has started, culture results (whether positive or negative) can help the follow-up physician choose the most appropriate therapy.

Bullous tinea pedis often does not respond to topical treatment. If the patient is experiencing minimal discomfort, a topical agent can be tried initially. In more severe cases, oral antifungal treatment is necessary. Itraconazole 200 mg qd for 14 days or terbinafine 250 mg po for 14 days are effective. The prescribing physician should be familiar with the potential drug interactions and the uncommon but serious side effects (hepatotoxicity and erythema multiforme/toxic epidermal necrolysis) prior to prescribing these medications.

Disposition

In addition to the specific treatment mentioned above, patients should be educated about aggravating or exacerbating factors. Patients should be told to keep their hands and feet as dry as possible. After bathing, web spaces should be thoroughly dried. A hair dryer may be helpful in achieving satisfactory drying. Socks should be changed anytime a patient notes that his or her socks are damp from sweating. Shoes and socks should be removed when possible.

The patient should also be instructed to follow up with a dermatologist if the eruption is not clear in four to six weeks.

HAND AND FOOT DERMATITIS

Hand and foot dermatitis simply means inflammation of the skin of the hands and/or feet. The term is used to encompass several more specific disorders. These include allergic contact dermatitis, irritant contact dermatitis, dyshidrosis, and atopic dermatitis of the hands.

Pathophysiology

As this term relates to several different diagnoses, the pathophysiology is based on the specific disorder. Allergic contact dermatitis is a delayed hypersensitivity reaction to one of many possible allergens. On the hands, allergens may include rhus (poison ivy/poison oak), nickel, chromate, and rubber components of gloves. Some of the more common agents that cause allergic contact dermatitis on the foot are rhus, rubber accelerators found in shoes, dyes in leather and socks, and dichromates used in tanning leather.

Irritant contact dermatitis is an immediate nonimmunological response from chemical damage to the skin. Strong irritants such as acids or phenol may cause severe immediate irritation ("chemical burn"). Weaker irritants including soaps, detergents, friction, and cold, dry air cause a more chronic dermatitis.

The cause of dyshidrosis is unknown. It tends to occur equally in men and women during early to mid-adulthood (ages 20 to 40).

Atopic dermatitis is more often a disease of infancy and childhood; however, persistence into adulthood is possible. Hand or foot involvement is usually not the only

cutaneous finding.

Clinical Features

In acute allergic contact dermatitis, erythema with papules, vesicles, and/or bullae is present. It is intensely pruritic and excoriations are noted. Chronic allergic contact dermatitis has less prominent vesiculation and more scale, lichenification, and fissuring. Distribution is the most helpful clue to aid in diagnosis. When the hands or feet are involved in allergic contact dermatitis, the eruption tends to be present on the dorsal surfaces sparing the palms, soles, and web spaces. The thick stratum corneum of the palms and soles prevents penetration of potential allergens. Furthermore, distribution with linear streaks suggests a plant allergy such as rhus hypersensitivity (Fig. 239-5 A). Sharp demarcation of footwear indicates a reaction to a component of the patient's shoes (Fig. 239-5 B). An eruption also present behind the earlobes, around the neck or at the site of a pant snap suggests a possible nickel allergy.

FIG. 239-5. Allergic contact dermatitis. A. Allergic contact dermatitis from exposure to poison ivy. Erythema, vesiculation and bullae are present on the fingers and the dorsal surfaces of the hands. Note the linear streak across the right hand. This finding is a diagnostic clue for rhus contact dermatitis (poison ivy).   B. Allergic contact dermatitis to the straps of sandals. Erythema, scale and excoriations are noted in a symmetric patterned distribution matching to this patient's footwear.

Irritant dermatitis resulting from a strong irritant like an acid or alkali initially begins as immediate burning in the exposed area. Vesiculation and bullae formation with surrounding erythema follow. In severe reactions, necrosis and ulceration may even be present. These eruptions often occur as a result of accidental exposure. Irritant dermatitis from weaker irritants presents as erythema, scale, and fissuring. Vesiculation is less prominent, and often is not present. Irritant contact dermatitis is a common problem in occupations that require frequent handwashing or water exposure, such as health care workers, bartenders, and housewives.

Dyshidrosis initially begins as very small, deep-seated, pruritic vesicles on the lateral aspects and the volar surfaces of the palms and soles. The dorsal surface of the distal phalanges may also become involved. A key feature separating this disorder from other dermatitides is the lack of erythema at the onset. Over time, the vesicles may form pustules or desquamate to leave small collarettes of scales. In chronic cases, erythema and scales become more prominent and may be difficult to distinguish from other forms of hand and foot dermatitis.

Atopic dermatitis of the hands and feet often presents as erythematous, pruritic scaly patches with prominent involvement of the dorsal surfaces as well as the palms and soles. Chronic atopic dermatitis will also have hyperpigmentation and lichenification and fissuring. Oftentimes, other areas of the body are involved. Common areas of involvement include the antecubital and popliteal fossae, the posterior neck, and the wrists and ankles.

Diagnosis

The diagnosis is made on clinical grounds. Differentiation between the above-mentioned disorders, however, may be extremely difficult or impossible at times. More than one disorder may be present at a time, such as atopic dermatitis complicated by irritant dermatitis. One should try to elicit an occupational or hobby history that may indicate a specific causative agent. A history of an atopic diathesis (atopic dermatitis, allergic asthma, allergic rhinitis) in the patient or other family members should be sought as well. If an allergen is suspected, referral to a dermatologist for skin patch testing can help determine the exact agent responsible. A fungal infection should always be considered in the differential diagnosis. A potassium hydroxide preparation can exclude this possibility. A dermatophytid eruption is another possibility. In this disorder, the hands break out in a dermatitic eruption as a result of a dermatophyte infection of the feet. Checking the patient's feet should be part of the clinical examination. Finally, psoriasis, lichen planus, pityriasis rubra pilaris, keratodermas, and autoimmune bullous diseases should be considered in the differential diagnosis. Rarely is a biopsy indicated, as it cannot differentiate between the different types of dermatitis.

Treatment

If an offending agent is discovered, it should be removed from the patient's environment. All antihistamine, anesthetic, antibiotic, and anti-itch creams should be stopped as they may cause a second allergy. In addition, water, soaps, detergents, and lotions should be avoided, as they may be irritating. The hands or feet should be well protected when performing any potentially irritating activities such as housecleaning, gardening, or hobbies using glues or chemicals. Friction should be avoided as well. Lubrication with products such as Vaseline petroleum jelly, Eucerin cream, or Aquaphor ointment should be used frequently and liberally.

Acute eruptions with vesiculation can be treated with an astringent soak. The most commonly used astringent is aluminum acetate (Burow's solution). One Domeboro's powder packet or tablet is mixed with one pint of water then applied with a towel or gauze to the affected area for 15 to 20 min qid. A high-potency topical corticosteroid such as fluocinonide (Lidex) ointment is then applied two to three times a day. Weaker nonfluorinated topical corticosteroids, such as hydrocortisone 2.5% or desonide, should be used on the face, in skin folds, and on children. Antihistamines are also valuable, especially to relieve nighttime pruritus. Hydroxyzine (Atarax) 25 to 50 mg every 6 hours should be tried initially. In severe cases with debilitating eruptions, systemic glucocorticoids are indicated. In allergic contact dermatitis secondary to rhus, the eruption usually persists for three to four weeks, thus treatment should continue throughout this period to prevent return of the eruption once the prednisone is stopped. Prednisone beginning at 40 to 60 mg with a 2- to 3-week taper is recommended. Relative contraindications to prednisone use include diabetes, hypertension, active peptic ulcer disease, psychiatric disease, and immunodeficiency. If prednisone is prescribed to such patients, close follow-up is necessary.

Chronic eruptions should be treated with high-potency topical corticosteroids two to three times a day. Ointments are preferred as they help with lubrication. Hydroxyzine can provide symptomatic relief from itching. Systemic glucocorticoids should be avoided in chronic cases. Although they may provide temporary relief, rebound disease after cessation of the glucocorticoid is common. Furthermore, patients become overly dependent on this medication and the chronic effects of corticosteroid therapy then become an issue.

Severe irritant contact dermatitis with skin necrosis should be treated in a similar manner as a thermal burn. Debridement, and even skin grafting, may be necessary. Immediate referral to burn specialists or a burn center is warranted.

Disposition

Hospitalization is rarely indicated except in instances of severe chemical burns. Burn specialists (either plastic surgeons or dermatologists) should be consulted and the patient should be treated in a burn center if necessary. If the diagnosis is in question, consultation by a dermatologist should be sought. All acute dermatitis can be treated initially in the emergency department. The patient should be instructed to follow up with a primary care physician or dermatologist if the eruption does not clear in three to four weeks, if systemic glucocorticoids are begun in the emergency department, or if patch testing is necessary. Chronic dermatitis should be seen by a primary care physician or dermatologist in two to three weeks to assess the need for prolonged treatment and to follow for possible complications to topical corticosteroids.

PSORIASIS

The hands and feet are common sites of involvement in psoriasis. Two types of psoriasis are seen. The first is psoriasis vulgaris or plaque-type psoriasis. Often, these patients have disease involvement of other areas especially the elbows, knees, scalp, and gluteal cleft. Sometimes, however, the hands or the feet may be the only involved site. The second type of psoriasis involving the palms and soles is palmoplantar pustulosis. This is a rare form of pustular psoriasis confined to the palms and soles.

Pathophysiology

Psoriasis is an inherited disease in which the principal abnormality is a shortening of the keratinocyte cell cycle resulting in an overproduction of cells 28 times normal. The causes underlying this rapid cell cycle are not clear; however, immunological factors play a complex role in this process.

Clinical Features

In psoriasis vulgaris, erythema, scales, and fissures are seen in discrete plaques on the palms or soles (Fig. 239-6*A*). Extensive disease may extend over the entire palms, soles and dorsal surfaces of the hands or feet. Onycholysis (separation of the nail plate from the nail bed), nail pits, and yellow discoloration of the nails help support the diagnosis of psoriasis. Hand and foot dermatitis, lichen simplex chronicus, and Reiter's syndrome should be included in the differential diagnosis.

FIG. 239-6. Psoriasis. **A.** In plaque type psoriasis, erythematous plaques with thick scale are present on the palms. Hand dermatitis and lichen simplex chronicus may be difficult to differentiate clinically from this type of psoriasis. **B.** Pustules in various stages of evolution are seen in this typical example of palmoplantar pustulosis.

In pustular psoriasis of the palms and soles, erythema, minimal scale, and numerous sterile pustules are seen. The pustules are in various stages of evolution from small pustules to larger confluent "lakes of pus" to crusts to rings of scale (Fig. 239-6*B*). It is most commonly seen bilaterally in the instep of the foot, the thenar, and hypothenar eminences of the hands. The differential diagnosis includes tinea pedis or manuum, *Staphylococcus aureus* infection, herpes simplex infection, and dyshidrosis.

Diagnosis

Complete examination of the skin focusing on the sites commonly affected by psoriasis including the elbows, knees, scalp, lower back, gluteal cleft, and nails may reveal other areas of involvement to aid in diagnosing psoriasis. If no other psoriatic plaques are noted, differentiation from hand and foot dermatitis can be difficult. A biopsy may be helpful in this instance. A KOH examination should be performed to rule out a dermatophyte infection. Bacterial and viral cultures should be obtained when disease is localized to one area.

Treatment

Initial treatment includes the use of topical corticosteroids, tar preparations, and lubrication. A tar solution containing 1 teaspoon of a tar emulsion such as Balnetar or Zetar in a quart of water, should be used to soak the palms and soles for 15 to 20 minutes twice a day. Application of a high- or ultra high-potency topical corticosteroid such as fluocinonide (Lidex) or clobetasol propionate 0.05% (Temovate) or betamethasone dipropionate (Diprolene) 0.05% ointment follows this soak. Liberal use of emollients such as Vaseline petroleum jelly, Aquaphor healing ointment, or Eucerin cream should be encouraged.

Disposition

The above-mentioned treatment should be discussed with the patient. The chronicity of this disease and the slow response to treatment should also be mentioned. Psoriasis of the palms and soles is exceedingly difficult to treat and the patient should be warned that complete clearing is unlikely and treatment is aimed at controlling symptoms. Because of the chronicity of this disorder, follow-up with a dermatologist in four to six weeks is recommended. The patient should be educated about other treatments, such as acitretin (Soriatane), psoralen-ultraviolet light A, or methotrexate, that are available should the above recommendations fail; however, referral to a dermatologist is recommended to commence such treatment. Immediate consultation with a dermatologist is usually not necessary, but follow-up in several days to four weeks is warranted, depending on the degree of involvement and severity of symptoms.

LICHEN SIMPLEX CHRONICUS

Epidemiology

Lichen simplex chronicus (LSC) is an extremely pruritic eruption that can involve any part of the body. Most commonly, the ankles, lower extremities, neck, scrotum, and vulva are involved. In LSC, the inciting event is often unknown. The pruritus is intense, thus leading to scratching. Scratching intensifies the itching, which then perpetuates the scratching.

Clinical Features

LSC presents as a one or several intensely pruritic well-demarcated plaques. As a result of chronic scratching and rubbing, lichenification is the prominent feature. Erythema, hyperpigmentation, and excoriations are also present. Scale is minimal. The ankles, shins, dorsal feet, and hands may be affected.

Diagnosis

The diagnosis is based on history and clinical examination. The differential diagnosis includes a dermatophyte infection (ringworm), nummular eczema, psoriasis, and squamous cell carcinoma. A KOH exam is helpful to rule out a dermatophyte infection. Psoriasis oftentimes involves numerous areas of the body, most commonly the elbows, knees, the lower back, the gluteal cleft, and the scalp. Psoriasis tends to have less pruritus, less lichenification, and more silvery scale. Nummular eczema is characterized by more lesions and less lichenification. If the diagnosis is in question, a skin biopsy is suggested.

Treatment

Interrupting the scratch-itch cycle is the most important aspect of treatment. High potency topical corticosteroids such as fluocinonide (Lidex) ointment should be applied to the plaque two to three times a day. Antihistamines should be used for pruritus and nighttime sedation. Benadryl or Atarax 25 to 100 mg every 6 hours is recommended.

Disposition

The chronicity of the disease and its slow response to treatment should be discussed with the patient. Furthermore, the sedating nature of antihistamines and their avoidance when driving or operating heavy machinery should also be discussed. Follow-up with a primary care provider or a dermatologist should be arranged in four to six weeks, especially if response to treatment has been minimal.

VENOUS STASIS DERMATITIS AND VENOUS LEG ULCERS

Epidemiology

Stasis dermatitis and venous leg ulcers result from chronic venous insufficiency. Stasis dermatitis and venous ulcers are seen in the middle-aged to elderly population. Approximately 80 percent of leg ulcers are venous stasis ulcers resulting from chronic venous insufficiency.

Pathophysiology

Chronic venous insufficiency is the cause of stasis dermatitis and venous leg ulcers. Chronic venous insufficiency is usually due to episodes of phlebitis or varicose veins. This results in poor venous return from the lower extremities leading to increased hydrostatic pressure and lower extremity edema. It is most common on the medial ankle where the inferior perforate connects the superior and deep venous systems and the hydrostatic pressures are the greatest.

Clinical Features

Dependent edema, erythema, and orange-brown hyperpigmentation characterize early stasis dermatitis. The medial distal legs and the pretibial leg are the areas most frequently affected. More chronic and severe cases may have bright weepy erythema and even ulceration [Fig. 239-7 (Plate 22)]. Like other dermatitic processes, pruritus is common. Bacterial infection may complicate stasis dermatitis. The presence of honey-colored crust and pustules suggest secondary bacterial infection. Cellulitis and lymphangitis may even be present.

FIG. 239-7 (Plate 22). Stasis dermatitis. Note the surrounding red-brown pigmentation and the central weepy erythema on the pretibial leg.

Stasis ulcers often begin within areas of stasis dermatitis. The medial and lateral malleolus and the medial aspect of the calf are the most common sites of involvement. The ulcer often has an aching quality with dependency. The ulcer has a punched out appearance with orange-brown hyperpigmentation at the borders and a moist pink base. Peripheral pulses are usually present.

Diagnosis

Diagnosis of stasis dermatitis is based on the history and physical examination. Other disorders to consider include allergic contact dermatitis (especially to topical preparations used to treat underlying stasis changes), lichen simplex chronicus, and xerotic dermatitis. Especially in association with acute exacerbation, secondary infection with *Staphylococcus aureus* should be excluded with a bacterial culture.

Stasis ulcers are also diagnosed on the basis of a history and physical examination. Bacterial cultures should be obtained if secondary bacterial infection is suspected. The differential diagnosis of leg ulcers is quite long and broad (Table 239-1). If the ulcer does not have the clinical findings mentioned above, other diagnoses should be considered, and appropriate history sought and tests performed. This is particularly important for certain disorders, such as arterial ulcerations, pyoderma gangrenosum, and polyarteritis nodosa, that require immediate attention. For instance, if peripheral pulses are absent and the patient has a history of claudication, vascular blood flow studies should be performed to rule out arterial ulcers. If the patient reports a rapidly developing ulcer that began as a pustule or erythematous nodule and has violaceous overhanging borders, pyoderma gangrenosum should be suspected. If the diagnosis is in question, consultation with a dermatologist is indicated.

TABLE 239-1   The Differential Diagnosis of Leg Ulcers

Treatment

Attempts should be made to determine and correct the underlying cause of dependent edema. Venous hypertension should be reduced by leg elevation and the use of support stockings. Weeping eruptions should be treated with an astringent compress like Domeboro's solution. A low- to midpotency topical steroid such as fluocinolone acetonide (Synalar) 0.025% cream or hydrocortisone 2.5% cream should be used twice a day. The patient should be told the medication is used to treat the erythema, scale, and pruritus. Hyperpigmentation will not respond to treatment; therefore, the medication should be discontinued when erythema, scale, and pruritus resolve. Oral antihistamines, such as Benadryl or Atarax, should be used for pruritus and for nighttime sedation. Secondary bacterial infection should be treated with cephalexin, dicloxacillin, or ciprofloxacin for 7 to 10 days. Evidence of cellulitis or lymphangitis may require hospitalization for intravenous antibiotics. Topical neomycin, antihistamine creams, and anesthetic creams should be avoided as they may cause allergic contact dermatitis when used in this setting.

Because venous leg ulcers are chronic and slow to heal, emergency department treatment should focus on treating underlying causes of edema, stasis dermatitis,

secondarily infected ulcers, cellulitis, or lymphangitis. Follow-up should be arranged with a dermatologist, with a vascular surgeon, or at a leg ulcer clinic for further treatment.

ERYTHEMA NODOSUM

Epidemiology

Erythema nodosum is an inflammatory eruption of the subcutaneous fat. It has numerous possible etiologies. As a result, all age groups can be affected [Fig. 239-8 (Plate 23)].

FIG. 239-8 (Plate 23). Erythema nodosum. An erythematous indurated nodule is seen. This patient's disease was initially diagnosed as cellulitis. However, after no response to antibiotics, a biopsy confirmed the diagnosis of erythema nodosum. Most patients with erythema nodosum will have multiple lesions.

Pathophysiology

Erythema nodosum is classified as a panniculitis–inflammation of the subcutaneous fat. Table 239-2 lists many of the potential causes of erythema nodosum. In about 40 percent of cases, the etiology remains unknown.

TABLE 239-2   The Causes of Erythema Nodosum

Clinical Features

Tender, warm, ill-defined erythematous nodules characterize erythema nodosum. It is most commonly seen on the pretibial area of the lower extremities. The upper extremities and trunk can occasionally be involved. Numerous lesions are usually present. Ulceration is not a feature of erythema nodosum and suggests the possibility of another type of panniculitis.

Diagnosis

Clinical exam is characteristic of a panniculitis. Individual lesions may be mistaken for bacterial cellulitis; however, the nodular component supports the diagnosis of erythema nodosum. If a presumed bacterial cellulitis has no obvious portal of bacterial entry, erythema nodosum should be considered in the differential diagnosis. If the diagnosis is unclear, a deep punch biopsy or an incisional biopsy including subcutaneous fat is indicated. After the diagnosis of erythema nodosum is established, one must search for possible etiologies. Work-up includes a thorough history and physical examination. Further evaluation, as directed by history and physical findings, may include a throat culture, a stool culture, a complete blood count, a chest radiograph to rule out sarcoidosis, and placement of a PPD.

Treatment

Therapy focuses on treatment of the underlying cause. If such a cause is not clearly established, symptomatic relief can be obtained with bedrest, leg elevation, and nonsteroidal anti-inflammatory agents. These measures can be instituted in the emergency department until the patient can be seen by dermatologist. Other treatments, including oral potassium iodide (SSKI) and systemic corticosteroids, may be required; however, they should not be started until the etiology is established.

PYOGENIC GRANULOMA

Epidemiology

Pyogenic granulomas most commonly occur in children and young adults. Pyogenic granuloma is also more common in pregnant women in whom it is referred to as granuloma gravidarum.

Pathophysiology

A pyogenic granuloma is a benign proliferation of immature capillaries occurring at the site of minor skin trauma. The name is a misnomer as it is neither an infection nor a granuloma.

Clinical Features

A pyogenic granuloma initially presents as a bright red, shiny papule with a thin collarette of hyperkeratosis. It may be ulcerated and tends to bleed profusely with minor injury. Later, the lesion reepithelializes and becomes a dull red to purple color. Although these lesions can occur anywhere on the body, the extremities, especially the hands, are the most common sites of involvement. The differential diagnosis includes amelanotic melanoma, squamous cell carcinoma, bacillary angiomatosis, and cutaneous metastasis.

Diagnosis

The diagnosis is often suspected on clinical grounds; however, a biopsy of the lesion should be performed to confirm the diagnosis and to rule out the above-mentioned disorders, especially an amelanotic melanoma. These two disorders can be indistinguishable by clinical examination alone.

Treatment

Referral to a dermatologist for biopsy is indicated. If the lesion is bleeding profusely in the acute setting, hemostasis can be obtained with pressure and electrocautery. Destruction of the lesion, excision, or a shave biopsy followed by electrodesiccation and curettage are the treatments of choice. These lesions will rarely resolve completely without treatment.

OTHER DISORDERS AFFECTING THE HANDS AND FEET

Several other generalized skin disorders have classic clinical findings on the palms and soles. These disorders are discussed in more detail in Chap. 241; however, they are mentioned briefly here so as to be reminded of these disorders when a patient presents with a complaint in one of these body regions.

Erythema multiforme has characteristic findings on the palms and soles. These lesions are erythematous macules with a violaceous, dusky or bullous center. They are commonly referred to as target or iris lesions. Discovering such lesions should incite a search for similar lesions on the rest of the body, hemorrhagic erosions on the mucosal surfaces, and conjunctival hemorrhage in the eyes.

Secondary syphilis also has characteristic palm and sole lesions. These lesions are red-brown to brown macules on the palms and soles. Although patients with darker pigmented skin may have several hyperpigmented macules as a normal finding, recent onset or failure of the patient to recall such lesions should increase the clinician's suspicion of secondary syphilis. These lesions are often asymptomatic and may be the only indication of secondary syphilis. A high index of suspicion is necessary, and appropriate further clinical examination and serology should be carried out.

Rocky Mountain spotted fever may also present initially with palm or sole lesions. These appear as blanching erythematous macules that later become nonblanching petechial lesions. These lesions start distally and spread proximally.

Kawasaki disease, scarlet fever, and toxic shock syndrome may all have palmar erythema as a prominent feature. The palms and soles will desquamate as these diseases progress.

Furthermore, when considering pruritic eruptions of the extremities, one must always think about scabies. The hands, feet, and elbows along with the groin are the most common areas of involvement. Diagnostic burrows will most likely be found in the hyperkeratotic skin of the palms and soles particularly along the web spaces and the wrist. When the scabetic mite burden becomes quite high, Norwegian scabies results. Thick hyperkeratosis resembling dermatitis results [Fig. 239-9 (Plate 24)]. See Chap. 242 for further discussion.

FIG. 239-9 (Plate 24). Norwegian scabies. The thick scale, erythema, and exudate resemble a foot dermatitis. This disorder should not be forgotten when presented with a patient with extremely pruritic scaly eruption. Norwegian scabies is more common in immunocompromised and debilitated patients.

Finally, all the major types of skin cancer including malignant melanoma, squamous cell carcinoma, and basal cell carcinoma can occur on the extremities.

240 DISORDERS OF THE GROIN AND SKIN FOLDS

Lisa May

When discussing the skin folds of the body, one is referring to the groin, intergluteal cleft, axilla, inframammary folds, and pannus folds. The skin folds have unique characteristics that set them apart from other regions of the body. For one, these areas are almost continuously occluded. As a result, scale does not develop; maceration and fissuring develop instead. This alters the appearance of papulosquamous diseases and inflammatory processes in this region. The occlusion also allows for the development of a warm, moist environment favorable to the growth of fungi, yeast, and bacteria. Finally, the skin folds—in particular, the groin, intergluteal cleft, and the axilla—are the major sites in the body of apocrine glands. Thus, certain disease processes of these structures such as hidradenitis suppurativa occur predominantly in this area. Although many skin diseases can affect the skin folds to some degree, this chapter focuses on common disorders where skin fold eruptions are the main cutaneous finding.

TINEA CRURIS

Tinea cruris is a fungal infection of the groin commonly called jock itch. Tinea cruris is very common in males. It is uncommon in females and exceedingly rare in children. Tinea cruris results from invasion of the stratum corneum by the dermatophyte types of fungi. It is transmitted from person-to-person via fomites and from animal (usually kittens or puppies)-to-person via direct contact or fomites.

Clinical Features

One sees erythema with a peripheral annular slightly scaly edge in the groin and extending onto the inner thighs (Fig. 240-1) and even the buttocks. The penis and scrotum are not affected. This feature is important in distinguishing tinea cruris from other eruptions in the groin as most other eruptions will affect the scrotum.

FIG. 240-1. Tinea cruris. Erythema with a more prominent, arciform leading edge on the inner thighs is typical of tinea cruris.

Other common disorders to be included in the differential diagnosis include candidiasis, erythrasma, lichen simplex chronicus, allergic and irritant contact dermatitis, and extramammary Paget's disease. A more extensive list of inflammatory processes of the intertriginous areas can be found in Table 240-1 . See the description under intertrigo for a comparison of the features of these disorders.

TABLE 240-1 Inflammatory Disorders of the Skin Folds

Diagnosis

The diagnosis is established by a positive potassium hydroxide (KOH) examination. A KOH preparation will demonstrate branching hyphae (Fig. 239-4). If a KOH

examination is negative, one of the other above-mentioned disorders should be considered.

Treatment

Antifungal creams such as clotrimazole (Lotrimin or Mycelex), ketoconazole (Nizoral), or econazole (Spectazole) twice a day is the initial treatment. Clotrimazole is suggested initially as it is of low cost and is nonprescription. Spectazole also has antibacterial properties and is preferred if maceration is present. Treatment also includes keeping the affected area as cool and dry as possible. Wearing loose-fitting clothing is recommended. Antifungal powders such as Zeasorb AF should be used on a daily basis to prevent recurrences.

Disposition

The patient should follow up with a primary care provider or dermatologist if the eruption has not resolved in 4 to 6 weeks.

CANDIDA INTERTRIGO

Candidal infections of the skin favor moist, occluded areas of the body. Although any skin fold may be involved, superficial candida infections are commonly seen in the diaper area of infants, the vulva and groin of women, the glans penis (balanitis) in uncircumcised males, and the inframammary and pannus folds of obese patients. Antibiotic therapy, systemic corticosteroid therapy, urinary or fecal incontinence, immunocompromised states, and obesity are predisposing factors. Women with vulvar or inner thigh involvement will often have vaginal candidiasis as well. Frequently, intertrigo is multifactorial with candida complicating other inflammatory intertriginous disorders.

Clinical Features

The typical presentation is erythema and maceration with surrounding small erythematous papules or pustules [Fig. 240-2 (Plate 25)]. These satellite pustules are a characteristic finding differentiating candida intertrigo from other inflammatory disorders affecting the skin folds. Patients will complain of burning or itching. The other inflammatory disorders listed in Table 240-1 should be considered in the differential diagnosis.

FIG. 240-2 (Plate 25). Candida intertrigo. Note the bright-red erythema, erosions, and satellite papules and pustules in this striking example of inframammary candida intertrigo. A KOH examination will confirm the diagnosis.

Diagnosis

The rim of satellite pustules helps to distinguish candida intertrigo from other eruptions of the skin folds. A KOH preparation of the pustules or a leading edge scale may demonstrate short hyphae and spores; however, these may be difficult to find in cases with just erythema and maceration. If candida is suspected but not visualized on KOH preparation and the diagnosis is in question, a fungal culture should be obtained.

Even if the diagnosis of candida intertrigo is confirmed by a KOH preparation, it is important to obtain a thorough history to rule out an underlying disorder that may be secondarily infected with Candida.

Treatment

Keeping the affected area dry and cool is a very important part of treatment and should be stressed to the patient. After bathing, air drying or drying with a hair dryer should be encouraged. Clothing should be loose and lightweight. Astringent solutions such as aluminum acetate (Burow's solution) aid in drying weepy inflamed eruptions. One Domeboro's powder packet or tablet is mixed with 1 pint of water, then applied with a towel or gauze to the affected area for 15 to 20 min qid. A topical antifungal cream such as clotrimazole, ketoconazole (Nizoral), or econazole (Spectazole) should be applied bid. Spectazole has the advantage of antibacterial properties as well; however, it is more expensive. The addition of hydrocortisone 1% cream bid can speed symptomatic relief and healing. Furthermore, drying powders, such as Zeasorb AF, should be used on a daily basis.

Patients with vulvar candidiasis should be evaluated for candida vaginitis and treated appropriately if found. Patients with candida balanitis often have a female sexual partner with candida vaginitis, so this person should be evaluated and treated as well. In infants or in adults with urinary or fecal incontinence, diapers or sanitary pads should be changed frequently. Zinc oxide paste applied over the antifungal agent provides a barrier to the irritation of urine and feces.

Disposition

Failure to respond to treatment may indicate another etiology of the eruption, and reevaluation by the patient's primary care provider or dermatologist should be sought.

INTERTRIGO AND DIAPER DERMATITIS

Intertrigo refers to inflammation of the skin folds. It is an irritant dermatitis resulting from moisture, heat, friction, and irritating substances like urine and feces. Intertrigo is common in the skin folds of obese patients where sweating and maceration occur. It is also a frequent occurrence in the diaper area of infants where it is referred to as diaper dermatitis.

Clinical Features

Intertrigo presents as erythema, maceration, and fissures in the occluded area of skin folds, especially the groin and inframammary fold. Satellite papules and pustules are absent. Burning and pruritus are present.

Diagnosis

Intertrigo is a diagnosis of exclusion. Other causes of skin fold erythema and fissuring such as candida intertrigo, erythrasma, tinea cruris, allergic contact dermatitis, seborrheic dermatitis, inverse psoriasis, and extramammary Paget's disease must be considered. Differentiating candida intertrigo from inflammatory intertrigo can be difficult. Candida intertrigo will have satellite pustules as a prominent feature. If positive, a KOH examination supports the diagnosis of candida intertrigo. A negative KOH examination, however, does not rule out this possibility, as yeast is difficult to obtain and visualize with this procedure. A scraping of peripheral scale or a

pustule to send for fungal culture is suggested.

Erythrasma is a bacterial infection caused by *Corynebacterium minutissimum*. Its distribution is the same as tinea cruris in the groin, but other skin folds may be affected as well. The color is often an orange-red color without a prominent leading edge. The diagnosis of erythrasma is confirmed by the presence of coral-red fluorescence under Wood's light examination.

Clinically, irritant dermatitis cannot always be distinguished from allergic contact dermatitis. A history should be taken to uncover any possible contact allergens or irritants such as neomycin-containing ointments, anesthetic creams, Benadryl cream, deodorants, feminine hygiene sprays, or other lotions, solutions, or home remedies.

Complete skin examination will help to uncover other signs of seborrheic dermatitis or psoriasis. Furthermore, extramammary Paget's disease and Bowen's disease (squamous cell carcinoma in situ) may be clinically indistinguishable from intertrigo—they may even be secondarily infected with candida. Little or no response to therapy are indications to biopsy the affected area to exclude these diagnoses.

Treatment

As this eruption results from irritation by moisture, heat, and friction, these factors should be eliminated. Keeping the areas dry and cool is helpful. The patient should avoid tight-fitting clothing, especially undergarments. Weight loss can help as well. All potential irritants should be avoided. In diaper dermatitis, disposable diapers are preferred because of their highly absorbent properties. Diapers should be changed frequently, and periods free of diaper wear to dry and cool the affected skin is recommended. Zinc oxide paste provides an excellent barrier to urine and fecal material.

It is a common occurrence for the practitioner to be uncertain of the diagnosis. As a result, treatment is often aimed at both anticandidal and anti-inflammatory therapy. Several pitfalls of this approach exist. First, if used alone, topical corticosteroids can cause persistence or worsening of candida intertrigo. Second, the commonly prescribed combination medications, Lotrisone and Mycolog, contain a high-potency fluorinated corticosteroid. The occlusive nature of skin folds allows for better and deeper penetration of these high-potency corticosteroids, resulting in an increased risk of steroid-induced atrophy and striae. If combination therapy is warranted, Vytone-HC 1% (Vioform and 1% hydrocortisone) has anticandidal effects with a mild topical corticosteroid more appropriate for use in the intertriginous areas.

For moist weepy intertrigo, astringent compresses can be used. Domeboro's compresses, as described above for candida intertrigo, are recommended.

Secondary bacterial impetiginization can occur and should be treated with oral antibiotics with staphylococcal and streptococcal coverage.

SEBORRHEIC DERMATITIS

Seborrheic dermatitis is one of the most common skin disorders. It most notably affects the scalp ("dandruff") and creases of the face and ears; however, other skin folds such as the intergluteal cleft, groin, the axilla, inframammary folds, and the umbilicus can be affected. Severe and extensive seborrheic dermatitis is more common in debilitated patients, patients with HIV, and patients with Parkinson's disease.

The exact cause of seborrheic dermatitis is unknown. Overgrowth of *Pityrosporon ovale,* a yeast that normally inhabits hair follicles and sebaceous ducts, with resultant inflammatory response has been implicated.

Clinical Features

Seborrheic dermatitis of the scalp and skin folds of the face presents as erythema with a waxy yellow scale. When seborrheic dermatitis affects other skin folds, erythema and maceration are noted. Extension of the eruption onto the pubic area and central chest may be seen.

Diagnosis

The diagnosis is made on clinical examination of the skin folds with special attention to the scalp and creases of the face. Without examination of the face and scalp, the groin or other skin fold involvement is hard to differentiate from the other inflammatory disorders such as candida intertrigo, inverse psoriasis, allergic contact dermatitis, or erythrasma.

Treatment

Patients should be told that treatment is not expected to result in a cure. Treatment is aimed at relieving signs and symptoms of disease; the eruption will return after treatment ceases. Shampoos can be used on the scalp and other hair-bearing areas. These include shampoos containing zinc pyrithione (Head and Shoulders), selenium sulfide (Selsun or extra-strength Head and Shoulders), salicylic acid (Neutrogena T-Sal), or tar preparations (Neutrogena T-Gel). Nizoral shampoo can be effective as well and is now available over-the-counter. Seborrheic dermatitis is very responsive to low-potency corticosteroids. Hydrocortisone 1% cream can be used in mild cases, while hydrocortisone 2.5% cream or desonide (DesOwen) cream or lotion may be required initially in more severe cases. If these initial treatment options fail, the patient should be instructed to follow up with a dermatologist.

LICHEN SIMPLEX CHRONICUS

The scrotum, vulva, and perianal area are common sites of involvement with lichen simplex chronicus. Clinically, lichenification, hyperpigmentation, and excoriation are prominent features (Fig. 240-3). Treatment is the same as for LSC in other areas except low-potency corticosteroid (hydrocortisone 2.5% or desonide) ointments should be used. In cases of perianal LSC, patients should be instructed to cleanse the perianal area thoroughly to remove fecal debris and tissue paper that may be irritating. Witch hazel pads are recommended for cleansing.

FIG. 240-3. Lichen simplex chronicus. Pronounced lichenification and hyperpigmentation is typical of lichen simplex chronicus. The scrotum is a common site of involvement.

HIDRADENITIS SUPPURATIVA

Hidradenitis suppurativa is a chronic scarring inflammatory disorder of the apocrine gland–bearing areas of the body. These glands are located predominantly in the groin, intergluteal cleft, vulva, and axilla. Hidradenitis suppurativa begins after puberty and is seen slightly more frequently in women. It is more likely seen in obese

patients. Hidradenitis suppurativa may be seen in association with acne conglobata, dissecting cellulitis of the scalp, and pilonidal cysts (the follicular occlusion syndrome).

The initiating event in hidradenitis suppurativa is occlusion of the apocrine gland and pilosebaceous follicular unit. The exact mechanism resulting in this occlusion is unknown. This occlusion results in the development of inflammatory nodules and abscesses. Bacterial infection is only a secondary process and not the cause of this disorder.

Clinical Features

Initially, hidradenitis suppurativa begins as a painful deep erythematous nodule usually in the axilla or groin. The inflammatory nodule may resolve on its own or develop into a sterile abscess that may open to the surface and drain. Such a lesion may persist and periodically drain, develop a sinus tract and continually drain, or heal with scarring. New lesions may develop in the same area and interconnect. Open comedones, which normally are not present in these body regions, may be seen. Comedones with multiple openings are characteristic of hidradenitis suppurativa. Scarring may be pitted, bridging, or hypertrophic (Fig. 240-4). The extent of involvement is variable with some patients experiencing only localized intermittent lesions with minimal scarring and others with continuously active disease in the axilla, groin, intergluteal cleft, and buttocks.

FIG. 240-4. Hidradenitis suppurativa. A typical example of hidradenitis suppurativa displaying active inflammatory nodules, sinus tracts, pitted scars, and double-headed comedones.

Diagnosis

The diagnosis is made clinically. The location, types of lesions, comedones, and scarring are clues to diagnosing hidradenitis. Other disorders to include in the differential diagnosis of mild disease include inflamed epidermal inclusion cysts, inflamed pilonidal cysts, and furuncles. Severe disease should be distinguished from cutaneous Crohn's disease, lymphogranuloma venereum, granuloma inguinale, and actinomyces. Epidermal inclusion cysts may be singular or multiple and usually have a distinct opening (punctum) to the surface. Usually, only one cyst is inflamed at a given time. Scarring is not a characteristic finding. The patient often gives a history of the presence of a nontender flesh-colored nodule from which cheesy, foul smelling material could be expressed. Pilonidal cysts are singular and located over the coccyx or sacrum in the midline. A furuncle is a staphylococcal abscess ("boils") resulting from folliculitis. Perianal cutaneous Crohn's disease may have a very similar clinical appearance to hidradenitis with inflammatory nodules, sinus tracts, and fistulas. A thorough history and physical examination will help identify or exclude this disease. If uncertain, a skin biopsy for histopathology and culture will differentiate hidradenitis from cutaneous Crohn's disease, lymphogranuloma venereum, granuloma inguinale, and actinomyces.

As secondary bacterial infection can occur, cultures of draining lesions should be performed.

Treatment

Medical and surgical treatment options exist for hidradenitis suppurativa. The therapy chosen depends on the extent and severity of the disease. Acutely inflamed nodules should be treated with intralesional corticosteroids (triamcinolone 3 to 5 mg/mL). Acutely inflamed abscesses should be incised and drained. Mild-to-moderate chronic disease should be treated with oral antibiotics in a similar manner as treating acne. This includes using tetracycline 500 mg PO bid, minocycline 50 mg PO bid, or erythromycin 500 mg PO bid for at least 1 month. If bacterial infection is discovered from bacterial culture results, antibiotic treatment should be tailored to the specific organism and its drug sensitivities. Surgical excision may be necessary if lesions do not respond to the above mentioned treatments. Such patients should be referred to a plastic or dermatologic surgeon.

In addition to the previously mentioned therapy, severe disease may require oral prednisone or isotretinoin (Accutane). Such patients should be referred to a dermatologist for management. Patients should be told about the chronicity of this disease. Aggravating factors such as tight-fitting clothing should be avoided. Obese patients should be encouraged to loose weight. Antibacterial cleansers (Hibiclens) or a topical antibiotic solution (Cleocin T) should be prescribed to prevent secondary bacterial infection.

SEXUALLY TRANSMITTED DISEASES

Sexually transmitted diseases are mentioned briefly so as not to forget them when presented with a patient with an eruption in these areas. Sexually transmitted diseases can occur in the intergluteal cleft, the perianal area, and the groin with or without genital involvement. The chancre of primary syphilis and condyloma lata of secondary syphilis can occur in these areas. The perineum or perianal area is a common site for primary or recurrent herpes simplex virus. The sacrum is also a common site of recurrent HSV. Condyloma acuminatum frequently involves the inguinal creases and perianal area in addition to the genitalia. Furthermore, pediculosis pubis ("crabs") and scabies should be considered in pruritic excoriated eruptions of the groin and axilla. Finally, the clinical findings in granuloma inguinale and lymphogranuloma venereum predominate in the inguinal folds.

241 GENERALIZED SKIN DISORDERS

William J. Brady
Daniel J. DeBehnke

This chapter describes selected generalized skin disorders in adults, and discusses their dermatologic diagnosis and treatment. Discussed below are erythema multiforme; toxic epidermal necrolysis (TEN); the toxic infectious erythemas; disseminated viral infections; Rocky Mountain spotted fever; meningococcemia; purpura fulminans; and the systemic bullous diseases.

ERYTHEMA MULTIFORME

Erythema multiforme (EM) is an acute inflammatory skin disease presenting across a spectrum. It ranges from a localized papular eruption of the skin (EM minor) to a severe, multisystem illness (EM major) with widespread vesiculobullous lesions and erosions of the mucous membranes, Stevens-Johnson syndrome (SJS). The disorder strikes all age groups with the highest incidence in young adults (age range 20 to 40 years), affects males twice as often as females, and occurs commonly in the spring and fall. Infection, especially mycoplasma and herpes simplex, drugs, especially antibiotics and anticonvulsants, and malignancies are common precipitating factors. However, there is no identifiable etiology in approximately 50 percent of cases. [1]

The pathogenesis of EM remains largely unknown. Most likely, it is the result of a hypersensitivity reaction with the demonstration of immunoglobulin and complement components in the cutaneous microvasculature on immunofluorescence studies of skin biopsy specimens, circulating immune complexes in the serum, and mononuclear cell infiltrate on histologic examination. [1,2]

Patients frequently experience malaise, fever, myalgias, and arthralgias. Diffuse pruritus or a generalized burning sensation can occur before the skin develops lesions. The morphologic configuration of the lesions is quite variable, hence the descriptor "multiforme." Maculopapular [Fig. 241-1*A* (Plate 26)] and target [iris, Fig. 241-1*B* (Plate 27)] lesions are the most characteristic. Erythematous papules appear symmetrically on the dorsum of the hands and feet, and the extensor surfaces of the extremities. The maculopapule evolves into the classic target lesion during the next 24 to 48 h. As the maculopapule enlarges, the central area becomes cyanotic, occasionally accompanied by central purpura or a vesicle. Urticarial plaques may also occur with or without the iris lesion in a similar distribution. Vesiculobullous lesions, which may be pruritic and painful, develop within preexisting maculopapules or plaques, usually on the extensor surface of the arms and legs, less frequently involving the trunk. Vesiculobullous lesions are most often found on mucosal surfaces, including the mouth, eyes, vagina, urethra, and anus; they may also be seen on the trunk. Ocular involvement occurs in approximately 10 percent of patients with EM minor while the SJS variant experiences ophthalmologic lesions in almost 75 percent of cases.

FIG. 241-1A (Plate 26). Erythema multiforme: Symmetrical, plaque-like lesions involving the flexor surface of the upper extremities—lesions which may be misdiagnosed as the IgG-mediated urticarial allergic reaction. Also note the erythematous macules on the palms. (Reprinted with permission from Brady W, DeBehnke D, Crosby D: Dermatologic emergencies. *Am J Emerg Med* 12:217, 1994.)
FIG. 241-1B (Plate 27). Iris or target lesion, a finding strongly suggestive of EM. This iris lesion is composed of a central bullous lesion with dusky, edematous center and erythematous halo. (Reprinted with permission from Brady W, DeBehnke D, Crosby D: Dermatologic emergencies. *Am J Emerg Med* 12:217, 1994.)

The various lesions develop in successive crops during a 2- to 4-week period, and crops heal over 5 to 7 days. Scarring is rarely a problem except in cases of secondary infection or in heavily pigmented patients in whom hypopigmentation or hyperpigmentation may occur. Recurrence may be noted on repeat exposure to the etiologic agent, a special concern in cases associated with herpes simplex infection or medication use. [3] The rate of EM recurrence is very high in children with HSV infection. For example, 75 percent of children with a prior history of HSV-related EM experienced erythema multiforme recurrence after *herpes simplex* virus reactivation.[3] Fluid and electrolyte disorders, as well as secondary infection from cutaneous sites, represent the most frequent complications, as well as the most common causes of death in the EM patient. The differential diagnosis of EM includes herpetic (both *herpes simplex* virus and varicella zoster virus) infection;

vasculitis; TEN; various primary blistering disorders (pemphigus and pemphigoid); urticaria; Kawasaki disease; and the toxic-infectious erythemas.

Outpatient treatment of EM minor with topical corticosteroids is possible, but steroids should not be applied to eroded areas of the skin. Dermatologic consultation and close follow-up are advised. Those patients with extensive disease, systemic toxicity, and/or mucous membrane involvement require hospitalization, optimally in the intensive care or burn unit setting.

Systemic steroids are commonly used and provide symptomatic relief, but are of unproven benefit in influencing the duration and outcome of EM. [4] Many authorities recommend a short, intensive steroid course, 60 to 80 mg/day of prednisone in divided doses, particularly in drug-related cases, with abrupt cessation in 3 to 5 days if no favorable response is noted. Systemic analgesic agents and antihistamines provide symptomatic relief. Stomatitis is treated with diphenhydramine and viscous lidocaine mouth rinses. Blisters are treated with cool, wet Burow's solution (aluminum sulfate/calcium acetate in aqueous solution) compresses. Ocular involvement should be monitored by an ophthalmologist; unfortunately, burst-steroid therapy does not appear to reduce either the chance of development or significance of existing ocular lesions. Acyclovir may reduce recurrence of HSV infection and, therefore, lessen the potential for another bout of EM; prolonged, prophylactic acyclovir therapy may reduce the chance of recurrent EM related to HSV.[3] EM, particularly SJS, has significant morbidity and a mortality of approximately 10 percent despite aggressive therapy.

TOXIC EPIDERMAL NECROLYSIS

Toxic epidermal necrolysis is an explosive dermatosis characterized by tender erythema, bullae formation, and subsequent exfoliation. Patients may be systemically ill on presentation. Many authorities consider the SJS variant of EM and TEN as the same process.[2] TEN is found in all age groups without predilection to gender. The syndrome has multiple possible etiologies with medications representing the most common cause.[1,2,5,6] Sulfa and penicillin antibiotics, anticonvulsants, and oxicam NSAIDs are the most frequent drug triggers for TEN.[7,8] Other causes include malignancy and human immunodeficiency virus (HIV).[6] In many cases, an etiology is not found.

The pathogenesis is poorly understood and may be partly an immunologic and partly a genetic predisposition. The tendency to develop TEN may be linked to a highly specific genetic defect in the detoxification of the culprit drug or its reactive metabolites.[9] Human lymphocyte antigen (HLA) typing has also suggested a possible genetic predisposition.

Patients with TEN often present with a one- to two-week prodrome of malaise, anorexia, arthralgias, fever, or upper respiratory infection symptoms. Skin tenderness, pruritus, tingling, or burning may be found at this time. Skin signs begin with a warm erythema, initially only involving the eyes, nose, mouth, and genitalia, but later becoming generalized. The erythematous areas become tender and confluent within hours. Flaccid, ill-defined bullae then appear within the areas of erythema. Lateral pressure with a finger on normal skin adjacent to a bullous lesion dislodges the epidermis producing denuded dermis, demonstrating Nikolsky's sign. The bullae form along the cleavage plane between the epidermis and the dermis. The epidermis is then shed in large sheets, leaving raw, denuded areas of exposed dermis. The average time of onset after exposure to the inciting agent is 2 weeks. Cutaneous extension follows an unpredictable time course, ranging from 24 h to 15 days with a minority of severe cases demonstrating rapid, extensive involvement within 24 h.

Prolabial blistering and erosive lesions are disfiguring and often impair adequate oral intake, contributing to hypovolemia. Ocular complications include purulent conjunctivitis, painful erosions, and potential blindness. Anogenital lesions are common. Additional mucous membrane involvement includes the gastrointestinal, urinary, and respiratory tracts. The two major complications and leading causes of death in TEN are infection and hypovolemia with electrolyte disorders. A broad range of pathogens is usually found, with staphylococcal and pseudomonal species predominating. The mortality rate has been reported as being between 25 and 30 percent. These clinical variables are associated with poor prognosis: advanced age; extensive disease; idiopathic nature; multiple medication use; steroid therapy; azotemia; hyperglycemia; leukopenia; and thrombocytopenia.[7] The differential diagnosis of TEN includes staphylococcal scalded skin syndrome (SSSS); EM, toxic shock syndrome (staphylococcal and streptococcal); exfoliative drug reactions; primary blistering disorders (pemphigus and pemphigoid); and Kawasaki syndrome.

Management of TEN requires hospitalization in a critical care setting or, optimally, a burn unit.[7] In most cases, therapy is similar to the approach for the burn patient. Immediate concerns center on the airway, because sloughing of airway and respiratory epithelium can occur. Hypovolemia and electrolyte abnormalities should be corrected. Prompt, aggressive antibiotic administration is necessary in suspected or documented infection; initial prophylactic antibiotics are not recommended by most. The advice of the burn center should be followed for any topical dressings that are applied before transfer.

EXFOLIATIVE DERMATITIS

Exfoliative dermatitis, a cutaneous reaction produced in response to a drug or a chemical agent or to an underlying systemic disease, is a condition in which most or all of the skin surface is involved with a scaly erythematous dermatitis. Males are affected twice as often as females, and most patients are over the age of 40. [10] The mechanisms responsible are not known although drug-induced exfoliative dermatitis may be mediated by an increased activity of sensitized suppressor-cytotoxic T lymphocytes.

Exfoliative dermatitis can have an abrupt onset, particularly when related to a drug, contact allergen, or malignancy, whereas exacerbations related to an underlying cutaneous disorder usually evolve more slowly. In many cases, exfoliative dermatitis tends to be a chronic condition with a mean duration of five years when related to a chronic illness; a shorter course often follows suppression of the underlying dermatosis, discontinuation of causative drugs, or avoidance of allergen. Both idiopathic and chronic disease-related exfoliative dermatitis can continue for 20 or more years; death is rare.

Generalized erythema and warmth are noted and are similar to that seen in the patient with TEN, but skin tenderness is usually lacking. Erythema is accompanied by scaling or flaking and the patient often complains of pruritus and skin tightness [Fig. 241-2 (Plate 28)]. The process usually begins on the face and upper trunk with progression to other skin surfaces. The patient usually has a low-grade fever. Excessive heat loss and hypothermia can complicate erythroderma. Widespread cutaneous vasodilation may result in high-output congestive heart failure. The disruption of the epidermis results in increased transepidermal water loss, and continued exfoliation can result in significant protein loss and negative nitrogen balance. Chronic inflammatory exfoliation produces many changes, such as dystrophic nails, thinning scalp and body hair, and patchy or diffuse pigmentation changes.
FIG. 241-2 (Plate 28). Exfoliative dermatitis—generalized, warm erythema accompanied by scaling or flaking.

The differential diagnosis of exfoliative dermatitis includes staphylococcal scalded skin syndrome, EM, TEN, toxic shock syndrome (staphylococcal and streptococcal), and Kawasaki disease. Considerable effort must be made to determine the underlying etiology, including evaluation for underlying malignancy, and biopsy of involved skin. Patients generally require emergent dermatologic consultation and admission. Hypothermia and hypovolemia should be corrected, and systemic corticosteroids are often given after consultation.

TOXIC INFECTIOUS ERYTHEMAS

A number of infectious syndromes caused by toxigenic bacteria with toxin-mediated dermatologic manifestations have been described, including toxic shock syndrome (TSS), streptococcal toxic shock syndrome (STSS), SSSS, bullous impetigo, and scarlet fever. In certain cases, the bacteria are colonizers with the disease resulting only from the toxin (e.g., TSS); in other instances, the toxigenic organism produces infection with clinical manifestations developing from both the infectious process and the presence of the toxin (e.g., STSS, SSSS, bullous impetigo, and scarlet fever).

Toxic Shock Syndrome

Discussion of the general features and management of TSS are discussed in Chap. 138, while the dermatologic features are discussed below.[11]

The dermatologic hallmark of TSS is nonpruritic, blanching macular erythroderma, a characteristic feature and a major criterion for the diagnosis [Fig. 241-3 (Plate 29)]. The erythroderma is usually diffuse, although it may be confined to the extremities or trunk and may resemble sunburn. The rash may be subtle and is often missed in heavily pigmented patients or when the patient is examined in a poorly illuminated room. Erythroderma may resolve in 3 to 5 days, and a fine desquamation of the hands and feet follows in 5 to 14 days. Other dermatologic manifestations include conjunctival and mucosal hyperemia, petechiae, alopecia, and fingernail loss. The differential diagnosis is broad and includes scarlet fever; Rocky Mountain spotted fever; leptospirosis; rubeola; meningococcemia; streptococcal TSS; SSSS; Kawasaki syndrome; toxic epidermal necrolysis; SJS; gram-negative sepsis; and exfoliative drug eruptions.

FIG. 241-3 (Plate 29). Blanching, nonpruritic erythroderma with a "rough" texture in a patient with toxic shock syndrome. (Reprinted with permission from Brady W, DeBehnke D, Crosby D: Dermatologic emergencies. *Am J Emerg Med* 12:217, 1994.)

Streptococcal Toxic Shock Syndrome

STSS is an uncommon clinical syndrome that involves multiple organ systems with fever, hypotension, and skin findings. [12] The causative agent of this clinical disorder is *Streptococcus pyogenes* (group A *Streptococcus*). Streptococcal species produce extracellular proteins called streptococcal pyrogenic exotoxins (SPEs). Invasive soft tissue streptococcal infection, such as cellulitis, myositis, or fasciitis, is a common factor in the etiology of STSS.

The clinical presentation of STSS includes fever, hypotension, skin edema, and erythema, or bullae [Fig. 241-4 (Plate 30)]. Subsequent desquamation occurs less commonly than during staphylococcal TSS. The same major and minor criteria used for the diagnosis of staphylococcal TSS can be helpful in identifying patients with STSS. According to a consensus document[13] clinical features must include isolation of group A streptococci (*S. pyogenes*) and hypoperfusion, as well as evidence of multisystem dysfunction. Because up to 75 percent of cases of STSS have associated soft-tissue infection, a thorough skin examination for the site of infection is warranted. Palpate muscle groups for tenderness, indicating possible myositis or fasciitis, and evaluate for secondary compartment syndrome. Treatment is oxygenation and fluid resuscitation. Because soft-tissue infection plays a large role in STSS, aggressive management of infection is essential. The site of infection should be identified, incised, and drained, and nonviable tissue debrided. Parenteral nafcillin, or oxacillin, or vancomycin, and a first-generation cephalosporin are often given as initial therapy.
FIG. 241-4 (Plate 30). Large bullous lesions on the lower extremity in a patient with streptococcal toxic shock.

Staphylococcal Scalded Skin Syndrome

Staphylococcal scalded skin syndrome develops in patients with clinically inapparent staph infections caused by an exotoxin produced by *Staphylococcus aureus.* It occurs primarily in infants and young children, and also in immunosuppressed adults or those with renal insufficiency. The exotoxins involved, collectively known as exfoliatin, are elaborated by the bacteria, released into the circulation, and cause acantholysis and intraepidermal cleavage of the skin. [14]

An episode of SSSS frequently begins as a clinically inapparent staphylococcal infection of the conjunctiva, nasopharynx, or umbilicus. The disease course can be divided into three phases: initial/erythroderma; exfoliative; and desquamation/recovery. Initially, the patient (or parent) notes the sudden appearance of a tender erythroderma, usually diffuse, although localized disease has been described. The involved skin may have a sandpaper texture. Tender erythema is prominent in the perioral, periorbital, and groin regions, as well as in the skin creases of the neck, axilla, popliteal, and antecubital areas. The mucous membranes are spared. The exfoliative stage begins on the second day of the illness. The erythematous skin wrinkles and peels off at sites of minor trauma or with minimal lateral pressure with the examiner's fingertip, illustrating the positive Nikolsky's sign (also found in TEN). Large, flaccid, fluid-filled bullae and vesicles then appear. These lesions easily rupture and are shed in large sheets; the underlying tissue resembles scalded skin and rapidly desiccates. After 3 to 5 days of illness, the involved skin desquamates, leaving normal skin in 7 to 10 days. The differential diagnosis for SSSS includes toxic epidermal necrolysis, TSS, exfoliative drug eruptions, and localized bullous impetigo.

Management includes fluid resuscitation and correction of electrolyte abnormalities, as well as identification and treatment of the source of the toxigenic staphylococcus with oxacillin or vancomycin. Corticosteroids are not recommended.

DISSEMINATED VIRAL INFECTIONS

Infectious Exanthems

Many viral infections are associated with generalized morbilliform cutaneous eruptions. The list is exhaustive, but the most common include adenoviruses; cytomegalovirus; coxsackie and echoviruses; Epstein-Barr virus; hepatitis B virus; human herpesvirus-6; paramyxovirus; respiratory syncytial virus; rotaviruses; rubella virus, and human immunodeficiency virus. Other agents associated with generalized eruptions include mycoplasma; *Borrelia* spp; *Legionella; Leptospira; Listeria;* meningococci; rickettsiae; and *Treponema pallidum.* Erythematous macules and papules, or, less often, vesicles and petechiae, usually develop centrally, sparing the palms and soles. Diagnosis and differential diagnosis are based upon history and physical examination. Drug eruption should always be considered in the differential. Skin lesions usually resolve in 7 to 10 days, and are treated symptomatically.

Herpes Zoster

Varicella zoster infections (VZI), also referred to as shingles or zoster, represent reactivation of the previously dormant virus, *Herpesvirus varicellae,* in a patient with an altered immune response. At reactivation, the virus travels down specific sensory nerves to the skin resulting in the skin manifestations of shingles. Patients with lymphoma, leukemia, or diabetes mellitus, and who are immunocompromised, are at risk for reactivated or disseminated infection. [15]

The rash of herpes zoster consists of clusters of vesicles and papules grouped on an erythematous base. Vesicles initially appear clear but become cloudy or purulent over several days. They eventually rupture and crust over. The lesions usually appear along an individual dermatome [Fig. 241-5 (Plate 31)]; less often, adjacent dermatomes are involved. The lesion clusters are usually discrete and separated by normal skin; in the severe case, the cluster may become confluent along the dermatome. Approximately 60 percent of all zoster infections involve the trunk, followed by the head, extremity, and perineal regions in decreasing incidence. [16] Unilateral involvement that abruptly halts at the midline is helpful in correctly identifying the rash; occasionally, a few lesions appear immediately beyond the midline. Involvement of the nose must prompt evaluation for corneal involvement [Fig. 241-6 (Plate 32)].

FIG. 241-5 (Plate 31). A single dermatomal involvement in a patient with herpes zoster infection in a thoracic distribution.

FIG. 241-6 (Plate 32). Herpes zoster ophthalmic infection: Facial zoster involving the ophthalmic branch of the fifth cranial nerve with nasal lesions strongly suggestive of corneal infection.

Approximately one-half of cases with VZI—particularly those patients with AIDS or reticuloendothelial malignancy—experience viremia and may exhibit solitary lesions totaling less than 30 scattered across the body. Patients with AIDS, using immunosuppressive medications, or with active reticuloendothelial malignancy more often demonstrate true dissemination in which widespread vesicular lesions are distributed evenly across the trunk, extremities, and head. In fact, patients with Hodgkin's disease are particularly prone to dissemination with 15 to 50 percent of cases demonstrating involvement of the skin, lungs, and central nervous system. Patients with disseminated herpes zoster infection require admission and treatment with parenteral antiviral therapy.

Herpes Simplex and Eczema Herpeticum

The vast majority of HSV type 1 or type 2 infections involve only localized areas of skin or mucous membranes. In neonates, and adults with atopic dermatitis, malignancy, immunosuppression, and the acquired immunodeficiency syndrome (AIDS), the HSV infection may disseminate, resulting in widespread vesicles, pustules, and ulcerations, and causing multisystem involvement. The neonate may acquire the infection either in utero due to maternal infection during pregnancy or during delivery. Adults undergoing chemotherapy or transplant recipients who are HSV seropositive may reactivate HSV and develop disseminated disease. Patients with atopic dermatitis are also at risk of disseminated disease, which is called eczema herpeticum. [17]

The vesicular rash, initially present in some form in up to 70 percent of patients, ranges from the scattered vesicle to full-body distribution. Lesions are vesicular, of similar size, 2 to 3 mm in diameter, clustered together in groups, and arrayed on an erythematous base [Fig. 241-7 (Plate 33)]. The lesions frequently umbilicate. Occasionally, the disseminated forms of HSV present cutaneously with different lesion morphology and appearance. Rather than grouped, the lesions may occur singularly with a widespread distribution; the lesions may also appear as pustules with purulent blister fluid. Bacterial superinfection is common. Regardless of their initial appearance, the lesions will ulcerate with crusting. A Tzanck preparation, in which fluid from an intact vesicle is applied to a microscope slide and stained with Wright's or Giemsa stain, often demonstrates multinucleated giant cells. If necessary, cultures of vesicle fluid can be obtained for confirmatory diagnosis. The patient's course may be complicated soon after by multiorgan failure. Treatment is admission to a critical care unit with parenteral antiviral therapy and antibiotics for bacterial superinfection.
FIG. 241-7 ([Plate 33]). Disseminated HSV infection in an immunocompromised adult patient; note the widespread distribution of vesicular lesions on an erythematous base.

Eczema herpeticum is an association of two common conditions—atopic dermatitis and HSV infection. The most severe forms of eczema herpeticum tend to occur in the young infant and the adult immunocompromised patient. Lesions appear initially in the area of the preexisting dermatitis, but eventually may disseminate. The underlying atopic dermatitis and bacterial superinfection may alter lesion appearance. Dermatologic consultation is usually necessary to aid in disposition decisions. Selected cases of local eczema herpeticum can be managed in the outpatient setting, with oral acyclovir and antibiotics. More severe or disseminated cases require admission.

DISSEMINATED GONOCOCCAL INFECTION

About 2 percent of patients with mucosal genitourinary (GU) infection will develop disseminated gonococcal infection (DGI). Risk factors for dissemination are not well known, but asymptomatic local disease and active menses seem to be somehow associated. Up to 75 percent of patients with DGI were diagnosed in either late pregnancy, the immediate postpartum period, or within one week of the onset of menses. Disseminated disease, once common in women, now is noted to occur with increased frequency in men. Disease manifestations result from both organism and immune complex dissemination. Fever, arthralgias, and multiple papular, vesicular, or pustular skin lesions characterize gonococcemia. The rash develops on the extensor surfaces of the wrists, palms, and hands and the dorsal aspects of the ankles and feet. The lesions, usually numbering less than 10 to 20, initially appear as small red papules or maculopapules [Fig. 241-8 (Plate 34)] with a petechial component and an erythematous periphery. Lesions either resolve rapidly or evolve into vesicles with purulent fluid, which develop gray necrotic centers. The necrotic center is theorized to be the embolic focus of the gonococcal organism. Ultimately, the lesions become hemorrhagic.
FIG. 241-8 ([Plate 34]). Disseminated gonococcal infection in a sexually active adult female; note maculopapule with a petechial component and an erythematous periphery located on the extensor surface of the wrist.

The differential diagnosis includes other petechial syndromes including Rocky Mountain spotted fever (RMSF); meningococcemia; staphylococcal acute endocarditis; vasculitides (particularly Henoch-Schönlein's purpura and leukocytoclastic vasculitis); enteroviral infections; bacterial sepsis (gram-positive and gram-negative) with disseminated intravascular coagulation; and typhus. The distribution of the rash is similar to that encountered in the RMSF patient, initially seen on the wrists and ankles. The number of lesions in the DGI arthritis-dermatitis patient, however, is markedly less compared to the total lesion count in both RMSF and meningococcemia cases. Further, the rash of DGI is pustular rather than obviously petechial and hemorrhagic, as are the lesions of RMSF and meningococcemia. Lastly, the DGI patient usually does not demonstrate systemic toxicity as commonly seen in RMSF and meningococcemia victims. Reiter's syndrome may be confused with the gonococcal arthritis-dermatitis syndrome. Patients with Reiter's syndrome present with urethritis, conjunctivitis, arthritis, and a psoriasis-like cutaneous eruption; patients with Reiter's syndrome do not demonstrate petechiae, macules, papules, or maculopapules.

The diagnosis of DGI is made in the sexually active patient with complaints of tenosynovitis, arthralgias, and the appropriate dermatologic findings. Gram's stain of fluid from unroofed lesions may demonstrate *Neisseria gonorrhoeae.* Blood cultures may be positive with an increased yield in the early phase of illness with active bacteremia, and urethral or cervical specimens can be obtained for culture or gonococcal antigen. Cultures of the various mucosal surfaces—i.e., cervical and vaginal—are frequently sterile in the patient with disseminated disease states. Antimicrobial agents of choice include ceftriaxone and ciprofloxacin; spectinomycin may be used in patients with intolerance to the initial treatment choices. Treatment regimens include ceftriaxone 1 g intravenously daily for seven doses or parenteral ciprofloxacin over a similar duration.

ROCKY MOUNTAIN SPOTTED FEVER

Rocky Mountain spotted fever, a potentially fatal multisystem illness caused by *Rickettsia rickettsii,* is introduced to humans via the tick vector. Without adequate, timely management, the mortality rate increases to 50 percent. After introduction of the organism to body tissues, it disseminates via the blood stream and invades vascular endothelium causing a necrotizing vasculitis. Constitutional symptoms of fever, headache, and myalgias develop about one week after exposure. The rash in classic RMSF is evident 4 days (range: 1 to 15 days) after the onset of fever and other symptoms. In a minority of patients, usually the adult, the rash is not noted during the entire disease course. This entity, Rocky Mountain "spotless" fever, occurs in approximately 15 percent of cases.

The rash first appears on the wrists and ankles, and rapidly spreads to the palms and soles [Fig. 241-9 (Plate 35)]. As the rash moves centrally, the proximal extremities, trunk, and face are involved. The skin lesions at onset are described as discrete macules or maculopapules that blanch with pressure. The initial lesions evolve into petechiae over two to four days, fade slowly over two to three weeks, and heal occasionally with resultant hyperpigmentation. Rarely, the petechiae may coalesce into ecchymotic areas with eventual gangrene of the distal extremities, nose, ear lobes, scrotum, and vulva—purpura fulminans. For further discussion of the treatment of this and other tick borne diseases, see Chap. 145.
FIG. 241-9 ([Plate 35]). A patient with Rocky Mountain spotted fever revealing petechiae on the ankles.

MENINGOCOCCEMIA

Meningococcemia is a potentially fatal infectious illness caused by the gram-negative diplococcus *Neisseria meningitidis.* Meningococcal disease presents across a wide clinical spectrum in both acute and chronic forms. The acute entities include pharyngitis, meningitis, and bacteremia. Meningococci are present in the nasopharynx of 2 to 20 percent of the general population (the carrier state); during epidemics, the organism is found in up to 30 percent of people without evidence of active disease.

The illness usually strikes patients younger than 20 years of age with the vast majority of cases occurring in children and infants younger than 5 years of age. Epidemic outbreaks occur when a particularly virulent strain of the organism is introduced into a closed, confined population. The highest rates of infection are reported in the winter and spring months, although sporadic cases appear throughout the year. The organism is transmitted through aerosolized droplets of respiratory secretions from asymptomatic carriers and less frequently from actively infected patients. The mortality rate ranges from 5 to 28 percent, although most patients treated appropriately early in the disease course recover. Patients with acute meningococcal infection who exhibit signs of circulatory insufficiency, a peripheral white blood cell count of less than 10,000 cells/μL, or a coagulopathy have a high probability of developing organ system failure followed by death. [18,19]

After exposure to the organism, clinical infection develops usually within 3 to 4 days (range: 2 to 10 days) and progresses rapidly to severe illness. The patient may complain of severe headache, sudden fever, altered mental status, nausea, vomiting, myalgias, arthralgia, and a stiff neck. A rash is frequently noted on presentation and is an invaluable clue to the correct diagnosis early in the disease course. The dermatological manifestations include petechia, urticaria, hemorrhagic vesicles, macules, and/or maculopapules [Fig. 241-10 (Plate 36)]. The classic petechial lesions are found on the extremities and trunk but also are noted on the palms, soles, head, and mucous membranes. The petechiae evolve into palpable purpura with gray necrotic centers, a pathognomic finding for meningococcal infection. The skin findings result from the organism's invasion and destruction of the endothelium. Histopathologic analysis shows an infectious vasculitis.

FIG. 241-10 (Plate 36). Early findings of meningococcemia with petechiae evolving into purpuric lesions. (Reprinted with permission from Brady W, DeBehnke D, Crosby D: Dermatologic emergencies. *Am J Emerg Med* 12:217, 1994.)

Fulminant meningococcal disease is found in less than 5 percent of patients, and presents with sudden prostration, petechiae with areas of ecchymosis, and distributive shock. This rapidly progressive version of meningococcemia is complicated by purpura fulminans, a severe form of disseminated intravascular coagulation. Large ecchymotic areas (usually the extremities, acral portions of the face, and genitalia) become necrotic or gangrenous. [18,19]

The diagnosis of acute meningococcal disease relies on recognition of an ill-appearing patient with an associated petechial rash and the nonspecific symptoms of fever, headache, altered sensorium, and body aches. Additional historical points, physical findings, and laboratory results supportive of the diagnosis include known exposure to active disease; rapid progression of nonspecific symptoms with the associated petechial rash; Gram's stain of skin lesions or cerebral spinal fluid demonstrating gram-negative intracellular diplococci; and latex agglutination of the cerebrospinal fluid. The differential diagnosis includes RMSF, TSS, acute gonococcemia, bacterial endocarditis, vasculitis (Henoch-Schönlein purpura or leukocytoclastic vasculitis), enteroviral infections, and bacterial sepsis (gram-positive and gram-negative) with disseminated intravascular coagulation.

Antibiotics must be given as soon as possible in a patient suspected of acute disease. In adults, an appropriate agent is ceftriaxone; due to the increased prevalence of cephalosporin-resistant pneumococcus, parenteral vancomycin is also often empirically given.

PURPURA FULMINANS

Purpura fulminans (PF) is a rare vascular disorder that is characterized by fever, shock, multiorgan failure, and the rapid development of hemorrhagic skin necrosis. It is associated with dermal vascular thrombosis resulting from vascular collapse and disseminated intravascular coagulation (DIC). Purpura fulminans can result from hereditary or acquired protein C deficiency, activated protein C resistance, or protein S deficiency. It may also result from any condition that causes DIC.

Purpura fulminans presents with the dermatologic triad of widespread ecchymoses, hemorrhagic bullae [Fig. 241-11 (Plate 37)], and epidermal necrosis. Commonly, cyanosis with initial ecchymoses and ultimate necrosis of the tip of the nose, ears, and genitalia frequently occur; in general, distal tissue areas with end-circulation are affected. Large confluent ecchymoses can develop, often on the extremities—from distal to proximal—as well as on the perineum, buttocks, and abdomen. The extremities are often involved symmetrically. Treatment is directed at the underlying cause.

FIG. 241-11 (Plate 37). Purpura fulminans with hemorrhagic bullae. (Reprinted with permission from Tangoren IA et al: Ecchymoses and epidermal necrosis in a 75-year-old man with bacteremia. *J Crit Illness* 13:108, 1998.)

BULLOUS DISEASES (Pemphigus Vulgaris and Bullous Pemphigoid)

Pemphigus vulgaris (PV) is a generalized, mucocutaneous, autoimmune, blistering eruption with a grave prognosis characterized by intraepidermal acantholytic blistering. Bullous pemphigoid (BP) is a generalized mucocutaneous blistering disease of the elderly, with an average age of 70 years at the time of initial diagnosis.[20,21] Although the blisters are deeper in the skin than in PV (below the epidermal basement membrane), the prognosis of BP is better with less associated comorbidity and a significantly more rapid response to therapy. [20,21]

The primary lesions of PV are vesicles or bullae [Fig. 241-12 (Plate 38)] that vary in diameter from less than 1 cm to several centimeters; they commonly first affect the head, trunk, and mucous membranes.[20,21] The blisters are usually clear and tense, originating from normal skin or atop an erythematous or urticarial plaque. Within

two to three days, the bullae become turbid and flaccid. Rupture soon follows, producing painful, denuded areas. These erosions are slow to heal and prone to secondary infection. Nikolsky's sign is invariably positive in PV and absent in other autoimmune blistering diseases. Mucous membranes are affected in 95 percent of PV patients; in as many as 25 percent, the mucous membranes are the primary sites of involvement. Blisters on mucous membranes are more transitory than blisters on the skin in that they are more vulnerable to rupture; this is particularly true in the mouth, where ragged ulcerative lesions readily develop after inadvertent biting of the tissues.

FIG. 241-12 (Plate 38). Scattered bullous lesions intermixed with erosions and painful inflammatory plaques.

BP is characterized by the presence of tense blisters (up to 10 cm in diameter) that arise from either normal skin or from erythematous or urticarial plaques; ulceration with tissue loss follows. Sites of predilection include the intertriginous and flexural areas. Pruritus, occasionally accompanied by a burning sensation, is noted with the appearance of the blistering. Lesions of the oral cavity occur in BP, but with less consistency and severity than in PV. Because the blisters in the oral cavity rupture very easily and heal without scarring, involvement in the mouth is often overlooked. Oral involvement may occur in as many as 40 percent of patients. It is unusual for oral mucosal lesions to precede the cutaneous eruption as in PV.

The differential diagnosis of PV and BP includes the vesiculobullous diseases; dermatologic consultation is required for diagnosis.

Limited oral intake and accelerated protein, fluid, and electrolyte losses through the involved skin can rapidly lead to hypoalbuminemia with significant hypovolemia and electrolyte disturbances in both PV and BP; therefore, dermatologic consultation is advised for treatment and disposition.

242 INFESTATIONS AND BUG BITES

Lisa May

HUMAN SCABIES

Human scabies is an infestation of the skin by *Sarcoptes scabiei*. Human scabies occurs worldwide and affects all races and social classes. It is a quite common disorder, accounting for approximately 2 percent of all dermatologic visits in the United States. The mite is transmitted from human to human by close physical contact. Although children and young adults are most commonly affected, infestation may occur at any age.

Pathophysiology

The scabetic mite resides in a burrow within the stratum corneum, the most superficial layer of the epidermis. Most individuals have an average of 12 mites at any given time. When the mite burden becomes high, numbering in the millions, a crusted form of scabies develops. This is called Norwegian scabies. It is most commonly seen in association with an immunocompromised state, particularly HIV; mental retardation; dementia; or physical disability. The time from infestation to clinical symptoms is about 3 to 4 weeks.

Clinical Features

Scabies tends to be an extremely pruritic eruption, often disturbing sleep (except Norwegian scabies, which tends to have minimal associated pruritus). The most common sites of involvement include the hands, feet, flexural surfaces of the elbows and knees, umbilicus, groin, and genitals. Facial involvement is usually seen only in infants. The pathognomonic lesion, or burrow, is a fine erythematous linear or curved lesion with central scale (Fig. 242-1). Burrows are most often visible in the web spaces of the fingers, the lateral aspects of the fingers, the volar surface of the wrists, the instep of the feet, and the shaft of the penis. Often, however, burrows are not present, especially in patients with excellent hygiene. Excoriations and pruritic papules may be the only visible cutaneous feature. Vesicles are often seen in infants and young children.

FIG. 242-1. Human scabies. Numerous scabetic burrows are visible near the axilla of this infant infested with scabies.

In Norwegian scabies (Fig. 239-9), one develops thick, dirty-appearing hyperkeratosis on the hands and feet. The nails are often affected as well. Because of the large mite burden, this form of scabies is highly contagious.

Diagnosis

The diagnosis is based on a high clinical suspicion and a positive scabies preparation. The diagnosis should be entertained when more than one family member itches. Other disorders to consider in the differential diagnosis include other bite reactions, body lice, atopic dermatitis, neurotic excoriations, and delusions of parasitosis. Suspected cases of scabies should be confirmed by performing a scabies preparation. To perform a scabies preparation, one scrapes or superficially shaves a lesion (preferably a burrow) with a 15 blade. The sample is placed on a glass slide, covered with immersion oil and a cover slip, and examined under the microscope. Mites, eggs, or scybala (feces) will be visible (Fig. 242-2). When possible, the diagnosis should be confirmed with a scraping prior to treatment.
FIG. 242-2. Scabies preparation. The immature mite, ova, and scybala (fecal pellets) are present in this scraping of a burrow. The presence of any one of these elements is considered a positive scabies preparation result.

Treatment

Topical scabicides are the treatments of choice. The topical preparation should be applied from the neck down to the feet, with special attention paid to applying the lotion around and under fingernails, in the web spaces of the fingers and toes, and in the umbilicus.

Permethrin 5% cream (Elimite) and lindane 1% lotion (Kwell) are equally effective. Either preparation should be left on overnight and rinsed off the following morning. Lindane is easier to apply and less expensive than permethrin, but lindane resistance has been reported. Furthermore, because of reports of neurotoxicity with the use of lindane in infants, this medication should not be used in children under 6 years of age or in pregnant women. Patients with extensive involvement should be treated again in 1 week.

All household members and sexual contacts at high risk of acquiring scabies should be treated concurrently even if they are asymptomatic, since a delay from the time of infestation to the development of symptoms exists. Nursing homes, institutions, hospital staff, and schools should be notified, and any symptomatic individuals should be treated. Bed linens, towels, and clothing should be washed and dried in a dryer on high heat.

Since pruritus is a common complaint, antihistamines, such as diphenhydramine hydrochloride (Benadryl) or hydroxyzine, should be prescribed as well. A mid-potency topical corticosteroid may also provide relief from itching. In addition, obvious secondary bacterial infection should be treated with an antistaphylococcal agent.

Disposition

Patients should be educated that itching may take weeks to subside. If they are still symptomatic in 2 weeks, they should seek follow-up for repeat evaluation and treatment.

PEDICULOSIS

Pediculosis capitis (head lice) is an infestation of the hair and scalp by the mite *Pediculus capitis. Pediculus corporis* is the body louse, and pubic lice is an infestation of the pubic hair by *Phthirus pubis.*

Head Lice

This disorder is most commonly seen in school-aged children or in children attending day-care centers. However, any age group can be affected. It is very uncommon in African Americans. The louse is passed from person to person via close contact. The organism may live away from a host on furniture, clothing, linens, hats, or hairbrushes for several weeks, and thus may be passed to another who comes in contact with these articles.

PATHOPHYSIOLOGY   Head lice feed off human blood and therefore remain close to the scalp. When the louse lays its eggs, the ova, or nits, are cemented to the hair shaft. The ova hatch within 7 days. The ova encasement remains attached to the hair shaft and grows out with the hair. By the time the nits are a distance of 1 cm or more away from scalp, they have probably hatched.

CLINICAL FEATURES   The patient usually experiences pruritus. This itching may be mild or quite intense. The occiput and posterior neck are common sites of pruritus, and excoriations on the neck may be noted.

DIAGNOSIS   The diagnosis is made on clinical inspection of the scalp for lice and nits (Fig. 242-3). Unlike flakes of scale, which can easily be moved up and down the hair shaft, nits are firmly attached to the shaft. If the diagnosis is in question, suspected organisms or ova can be viewed underneath a microscope.

FIG. 242-3. Head lice. Nits are clearly visible, firmly attached to the hair shafts.

TREATMENT   Two important aspects of treatment should be addressed: treating the current infection and preventing reinfestation. Several agents may be used to treat the infestation. Permethrin 1% (Nix) rinse should be used as first-line therapy. Unlike lindane and pyrethrins, permethrin is ovacidal as well as pediculicidal. After shampooing, the treatment should be applied to the scalp for 10 min. For cosmetic reasons, nits can be removed by rinsing the hair in a 50% vinegar solution and then combing the hair with a fine-toothed comb.

To prevent reinfestation, all close contacts should be examined and affected individuals treated, including family members, classmates at school or day care, roommates, or health care workers in an institutional setting. Schools and day-care centers should be notified so that appropriate measures can be undertaken to evaluate other individuals.

Clothing, hats, and bed linens should be washed with hot water and dried in a dryer on high heat for 20 to 30 min. Carpets and sofas should be thoroughly vacuumed. Hairbrushes should be washed in hot water with the pediculicide product.

Patients should be reexamined in 7 to 10 days.

Pediculosis Pubis

In general, pubic lice is a sexually transmitted disease. Rarely, it may be passed from person to person via infested clothing, bed linens, and so on. Affected individuals should be evaluated for other sexually transmitted diseases. One report indicated that as many as 30 percent of individuals with pubic lice have another sexually transmitted disease. In children, the possibility of sexual abuse should be considered.

As with head lice, the main complaint with pubic lice is itching, which may vary in intensity. Pubic hair of the groin is most commonly infested, but body hair and eyelashes may be affected as well. Close inspection reveals the lice and nits (Fig. 242-4).
FIG. 242-4. Pubic lice. Pubic lice are seen on the skin surface, and nits are attached to the pubic hairs.

Treatment involves the same medications as for head lice, listed above. Permethrin (Nix) is the preferred initial therapy and should be applied to the affected area for 10 min and then rinsed. Eyelash infestations should be treated by manually removing as many lice and nits as possible and then applying petrolatum to the lashes two to three times a day for 10 days.

Pediculosis Corporis

Body lice is currently uncommon in the United States. Infestation is more likely to occur in persons with poor hygiene or overcrowded living conditions. The lice reside on hair-bearing areas of the body but attach their nits to clothing. The lice and nits can survive as long as 30 days without contact with a human host. Clinically, the bite is often not perceived by an individual but leaves a pruritic red urticarial papule. This lesion is not distinguishable from other bite reactions. A clue to diagnosis is that areas not covered by clothing, such as the face and hands, are usually spared. A high index of suspicion is needed, especially in patients with poor hygiene. Close inspection of clothing reveals nits, especially along clothing seams.

The body louse is the vector for epidemic typhus fever (*Rickettsia prowazeki*), trench fever (*Rickettsia quintana*), and relapsing fever (*Borrelia recurrentis*).

Treatment is similar to that for head or pubic lice. Since the nits can survive long periods without human contact, infested clothing and linens should preferably be destroyed. If not, recommendations include washing and drying on hot cycles and ironing the seams of the textiles. Oral antihistamines and topical corticosteriods may be necessary when itching is severe. Secondary infection, if present, should be treated.

SPIDER BITES

Although spiders are ubiquitous and instill fear in many individuals, significant disease is very uncommon. Numerous spiders may bite, leaving an urticarial papule with two central puncture wounds. Only the bites of two types of spiders in the United States result in significant reactions: *Loxosceles reclusa* (the brown recluse spider) and *Latrodectus mactans* (the black widow spider).

Brown Recluse Spider Bites

As the name implies, the brown recluse spider is a reclusive organism. Humans encounter this spider in attics, storage sheds, crawl spaces, and woodpiles. Encounters with humans are uncommon.

PATHOPHYSIOLOGY   Brown recluse spiders are not aggressive and bite humans in self-defense. The venom results in epidermal and subcutaneous necrosis. This reaction is a local process around the bite site.

CLINICAL FEATURES   Because the bite itself is painless, patients cannot recall being bitten. Only a history of potential exposure can be elucidated. Rarely does a patient see the bite or capture the spider. About 6 to 8 h after the bite, pain associated with a red-to-violaceous discoloration develops. Two central puncture wounds are often visible on close inspection. Initially, the bite site may look like a bruise. It may even form a bulla. Over the next several hours to days, necrosis of the skin and subcutis will occur (Fig. 242-5). This reaction may remain localized or spread to 25 cm in diameter. The spread is in a gravitational direction. Healing is very slow and results in scarring. Secondary infection is common.

FIG. 242-5. Brown recluse spider bite. A central area of necrosis with surrounding erythema is noted.

Systemic symptoms are unlikely, but if they occur, the victim experiences fever, malaise, nausea, vomiting, hemolytic anemia, thrombocytopenia, disseminated intravascular coagulation, seizures, and coma.

DIAGNOSIS   Diagnosis is based on history of potential exposure and clinical course. The spider varies from tan to dark brown and has a violin-shaped marking on its back. It ranges from 0.2 to 2.5 cm in length. Because of the distinct marking, the brown recluse spider is often known as the violin or fiddle-back spider.

The differential diagnosis includes necrotizing fasciitis, pyoderma gangrenosum, toxic reactions to other biting organisms, and infectious processes.

TREATMENT   Initial treatment includes elevation of the affected area, inactivity, and ice compresses to decrease erythema and edema and prevent the spread of venom. Additional treatment for brown recluse spider bites is controversial and includes dapsone, débridement and skin grafting, and systemic corticosteroids. For small areas of involvement, observation and prevention of secondary infection are recommended. Dapsone, a leukocyte inhibitor, has been reported to prevent progression. Dapsone doses should begin at 25 mg twice daily. Patients should be monitored closely for side effects, including hemolysis and agranulocytosis. Dapsone should not be prescribed to individuals with glucose-6-phosphate dehydrogenase deficiency.

Débridement and skin grafting should be delayed until wounds have stabilized, since the venom may delay wound healing. The role of systemic corticosteroids is also controversial. They are recommended for systemic symptoms. Consultation by a dermatologist or other physician with experience in bite reactions should be sought to rule out other potential causes and determine the most appropriate course of therapy. Outpatient management with close follow-up is appropriate for mild-to-moderate cases. Extensive necrosis, rapid progression, or systemic symptoms may require close monitoring in a hospital setting.

Black Widow Spider Bites

Black widow spider bites are rare but serious. Black widow spiders live in webs close to the ground in secluded areas, such as under rocks or logs or in barns, sheds, or outhouses. Only female black widow spiders are capable of envenomation.

CLINICAL FEATURES   The bite of a black widow spider may or may not be painful. Black widow spiders release a neurotoxic venom upon biting the victim. Local reaction is minimal, with mild erythema and edema. Within 20 to 40 min of the bite, the victim begins to develop muscle cramps locally and then generally. A painful, rigid abdomen, mimicking an acute abdomen, is seen. Other systemic symptoms include nausea, vomiting, anxiety, diaphoresis, respiratory distress, urinary retention, hypertension, shock, and coma. In less than 1 percent of cases, death results. Symptoms generally peak in 2 to 3 h and resolve over 2 to 3 days.

DIAGNOSIS   Diagnosis is based on potential exposure, clinical history, or identification of the organism. The red hourglass marking on the undersurface of its abdomen readily identifies the spider.

TREATMENT   In most cases, treatment is supportive. Muscle relaxants and intravenous calcium gluconate may be useful. Narcotics and benzodiazepines should be used judiciously for pain relief. Antivenin (Lyovac) is available but should be reserved for those at greatest risk of morbidity, including the very young, the elderly, pregnant women, and those with cardiovascular disease. Since the antivenin is a horse serum preparation, risks include anaphylaxis and serum sickness.

TICK BITES

Tick bites are common in the United States and are vectors for several serious systemic diseases, including Rocky Mountain spotted fever, Lyme disease, ehrlichiosis, and tularemia. These diseases are discussed elsewhere in this text.

The bite of a tick is usually painless. It may become pruritic over time. Through the mouth parts, the tick cements itself to the skin to obtain a blood meal. As a result, ticks are difficult to remove from the skin. A tick can be recognized as a dark-brown to black organism firmly adherent to the skin. It enlarges as its body becomes engorged with the host's blood. The best approach to removing a tick is to grasp it with tweezers as close to the skin as possible and gently pull with steady pressure. Methods such as burning the tick with a flame, pouring alcohol on it, or covering it with petroleum jelly will not dislodge the tick. If the entire tick is not removed, the patient may develop a foreign-body reaction, which is best treated by excision of the area.

OTHER BITES

Numerous other organisms bite and sting. Common bites include those of mosquitoes, chiggers, fleas, bedbugs, and flies. Some of these insects are disease vectors, and such diseases are discussed elsewhere in this text. The type and distribution of the lesion produced provide hints as to the causative insect.

For instance, mosquitoes and flies tend to bite exposed skin, producing urticarial pruritic papules. Chiggers ("red bugs") are mites that dwell on the ground. They crawl up clothing and bite in high-temperature areas, usually around elastic bands of socks, shirts, and pants. Their bite produces an intensely itchy papule or vesicle. Fleas jump from the ground or furniture. Thus, their bites are seen on the exposed areas around the ankles. Flea bites may be papular or vesicular. Bedbugs reside within walls and mattresses of homes or hotels and tend to bite victims in rows of three ("breakfast, lunch, and dinner bites"). Insects that bite, but not those that sting, may be repelled by insect repellent, such as diethyltoluamide (DEET). Symptomatic treatment, if necessary, consists of topical corticosteriods and oral antihistamines.

HYMENOPTERA STINGS

Hymenoptera includes bees, wasps, hornets, and fire ants. When provoked, these insects inject their stinger into the victim. Bees can only sting once, but yellow jackets, other wasps, and hornets can sting repeatedly. The sting is initially very painful. Local erythema and swelling occur. Local and systemic hypersensitivity reactions can also occur. Local hypersensitivity reactions result in exaggerated swelling. If the sting occurs around the mouth or neck, airway compromise may result. Systemic hypersensitivity is an anaphylactic response, and its recognition and treatment are discussed elsewhere in this textbook.

Fire ants are seen in the southern United States but continue to migrate northward. They dwell in mounds on the ground. When the mound is disturbed, numerous fire ants rapidly run out of the mound. As a result, the victim is usually stung by many fire ants simultaneously. Each ant can sting repeatedly. Anaphylaxis has been reported following fire ant bites. Their sting is very painful and results in a pustule with an erythematous base (Fig. 242-6).

FIG. 242-6. Fire ant bites. This individual unknowingly disturbed a fire ant mound. She received numerous painful stings that developed into pustules with an erythematous base.

Initial treatment of hymenoptera stings includes removing the stinger as quickly as possible, since the stinger continues to release venom. A lateral motion with a knife, fingernail, or credit card is preferred over trying to pull the stinger straight out. Elevation and ice compresses can prevent further swelling.

Edward E. Cornwell III

Trauma in America remains a major public health challenge, accounting for nearly 150,000 deaths each year and an enormous burden to both the health care system and the economy in general. Injury is the fourth leading killer of Americans and the single greatest cause of death before the age of 45. Trauma causes more deaths among children and adolescents (ages 1 to 19) than all diseases combined. Apart from the loss of life, the economic burden (>$100 billion annually) and the number of years of life lost before age 65 (>4.1 million) due to traumatic injury exceed those same measures due to cancer and heart disease combined. [1,2 and 3]

TRAUMA SYSTEMS

The importance of a systems approach to trauma care becomes clear when one considers the timing of death occurring secondary to traumatic injuries. The pattern of mortality takes on roughly a trimodal distribution where three peak occurrences are seen. The first peak occurs in the prehospital setting largely due to devastating head and major vascular injuries. Efforts to reduce deaths in this setting are largely societal, complex, and multidisciplinary and include such multifaceted activities as drunk driving laws; safe road construction; seat belt, helmet, and airbag laws; and violence-prevention activities such as counseling, education and outreach efforts, handgun control, and dissemination of conflict resolution skills. [4,5] A second peak incidence of deaths due to traumatic injuries occurs in the early minutes and hours after a patient's arrival at the hospital. Deaths in this peak are largely due to major head, chest, and abdominal injuries. Attempts to decrease deaths in this setting are largely aimed at rapid transport of patients to the most appropriate facility and prompt resuscitation and identification of injuries requiring surgical intervention. This is the most important function of a trauma system. The third peak in the trimodal distribution of deaths occurs in the intensive care unit where the sequelae of organ hypoperfusion experienced in the early postinjury period are seen. Specifically, patients who have survived the initial injury, transport, and operative resuscitation die in this setting as a result of the systemic inflammatory response syndrome and multisystem organ failure.

In recognition of the need to establish a system where injured patients are rapidly triaged to the most appropriate setting, Congress passed the Trauma Care Systems Planning and Development Act of 1990.[2] This act required each state to develop a Model Trauma Care System Plan to be used as the reference document. Since this act did not carry with it specific appropriated funds, the level of implementation has varied from state to state. Ultimately, each state must determine the appropriate facility for various types of injuries, and some states have come to rely on a verification process offered by the American College of Surgeons in order to designate certain hospitals as trauma centers. [6] An effective trauma system requires the teamwork of emergency medicine, trauma surgery, and trauma care subspecialists.

While each state ultimately has responsibility for designating trauma centers, some have come to rely on the guidelines of the American College of Surgeons. [7] Examples of requirements of various levels of trauma centers are listed in Table 243-1. In addition to the listed essentials, a trauma center must have all the required features of lower-level trauma centers.

TABLE 243-1   Essential Characteristics of Levels I, II, and III Trauma Centers

In short, trauma centers are verified on the basis of commitment of personnel and resources needed to maintain a state of readiness to receive critically injured patients. A well-functioning trauma system ensures that *not only are there appropriately designated trauma centers but also specific triage criteria to designate which patients should be transported to these centers* (Table 243-2).

TABLE 243-2   Maryland Criteria for Mandatory Transport to a Trauma Center

PRIMARY SURVEY

In accordance with the principles of advanced trauma life support, injured patients are assessed and treated in a fashion that establishes priorities based on their presenting vital signs, mental status, and injury mechanism.[8] A process that consists of an initial primary assessment, rapid resuscitation, and a more thorough secondary survey followed by diagnostic tests and ultimate triage constitutes the initial approach to trauma care (Table 243-3).

TABLE 243-3   A Step-by-Step Procedure for Trauma Resuscitation

When available, a history obtained from a patient, witnesses, or prehospital provider may provide important information regarding circumstances of the injury (single-car accident, a fall, exposure, smoke inhalation), preexisting medical conditions (depression, cardiac disease, pregnancy), or medications (steroids, b blockers) that may suggest certain patterns of injury or the physiologic response to injury.

A *primary survey* is undertaken quickly with the goal of identifying and treating life-threatening conditions. Specific lethal problems (discussed in further detail below) that should be identified immediately are airway obstruction, tension pneumothorax, massive hemorrhage, open pneumothorax, flail chest, and cardiac tamponade. During the primary survey, the following are quickly assessed:

   a. *A*irway maintenance with C-spine control
   b. *B*reathing/ventilation
   c. *C*irculation with hemorrhage control
   d. Neurologic *d*isability
   e. *E*xposure, where the patient is completely undressed

Some specific points are emphasized regarding the various components of the trauma evaluation.

Airway with C-Spine Control

Rapid assessment for airway patency includes inspecting for foreign bodies or maxillofacial fractures that may result in airway obstruction. The chin-lift or jaw-thrust maneuver or the insertion of an oral or nasal airway is a first response for the patient making inadequate respiratory effort. A two-person technique is suggested, where one devotes undivided attention to maintaining in-line immobilization and preventing excessive movement of the cervical spine. Comatose patients (Glasgow Coma Scale score 3–8; see "Disability" below) should be intubated tracheally to protect the airway and to prevent the secondary brain injury that occurs with hypoxemia. Log rolling and pharyngeal suction may be necessary to prevent aspiration if the patient vomits. A team approach, where surgeons and emergency medicine physicians work together, is utilized for patients whose anatomy or severe maxillofacial injury precludes endotracheal intubation. In such cases, a surgical airway by means of cricothyroidotomy may be necessary. Agitated trauma patients suffering from head injury, hypoxia, or drug- or alcohol-induced delirium may present a danger to themselves. In these circumstances, paralyzing agents such as succinylcholine or vecuronium, along with a small dose of diazepam or midazolam, may be necessary to enable safe airway management. See Chap. 15 for details, dosages, and techniques.

The issue of C-spine clearance is one that has received much attention in the recent past. Ultimately, "clearance" of a C-spine is both a radiologic and a clinical undertaking. This implies that patients who do not demonstrate evidence of bony fractures or subluxation on x-ray may still have significant injuries that are not appreciated if they cannot cooperate with a thorough physical examination. On the other hand, precious time should not be expended on multiple views in patients who have critical head, thoracic, and abdominal injuries that may require rapid intervention. In these patients, after a cross-table lateral view of the C-spine, the cervical collar should be left in place until the patient ultimately can cooperate with the clinical examination or undergo more sophisticated studies (e.g., CT scans or MRI of the spine).

Finally, the practice of obtaining multiple C-spine x-rays in awake, alert patients with normal examinations (no pain or tenderness with the neck in neutral position and rotated in all four directions) is excessive. A prospective study undertaken at a large level I trauma center evaluated nearly 2000 patients admitted with blunt trauma.[8] Five-hundred and forty-nine of these patients were alert, oriented, and clinically nonintoxicated and had a normal neck examination. These patients subsequently underwent anteroposterior, lateral, and odontoid views of the cervical spine at a minimum. Additional films were necessary for clearance in 59 percent of patients. The total resources used on these 549 patients were 2272 spine films, 78 CT scans, 1 MRI, and 17 additional hospital days just to clear the C-spine. There was not a single injury identified in this group of patients, suggesting that clinical examination alone is reliable to assess the neck in blunt trauma patients who are alert, nonintoxicated, and have no neck symptoms.

Breathing

With the patient breathing or now intubated and being ventilated with 100% oxygen, the thorax and neck should be inspected, auscultated, and palpated to detect abnormalities such as a deviated trachea, crepitus, flail chest, sucking chest wound, fractured sternum, and absence of breath sounds on either side of the chest. Possible interventions here include application of an occlusive dressing to a sucking chest wound, withdrawal of the endotracheal tube from the right mainstem bronchus; reintubation of the trachea if no breath sounds are heard, and insertion of large chest tubes (38Fr) to relieve hemopneumothorax. Evacuated blood should be collected in an autotransfusion device. The volume of blood that returns should be noted immediately, since 1500 cc of hemorrhage may require a thoracotomy.

Circulation with Hemorrhage Control

Hemorrhagic shock, a common cause of postinjury death, should be assumed to be present in any hypotensive trauma patient until proven otherwise. Direct pressure should be used to control obvious external bleeding, and a rapid assessment of hemodynamic status is essential during the primary survey. This includes evaluation of level of consciousness, skin color, and presence and magnitude of peripheral pulses. Attention should be paid to the specifics of heart rate and blood pulse pressure (systolic minus diastolic blood pressure), particularly in previously young, healthy trauma patients (Table 243-4).

	Class I	Class II	Class III	Class IV
Blood loss (mL)*	Up to 750	750–1500	1500–2000	>2000
Blood loss (percent blood volume)	Up to 15%	15–30%	30–40%	40%
Pulse rate	<100	100–120	120–140	>140
Blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure (mmHg)	Normal or increased	Decreased	Decreased	Decreased

*Assumes a 70 kg patient with a preinjury circulating blood volume of 5 L.
BV = blood volume.

TABLE 243-4   Estimated Fluid and Blood Losses Based on Patient's Initial Presentation

Not all hemorrhage is hemorrhagic shock, and the unsuspecting clinician may fail to appreciate ongoing hemorrhage with blood loss of up to 30 percent of the circulating blood volume. While class I hemorrhage (loss of up to 15 percent of circulating blood volume) is associated with minimal symptoms and is clearly not shock, class III hemorrhage associated with gross hypotension is readily appreciated as a state of hypoperfusion. Yet, consider a young, healthy trauma victim who has lost 25 percent of his circulating blood volume (class II hemorrhage) and had a preinjury blood pressure of 130/70 mmHg and a pulse rate of 60. If this patient experiences a 50 percent increase in his pulse rate (to a rate of 90) and a greater than 50 percent decrement of his pulse pressure (from 130/70 mmHg pulse pressure of 60 to 116/90 mmHg pulse pressure of 26), the unsuspecting clinician may assume that the patient is "hemodynamically stable." A false sense of security may lead to delays in aggressively pursuing the source of bleeding (ultrasound, peritoneal lavage, operative exploration). From this example it should be clear that the practice of omitting diastolic blood pressures (and reporting "116/palpable," thus omitting the pulse pressure) is potentially hazardous. The alert, suspicious clinician identifies hemorrhage before it reaches the class III category of obvious shock.

Two large intravenous lines should be established and blood obtained for laboratory studies. While there are varying preferences, I prefer a percutaneous large line in the groin for unstable patients in whom upper extremity veins are not available. This is so because subclavian lines are potentially dangerous in the hypovolemic patient, saphenous vein cutdown at the ankle may not be appropriate for the patient with an injured lower extremity, and complications encountered from the femoral venous line may be minimized if the line is removed quickly on completion of resuscitation in the early postoperative period. Unstable patients without an obvious indication for surgery should be assessed for their response to 2 L of rapid infusion of crystalloids. If there is not marked improvement, type O blood should be transfused (O-negative for females of childbearing age). Auscultation for breath sounds and heart sounds and inspection of neck veins are included in the assessment of circulation because two major causes of hypotension may be present in trauma patients with minimal blood loss: *cardiac tamponade* (hypotension, agitation, distended neck veins, muffled heart sounds) and *tension pneumothorax* (hypotension, distended neck veins, absent breath sounds).

Echocardiography and abdominal ultrasonography, now becoming available in many emergency departments, are rapid, noninvasive ways to assess for fluid in the pericardium and peritoneal cavity.

A discussion of the longstanding controversies involving *fluid resuscitation* is beyond the scope of this chapter. However, reference must be made to a landmark paper published by Bickell and associates.[9] In their prospective, randomized study of victims of penetrating torso injuries in Houston, patients were randomized to receiving immediate IV fluid resuscitation versus withholding fluid until operative intervention could be undertaken. A lower mortality was identified among the group with delayed fluid resuscitation, prompting the authors to speculate that giving fluids before operative control could be achieved is harmful. However one interprets this study, the fact that there were inordinate delays (sometimes >50 min) between hospital arrival and surgical intervention should help achieve consensus around at least one concept: the importance of rapid triage of critically injured patients, particularly those with penetrating trauma, to an appropriate trauma center. One is hard pressed to identify any beneficial interventions that would justify a delay in rapid transport.

The inability, after nearly three decades, to demonstrate an unequivocal advantage of colloid therapy (which is more expensive than crystalloids) has led to near-universal acceptance of a balanced salt crystalloid (normal saline or Ringer's lactate) as the fluid of choice for initial resuscitation.

Disability

An abbreviated neurologic evaluation should now be performed, including level of consciousness, pupil size and reactivity, and motor function. The Glasgow Coma Scale (Table 243-5) should be used to quantify the patient's level of consciousness: possible scores range from 3 (no response) to 15 (high response on all measures). Despite the common comorbid presence of drug and alcohol abuse in trauma patients, it is only safe to assume that patients presenting with a GCS score of less than 15 and an appropriate mechanism have a head injury until proven otherwise. The GCS can be utilized to determine the severity of injury (minor injury GCS 13 and 14, moderate injury GCS 9 to 12, severe injury–coma GCS 3 to 8) and therefore the urgency with which the CT scan is obtained. New head injury guidelines have been formulated by an evidence-based methodology performed by the Brain Trauma Foundation in conjunction with the American Association of Neurological Surgeons.[10,11] Among the updated recommendations are (1) a suggested guideline for the placement of devices for intracranial pressure (ICP) monitoring for head-injured patients with GCS scores of 3 to 8 and a traumatic intracranial lesion and (2) concerns about prolonged prophylactic hyperventilation in the absence of an identified increase in ICP. The result of these two recommendations produces a heightened emphasis on the importance of the head CT scan. Only a head CT would identify the intracranial lesion that would lead to placement of an ICP catheter, and it is only with identification of such an increase in ICP that prolonged hyperventilation (until recently a practice routinely taught) can be justified. Accordingly, patients who are comatose after head injury should be intubated with in-line neck immobilization and transported to the CT scanner with the same sense of urgency that a hypotensive patient with a gunshot wound to the abdomen would be rushed to the operating room.

Measure	Response	Score
Eye opening	Opens:	
	Spontaneously	4
	To verbal command	3
	To pain	2
	No response	1
Verbal	Oriented and converses	5
	Disoriented and converses	4
	Inappropriate words	3
	Incomprehensible sounds	2
	No response	1
Motor	Obeys verbal command	6
	To painful stimulus:	
	Localizes pain	5
	Flexion-withdrawal	4
	Abnormal flexion (decorticate rigidity)	3
	Extension (decerebrate rigidity)	2
	No response	1

TABLE 243-5   The Glasgow Coma Scale Measure of Level of Consciousness

Exposure

No primary survey is complete without thoroughly disrobing the patient and examining the total body surface area carefully for bruises, lacerations, impaled foreign bodies, and open fractures. If hemodynamically stable and if the airway is ensured, the patient should be logrolled, with one attendant assigned to maintain cervical stabilization. Check the back, and thoracic and lumbar spine for tenderness. Check the gluteal cleft and perineum for injury. When the exam is completed, the patient should be covered with warm blankets to prevent hypothermia.

When derangements in any of the components of the primary survey are identified, treatment is undertaken immediately. Once the primary survey is complete, securing of the airway, intravenous catheters as well as urinary and gastric catheters, and monitors should be achieved. At this point a *secondary survey,* a more thorough head-to-toe evaluation, is undertaken. It should be stressed that the secondary survey is not initiated until the primary survey (ABCs) is assessed to be adequate and resuscitation has been initiated.

SPECIFIC INJURIES OF IMPORTANCE

Having discussed the initial assessment of the injured patient, emphasis is placed on specific injuries of importance. These injuries are critical in that they are identified during the primary survey, represent impending demise, and require an immediate response.

Traumatic Arrests   In most emergency medical systems, paramedics transport patients without vital signs to a hospital while cardiopulmonary resuscitation (CPR) is initiated (unless obvious signs of death are present). On arrival to the Emergency Department (ED), a critical decision must be made regarding the level of intervention. A recently published large series analyzing 862 patients undergoing ED thoracotomy at a regional trauma center yields interesting information.[12] There were 385 patients (45 percent) with blunt trauma, 147 (17 percent) with stab wounds, and 330 (38 percent) with gunshot wounds. The overall number of neurologically intact survivors was 34 (3.9 percent), and the series was large enough and sufficiently equally divided among mechanisms of injury to permit subgroup analysis. There were 259 patients with blunt trauma and no vital signs in the field. There were no survivors in this group. This is a consistent finding among other series, and clearly ED thoracotomy for this group of patients should be abandoned. The greatest proportion of neurologically intact survivors was among patients with stab

wounds to the chest (20 of 109, 18 percent). Their survival rate improved to 23 percent among thoracic stab wound victims with vital signs in the field and to 38 percent among those who were moribund but had some vital signs on arrival to the ED. Therefore, the strongest recommendation for ED thoracotomy can be made for victims with penetrating chest trauma with witnessed signs of life in transport or the ED and at least cardiac electrical activity on arrival. [12,13,14 and 15] More liberal indications (although not with total consensus) would include victims with abdominal trauma with cardiac electrical activity, in whom thoracotomy is performed for resuscitation and aortic cross-clamping before operating room laparotomy rather than for hemorrhage control, and patients with blunt torso trauma who have some vital signs on arrival.

Severe Head Trauma   Head trauma with coma (GCS 3 to 8) suggests that rapid assessment of the intracranial injury must be undertaken and the patient should be intubated for airway protection and to avoid secondary brain injury associated with hypoxemia. These patients present a dilemma, because ultimately they may be found to have anything ranging from a normal head CT scan to a devastating, nonsurvivable brain injury. The challenge is to quickly identify patients with intracranial injuries that may benefit from neurosurgical evacuation. In such cases, minutes may make a difference in the ultimate patient outcome. Accordingly, all nonessential procedures should be prioritized to a time after the head CT is performed. The patient is intubated with in-line neck immobilization, and the C-spine collar is reapplied. A rapid chest x-ray may be justifiable to rule out pneumothorax and to assess endotracheal tube placement, particularly if the film can be developed as the patient is being transported to the CT scan suite. This implies that in the well-run trauma center the critically multisystem-injured patient has ongoing diagnostic workup and therapeutic resuscitation occurring in a smooth transition between ED, x-ray suite, operating room, and postoperative intensive care setting.

Tension Pneumothorax, Open Pneumothorax, and Massive Hemothorax   These are all diagnoses that should be made during the primary survey requiring rapid placement of a chest tube. Absent breath sounds on the side of a gunshot wound, stab wound, or chest wall ecchymosis (associated with tympany in the case of pneumothorax and percussion dullness in the case of hemothorax) in a patient with respiratory distress and tachycardia suggest the diagnosis.

Abdominal Gunshot Wounds with Hypotension   This deserves special mention. Palpation tenderness elicited on ED admission identifies the need for surgery and should prompt *immediate transport to the operating room* without further workup. Placement of nasogastric, urinary, and intravenous catheters should proceed in the operating room as the patient is being prepared for general anesthesia. The importance of time is emphasized because of the large amount of hemorrhage necessary (>2 L in the 70-kg patient) to produce severe hypotension in a young, previously healthy patient. A false sense of security with these patients brought on by the absence of hypotension is hazardous. [16]

SECONDARY SURVEY

While resuscitation continues, a secondary survey should be undertaken. The secondary survey is a rapid but thorough physical examination for the purpose of identifying as many injuries as possible. With this information, the resuscitating physician and his or her surgical colleague can set logical priorities for evaluation and management. Frequent assessments of the patient's blood pressure, pulse rate, and central venous pressure should continue.

The examination is conducted in a head-to-toe fashion, beginning with the scalp. Scalp lacerations can bleed profusely. This bleeding can be controlled with plastic Raney clips that grasp the full thickness of the scalp and galea. The tympanic membranes should be visualized to detect hemotympanum, and the pupil examination should be repeated. if epistaxis is a problem, a Foley catheter or a nasal balloon should be inserted to provide posterior tamponade. The examination continues over the neck and thorax. A lateral cervical spine x-ray (if not already obtained), a chest x-ray, and an anteroposterior pelvic x-ray should be obtained while the secondary survey continues. A 32-Fr gastric tube should be inserted into the stomach and connected to suction. When there is facial trauma or basilar skull fracture, the gastric tube should be inserted through the mouth rather than the nose. The urinary meatus, scrotum, and perineum are inspected for the presence of blood, hematoma, or laceration.

A rectal examination is done, noting sphincter function and whether the prostate is boggy or displaced. Rectal blood should be noted. If the prostate is normal and there is no blood at the urethral meatus, a Foley catheter can be placed in the bladder. If a urethral injury is suspected (meatal blood present), a urethrogram should be obtained prior to passing the catheter. If the prostate is displaced, it should be assumed that the urethra is disrupted. Catheterization should not be attempted if the urethra is injured. The urine should be examined for blood. If the patient is a woman of childbearing age, a pregnancy test should be obtained. A bimanual vaginal examination should be performed. If blood is present, a speculum examination will be necessary to identify a possible vaginal laceration in the presence of a pelvic fracture. Palpate all peripheral pulses. The patient should be logrolled to either side while keeping the neck immobilized so that every inch of the patient's body is seen and felt. The extremities should be evaluated for fracture and soft tissue injury. Peripheral pulses should be felt. A more thorough neurologic examination can now be done, carefully checking motor and sensory function.

Radiographic Imaging

In patients who are not rapidly transported to the operating suite or the CT scanner after the initial assessment, standard radiographic imaging includes   *lateral C-spine, chest, and pelvic radiographs.* The chest x-ray and pelvic films image the three regions (left hemithorax, right hemithorax, and extraperitoneal pelvis) outside the true peritoneal cavity that can accommodate volumes of hemorrhage sufficient to produce gross hypotension. X-rays in penetrating trauma are dictated by bullet entry site and include a chest x-ray for patients with torso penetrating trauma and appropriate extremity films to rule out fractures in patients with penetrating extremity injuries.

Echocardiography has become a useful diagnostic tool for emergency medicine physicians and trauma surgeons. [17] A focused abdominal sonographic examination for trauma (FAST) is a rapid diagnostic tool performed with a 3.5-MHz probe that assesses for fluid in (1) the pericardium, (2) the hepatorenal recess of Morrison (a common location for blood in patients with hemoperitoneum), (3) the pelvis around the bladder, and (4) the perisplenic region. Abdominal sonography in the trauma patient is rapidly supplanting *diagnostic peritoneal lavage* as the procedure of choice to detect hemoperitoneum in the unstable trauma patient for whom transport to the CT suite is unsafe.

DISPOSITION

Options include moving the patient to the operating room, admission to the hospital, or transfer to another facility. The primary and secondary survey must have been completed, and a gastric tube and a Foley catheter should be in place unless a urethral injury was detected. In most urban hospitals, the trauma surgeon should have been present for the secondary survey, and he or she should assume direction of the diagnostic workup and disposition of the case at that time. In rural hospitals that transfer severe trauma cases, the resuscitating physician should relate all the physical findings discovered during the primary and secondary surveys to the physician receiving the patient. Laboratory results, x-rays, and the flow sheet showing blood pressure, pulse, fluids infused, urine output, gastric output, and neurologic findings should accompany the patient. If a diagnostic peritoneal lavage was performed, a sample of the lavage fluid should accompany the patient. A patient who is being transported to another facility should be accompanied by personnel capable of administering fluids and monitoring vital signs and pupillary changes. Mannitol should be available if there is neurologic deterioration enroute.

The hallmark of trauma care in patients without obvious indications for surgery identified on the initial assessment is   *serial examination.* An *observation area* is extremely useful for these patients. Such an area (typically with nursing care provisions analogous to those of an intermediate care unit in most hospitals) allows for serial observations of patients with (1) closed head trauma who have regained consciousness but require repeat neurologic examinations, (2) penetrating abdominal wounds (stab wounds or tangential gunshot wounds) who require repeat abdominal examinations, (3) patients receiving repeat chest x-rays for penetrating chest trauma without pneumothoraces, (4) blunt abdominal trauma with normal physical examination on initial evaluation, and (5) documented blunt injuries to the liver, spleen, or kidney who are clinically stable and are being managed nonoperatively. An observation area for these patients should allow for more rapid triage from the ED and for serial evaluations of multiple patients in a convenient setting and should provide for rapid transport to the operating room in patients whose clinical examination deteriorates.

244 PEDIATRIC TRAUMA

William E. Hauda II

Trauma is the leading cause of death and disability in children over 1 year of age. The most common reason for injury is a motor vehicle crash. Because children have different anatomy and physiology, the management of injuries in children differs is some respects compared with adults. Knowledge of these differences is crucial for emergency physicians to provide expedient and effective care to injured children. Many injuries can be initially managed in a general hospital emergency department (ED), but care of the most seriously injured children requires prompt triage and transportation to a designated pediatric trauma center.

EPIDEMIOLOGY

Trauma is responsible for over 600,000 pediatric hospitalizations each year in the United States, [1] and is the second leading cause of ED visits after infections. [2] Head injury is the most frequent cause of death. [3] Motor vehicle injuries are the leading cause of death among children over the age of 1 year, accounting for 18 percent of all deaths and 37 percent of all deaths due to trauma. [4] Motor vehicle crashes are also the most frequent cause of injury. [1,3] Alcohol use by a driver is a factor in almost 25 percent of these crashes. [5] Under the age of 1 year, suffocation is the most common cause of death due to injury. [4] The other leading causes of death are drowning, fire/burn, and firearms. Death rates for boys over the age of 5 is twice the rate for girls. [4] Children who are economically disadvantaged are 2.6 times more likely to die from trauma.

Homicide accounts for about 25 percent of pediatric deaths. Infants are 10 times more likely to die from homicide than are children 5 to 9 years of age. [4] Rates of death from injury among children have declined over the past 10 years in the United States in all categories except for firearms, suffocation, and poisoning.

TRAUMA RESUSCITATION PRIORITIES

The priorities in managing children with traumatic injuries do not differ greatly from that of injured adults (see Chap. 243). However, as with nontraumatic resuscitation, emphasis is placed upon airway management and the recognition and treatment of shock. Injuries and conditions that require immediate lifesaving intervention are treated during the primary survey (Table 244-1). All other conditions are identified and managed during the secondary survey.

TABLE 244-1 Primary Survey Goals

A team approach will help to minimize confusion during the initial resuscitation. Tasks for individual members of the team include airway management, cervical spine stabilization, intravascular line placement, assessment of the child by system, and preparation and administration of mediations and fluids. A team leader not directly involved in patient care can facilitate the overall management of the patient because that person is not dedicated to a particular task.

Airway

The most important step in trauma care for children is airway intervention. Many preventable traumatic deaths among children are due to loss of an adequate airway or due to hypoxia. Proficient training in airway skills and aggressive airway management leads to a reduction in the number of pediatric deaths. Often, only airway opening and support are needed to prevent death. However, because pediatric trauma patients infrequently require intubation, many health care providers have inexperience with more advanced methods. [6] Proficient management of a child's airway requires an understanding of the anatomy of children (see Chap. 11, "Pediatric Airway Management").

OXYGEN   High-flow oxygen should be applied to all trauma patients. Patients who are not hypoxemic initially may become so as their condition changes if they are not given supplemental oxygen. A non-rebreathing mask is the usual method of delivery, but blow-by oxygen is acceptable in a child who fights having the face mask. Continuous-pulse oximetry should be monitored.

BASIC AIRWAY MANEUVERS   Basic airway techniques are covered in detail in Chap. 11, "Pediatric Airway Management." In the trauma patient, care must also be taken to avoid injuries to the head or neck while managing the child's airway. The cervical spine should be protected by stabilization, not traction, with one provider dedicated to this task. The airway should be opened by using the jaw-thrust technique. This technique minimizes movement of the cervical spine, yet still easily opens the airway. Prolonged maintenance of the jaw-thrust can be tiring. Thus, in an unconscious child, placement of an oral airway can be considered, whereas, if the child is conscious or has an intact gag reflex, a nasopharyngeal airway should be used instead. Constant reassessment of the airway status is necessary, as airway

adjuncts can become occluded by blood, vomit, or tissue swelling.

ENDOTRACHEAL INTUBATION   If the airway cannot be maintained by basic maneuvers, the child requires hyperventilation, or access is needed for medication administration, then the child should be intubated by the oral route. The most experienced airway provider should perform the intubation. A trauma patient who is a child requires several considerations beyond the normal concerns. First, cervical spine stabilization must be maintained throughout the procedure. Excessive cervical spine movement can occur during endotracheal intubation. Thus, at least two persons will be needed to perform the intubation: one for cervical spine stabilization and one to intubate. Secondly, selection of the induction agents requires consideration of the patient's hemodynamic state, risks, and likelihood of cerebral injury. For example, the use of ketamine must be avoided in head-injured patients. The propensity for thiopental to cause hypotension minimizes its utility in trauma patients. Frequently used agents include fentanyl and etomidate. The choice of a paralytic agent is less dependent on a child's condition. Succinylcholine or vecuronium are commonly used. Third, some patients will require pretreatment with pharmacologic agents prior to intubation. Lidocaine should be considered in head-injured patients, although the importance of using it has not been firmly established. Atropine should be given to all patients younger than age 6, especially if succinylcholine will be used as the paralyzing agent.[7] These issues are covered in detail in Chap. 10, "Pediatric Cardiopulmonary Resuscitation" and in Chap. 11, "Pediatric Airway Management."

SURGICAL AIRWAY   Rarely will the emergency physician or emergency medical service provider need to perform a surgical airway on a child. However, the difficulty with performing this technique has perpetuated the need for preparation and training. Because of the relative small size of a child's airway, needle cricothyroidotomy is the preferred first attempt at securing a surgical airway. A 14- to 16-gauge catheter is placed through the cricothyroid membrane and is attached to a jet insufflator. A bag-valve mask can be used for a short time, but high pressures are needed to ventilate through the small catheter. Although ventilation will be limited, oxygenation is achievable for up to 2 h, or until a more definitive airway can be established by additional oral attempts or more advanced techniques.[8] (See Chap. 11, "Pediatric Airway Management.")

Cervical Spine

The cervical spine must be immobilized in any patient with a suspected spinal injury until cervical spine injury can be excluded. Immobilization is performed at the same time that airway management is started. Cervical spine immobilization can be provided by the same individual that maintains the jaw thrust. Whenever possible, a hard cervical collar should be used. However, due to the limited number of sizes available, a properly fitting collar may not be possible. Omitting the application of a cervical collar is acceptable in children for whom no properly fitting rigid collar is available. The child should be placed on a spinal board or in a pediatric immobilizer designed for trauma immobilization. The head should be secured to the board by using towel rolls or commercially available head blocks and tape applied across the forehead and under the chin of the collar. If a collar is not used, tape should not be applied under the chin, because this may prevent the mouth from opening. The child's body is secured to the board by straps or wide cloth tape. Blanket rolls should be placed on either side of the child to prevent lateral movement of the child if logrolling becomes necessary to clear the airway. Clearance of the child's cervical spine by clinical or radiographic methods should wait until the primary survey is completed.

Breathing

All trauma patients should receive supplemental oxygen. Assessment of breathing entails identifying inadequate oxygenation or ventilation or the potential for deterioration. Children with respiratory failure should have positive pressure ventilation (PPV) started immediately. PPV may render an innocuous pneumothorax into a compromising injury, and such a possibility should be actively monitored. If the presence of a small pneumothorax is already known, a tube thoracostomy may be appropriate early in the resuscitation efforts. Children with respiratory distress may not have a striking presentation, but still require immediate attention to minimize complications. Cyanosis, poor end-organ function, and desaturation on pulse oximetry will identify a child with severe hypoxemia. A child with mild hypoxemia may manifest more subtle signs, such as agitation and poor capillary refill. Signs of inadequate ventilation in the young child include tachypnea, nasal flaring, grunting, retractions, and stridor or wheezing. Often, signs of inadequate oxygenation and ventilation will coexist in children. Auscultation of the chest can identify a large pneumothorax or hemothorax. Because breath sounds are easily transmitted across a small chest, breath sounds should be sought in both axilla. If signs of inadequate oxygenation do not improve rapidly with high-flow oxygen administration, then PPV must be started.

TENSION PNEUMOTHORAX   The classic presentation of a tension pneumothorax is absent breath sounds, tympany, hypotension, and jugular venous distention due to high intrathoracic pressures. Children rarely have this complete presentation. If suspected during the primary survey, a catheter decompression should be performed, followed by tube thoracostomy.

MASSIVE HEMOTHORAX   The classic presentation of a massive hemothorax is absent breath sounds, dullness to percussion on the affected side of the chest, and hypotension. Jugular venous distention is unlikely because the circulatory volume is low. Tube thoracostomy is needed for effective management. Operative thoracotomy should be considered if the initial drainage is greater than 15 mL/kg or the chest tube output exceeds 4 mL/kg/h.

OPEN PNEUMOTHORAX   The skin wound of an open pneumothorax should be occluded on three sides with a dressing of petrolatum gauze or a plastic sheet. An open pneumothorax may be associated with a tension pneumothorax. An occlusive dressing is applied and air can no longer escape through the wound; leaving one side of the dressing open to act as a flutter valve will minimize the development of a tension pneumothorax. A tube thoracostomy need only be performed after completing the primary survey.

Circulation

Hypovolemic shock is the most common form of shock in children. Recognizing the subtle early signs of shock can be daunting even for experienced emergency physicians. Children can maintain an adequate blood pressure, even in the face of severe blood loss, but other signs of shock will be apparent. Monitoring blood pressure alone to diagnose shock is unreliable in pediatric patients. Signs of shock include tachycardia, cool extremities, capillary refill time longer than 3 s, altered level of consciousness, weak distal pulses, and low urine output. Hypothermia can be a confounding factor, because it also can affect skin perfusion.

The treatment of shock in trauma is based on the same principles as other forms of hypovolemic shock. Crystalloid fluid boluses of 20 mg/kg given over 20 min or less are used to resuscitate the child. If two boluses of crystalloid fail to correct signs of shock, then blood (packed red blood cells) should be given using 10 mL/kg boluses. In small children, the blood bank should hold several aliquots from a single donor unit to minimize the risk of a transfusion reaction.

CARDIAC ARREST   Absent pulses in a child with traumatic injuries portends a poor outcome. In children with penetrating chest or abdominal trauma, a resuscitative thoracotomy can be lifesaving if vital signs were recently lost. In children with traumatic arrest from blunt trauma, the outcome is always death.[9] Standard advanced cardiac life-support algorithms are followed, but most commonly injured children will have asystole or pulseless electrical activity. Early administration of blood products should be used and any identified injuries treated.

CARDIAC TAMPONADE   This condition is rare in children. Most commonly it results from penetrating trauma. Beck's triad consists of hypotension, muffled heart sounds, and jugular venous distention. Diagnosis can be confirmed by echocardiography prior to treatment. Initial fluid boluses may be temporizing, but pericardiocentesis and resuscitative thoracotomy can be lifesaving.

VASCULAR ACCESS   Achieving vascular access is one of the most difficult tasks in an injured child. In an adult patient, "two large bore" intravenous lines are placed; in a child, placing a single functioning intravenous line is often considered a success. Ideally two lines are placed so that blood and medications or fluids can be given simultaneously. Practically, a functioning intravenous line is all that may be readily achieved, and is usually adequate. Consideration should be given to early intraosseous line placement in a severely injured child, because any fluids, medications, or blood products can be given through this line. The femoral vein is the next easiest site because of the identifiable landmarks and the relative ease of the procedure compared with other central venous lines in children (see Chap. 17, "Vascular Access").

Disability

The next goals in the primary survey are to identify neurologic abnormalities in the child. Level of consciousness is assessed by either the Glasgow Coma Score (GCS) or the AVPU system wherein the child's consciousness is rated as (presesnt or absent): *A*lert, responds to *V*erbal stimuli, responds to *P*ainful stimuli, or *U*nresponsive. The GCS is commonly used in trauma databases, and lower scores have been associated with increased mortality rate. An arbitrary cutoff of 8 is often quoted as the score that should prompt endotracheal intubation in trauma patients. This point has been chosen because mortality rate is greatly increased with GCSs

below this level. The AVPU system is recommended by the American Heart Association as an easier system to use.[7]

A pupillary exam is used to recognize early signs of increased intracranial pressure and herniation. Several case reports can be found of children with a high level of consciousness who had a dilated pupil and then rapidly developed a herniation syndrome.

Examination of the motor strength of each limb concludes the disability exam. Gross strength is all that is noted during the primary survey, so that paralysis from a spinal cord or central neurologic event is recognized. If a spinal cord injury is strongly suspected, then IV steroids are started immediately [10] (see discussion below).

Exposure

The final part of the primary survey serves to identify any important wounds and to detect or prevent hypothermia. Actively bleeding wounds or penetrating wounds will direct the priority of actions taken during the resuscitation and secondary survey. Bleeding is controlled by direct pressure, using air splints on the extremities if needed. A rectal temperature should be obtained for all pediatric trauma patients, but especially if the temperature outside is cool. Children become hypothermic much easier than adults due to their high body surface area. Hypothermia can develop in the emergency department despite a seemingly comfortable ambient temperature. Whenever possible, keep the child covered. Warm fluids to 40°C if large amounts of IV fluids or blood products are used.

Prehospital Considerations

Standards of care in the prehospital environment have been slow in developing. Many pediatric patients are being treated in systems which lack the experience and standards of care that are needed to manage children appropriately. IV access is the prehospital advanced life-support intervention that is most often performed, [6] although the beneficial effects may be rare.[11] IV success rates are as high as 93 percent.[6] Airway management, however, is often more difficult, with many studies showing success rates from 57 to 79 percent, far lower than the success rates with adult patients. Minimizing scene times is an important issue in pediatric trauma management. Placing IV lines en route to the hospital unless a prolonged extrication is required can shorten field times. [6]

POSTRESUSCITATION PRIORITIES

Secondary Survey

The goal of the secondary survey is to identify all other injuries to a trauma patient. It does not begin until the completion of the primary survey. All body areas are completely examined. Resuscitation priorities are established, and any life-threatening injuries should already have been managed. Any needed x-rays, laboratory studies, or diagnostic procedures in the ED are also performed during this phase.

The presence of family will often be helpful to calm and console frightened and injured children. Additionally, during this phase a complete history should be obtained using the AMPLE format (*A*llergies, *M*edications, *P*ast medical history, time of *L*ast meal, *E*vents leading up to the injury).

Stabilization

In this phase, all of the child's injuries are managed definitively, or the child is stabilized sufficiently to allow safe transfer to a facility that can provide a higher level of care. Continual reassessment is crucial, because some injuries may be only manifest over time and complications from therapeutic interventions can occur. Emphasis is placed on monitoring the airway and circulatory status of pediatric trauma patients. Endotracheal tube dislodgment, development of a pneumothorax, regurgitation of stomach contents, occult hemorrhage causing shock, and worsening neurologic function are all frequently seen in injured children. Careful monitoring of fluid administration will prevent inadvertent overhydration. Analgesia and sedation should be used judiciously; often these elements are neglected in injured pediatric patients.

Referral to Pediatric Center

Pediatric trauma centers are designed to provide optimal care to pediatric trauma patients by having all pediatric specialties immediately available to the children. This is a capability-oriented approach. Designation of the trauma center is done by the state government, and the requirements vary from state to state. Several capabilities would be ideal for the pediatric trauma center. [12] The hospital should have a dedicated pediatric trauma service directed by a pediatric trauma surgeon. Comprehensive pediatric services should be available from scene care to rehabilitation and reintegration into the family and society. The trauma team should be immediately available at all times and be capable of treating at least two patients simultaneously. Other pediatric specialists should be on site or immediately available including emergency medicine, anesthesiology, neurosurgery, radiology, orthopedics, pediatric intensive care, and nursing. A pediatric intensive care unit is essential.

Use of trauma triage scores can help identify a child who needs a more experienced team for care. However, not all systems are easy to use. Two common scores used are the pediatric trauma score (PTS) and revised trauma score (RTS) (Table 244-2). Advantages of these scores over other systems are that they include physiologic variables instead of relying only on anatomic variables. Higher numbers are associated with a higher likelihood of survival and, thus, a reduced need for trauma center care. A child with an RTS of less than 12 or a PTS of less than 8 should be taken to a trauma center.

	−1	+1	+2
Size (kg)	<10	10–20	>20
Airway	Unmaintained	Maintained	Normal
Systolic blood pressure (mmHg)	<50	50–90	>90
Level of consciousness	Comatose	Altered	Awake
Wounds	Major open	Minor open	None
Skeletal trauma	Open/multiple	Closed	None

A

Number	Glasgow Coma Score	Systolic Blood Pressure	Respiratory Rate
4	13–15	>89	10–29
3	9–12	76–89	>29
2	6–8	50–75	6–9
1	4–5	1–49	1–5
0	3	0	0

TABLE 244-2   A. Pediatric Trauma Score B. Revised Trauma Score

Some indications for transfer to a pediatric trauma center are listed in Table 244-3.

Mechanism of injury	Ejected from motor vehicle
	Fall greater than 3 times child's height
	Prolonged extrication
	Death of another occupant in motor vehicle
Anatomic injury	Multiple severe trauma
	More than three long bone fractures
	Spinal fractures or spinal cord injury
	Amputations
	Severe head or facial trauma
	Penetrating head, chest, or abdominal trauma

TABLE 244-3 Indications for Transfer to a Pediatric Trauma Center

The need to transfer a patient to a pediatric trauma center should be based on the need for treatment that the initial hospital cannot provide. Ideally, a seriously injured child would receive care from a pediatric trauma specialist. However, this is impractical and not always achievable. Additionally, adolescents (age 12 and over), whose anatomic and physiologic characteristics are essentially those of adults, account for up to 50 percent of injured children. Younger children may do better with pediatric traumatologists. Children are more likely to have successful nonoperative management of blunt trauma injuries at a designated pediatric trauma center.[13] At least one study has shown that pediatric patients can be appropriately managed in "adult" trauma centers, but the data may be biased by not including children referred to a pediatric trauma center from the prehospital environment. There are no studies to date that have shown that children receive better care in an "adult" trauma center as compared with a designated pediatric trauma center.

Transportation

Because only 8 percent of hospitals have a pediatric intensive care unit, most critically injured children will need transportation to another facility. The first step is to assure that all identified injuries are treated to the best ability of the referring hospital and that the child is maximally stabilized. Few areas possess a dedicated pediatric critical care transport team to manage the patient during the transportation. The next best option is to have a critical care transport team with some pediatric experience (pediatric nurse or pediatrician) traveling with the child. Indications for pediatric critical care experience on the transport team are endotracheal intubation, potential airway compromise, spinal injury, hemodynamic instability, pressor infusions, skull fractures, pelvic fractures, or a child currently receiving blood products. Standard advanced life-support crews can be used for children without airway problems or hemodynamic instability. Increasingly, pediatric trauma centers have their own home-based interhospital transport systems and will arrange transportation from referring sites.

MANAGEMENT OF INJURIES

Head Trauma

Cerebral trauma is the leading cause of death due to injury in children.[14] Most of these deaths occur outside of the hospital. The most common mechanisms of injury differ by age. Falls are most frequent in children less than 2 years of age. Preschoolers also are most frequently injured in falls, but motor vehicle crashes account for 25 percent. In school-age children, falls and motor vehicle crashes occur with equal frequency. Lastly, in adolescents, sports injuries and motor vehicle crashes are about equal.

Children frequently have head injuries because of several factors. A child's head encompasses a relatively larger proportion of body mass and area. The bones of the neck are not fully developed, so the head is attached on a largely ligamentous connection. The incompletely myelinated brain is more susceptible to shear forces during trauma. Because of cartilage in the skull and the presence of open sutures, young children are better able to tolerate increased intracranial pressure than are adolescents and adults.

CLINICAL FINDINGS   Most children will have suffered a mild head injury and present with no or few symptoms in the ED. Common symptoms associated with head injury include vomiting, headache, and lethargy.[15] For children with more significant cerebral injuries, the signs and symptoms are not markedly different from those for adults. The most difficult aspect of evaluation is often the neurologic exam. It is difficult to ascertain inappropriate behavior or mental status particularly in the very young. Level of consciousness can be rated by the AVPU system or the GCS. A pupillary exam can identify impending herniation even in a child without distress. Asymmetry of spontaneous movements is, of course, a telling clue. Older children can then be asked to move their fingers and toes. Sensory function should be assessed by withdrawal from pain or the ability to feel touch in older children. In young children, look for signs of fontanelle fullness (increased intracranial pressure ICP) or retinal hemorrhages (shaken baby syndrome).

INCREASED INTRACRANIAL PRESSURE   Signs of increased ICP in children are most commonly vomiting, dizziness, headache, irritability, and decreased level of consciousness. Management is not remarkably different from adult management (see Chap. 11). Aggressive hyperventilation in children has been associated with worsened cerebral ischemia as compared with more moderate hyperventilation in head-injured children.[16] Children with suspected increased ICP should be mildly hyperventilated (P_{CO_2} 30 to 34 mmHg) and should have their hemodynamic status maximized with judicious use of fluids and blood. Fluid restriction should not be an acute consideration. The head of the bed should be elevated to 20° to 30°, and the neck should be straight, to optimize venous drainage. IV mannitol in a dose of 0.5 to 1.0 g/kg can be used to lower ICP. Although mannitol may acutely lower ICP by removal of free water and decreased blood viscosity, frequent administration will lead to increased serum osmolality. Further, it is felt that, initially following administration, ICP may in fact be transiently increased due to an initial increase in intravascular volume. Although concern has frequently been expressed, neither phenomenon has been shown to be detrimental clinically. Local preferences will dictate practice. Lasix (furosemide) (1.0 mg/kg) may decrease edema, as well. Currently, no studies have shown steroids to be helpful. Aggressive hyperventilation should be reserved for children with signs of impending herniation.

POSTTRAUMATIC SEIZURES   Seizures following traumatic head injury are relatively uncommon, occurring in about 5 percent of hospitalized patients. [17] About half of these patients will never have a seizure again. Of the remaining half, 50 percent have rare seizures and 50 percent have frequent seizures. Children with loss of consciousness, lower GCS, longer duration of coma, and computed tomography (CT) scan abnormalities are at increased risk for seizures. Intracranial injuries most commonly seen are subdural hemorrhages, depressed skull fractures, and intracranial lacerations. [17] Only 50 percent of children with posttraumatic seizures will have abnormalities on CT scanning.[17] Use of anticonvulsant medication as prophylaxis in the absence of a seizure or following a single seizure is controversial. Children with two or more seizures, or seizures lasting more than a few minutes, should receive anticonvulsant therapy. Prophylactic anticonvulsant therapy should be strongly considered in a child with a GCS under 8, even if no seizures have yet occurred, because the risk of developing acute posttraumatic seizures is high and many of these children already have high ICPs that will increase further with a seizure. [17]

Although phenytoin has been the standard anticonvulsant studied, the improved safety profile of fosphenytoin will likely cause its replacement. Dosage is the same (17 mg/kg IV load) except that fosphenytoin is measured in phenytoin equivalents. Acute seizures should be managed with a benzodiazepine such as lorazepam, midazolam, or diazepam.

As with adults, proximity of seizure to the event predicts long-term likelihood of epilepsy. Immediate seizures are least likely to result in long-term problems. [17]

RADIOGRAPHY   Since the primary goal of the evaluation is to identify increased ICP and to identify injuries that require surgical intervention, plain films are rarely appropriate. In suspected child abuse, skull films are essential to document current or past skull fractures. A child who will undergo a CT examination does not need plain films unless a skull fracture is strongly suspected (subgaleal hematoma may be a clue) and the CT does not show a fracture. A CT scan is indicated in children who fall into a moderate- or high-risk category (Table 244-4).[18] Children in the low-risk category generally do not need a CT scan unless other circumstances, such as lack of follow-up, dictate a need for a study.

Low Risk	Moderate Risk	High Risk
No symptoms	Persistent vomiting	Penetrating injury
Dizziness	Altered level of consciousness after injury or at baseline	Depressed level of consciousness
Headache	Loss of consciousness >3 min	Focal neurologic findings
Vomited 1–2 times	Posttraumatic seizure	Signs of herniation
Loss of consciousness <5 min	Alcohol/drug intoxication	
Minor soft tissue injury	Age <2 years and symptoms	
	Multiple trauma	
	Serious facial injury	
	Suspected abuse	
	Basilar or other skull fracture	
	Vomiting >8 h from injury	

Source: Adapted from Masters et al,[8] with permission.

TABLE 244-4 Risk Groups for Head Computed Tomographic Evaluation

Obtaining a CT scan in a young child will often require sedation and the inherent risks associated with it. Midazolam (0.1 mg/kg IV) is commonly used. Obviously, preparations must be made for the unexpected deterioration of a child's condition after sedatives are used.

MANAGEMENT   Children in the low-risk category can be safely discharged home to follow up with the primary care provider by phone or in person. Discharge instructions should clearly state the need to return to the ED if any symptoms in the moderate-risk category occur. Children who have an intracranial injury or skull fracture should have an immediate neurosurgical consultation in the ED or shortly after being admitted. These patients must be managed in a pediatric intensive care unit.

SPECIFIC INJURIES   **Scalp Injuries**   Because the scalp is richly vascularized, some children have developed shock due to significant blood loss, violating the dogma that "head injuries do not cause shock." The area under a laceration should be palpated to determine if a skull fracture is present.

Concussion   By definition, these are transient injuries with no demonstrable cerebral injury on CT scan. Other symptoms often coexist in children, such as dizziness, vomiting, and headache. Amnesia is frequent and may be antegrade or retrograde in relation to the event. No specific management is needed except analgesia and observation, often in the home setting if the parent is responsible. Most children will have no long-lasting effects from a concussion, but long-term cognitive and behavioral changes have been described after even apparently trivial trauma.

Contusion   A contusion is a focal area of bruising or tearing of brain tissue. These are the most common injuries seen on CT scans of children following head injury. Management includes hospital observation and neurosurgical evaluation. Some patients will worsen and require supportive care for cerebral edema, but these children rarely require operative intervention. Most children with such injuries do well.

Epidural Hemorrhage   These uncommon injuries are greatly feared because they can occur after seemingly minor trauma.[15] Falls from heights less than 5 ft (<2 m) are associated with epidural bleeds in children under 5 years of age.[15] Usually these injuries are due to a fall, with a direct blow to the side of the head. The classic description of a brief loss of consciousness followed by a lucid interval, with subsequent clinical deterioration is relatively uncommon, occurring in only about 25 percent of patients with epidural hemorrhage.[15] Patients will often have vomiting or a headache. As consciousness becomes altered, the ipsilateral pupil may dilate. Hemiparesis and seizures are late signs. Surgical drainage is often required, although some small epidural hemorrhages can be observed in the intensive care unit setting. Prognosis is excellent for a child whose results on neurologic examination are normal at the time of diagnosis, suggesting that early identification of epidural bleeds may improve outcome.[15]

Subdural Hemorrhage   Often these injuries are caused by shearing of the bridging venous vessels to the brain. Either direct trauma or indirect shaking has been known to cause these injuries. Patients will present with signs of increased ICP. Although the presentation of syncope with the so-called lucid interval has traditionally been associated with epidural hematomas, the presentation is more likely to point to a subdural hematoma, not because of greater association, but because subdural hematomas are much more common. Subacute or chronic subdurals may require contrast-enhanced CT scanning to detect the isodense lesion. Hemorrhage size and altered mental status are the primary indicators for operative intervention.

Intraparenchymal Hemorrhage   These injuries are associated with substantial force, a penetrating injury, or a predisposing factor such as a vascular malformation. Signs of increased intracranial pressure will usually be present. Management is determined by the extent and location of hemorrhage.

Skull Fractures   Three basic types of skull fractures occur: linear, depressed, and basilar skull fractures.

LINEAR SKULL FRACTURES   These are the most common of all pediatric skull fractures and usually occur at the point of impact. Associated intracranial hemorrhage occurs in up to 50 percent of parietal fractures and 75 percent of occipital fractures. Subgaleal hemorrhages are also commonly seen. The presence of a skull fracture mandates a CT scan and inpatient observation. Children with isolated linear skull fractures can be observed on a pediatric ward, but prompt neurosurgical intervention must be available.

DEPRESSED SKULL FRACTURES   CT scanning occasionally misses these injuries, so plain skull films should be obtained in a child with a normal CT scan and a suspicion of a depressed fracture. Tangential views are often necessary. Neurosurgical management depends on the nature of the injury, but intensive care unit admission is required of all patients.

BASILAR SKULL FRACTURES   Unlike the other skull fractures, basilar skull fractures are best seen on a CT scan. Signs that suggest the presence of a basilar skull fracture include periorbital bruising (raccoon eyes), hemotympanum, mastoid bruising (Battle sign), and cerebrospinal fluid atorrhea or rhinorrhea. Management is usually symptomatic and requires neurosurgical expertise.

Spinal Trauma

Spinal trauma is relatively uncommon in young children but is more commonly seen in adolescents.[19] Cervical spine injuries predominate, although thoracic and lumbar injuries also occur (see lap-belt syndrome, below). Fractures or dislocations not related to birth trauma are very rare in children less than 16 months of age, having yet to be reported in the literature. Motor vehicle crashes are the most common reason for spinal injury, followed by falls and sports events. In young children, falls predominate and, in older children, motor vehicle crashes predominate. Due to increased flexibility of the spine and spinal column in younger children, fractures and dislocations rarely occur with minor trauma, and spinal cord injury without radiographic abnormality (SCIWORA) can occur. Adolescents more commonly have fracture patterns similar to those of adults. Also, 50 percent of spinal injuries and 67 percent of cervical spinal injuries in children under the age of 12 occur between the occiput and C2. By comparison, adolescents and adults more commonly experience lower cervical spine injuries.[19] Younger children also less frequently have thoracic or lumbar injuries. Signs and symptoms of spinal cord injury are nearly always evident in the pediatric population when present following injury. Part of the reason for this pattern of injury is that an immature child's spine and an adult's spine have several differences (Table 244-5).

Ligamentous laxity

Underdevelopment of supporting muscles

Partially ossified vertebrae

Wedge-shaped vertebrae

Horizontal facet joints

Higher fulcrum of flexion

Instability of atlanto-occipital joint

TABLE 244-5 Spinal Column Differences in Children

Children with incomplete spinal cord deficits have a better prognosis for improvement in neurologic condition than those children with complete spinal cord injuries. Spinal cord trauma is associated with a higher mortality rate in children than in adults.

CLINICAL FINDINGS   Presentation is related to the presence or absence of a spinal cord injury. Children with fractures only will have pain, tenderness, or overlaying soft tissue injury. Children with spinal cord injuries with or without fracture will present based on the type of spinal cord injury.

Over 50 percent of children with SCIWORA have a delayed onset of paralysis, sometimes up to 4 days. [20] Many of these children have transient paresthesias, numbness, or weakness at the time of or shortly after the injury. Because most spinal injuries fail to improve substantially, even in children, the most important factor in prognosis is the initial neurologic status. [20] Children with fractures and neurologic symptoms do worse than children with SCIWORA alone. [20]

RADIOGRAPHY   Cervical spine radiographs should be obtained on any patient with neurologic symptoms including coma, or if any symptoms are referable to the neck. Up to 66 percent of spinal cord injuries in children have no radiographic abnormality and thus fall into the category of SCIWORA. [20] Widening of the prevertebral soft tissues to 8 mm or more in front of C2 or more than 75 percent of the adjacent vertebral body width is considered abnormal. In infants, however, this becomes less reliable.

In alert unintoxicated adult blunt trauma patients without neck symptoms, cervical spine radiographs can be forgone and cervical spine immobilization can be released. Because children have a much lower frequency of cervical spine fractures, following this algorithm in children is appropriate. Any child with neurologic complaints, neck pain, limited neck movement, neck tenderness, or evidence of neck trauma, must have plain films consisting of at least three views: lateral, anteroposterior, and odontoid. The single lateral cervical spine radiograph has been shown to miss fractures and result in a delay in diagnosis. [21] If the child has neck pain but no neurologic symptoms, plain radiography is generally all that is required to clear the cervical spine. Occult fractures and misinterpretation of plain films do occur, so if there is any doubt, a CT scan should be obtained. If the child had paresthesias, numbness, or weakness or currently has neurologic symptoms, a CT scan is also recommended. [20] If all plain film radiographs are negative, but the diagnosis of SCIWORA is being entertained, then a flexion and extension lateral cervical spine x-ray must be obtained to identify any ligamentous instability. This is not detectable on CT scan. These films should be done under close supervision and only in an awake and cooperative patient. Fluoroscopy may be helpful, as well. Anytime the diagnosis of SCIWORA is considered, the child requires a neurosurgical consultation from the ED and admission for observation. [20]

MANAGEMENT   Treatment of spinal cord injuries in the prehospital and ED settings consists of immobilization, diagnosis of the specific injury, and steroid administration. Prehospital personnel must be instructed that an infant's relatively large head may cause the neck to flex in the standard supine position, so they require padding behind the shoulders to prevent this. Steroids should be started if there is evidence of a neurologic deficit with a loading dose of 30 mg/kg of methylprednisolone. [10] Steroids should be started within 8 h of the injury. Those who receive steroids within 3 h should be maintained on steroids for 24 h. Those who receive steroids 3 to 8 h after the injury require maintenance for 48 h. The maintenance dose is 5.4 mg/kg/h. The maintainance dose is initiated 45 min after the initial bolus. Children with a spinal cord injury require immediate neurosurgical consultation. If a spinal fracture is also present, a pediatric orthopedist should also be consulted.

Chest Trauma

Children, with their relatively compliant chest walls, may not show external evidence of serious intrathoracic trauma. Blunt trauma occurs more frequently than penetrating trauma and may be equally as serious. Isolated chest trauma in children carries a 4 to 12 percent mortality rate. Most children with chest trauma will have other significant injuries. In a multiply-injured child, death is 10 times more likely if chest trauma is present. [22] Penetrating chest injuries are becoming more frequent as the number of firearm injuries steadily increases in the United States. Children under the age of 12 are more likely to be injured in unintentional crossfire and require a longer hospitalization than do adolescents and adults.

Evaluation of a patient who has evidence of, or who has a good mechanism for, chest injury should include a thorough physical examination looking for bony defects, crepitus, paradoxical chest movement, and unequal breath sounds. A chest x-ray should be taken. To minimize interruption of the resuscitation, a supine chest x-ray can be initially obtained. A rib fracture is a sensitive indicator of serious underlying injury. [22] The most common injury is pulmonary contusion, but this may not be visible on the early ED chest x-ray. [22]

Most injuries requiring emergent treatment can be identified on the standard supine anteroposterior chest x-ray. Mediastinal widening is common on supine chest x-rays, but aortic injury is quite rare in children who survive to the ED. An upright chest x-ray, preferably using posteroanterior technique, will often obviate the need for additional studies. Aortography is still considered essential to exclude aortic injury, when suspected, although contrast-enhanced spiral CT scanning may also identify aortic injury. If an abdominal CT scan is obtained, additional occult chest injuries are often detected, but these rarely require emergent therapy.

Tube thoracostomy alone is usually sufficient management for pneumothorax or hemothorax, both of which are uncommonly associated with blunt trauma in children. Other specific injuries should be managed as outlined in the primary survey section. Emergent thoracotomy should be performed selectively as with adults. Survival from pulseless arrest at the scene or en route to the ED is rare in both blunt and penetrating trauma. [9] Only children who have sustained penetrating trauma and experience a loss of vital signs in the ED should have a resuscitative thoracotomy performed. In all other cases, the attempt is futile and the financial costs are high. [9]

Abdominal Trauma

DIAGNOSIS   The physical examination of a child's abdomen is frequently misleading in the detection of intraabdominal injury. Children with severe injuries can have minimal physical findings, while other children may have occult serious injuries. Physical exams have been shown to be unreliable in up to 45 percent. In most children with abdominal symptoms or a mechanism of injury to the abdomen, an investigative study should be obtained.

Diagnostic peritoneal lavage (DPL) has been shown to be quite accurate in the identification of serious intraabdominal injury in children. [23]

False-negative DPLs are unusual. False-positive rates are in the range of 4.5 to 14 percent. [23] DPL criteria considered indicative of the need for laparotomy in children are listed in Table 244-6. Elevated amylase levels are associated with pancreatic injury and bowel injury. [24] Because DPL is invasive and most children will not need an operation to manage their injuries (see below), abdominal CT scan is gaining popularity. A DPL is indicated, however, in children who have hemodynamic instability or other nonabdominal injuries that require immediate operative management. Some authors have also advocated use of DPL before CT scan in stable patients with an equivocal exam, because of its higher sensitivity; if the DPL is positive by red blood cell (RBC) criteria only, then a CT scan is performed to determine the need for laparotomy based on the extent of solid organ injury. [23]

Study	Greater Than or Equal to
Red blood cells	
Blunt	100,000 RBCs/μL or gross blood
Penetrating—stab	100,000 RBCs μL or gross blood
Penetrating—gunshot	5,000 RBCs/μL or gross blood
White blood cells	
Blunt	500 WBCs/mm³
Penetrating	500 WBCs/mm³
Gastric contents	Any
Amylase	20 IU/L
Alkaline phosphatase	6 IU/L

TABLE 244-6   Criteria for a Positive DPL

Abdominal CT scanning has been recommended for management of hemodynamically stable children with potential intraabdominal injury. Advantages of CT scanning include its noninvasiveness and the ability to visualize the retroperitoneum. Disadvantages of CT scanning include time spent in radiology away from the trauma room, lower accuracy for hollow organ and pancreatic injury, and radiation exposure. Indications for obtaining a CT scan in children include abdominal tenderness,

abdominal distention, abdominal bruising, hematuria, vomiting, neurologic obtundation, dropping or low hematocrit, and absent bowel sounds. [25] CT scan and operative findings correlate within splenic injury grade level in 86 percent of cases. [26] Normal CT findings in blunt trauma are strongly predictive of both no-future-deterioration and no-need-for-future operative intervention. [25] Normal CT findings virtually eliminate an intraabdominal injury; however, subtle signs such as unexplained peritoneal fluid, bowel wall enhancement, and bowel wall thickening are associated with bowel trauma. [25]

Ultrasound screening of the abdomen prior to CT has been shown to reduce the need for abdominal CT scans without missing significant injuries. [27] Currently, there is insufficient reported experience to recommend its routine use in the evaluation of pediatric trauma patients.

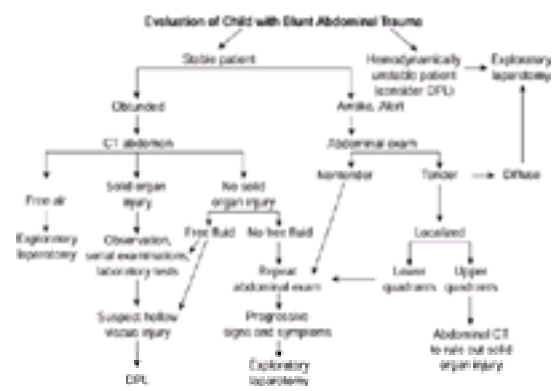
The general approach to evaluation of the abdomen in a child is outlined in Fig. 244-1.[28]


FIG. 244-1. Management algorithm for a child with suspected blunt abdominal injury. In an alert child, we heavily rely on the presence or absence of abdominal tenderness when making decisions for further evaluation. In a child with a closed head injury, an abdominal CT scan gives the most information but does not exclude hollow organ injury. *Abbreviations:* CT, computed tomography; DPL, diagnostic peritoneal lavage.

SPLENIC TRAUMA   The spleen is the most commonly injured abdominal organ in children. Children are more likely to be hemodynamically stable than adults even with the same degree of splenic injury.[26] Children with splenic injuries are more likely to be managed nonoperatively than adults. [26] Several reasons are thought to explain this difference. The spleen in children has a thicker capsule. There are larger amounts of elastin and smooth muscle in both the capsule and the splenic vessels. Children tend to have lower-velocity injuries and overall lower Injury Severity Scores. [26] Children who are more likely to require operative intervention include those with a higher Injury Severity Score, an injury sustained in a motor vehicle crash, or a greater amount of hemoperitoneum. Any child who requires a splenectomy should receive pneumococcal vaccine to prevent postsplenectomy sepsis.

HEPATIC TRAUMA   The liver is the second most commonly injured abdominal organ in children. Similar to splenic trauma, these injuries can often be managed conservatively. The rate of fatal hemorrhage is higher with hepatic injury than with splenic injury. Diagnosis is often made by abdominal CT scanning in stable trauma patients. Unstable patients often require operative intervention to control hemorrhage.

PANCREATIC TRAUMA   Although pancreatic trauma is uncommon in children, occurring in less than 10 percent of blunt trauma patients, trauma is the most common cause of acute pancreatitis. Handlebar injuries are the most common mechanism of injury and often cause isolated pancreatic trauma. [29] A high index of suspicion is required because symptoms are often delayed and morbidity is related to delay in diagnosis. Serum amylase levels are often elevated, but the degree of elevation does not correlate with the degree of pancreatic injury. [29] Serum lipase levels have not been studied in children. CT scanning has at best an 85 percent sensitivity to identify pancreatic injury in the acute setting. [25] Sensitivity is highest when both oral and IV contrast are used. Children with abdominal pain and an elevated serum amylase require an abdominal CT scan and should be hospitalized for observation even if the CT scan findings are normal. [29] Complications of pancreatic injury include pseudocyst formation, acute pancreatitis, and relapsing pancreatitis.

BOWEL TRAUMA   Intestinal injuries occur in less than 5 percent of children with blunt abdominal trauma. The jejunum is most frequently injured, followed by the ileum and cecum. The duodenum is particularly prone to the development of hematomas in the wall, leading to obstruction. The physical examination is often quoted as being unreliable in diagnosing bowel injury following blunt trauma. Children with abdominal wall injuries (bruising or abrasions), tenderness on palpation, or a mechanism of a direct blow to the abdomen require further investigation to rule out bowel injury. In hemodynamically stable patients, a contrast-enhanced CT scan can often increase the suspicion of a bowel injury. CT scans are diagnostic for bowel injury in only 25 percent of cases. Pneumoperitoneum or extravasation of enteral contrast is considered diagnostic of bowel injury and requires immediate laparotomy. Nondiagnostic findings include free peritoneal fluid without solid organ injury and bowel wall enhancement or thickening. A child with a tender abdomen and these nondiagnostic but suggestive radiographic findings requires an exploratory laparotomy or DPL to rule out an intestinal perforation. [26] Complications of bowel injury include peritonitis, obstruction, and intestinal strictures.

Bowel injury is associated with seat-belt use in less than 5 percent of children admitted to trauma centers. A particular entity, the lap-belt complex, consists of intestinal or mesenteric injury with a concomitant lumbar spine injury due to a lap belt. It has also been shown to occur with three-point restraints (lap belt/shoulder-harness restraints) when the lap belt is incorrectly positioned over the abdomen. The intraabdominal injury often occurs at the midlumbar level. Most commonly, the jejunum is injured. Any child with a lumbar fracture or an anterior abdominal bruise from a seat belt must have a thorough search for intraabdominal injury. If a spinal injury is present, but the CT scan is negative, the child should be admitted for observation or a DPL should be performed.

Pelvic and Genitourinary Trauma

Trauma to the genitourinary (GU) tract should be considered in all children with multiple trauma, a pelvic fracture, or injury to the flank, back, or groin. GU injuries are uncommon in children, occurring in only 10 percent of trauma patients. Symptoms and physical findings are often nonspecific, including back pain, abdominal pain, hypotension, and abdominal wall trauma. Pelvic fractures, particularly anterior ring fractures, are associated with urethral and bladder injury. Children are less likely to die of hemorrhage from a pelvic fracture than are adults. Often, other coexisting injuries mask the signs and symptoms of GU trauma in a multiply-injured child.

Hematuria is considered the hallmark finding in GU trauma, although it is a nonspecific finding. The degree of hematuria does correlate with the severity of injury, although renal pedicle disruption can be associated with no hematuria. [30] The radiographic evaluation of an injured child with hematuria is based on clinical presentation. Children with gross hematuria or more than 20 RBCs/hpf and unstable vital signs or the emergent need for operative intervention for other injuries require an IVP in the ED. Children who have hematuria of more than 10 RBCs/hpf and stable vital signs should have CT of the abdomen performed. Asymptomatic microscopic hematuria in children with blunt trauma and no apparent injuries is a low-yield indication for emergent abdominal CT scanning. These cases can be followed as outpatients.

Cystourethrography is required on all patients with suspected lower urinary tract injuries (for example, blood at urethral meatus, high prostate, or anterior pelvic fracture). Straddle injuries account for 20 percent of the cases of urethral injury (motor vehicle crashes account for most of the other 80 percent). Straddle injuries are also associated with pubic fractures, testicular injuries, and labial or scrotal hematomas and lacerations. Sexual abuse should be considered in a girl with a straddle injury and a history that does not seem compatible with the injury.

Burns

Despite continuing improvement in burn care, many children continue to suffer death and significant morbidity from burns. Burns are the second most common cause of accidental death among children under the age of 4 years. Younger children are more commonly injured by scalding water, accidental spills being twice as frequent as intentional immersions. Older children are more commonly burned by flame. [31]

DIAGNOSIS   Resuscitation principles are unchanged for pediatric burn patients. [32] Management of airway and circulation is paramount. Any traumatic injuries should be managed without regard to the burn itself. Aggressive airway management is crucial, as large burns may require high-volume fluid resuscitation, leading to airway

edema and the inability to intubate the child later. Early intubation particularly with inhalational burns cannot be overemphasized. Burn surface area (BSA) cannot always be estimated by the "Rule of Nines" in children because the proportion of body surface area changes with growth. A Lund and Browder chart that is age-appropriate should be used (see Fig. 194-2). Alternately, the burn area can be estimated by using the child's palm as 1 percent. Fluid resuscitation can be estimated by the Parkland formula (4 mL/kg × %BSA), the modified Brooke formula (2 mL/kg × %BSA), or the Shriners formula (5000 ml × BSA in m^2 + 2000 mL × total surface area in m^2). All formulas call for one-half the estimated fluid to be given in the first 8 h after the burn, the second one-half in the following 16 h so that the total volume is given in 24 h. All resuscitation formulas are a guide only. Proper management requires that the response to fluid administration be carefully monitored and adjustments be made individually.[32]

CRITERIA FOR BURN CENTER REFERRAL Table 244-7 lists the criteria for referral to a burn center from the American Burn Association. Predictors for mortality rate in children by importance are burn size over 30 percent, age less than 4 years, and the presence of an inhalation burn. [31] Any questions regarding an individual patient should be directed to the regional burn center.

Second- and third-degree burns over 20 percent body surface area

Third-degree burns over 10 percent burn surface area

Second- and third-degree burns over 10 percent burn surface area in child under 10 years old

Second- and third-degree burns on face, hands, feet, genitals

Second- and third-degree circumferential burns

Electrical burns

Lightning burns

Chemical burns on face, hands, feet, genitals

Inhalation burns

Patients with burns and significant preexisting medical disorders that affect burn management

Inability or inexperience in pediatric burn management at referring facility

TABLE 244-7   Criteria for Burn Center Referral

245 GERIATRIC TRAUMA

O. John Ma
Daniel J. DeBehnke

With the rapid growth in the size of the elderly population, the incidence of geriatric trauma is expected to increase as well. Although the elderly experience the same types of injuries that younger individuals do, there are differences in the incidence and patterns of trauma. Emergency physicians need to be aware of many of these unique injury mechanisms and patterns associated with geriatric trauma. Elderly patients also respond differently to traumatic injuries because age-related changes may produce a diminished physiologic reserve. Therefore, special management principles need to be applied in caring for geriatric trauma victims.

EPIDEMIOLOGY

Persons 65 years of age and older represent a large and growing segment of the population. According to the 1990 United States Census, 30.9 million people, representing 12.5 percent of the total population, were 65 years of age or older. This marked a 21.3 percent increase in this segment of the population from the 1980 Census figures. The U.S. Census Bureau projects that those over 65 years of age will increase to 52 million by the year 2020. The number of people over 85 years of age also is growing at an accelerated pace, with estimates that they will number 6.7 million by the year 2020. [1]

While persons over 65 years of age represent 12 percent of the population, they account for 36 percent of all ambulance transports, 25 percent of hospitalizations, and 25 percent of total trauma costs.[1] Although the elderly are less likely to be involved in trauma compared with other age groups, they are more likely to have fatal outcomes when they are injured. Approximately 28 percent of deaths due to accidental causes involve persons 65 years of age and older. Also, the elderly have the highest population-based mortality rate of any age group. [1]

Definitions

Defining the term *elderly* is a difficult task because it involves both chronologic and physiologic components. The literature has divided the elderly population into two groups: the *young old* (65 to 80 years of age) and the *old ola* (80 years of age and older).[1] Although this is a somewhat arbitrary division, it is helpful in interpreting the literature on geriatric trauma.

One of the difficulties in describing the elderly population is the potential discrepancy between chronologic age and physiologic age. *Chronologic age* is the actual number of years the individual has lived. *Physiologic age* describes the actual functional capacity of the patients' organ systems in a physiologic sense. Comorbid disease states such as diabetes mellitus, coronary artery disease, renal disease, arthritis, and pulmonary disease can decrease the physiologic reserve of certain patients, which makes it more difficult for them to recover from a traumatic injury.[2,3] *Physiologic reserve* describes the various levels of functioning of the patients' organ systems that allows them to compensate for traumatic derangement. For example, a 65-year-old patient with diabetes, arthritis, and chronic obstructive pulmonary disease may have less physiologic reserve and hence an older physiologic age compared with an 80-year-old without any comorbid conditions.

CLINICAL FEATURES

Common Mechanisms of Injury

The elderly will experience similar types of injuries that younger individuals do. There are differences, however, in the incidence and patterns of injury for elderly patients compared with younger persons.

Falls

Falls are the most common accidental injury in patients over 75 years of age and the second most common injury in the 65 to 74 age group. Fifty percent of elderly persons who fall do so repeatedly. Most individuals who fall will do so on a level surface, and most will suffer an isolated orthopedic injury. [1,4] Falls are reported as the underlying cause of 9500 deaths each year in patients over the age of 65 years. Many falls in the elderly population occur in residential institutions such as nursing homes. In the over 85 age group, 20 percent of fatal falls occur in nursing homes. [4]

There are age-related changes in postural stability, balance, motor strength, and coordination that make the elderly more prone to tripping and falling and may explain the increased incidence of falls in this population. Also, decreased visual acuity and increased memory loss can cause the patient difficulty in recognizing and avoiding environmental hazards. Acute, preexisting, and chronic diseases also may lead to falls. Syncope has been implicated in many cases of elderly patients who fall, and this may be secondary to dysrhythmias, venous pooling, autonomic derangement, hypoxia, anemia, or hypoglycemia. Other contributing factors include alcohol and medications, most notably sedative, antihypertensive, antidepressant, diuretic, and hypoglycemic agents. [4]

Motor Vehicle Crashes

Motor vehicle–related injuries rank as the leading mechanism of injury that brings elderly patients to a trauma center in the United States. Motor vehicle crashes are the most common mechanism for fatal incidents in elderly persons through 80 years of age.[1] Emergency physicians should anticipate an increase in motor vehicle trauma involving the elderly due to the growth in this subset of the population and the increase in elderly drivers and occupants. Recent data by Li and colleagues [5] have shown that the crash fatality rate among the elderly is considerably higher than for younger age groups. As noted earlier, similar effects of acute and chronic medical conditions can influence the incidence of motor vehicle crashes. The patient may have decreased cerebral and motor skills and may have memory and judgment losses that can compound the difficulty in operating a motor vehicle. The patient also may have decreased auditory or visual acuity that makes it more difficult to recognize dangerous traffic situations. Furthermore, decreased strength and slower reaction times may hinder an individual's ability to respond to a hazardous traffic situation.[1] One study reported that the number of motor vehicle crashes per driver's license increased with age in elderly drivers. Elderly drivers

typically collided in an intersection with a crossing vehicle, which they reported not noticing or seeing so late they did not have enough time to avoid it. [6]

Pedestrian-Automobile Accidents

When elderly patients are struck by automobiles, devastating injuries may result. The 65 and older age group accounts for 22 percent of pedestrian-automobile fatalities in the United States.[1] Elderly pedestrians struck by a motor vehicle are much more likely to die compared with younger pedestrians.[7] Postural changes due to musculoskeletal decline may lead to kyphosis, which results in difficulty in lifting the head to see and obey traffic signals. Traffic signals, which operate at a crossing rate of 4 ft/s, may not account for the elderly's slower walking speeds.[1] Thus elderly individuals may not have enough time to safely cross an intersection. Reduced peripheral vision and decreased hearing may limit access to information needed to make rational decisions about crossing the street. Again, cognitive, memory, and judgment skills may be diminished and could play a role in pedestrians being struck by automobiles.

Violence

The overall increase in violent crimes in the United States has not spared the elderly. Violent assaults account for 4 to 14 percent of trauma admissions in this age group. Elderly persons are seen as ideal targets for robberies because they may possess various age-related physical deficiencies. [1] Just as in the younger population, ethanol consumption by the assailant or victim has been found to be involved in the majority of fatal assaults. While blunt trauma, to date, has been the most frequent injury mechanism, penetrating injuries are on the rise.[1] Emergency physicians also should have a heightened suspicion for elder or parental abuse in the geriatric trauma patient (see Chap. 292, "Abuse in the Elderly and Impaired").

DIAGNOSIS AND ASSESSMENT

Primary and Secondary Surveys

As in all trauma patients, the primary survey should be conducted expeditiously. Special attention should be paid to anatomic variations that may make airway management more difficult. These include the presence of dentures (which may occlude the airway), cervical arthritis (which adds danger to extending the neck), or temporomandibular joint arthritis (which may hinder mouth opening). A thorough secondary survey is essential to uncover less serious injuries. These injuries, which include various orthopedic and "minor" head trauma, may not be severe enough to cause problems during the initial resuscitation but cumulatively may cause significant morbidity and mortality. An important point to note is that patients with no apparent life-threatening injuries actually can have potentially fatal injuries if there is some degree of limited physiologic reserve. Seemingly stable geriatric trauma patients can deteriorate rapidly and without warning.

History

Since elderly patients may have a significant past medical history that affects their trauma care, obtaining a precise history is vital. Often the time frame for obtaining information about the traumatic event, past medical history, medications, and allergies is quite short. Medical records and consultation with the patient's family physician may be helpful. Family members also may be able to provide information regarding the traumatic event and the patient's previous level of function.

Vital Signs

Early assessment and frequent monitoring of vital signs are essential in the geriatric trauma patient. The clinician, however, should not be led into a false sense of security by "normal" vital signs. In a study by Scalea and colleagues [8] of 15 patients initially considered to be hemodynamically "stable," 8 had cardiac outputs of less than 3.5 L/min and none had an adequate response to volume loading. Of 7 patients with a normal cardiac output, 5 had inadequate oxygen delivery.

There is progressive stiffening of the myocardium with age that results in a decreased effectiveness of the pumping mechanism. An 80-year-old will have approximately 50 percent of the cardiac output of a 20-year-old even without significant atherosclerotic coronary artery disease. The myocardium also becomes less sensitive to endogenous and exogenous catecholamines. Conduction defects may be exacerbated by the stress of illness or trauma. A normal tachycardic response to pain, hypovolemia, or anxiety may be absent or blunted in the elderly trauma patient. [9] Medications such as beta blockers may mask tachycardia and hinder evaluation of the elderly patient. Emergency physicians should be wary of a "normal" heart rate in the geriatric trauma victim.

RECOGNITION AND DIAGNOSIS OF COMMON INJURY PATTERNS

Head Injury

With aging, the brain undergoes progressive atrophy and decreases in size by about 10 percent between the ages of 30 and 70 years. [10] Subtle changes in cognition, memory, and data acquisition may confound the emergency physician's evaluation of the elderly patient's mental status. When evaluating the patient's mental status during the neurologic examination, it would be a grave error to assume that alterations in mental status are due solely to any underlying dementia or senility.

Elderly persons suffer a much lower incidence of epidural hematomas than the general population. [10] This has been attributed to the relatively more dense fibrous bond between the dura mater and the inner table of the skull in older individuals. There is, however, a higher incidence of subdural hematomas in elderly patients. As the brain mass decreases with advancing age, there is greater stretching and tension of the bridging veins that pass from the brain to the dural sinuses. The increased "dead space" within the skull may delay symptoms of intracranial bleeding.[9,10] More liberal indications for computed tomographic (CT) scanning are justified.

Cervical Spine Injuries

In one study[11] cervical spine injuries in patients 60 years of age and older accounted for 12 percent of the injuries. The pattern of cervical spine injuries in the elderly is very different than in younger patients. Ryan and associates [11] found that the incidence of C1 and C2 fractures rose as the population aged. This rise in upper-level fractures was due to a significant increase in the incidence of odontoid fractures in the elderly. When the elderly trauma patient presents with neck pain or a potential mechanism for spine injury (fall, mvc), emergency physicians need to place special emphasis on maintaining cervical immobilization until the cervical spine is properly assessed. Because underlying cervical arthritis may obscure fracture lines, the elderly patient with persistent neck pain and negative plain radiographs should undergo CT scanning of the neck, and flexion-extension views if imaging is negative but symptoms or suspicion for injury persists.

Chest Trauma

Chest trauma, both minor and severe, can compromise elderly individuals. In blunt trauma, there is an increased incidence of rib fractures due to osteoporotic changes. The pain associated with rib fractures, along with any decreased physiologic reserve, may predispose patients to respiratory complications. [12] More severe thoracic injuries, such as hemopneumothorax, pulmonary contusion, flail chest, and cardiac contusion, can quickly lead to decompensation in elderly individuals whose baseline oxygenation status may already be diminished.

Geriatric patients are more susceptible to developing hypoxia and respiratory infections following trauma. In the elderly, diminished elasticity of the lungs along with progressive changes in the chest wall can lead to a reduction in pulmonary compliance and in the ability to cough effectively. Total lung surface area decreases as alveolar and small airway support diminishes with advancing age. There also is reduced mucociliary clearance of foreign material and bacteria and increased colonization of the oropharynx with gram-negative organisms. All these factors result in an increased risk for elderly patients to develop nosocomial gram-negative pneumonia.[9,12]

Also, the great vessels tend to be more rigidly fixed, allowing for easier disruption from transmitted forces.

The main therapeutic goal is aggressively maintaining adequate oxygen delivery. Frequent arterial blood gas analysis may provide early insight into elderly patients' respiratory function and reserve. Prompt tracheal intubation and use of mechanical ventilation should be considered in patients with more severe injuries, respiratory rates greater than 40 breaths per minute, or when the Pa_{O_2} is less than 60 mmHg or the Pa_{CO_2} is greater than 50 mmHg. While nonventilatory therapy helps to prevent

respiratory infections and is always desirable, early mechanical ventilation may avert the disastrous results associated with hypoxia. [12]

Emergency physicians should remember that chest trauma alone does not necessarily forecast a bleak outcome. In one series, most of the patients sustaining blunt chest injuries were discharged home to their preinjury level of independence. [12]

Abdominal Trauma

The abdominal examination in elderly patients is notoriously unreliable compared with younger patients, even in the absence of distracting pain, injuries, or altered sensorium. Even with an initially benign physical examination, emergency physicians must have a high index of suspicion for intraabdominal injuries in patients who have associated pelvic and lower rib cage fractures. For older patients, the adhesions associated with previous abdominal surgical procedures may increase the risk of performing diagnostic peritoneal lavage in the emergency department. [1] Therefore, CT scanning with contrast material is a valuable diagnostic test. It is important to ensure adequate hydration and baseline assessment of renal function prior to the contrast load for the CT scan. Some patients may be volume depleted due to medications such as diuretics. This hypovolemia coupled with contrast administration may exacerbate any underlying renal pathology. [1] For unstable patients, and especially those with multiple scars on the abdominal wall from previous procedures, the trauma ultrasound examination is the ideal diagnostic study to detect free intraperitoneal fluid. In prospective studies by emergency physicians and trauma surgeons, ultrasonography has been demonstrated to be highly sensitive and specific for the identification of free intraperitoneal fluid. It also is rapid, portable, noninvasive, and easily repeatable. [13]

Orthopedic Injuries

HIP FRACTURES   Many elderly patients are predisposed to orthopedic injuries due to osteopenic and osteoporotic changes in their skeletal structure. Hip fracture is the single most common diagnosis that leads to hospitalization in all age groups in the United States. Hip fractures occur primarily in four areas: intertrochanteric, transcervical, subcapital, and subtrochanteric. Intertrochanteric fractures are the most common, followed by transcervical fractures. [9] Emergency physicians must be aware that pelvic and long bone fractures are not infrequently the sole etiology for hypovolemia in elderly patients. Timely orthopedic consultation, evaluation, and treatment with open reduction and internal fixation should be coordinated with the diagnosis and management of other injuries.

LONG BONE FRACTURES   Long bone fractures of the femur, tibia, and humerus may produce a loss of mobility with a resulting decrease in the independent lifestyle of elderly patients. [9] Geriatric patients who present with femoral fractures have been found to have a significantly higher rate of preexisting medical conditions than patients with proximal humeral fractures. [14] Early orthopedic consultation for intramedullary rodding of these fractures may result in increased early mobilization.

UPPER EXTREMITY INJURIES   Falls on the outstretched hand increase the elderly's risk for Colles's fractures. After the diagnosis is confirmed by radiographs, these fractures usually can be treated with closed reduction and immobilization. The incidence of humeral head and surgical neck fractures in elderly patients also is increased by falls on the outstretched hand or elbow. [9] Localized tenderness, swelling, and ecchymosis to the proximal humerus are characteristic of these injuries. Early orthopedic consultation and treatment with a shoulder immobilizer or surgical fixation should be arranged. Social services may need to be contacted to arrange for assistance with routine daily activities for some elderly patients being discharged home after an orthopedic injury.

TREATMENT

Special Management Principles

Emergency physicians often are faced with the challenging task of assessing elderly trauma patients' cardiovascular status and reserve. First, recent work by Ma and colleagues [15] has demonstrated that elderly trauma patients are less likely to be appropriately transported to trauma centers. Therefore, significantly injured older patients may have their injuries underappreciated yet present to nontrauma centers. The work by Scalea and colleagues [8] demonstrated that trauma physicians themselves frequently fail to recognize the severity of hemodynamic instability in geriatric patients. Therefore, early invasive monitoring has been advocated to help physicians assess the elderly's hemodynamic status. Scalea and coworkers showed that by reducing the time to invasive monitoring in elderly trauma patients from 5.5 to 2.2 h, and thus recognizing and appropriately treating occult shock, the survival rate of their patients increased from 7 to 53 percent. Survival was improved because of enhanced oxygen delivery through the use of adequate volume loading and inotropic support. These authors concluded that urgent invasive monitoring provides important hemodynamic information early, aids in identifying occult shock, limits hypoperfusion, helps prevent multiple organ failure, and improves survival. [8]

The insertion of invasive monitoring lines seldom occurs in some emergency departments because of institutional practice and availability of equipment. Given the clear empirical evidence for the value of rapid assessment and early intervention, [8] every effort should be made by emergency physicians to expedite emergency department (ED) care of elderly trauma patients and prevent unnecessary delays. In the ED evaluation of blunt trauma patients, the chest radiograph, cervical spine series, and pelvic radiographs are necessary diagnostic tests during the secondary survey. After ordering this set of plain radiographs, emergency physicians must resist the temptation of trying to appease consultants by immediately obtaining plain films of every other body region that may have sustained minor trauma. While it is vital to be thorough in the diagnosis of occult orthopedic injuries, expending a great deal of time in the radiology suite, especially if off-site, may compromise patient care. Only a few radiologic studies, such as emergent head and abdominal CT scans, can take precedence over obtaining vital information from invasive monitoring, depending on the situation. Elderly trauma patients will benefit most from an expeditious transfer to the intensive care unit so that their hemodynamic status can be further monitored. After ensuring that their hemodynamic status has been stabilized, patients can be transported back to the radiology suite for further plain radiographic studies. If in doubt, extremities can be temporarily splinted.

In the ED, emergency physicians must make critical management decisions regarding volume resuscitation without the benefit of sophisticated invasive monitoring devices. Geriatric trauma patients can decompensate with overresuscitation just as quickly as they can with inadequate resuscitation. [9] Elderly patients with underlying coronary artery disease and cerebrovascular disease are at a much greater risk of suffering the consequences of ischemia to vital organs when they become hypotensive after sustaining trauma. During the initial resuscitative phase, crystalloid, while the primary option, should be administered judiciously because elderly patients with diminished cardiac compliance are more susceptible to volume overload. Strong consideration should be given to early and more liberal use of red blood cell transfusion. This practice early in the resuscitation would enhance oxygen delivery and help minimize tissue ischemia.

DISPOSITION

Prevention, Prognosis, and Outcome

For elderly patients who are discharged home after sustaining an injury from a fall, it is appropriate for emergency physicians to encourage them to work with their primary care physician to arrange for a social worker to conduct a home safety assessment to help prevent future falls. Chronic medications that may adversely affect the vestibular system, cause profound sedation, or produce postural hypotension should be identified; patients can then discuss alternative therapies or dosages with their primary care physicians. [4] When discharging home a patient with a new medication prescription, emergency physicians should select drugs that are least centrally acting, least associated with postural hypotension, and have the shortest duration.

Among geriatric trauma patients who are hospitalized, the mortality rate has been reported to be between 15 and 30 percent. These figures far exceed the mortality rate of 4 to 8 percent found in younger patients. [1] In general, multiple organ failure and sepsis cause more deaths in elderly patients than in younger trauma victims. [16] Geriatric patients also are more likely to die following minor traumatic events. [17]

Several markers for poor outcome in elderly trauma victims have been determined. Age greater than 75 years, Glasgow Coma Scale score of 7 or less, presence of shock on admission, severe head injury, and the development of sepsis are associated with worse outcome and higher mortality figures. [18] The Injury Severity Score has been found by many investigators to have poor correlation with mortality rates. [19]

The ultimate goal in care of elderly trauma patients is to return them to their preinjury state of independent function. There are conflicting data on the ability of elderly patients to return to independent living. A study by Oreskovich and colleagues [20] showed a mortality rate of 15 percent among their geriatric trauma patients, and a dismal 12 percent of patients returning to their baseline independent state. Public debate has raised questions about the ethics and cost-benefits of trauma care for the elderly. However, DeMaria and colleagues [21,22] demonstrated that immediately after discharge, one-third of trauma survivors return to independent living, one-third return to dependent status but living at home, and one-third require nursing home facilities. Altogether, at long-term follow-up, 89 percent returned home after trauma

and 57 percent returned to independent living. The findings of DeMaria and colleagues are supported by the investigation of van Aalst and colleagues, [18] who also showed that the majority of their elderly trauma patients regained an independent level of function.

Many questions regarding the ultimate outcome of geriatric trauma patients remain unanswered. In light of the investigations by DeMaria [21] and van Aalst [18] and their colleagues showing that elderly patients can return to independent living after trauma and the study by Scalea and colleagues [8] demonstrating the beneficial effect of early invasive monitoring, it appears that aggressive resuscitation efforts for geriatric trauma patients are warranted.

In summary, the acute management principles of geriatric trauma continue to evolve. Emergency physicians must remain familiar with the various mechanisms of injury unique to the elderly trauma patient. Special management and treatment axioms, outlined in Table 245-1, should be applied early when caring for the geriatric trauma patient.

1. Assume that patients have limited physiologic reserve.
2. Seemingly minor injuries may actually be life-threatening in the face of limited physiologic reserve.
3. "Stable" patients may quickly become unstable, with little warning.
4. Low threshold for ordering of head and abdominal CT scanning is justified.
5. Early invasive hemodynamic monitoring often will provide valuable diagnostic and resuscitation information.
6. Early, aggressive oxygen use and mechanical ventilation may be necessary in some patients.
7. Blood transfusion for volume replacement early in the resuscitation phase will improve oxygen delivery in hypovolemic patients.
8. Overresuscitation is as detrimental as inadequate resuscitation.
9. The patient's environment and social situation need to be considered as potentially playing a major role in the trauma suffered and for convalescence, particularly if the patient is to be discharged from the ED.

Nelson Tang

An injured pregnant woman presents two patients, simultaneously requiring timely and effective evaluation, stabilization, and definitive care. Furthermore, the inherent changes in maternal anatomy and physiology during pregnancy make effective diagnosis of serious injury more difficult and may result in delays in recognition and initiation of therapy. As in other aspects of trauma care, injuries in pregnancy require a thoughtful and consistent approach to diagnosis and treatment.

Trauma remains the leading cause of nonobstetric morbidity and mortality in pregnant women. The conventional paradigm that fetal survival depends wholly on maternal stabilization and well-being is fundamentally accurate. It has become increasingly apparent, however, that especially in relatively minor traumatic events the severity of maternal injuries may be a poor predictor of fetal distress and outcome.[1,2 and 3] Successful outcomes for both mother and fetus require a collaborative effort among the prehospital provider, emergency physician, trauma surgeon, obstetrician, and neonatologist.

EPIDEMIOLOGY

It has been consistently estimated that significant trauma complicates 6 to 7 percent of all pregnancies.[2] Trauma during pregnancy is associated with an increased risk of preterm labor, placental abruption, fetal-maternal hemorrhage, and pregnancy loss. Maternal trauma-related mortality rate does not appear to be different from that of nonpregnant women.[4,5]

The most common cause of blunt abdominal trauma is motor vehicle crash, accounting for up to 70 percent of acute injuries. This is followed by falls and direct assault in decreasing order of frequency.[1,2,6] The incidence of falls appears to increase with advancement of pregnancies, presumably due to alterations in maternal balance and coordination. Minor abdominal trauma may yet result in fetal demise. Up to 5 percent of patients with minor trauma may experience abruption. The role of domestic violence during pregnancy is of significant concern, with one large series describing more than 31 percent of trauma in pregnant women as intentional injuries and as many as 88 percent of those cases implicating the husband or boyfriend as perpetrator.[7] Whether this represents a change in epidemiology or reporting, the need for vigilance by emergency physicians for domestic or intimate violence during pregnancy is clear.

Penetrating injuries are less common than blunt trauma during pregnancy. Gunshot wounds are the most common form of penetrating trauma. Some of these injuries may be self-inflicted and represent attempts to terminate pregnancies.[6] Fetal mortality rates in penetrating injuries are as high as 70 percent. While the rate of maternal visceral injuries is 19 to 38 percent, there remains a 60 to 90 percent chance of fetal injury. This is presumably due to the protective effect of the gravid uterus on maternal viscera.

PHYSIOLOGIC CHANGES OF PREGNANCY

A normal pregnancy creates complex changes in maternal anatomy and physiology, many of which begin as early as the first trimester and continue throughout its term. Significant alterations to the maternal reproductive, cardiovascular, respiratory, and gastrointestinal systems as well as maternal anatomy make the evaluation of an acutely injured pregnant patient more difficult. An understanding of these physiologic changes is essential to the appropriate diagnosis and management in such cases. These are discussed in detail in Chap. 99, "Normal Pregnancy," but will be noted here in brief.

Maternal blood volume begins to expand at approximately week 10 of gestation and peaks at 45 to 50 percent increase from baseline at week 28, resulting in a state of hypervolemia. Red cell mass increases to a lesser extent, leading to the relative physiologic anemia of pregnancy. Cardiac output is increased by 1.0 to 1.5 L/min at week 10 of pregnancy and remains elevated until the end of pregnancy. Heart rate in the mother is generally increased by 10 to 20 beats per minute in the second trimester, accompanied by decreases in systolic and diastolic blood pressures of 10 to 15 mmHg.

These changes can be frequently misleading during maternal resuscitation in trauma and make clinical findings difficult to interpret. A pregnant woman may lose 30 to 35 percent of circulating blood volume before manifesting hypotension or clinical signs of shock.[2] Uterine arteries vasoconstrict, resulting in diminished fetal blood flow and tissue oxygenation before significant evidence of maternal hypovolemia.

After week 12 of gestation, the uterus becomes an intraabdominal organ, removing it from the relative protection of the maternal pelvis and making it more susceptible to direct injuries. The bladder also moves anteriorly into the abdomen in the third trimester of pregnancy, increasing its susceptibility to injury. Uterine blood flow may increase to upward of 600 mL/min, making severe maternal hemorrhage from uterine injury possible. The gravid uterus also causes passive stretching of the abdominal wall and peritoneum as it enlarges and may lead to diminished sensitivity to injury and irritation from intraperitoneal blood.[4] At or about week 20 of gestation, the expanding mass of the gravid uterus may lead to the supine hypotension syndrome in which venous return and cardiac output are diminished by compression of the maternal inferior vena cava in the supine position. The enlarging uterus may additionally cause engorgement of lower extremity and lower abdominal vessels, predisposing the patient to severe retroperitoneal hemorrhages in acute injuries to these areas.

As pregnancy progresses, the diaphragm is raised by as much as 4 cm and tidal volume increases by 40 percent as residual volume diminishes by 25 percent. Functional residual capacity is similarly decreased, and the compensatory increase in ventilation results typically in respiratory alkalosis. Serum pH is usually maintained at normal values by renal compensation. These changes may significantly impair the ability of a pregnant trauma patient to compensate for respiratory compromise.

The gastrointestinal tract demonstrates diminished motility, and there is delayed gastric emptying during pregnancy. This increases the likelihood of gastroesophageal reflux and the potential for aspiration from acute injuries as well as from resuscitative interventions, including endotracheal intubation. The small bowel is moved upward in the abdomen by the enlarging uterus, protecting the small bowel to some degree from lower abdominal injuries. It does, however, increase the chance of complex bowel injuries in penetrating trauma of the upper abdomen.[4] The liver is typically unaffected by pregnancy, and the most common etiology of abdominal hemorrhage remains splenic injury, as in nonpregnant patients.

MATERNAL AND FETAL INJURIES

Until about week 12 of gestation, the uterus is protected to a large degree by the bony structure of the maternal pelvis. As a result, direct fetal injury is relatively infrequent in blunt abdominal trauma during pregnancy. When fetal injuries do occur, they are typically seen in later gestation and tend to involve the fetal skull and brain. These injuries are frequently sustained in association with fractures to the maternal pelvis when the fetal head is engaged. When the uterus is penetrated by a sharp object or projectile, the fetus has a high probability of sustaining injury.[6,8]

Uterine rupture is a relatively uncommon complication of blunt trauma sustained during pregnancy. Its incidence has been reported as 0.6 to 1.0 percent of injuries in pregnancy and is more likely to occur during the late second and third trimesters and when there is direct and forceful impact upon the uterus.[4,6] The fetal mortality rate in such cases is nearly 100 percent, whereas maternal mortality is less than 10 percent. The presentation of uterine rupture may be quite nonspecific, but loss of

the palpable uterine contour, ease of palpation of fetal parts, or radiologic evidence of abnormal fetal location is suggestive of the diagnosis.

Uterine irritability and the onset of preterm labor may be precipitated by acute abdominal trauma during pregnancy. Numerous reports have noted the management of premature labor in pregnant trauma patients with tocolytic agents, but the use has not been generally recommended and requires individualization. [1,9] Tocolytic agents have numerous described adverse side effects, such as fetal and maternal tachycardia, which may complicate the evaluation of trauma patients. Additionally, their use may further impair the ability to diagnose other significant traumatic injuries, specifically placental abruption. If tocolytics are considered, an obstetrician should be consulted prior to administration.

Second only to maternal death, abruptio placentae is the most common cause of fetal death. Abruptio placentae complicates 1 to 5 percent of minor injuries during pregnancy and up to 40 to 50 percent of major traumas.[1,6] Placental abruption has been described as being caused by the deformation of the elastic uterus around the relatively inelastic placenta. Further exacerbated by increased intrauterine pressures, shear forces are applied to the placental base, leading to separation from the uterine wall. Findings consistent with abruptio placentae include abdominal pain, vaginal bleeding, and tetanic uterine contractions. Placental abruption may also lead to the introduction of placental products into the maternal circulation, stimulating disseminated intravascular coagulation (DIC). The correlation and predictive value of DIC with respect to fetal mortality remains unsettled.[7,10]

The fetal and maternal circulations are normally separate during pregnancy, and fetal red blood cells may enter the maternal bloodstream in cases of traumatic injury. The incidence of such fetal-maternal hemorrhage in trauma during pregnancy is four to five times that which occurs in pregnancies not complicated by injury. [4,6] Fetal-maternal hemorrhage occurs in over 30 percent of significant trauma in pregnant patients and is implicated in the sensitization and subsequent isoimmunization of Rh-negative patients. As little as 0.1 to 0.3 mL of fetal cells is sufficient to sensitize 70 percent of Rh-negative women. [11] The fetal hemorrhage itself poses the direct risks of fetal hypovolemia, anemia, distress, and death. Anterior placental location appears to be associated with increased risk of fetal-maternal hemorrhage. [1]

EMERGENCY TREATMENT

Prehospital Care

An effort to ascertain the possibility of pregnancy should be made during the initial evaluation of all acutely injured women of childbearing age. As in the care of all trauma victims, initial priorities remain the ABCs of resuscitation. All pregnant trauma patients should receive supplemental oxygen, as the gravida becomes less able to compensate for hypoxia. Similarly, early intubation must be considered when indicated by the nature or severity of injuries. Peripheral intravenous lines with crystalloid infusions should be initiated in the prehospital setting.

For pregnant patients beyond 20 weeks of gestation who must be transported in the supine position or in whom spinal immobilization is indicated, a wedge should be placed under the right hip area tilting the patient toward her left side to avoid hypotension from inferior vena cava compression by the gravid uterus. Alternatively, the uterus may be manually maneuvered to the left side of the abdomen by transport personnel. Pneumatic antishock trousers are rarely used now, but if considered in a pregnant patient, the abdominal compartment must not be inflated, because that may cause uteroplacental compression and impair venous return to the heart. An integral part of the prehospital role in trauma management is the appropriate triage to receiving facilities. If pregnancy in a trauma patient is identified or suspected, transport should be initiated to a designated trauma center with sufficient capabilities to manage such patients. Advanced notification of the receiving facility should be made to enable the assembly of the appropriate hospital personnel to continue the resuscitation and management efforts.

Emergency Department Management

Upon arrival in the emergency department, the prehospital resuscitative measures already undertaken should be reviewed and continued as appropriate. Since maternal stability and survival offer the best chance for fetal well-being, initial efforts must be directed toward the adequate resuscitation of the mother. No critical interventions or diagnostic procedures should be withheld from the treatment of pregnant trauma patients out of concerns for potential adverse fetal consequences. A trauma surgeon and obstetrician should be involved early in the evaluation and management of a significantly traumatized pregnant patient.

The initial sequence of trauma resuscitation is unchanged in the emergency treatment of an injured pregnant patient. The patient is kept in the left lateral decubitus position to the extent possible to minimize vena caval compression. Securing the airway and ensuring the adequacy of ventilation in addition to the administration of supplemental oxygenation are of primary concern. Gastric tube decompression must be performed early, since delayed stomach emptying makes the possibility of aspiration a particular concern during pregnancy. Sources of hemorrhage should be identified and controlled, because maternal blood loss and hypovolemia occur at the expense of fetal hypoperfusion. Adequate large-bore vascular access is essential, and crystalloid infusions may need to be adjusted upward by as much as 50 percent to account for the additional plasma volumes in pregnancy.[4,8] The use of vasopressor agents poses a risk of impaired uterine perfusion and should not be initiated until adequate volume replacement has been administered. Their use should not be restricted, however, if required for maternal resuscitation. Initial laboratory studies include complete blood counts, blood typing, and Rh status, as well as coagulation profiles to determine the possibility of DIC. Low serum bicarbonate levels have been shown to be associated with adverse fetal outcomes, and routine determination of the levels may be of predictive value. [2] After the primary trauma survey, an organized and methodical secondary system survey must be performed to ensure the identification of all potential injuries.

Attention should next be turned to the gravid abdomen. Gestational age can be assessed rapidly by palpating uterine fundal height. At week 20 of gestation, the fundus may be palpated at or about the level of the umbilicus. The abdomen and uterus should be examined for evidence of injury as well as palpated for uterine tenderness or contractions. If abdominal or pelvic trauma is suspected, a sterile pelvic examination is indicated to inspect for injuries of the lower genital tract, vaginal bleeding, or rupture of amniotic membranes. Fluid in the vaginal canal with pH of 7 is suggestive of amniotic fluid, whereas a pH of 5 is consistent with vaginal secretions. A branchlike pattern upon drying of vaginal fluid on a microscopy slide or "ferning" is also diagnostic of amniotic fluid.

The Kleihauer-Betke assay is an acid elution technique that differentially stains fetal and maternal red blood cells based on differences in hemoglobin and may be performed on maternal blood to quantify the degree of fetal-maternal hemorrhage in Rh-negative gravidas. The sensitivity of the typical laboratory Kleihauer-Betke test is generally incapable of detecting small quantities of transfused fetal blood. Thus, administration of one prophylactic dose of Rh immune globulin (RhoGAM) is indicated with all Rh-negative pregnant trauma patients beyond 12 weeks of gestation who are evaluated for abdominal injury. One 300-μg dose of RhoGAM protects against 30 mL of fetal blood. The use of the Kleihauer-Betke test may be helpful in identifying greater amounts of fetal-maternal inadvertent transfusion and determining the need for additional doses of immune globulin. Its utility, however, as a predictor of fetal morbidity or adverse pregnancy outcome has not been demonstrated.[1,9,12] Tetanus prophylaxis has no deleterious fetal effects and should be routinely administered as indicated following trauma.

The indications for emergent laparotomy remain unchanged in the evaluation of pregnant trauma patients. Similarly, diagnostic peritoneal lavage (DPL) and abdominopelvic computed tomography (CT) scan remain valid modalities for the evaluation of intraabdominal injuries from acute trauma. DPL should be performed with an open, supraumbilical technique in patients with evidence of a gravid uterus. The fetus appears to tolerate surgery and anesthesia well if adequate oxygenation and uterine perfusion are maintained.[6] The performance of emergent DPL and surgery have not been shown to have an association with fetal loss, and these procedures should not be withheld out of concern for fetal compromise when indicated in trauma. [2] Additionally, a recent large multi-institutional retrospective review has shown that emergent cesarean delivery results in a fetal survival rate as high as 75 percent when gestation is at or longer than 26 weeks, fetal heart tones are present on admission, and the procedure is performed at the earliest indication of fetal distress. [3]

Radiologic Evaluation

The use of diagnostic radiologic imaging in the emergency treatment of pregnant trauma patients adheres to the fundamental principles of trauma management. While the judicious acquisition of studies is indicated to minimize fetal exposure to the potential effects of ionizing radiation (Table 246-1), no tests should be withheld if necessary for appropriate maternal evaluation and treatment. The principal concerns regarding radiation exposure in utero are the possibilities of childhood neoplasia, fetal loss, congenital malformations, and microcephaly. [13] Thus, studies should be limited to those needed, as radiation exposure sequelae are cumulative. The greatest risk to fetal viability is within the first 2 weeks following conception, and the highest potential for malformation is during embryonic organogenesis from 2 to 8 weeks after conception.[13] Adverse fetal effects due to radiation exposure are negligible from doses of less than 10 rad. The standard trauma plain radiographs, such as cervical spine, chest, and pelvis films, deliver significantly less than 1 rad each. [4,13] Fetal exposure can be further decreased by appropriate shielding of the maternal abdomen and pelvis during many studies.

Radiologic Study	Exposure (rad)
Cervical spine film	≤0.001
Chest film	0.001–0.005
Abdomen film	0.10–0.5
Pelvis film	0.15–0.5
Lumbar spine film	0.5–1.5
Head CT scan	0.05–0.1
Abdominopelvic CT scan	1.0–5.0

Abbreviation: CT, computed tomography.

TABLE 246-1   Fetal Radiation Exposure from Common Radiologic Studies

Abdominopelvic CT scanning, pelvic angiography, and pelvic fluoroscopy result in the highest delivered doses of radiation. The amount is typically 2 to 5 rad, with some variation due to equipment quality, techniques used, and duration of study. [4,13] Radiation exposure in CT may be reduced by performing modified studies and the use of dose-reducing techniques, such as reducing the number of slices obtained. [13] Diagnostic evaluations with magnetic resonance imaging and ventilation-perfusion scanning have not been reported to cause adverse pregnancy outcomes. Potential effects of contrast agents have not been definitively studied, and their use requires individualization.

Fetal Assessment

A rapid assessment of fetal condition should be initiated with auscultation of fetal heart tones to determine fetal viability and identify fetal distress. Assessment of fetal heart tones may be augmented by use of a Doppler stethoscope or ultrasound. It has been suggested that fetal viability in the setting of trauma is directly related to the presence or absence of fetal heart tones on presentation, and that if these are confirmed absent, then the remainder of treatment efforts be directed solely at maternal resuscitation. [3] Normal fetal heart rates are in the range of 120 to 160 beats per minute. The most likely cause of fetal bradycardia is acute hypoxia. In acute injuries, maternal hypotension, hypothermia, respiratory compromise, or placental abruption are likely etiologies. Similarly, in the setting of acute trauma, the finding of fetal tachycardia may also represent a hypoxic or hypovolemic state.

The use of bedside ultrasound has become an increasingly valuable adjunct to initial trauma assessment and management. Portable ultrasound has been shown to be rapid, noninvasive, and facilitates serial examinations. [14] In cases of trauma during pregnancy, ultrasonography may also be of particular value in the evaluation of general fetal condition. Fetal size and estimated gestational age, the presence of fetal heart motion, fetal activity or demise, placental location, and amniotic fluid volume can be assessed. [4,15] The efficacy of ultrasound, however, for the diagnosis of specific trauma-related injuries remains unproven. Several recent reports have suggested the relative inability of ultrasound to diagnose uterine rupture or fetal-placental injuries, and its sensitivity is insufficient to exclude the diagnosis of placental abruption. [12,15] The intraabdominal anatomic distortions of late third-trimester pregnancy may further limit the diagnostic capability of ultrasound in acute trauma.

In the management of blunt trauma during pregnancy, external fetal monitoring is indicated for gestational age estimated beyond 20 weeks. The initiation of fetal tocodynamometry is recommended at the earliest possible stage of evaluation following maternal stabilization, preferably in the emergency department. Fetal monitoring is utilized to assess both uterine contractile activity as well as fetal heart rate. Beyond the viable gestational age of 23 weeks, the presence of fetal tachycardia, lack of beat-to-beat or long-term variability, or late decelerations on tocodynamometry are diagnostic of fetal distress and may be indications for emergent cesarean delivery.

The identification of frequent uterine activity on external fetal monitoring has been shown to be a sensitive predictor of abruptio placentae beyond 20 weeks of gestation. In a major prospective study, no cases of abruptio placentae were identified unless more than 8 contractions per hour were found during the first 4 h of tocodynamometry. [1] A minimum of 4 h of external tocodynamometric monitoring appears to be predictive of immediate adverse pregnancy outcomes and is indicated for all pregnant patients evaluated for trauma. Patients demonstrating 3 to 7 contractions per hour of persistent uterine irritability should have tocodynamometry extended to a minimum of 24 h. They may subsequently be safely discharged if uterine contractions abate and other reasons for further evaluation do not exist. Patients with fewer than 3 contractions per hour during an initial 4-h observation period can be safely discharged. This approach has been shown to have the same pregnancy outcomes among discharged patients when compared with uninjured controls.

PERIMORTEM CESAREAN DELIVERY

The need to perform perimortem cesarean delivery in cases of maternal cardiac arrest arises extremely infrequently. Nevertheless, it involves complex ethical, medical, and emotional considerations. The largest review of reported attempts to date in the literature revealed fewer than 200 successful fetal outcomes from the procedure. [16] The time to delivery from the onset of maternal arrest was found to be critical to fetal survival with good neurologic outcome. Excellent outcomes were reported when delivery took place within 5 min of maternal death. Survival was unlikely if delivery occurred after 20 min of maternal arrest. It has since been recommended that the procedure be performed after 4 min of maternal resuscitation. Recently, the first successful out-of-hospital perimortem cesarean delivery was reported and with a time interval of 34 min between maternal collapse and delivery, although with severe neurologic deficits in the infant. [17]

Consideration of perimortem cesarean delivery must be made only after immediate and optimal advanced maternal cardiopulmonary resuscitative measures have been instituted. The procedure may be attempted in gestations estimated at beyond 23 weeks [17] (Table 246-2). Full maternal resuscitation must continue unabated while preparing for and during the actual delivery. It is universally recommended that the procedure be performed rapidly with the most readily available materials and that a single vertical incision be made to enter the peritoneum, followed by a vertical uterine incision to deliver the fetus. Successful maternal revival following fetal delivery has been reported. Improved venous return to the central circulation, increased maternal oxygen delivery following removal of the high uterine demand, and decreased pooling of blood in the uteroplacental circulation have all been suggested explanations.

Gestational Age (Weeks)	Survival (%)

DISPOSITION

The decision to admit or discharge after the emergency assessment and management of a pregnant trauma patient is ultimately based on the nature and severity of

presenting injuries. Patients suffering severe multisystem trauma will have their further management assumed by trauma surgeons and consultant obstetricians. Even in cases of seemingly minor but potentially significant injuries, admission to a trauma service capable of further observation and management is appropriate. Patients who demonstrate evidence of fetal distress or uterine irritability during the initial assessment require admission under the extended evaluation and care of an obstetrician capable of emergency delivery as necessary. Patients who must be transferred to other facilities for definitive trauma or obstetric care must be appropriately stabilized prior to transfer, with provisions for an appropriate level of care during transport. There must be strict adherence to transfer policies that comply with COBRA and EMTALA regulations. Clearly, the ongoing need for an interdisciplinary approach to patient management in such cases remains even after admission.

Although external fetal monitoring may be initiated in the emergency department, the monitoring is typically continued in the labor and delivery suite under the direction of an obstetrician. If the extended period of monitoring demonstrates no evidence to suggest fetal or maternal injury or distress, the patient may be discharged. Upon discharge, the patient must be carefully advised to seek medical attention immediately if she should develop abdominal pain or cramping, vaginal bleeding, leakage of fluid, or perception of diminished fetal activity. The decision to discharge an injured pregnant patient from the emergency department must be made carefully. A high index of suspicion should be maintained for occult injuries as well as a low threshold for obstetric consultation when indicated. To screen for the possibility of interpersonal violence, a thorough social services evaluation or referral should be made in all but the most obvious cases of accidental injury. Adequate obstetric follow-up care must be ensured for all pregnant trauma patients when discharged from the emergency department.

247 HEAD INJURY

Thomas D. Kirsch
Salvatore Migliore
Teresita M. Hogan

EPIDEMIOLOGY

Injuries are the leading cause of death in persons less than 45 years old with up to 50 percent of these due to head trauma. This chapter discusses all aspects of head injuries, but focuses on the more severe category of injuries now referred to as traumatic brain injuries (TBI). According to national data, approximately 1.5 million people per year sustain a nonfatal TBI. More than 370,000 persons are hospitalized annually with TBI, and 52,000 per year sustain a fatal TBI. [1] In 1996, there were more than 750,000 ED visits for intracranial head injuries and 2.6 million visits for open wounds to the head. [2] TBI is also the major cause of traumatic disability in the United States, leading to 80,000 annual cases of residual neurologic disability. The costs for treatment of both acute and chronic TBI have been estimated to be $4 billion dollars annually. [3]

The most commonly affected groups are young male adults. The elderly and young children are also at greater risk because of underlying anatomic and physiologic factors. In addition, alcoholics are at an increased risk for TBI. Ethanol-intoxicated individuals have a 40 percent greater chance of sustaining a head injury than sober individuals.[4] The causal agent for TBI a mortality varies greatly by age and other demographic factors. For example, the leading cause of TBI-related deaths in the 15- to 24-year-old age group is gunshot wounds, while for those over 65 years it is falls.

ANATOMY

The scalp is composed of five layers; skin, subcutaneous tissue, galea, areolar tissue, and the pericranium. There is potential for severe blood loss due to the heavy blood supply in the subcutaneous tissue and the loose areolar connection to the pericranium.

The skull is a rigid container made up of eight major bones. The bones of the skull have two solid layers separated by cancellous bone, which adds further rigidity and strength. The inner surface of the skull is lined by the dura. While protecting the brain from external forces, the rigid skull does not allow for the expansion of the intracranial contents. Fractures of the skull, particularly of the temporal bone can disrupt the enclosed meningeal artery and lead to epidural hematoma.

The adult brain weighs between 1300 and 1500 g and occupies 80 percent of the total volume of the skull. The brain's three basic structures—the cerebral hemispheres, the cerebellum and the brainstem—are divided by two major fixed dura attachments. The *falx cerebri* vertically separates the two major halves of the cerebrum down to the level of the brainstem. The *tentorium cerebelli* separates the cerebellum and brainstem from the cerebrum at the base of the skull. The inner edge of the tentorium cerebelli is the site of the most common brain herniation syndrome, uncal herniation. The cerebrum is further anatomically divided into major lobes named after the bones overlying them: frontal, temporal, parietal, occipital.

The brain is covered with multiple anatomic layers and potential spaces. The outermost layer next to the skull is the *dura*. It is between the dura and the skull where bleeding from the meningeal arteries causes epidural hematomas. Underneath is a thinner fibrous material called the *arachnoid*. The *pia* is closely associated with the gray matter of the brain and is the inner most layer. Between the arachnoid and the pia is the *subarachnoid space* where cerebrospinal fluid (CSF) circulates. In the average adult, there is 150 mL of CSF surrounding the brain and spinal cord. Approximately 500 mL of CFS is produced in the choroid plexus of the lateral ventricles each day.

PATHOPHYSIOLOGY

Physiology

The brain accounts for only 2 percent of total body weight, but consumes 20 percent of the body's total oxygen requirement and 15 percent of total cardiac output. The volume of cerebral blood flow (CBF), the cerebral perfusion pressure (CPP), and the blood oxygen levels determine the amount of oxygen delivered to cerebral tissue. Under normal circumstances the major regulatory mechanisms of CBF are the P_{CO_2}, blood pressure, and pH. As hypotension or hypoventilation leads to increased P_{CO_2} and decreased pH, the cerebral vasculature dilates to increase CBF and deliver more oxygen. Vasoconstriction occurs with hypertension, hypocarbia and alkalosis. CBF is also responsive to P_{O_2}, with cerebral vasodilatation occurring as P_{O_2} decreases.

Because it is not possible to accurately measure the CBF in a clinical setting, the CPP is used as a surrogate indicator for monitoring. The CPP is the pressure gradient against which cerebral perfusion must work and is the result of the mean arterial pressure (MAP) minus the intracranial pressure. [5] This is summarized by the equation, CPP = MAP − ICP. Under normal conditions, the ICP is 0 to 10 mmHg. Therefore, CPP is closely related to the MAP. The brain has the ability to maintain a constant cerebral blood flow by vasodilatation or vasoconstriction to counter changes in the MAP in hypotensive or hypertensive settings. This self-maintenance is known as *autoregulation* and functions when the CPP is between 50 and 150 mmHg (Fig. 247-1). Outside this range autoregulation is disrupted, and CBF follows a more linear passive-pressure relationship to CPP. Patients with TBI often lose autoregulation and CBF follows a linear relationship directly proportional to the CPP. Under these conditions, normal cerebral blood flow may not be restored until the CPP is greater than 90 mmHg. [5] Below this value, cerebral blood flow may not be sufficient to support cerebral oxygenation, resulting in tissue ischemia. In 1996, the Brain Trauma Foundation made several recommendations regarding CPP, MAP, and ICP for patients with TBI.[6] CPP should be maintained at 70 mmHg or greater. To achieve this, two things must occur: the MAP must be 90 mmHg or greater (which would mean a SBP of 120 to 140 mmHg) and the ICP no greater than 20 to 25 mmHg.[6] Under these guidelines, any patient with severe TBI must have a MAP >90 mmHg maintained. If this is achieved and the patient exhibits progressive neurologic deterioration or evidence of herniation not attributable to extracranial

sources, then the ICP is most likely elevated and CPP decreased. In this situation, CSF drainage by ventriculostomy is the best intervention, followed by mannitol given as a bolus. Hyperventilation should not be used prophylactically due to potentially serious side effects from decreased CBF. If it is used prophylactically, then a Paco$_2$ of 30 to 35 mmHg should be maintained. Hyperventilation should only be performed for treatment of documented intracranial hypertension. It is generally reserved for increased ICP that is refractory to treatment modalities such as adequate CPP, CSF drainage, sedation, neuromuscular blockade, mannitol. [6]
FIG. 247-1. Normal cerebral blood flow autoregulation curve and the abnormal relationship in TBI. In normal settings (solid line) the CBF remains relatively constant between a CPP of 50–150. Outside these ranges the relationship of CBF to CPP is more direct and linear. For patients with TBI, the relationship is direct through all CPP (dotted line).

The calvarium is a closed space housing three components: the brain, blood, and CSF. Volume increase in one of these components leads to either a decrease in another component or an increase in intracranial pressure. Patients with a TBI-caused mass lesion or cerebral edema have an increase in brain volume. Initially, as pressure increases, the CSF is displaced into the spinal canal, a process called *CSF buffering*. The elastic properties of the brain provide further compensation by allowing tissue compression. As the volume increases beyond the regulatory capacity, the ICP increases, leading to decreased CBF, the loss of autoregulation, and tissue ischemia or herniation. Rapid rises in the ICP can lead the *Cushing reflex* of hypertension, bradycardia, and respiratory irregularities. This triad is classic for an acute rise in ICP, but is seen in only one-third of cases, and is more common in children than adults.

Traumatic Brain Injury

TBI results from either direct or indirect forces to the brain matter. Direct injury is caused immediately by the forces of an object striking the head or by penetrating injury. Indirect injuries are from acceleration/deceleration forces that result in the movement of the brain inside the skull. These injuries are caused by the shearing forces generated by the variable movements of different areas of the brain against one another and by the impact of the brain against the skull.

PRIMARY INJURY   TBI is further described as either primary or secondary injury. Primary neuronal damage occurs immediately at impact and is dependent upon the cause and severity of the inciting event. These injuries are irreversible and therefore prevention of the injury event and mitigation of the injury forces applied to the brain are the only means to reduce morbidity and mortality. Preventive measures include safer roads, barriers to prevent falls, and gun control legislation. In addition, bicycle and motorcycle helmets, seatbelts, airbags, and soft surfaces on playgrounds are effective in reducing the morbidity and mortality from TBI.

SECONDARY INJURY   Secondary damage occurs from minutes to days after the event. Secondary injuries result from either intracranial or systemic causes. Secondary intracranial injuries are the result of neurophysiologic and anatomic changes at the cellular level. Besides the direct damage to cells, secondary injuries cause cerebral edema that, along with mass lesions such as epidural and subdural hematomas, increases the ICP. [7]

Systemic Causes   Once an injury has occured, the greatest benefit for patients can be provided by preventing the systemic causes of secondary injury. These include correcting hypoxemia, hypotension, anemia, hyperglycemia, and hyperthermia, and evacuation of intracranial masses. Hypotension (SBP <90) and hypoxemia (Po$_2$ <60) have been associated with a doubling of TBI mortality. [8] Anemia (hematocrit <30 percent) also leads to increased mortality due to decreased oxygen-carrying capacity. Patients with acute subdural hematomas have a 30 percent mortality rate if operated on within four hours compared to a 90 percent mortality rate after four hours. [9]

BRAIN HERNIATION   When intracranial pressure increases beyond the capability of physiologic and limited physical compensation, brain herniation can occur. There are four major brain herniation syndromes: uncal and central transtentorial, cerebellotonsillar and upward posterior fossa. The most common site of herniation occurs when the uncus of the temporal lobe is displaced inferiorly through the medial edge of the tentorium (Fig. 247-2). This is usually due to an expanding lesion in the temporal lobe or lateral middle fossa. Uncal transtentorial herniation leads to compression of the third (occulomotor) nerve, causing an ipsilateral fixed and dilated pupil. Further herniation compresses the pyramidal tract leading to contralateral motor paralysis. In 20 percent of cases, the pupillary changes are contralateral, or motor changes are ipsilateral, so decompressive trephination ("burr holes") should be bilateral when trephination on the expected side does not yield expected results.
FIG. 247-2. Anterior view of transtentorial uncal herniation caused by a large hematoma. Note the skull fracture overlying the hematoma.

Central transtentorial herniation is less common and occurs with midline lesions in the frontal or occipital lobes, or in the vertex. The most prominent symptoms are initial bilateral pinpoint pupils, bilateral Babinski's signs and increased muscle tone. This is followed by fixed midpoint pupils, prolonged hyperventilation, and decorticate posturing.

Cerebellotonsillar herniation occurs when the cerebellar tonsils herniate through the foramen magnum. This causes pinpoint pupils, flaccid paralysis, and sudden death. Upward transtentorial herniation results from a posterior fossa lesion and leads to a conjugate downward gaze with absence of vertical eye movements, pinpoint pupils, and rapid death.

THE CLINICAL SPECTRUM OF TBI

The Glasgow Coma Scale (GCS) was developed as a standardized scoring system allowing reliable interobserver neurologic assessment of patients with head injuries. [10] An accurate GCS score can only be obtained after resuscitation. A GCS during the initial resuscitation phase has limitations and may be artificially low. The postresuscitation GCS is used to categorize the severity of traumatic brain injuries and is based upon three factors: eye opening, verbal function, and motor function

([Table 247-1](#)). The best response in a stabilized patient from each area is added for a score that ranges from 3 to 15. The GCS for intubated patients cannot be assessed for verbal response, and paralyzed patients cannot be assessed for any of the three categories. The following recommendations are based on nonintubated, nonsedated postresuscitation GCS. A GCS of less than 9 is considered a severe TBI, moderate is 9 to 13, and mild is 14 to 15.

TABLE 247-1   The Glasgow Coma Scale for All Age Groups

Mild TBI

Mild TBI traditionally included patients with a GCS of 13. But studies have shown that 38 percent of patients with a GCS of 13 have findings on CT scan and 8 percent require neurosurgical intervention. Only 10 percent of patients with a GCS score of 15 will have positive CT scans, less than 1 percent will require surgery. [11] Therefore, most authors now include patients with a GCS of 13 in the moderate TBI group.

Mild TBI accounts for 70 to 80 percent of all patients with head injuries seen in the emergency department. These injuries have been increasingly recognized as a significant cause of long-term morbidity. Furthermore, approximately 3 percent of patients presenting with mild TBI may "talk and deteriorate" within 48 h postinjury. [12]

With a report of a blow to the head, mild TBI patient presentations range from asymptomatic to confusion or amnesia for the event. Brain CT scans are indicated for almost all patients with a GCS of 14 or less. For those with a GCS of 15, specific symptoms or physical findings indicate the need for a CT scan. These include a reported loss of consciousness or posttraumatic seizure, a history of a coagulopathy, vomiting or amnesia ([Fig. 247-3](#)). Physical findings indicating the need for a brain CT include a skull fracture, large subgaleal swelling, focal neurologic findings, unexplained asymmetric pupils, distracting injuries or intoxication. [13]

FIG. 247-3. Algorithm for the evaluation and treatment of mild brain trauma.

Patients with an initial GCS score of 15 that is maintained, and a normal CT scan may be discharged home. Those with a positive CT scan require neurosurgical consultation and admission. Admitting patients with mild TBI for observation without a CT scan should be done with caution, as patients may rapidly deteriorate requiring an emergent CT scan and neurosurgical intervention. This delay in identifying an intracranial mass may increase morbidity and mortality. It has been suggested that the most cost-effective and prudent approach is to CT scan these patients as part of the emergency department evaluation and to discharge those with negative scans and normal exams, rather than admitting them for observation. [14]

Patients with an initial GCS score of 14 and a normal CT scan should be observed in the emergency department for 6 to 12 h. This group can be discharged home if they remain neurologically intact and improve their GCS score to 15. Any patient discharged home should have a reliable home companion who can competently carry out appropriate head injury instructions.

Most mild TBI patients return to full recovery within weeks after the injury and by one year, 85 to 90 percent are effectively recovered. Unfortunately, 10 to 15 percent will continue having complaints such as impaired memory, inability to concentrate, headaches, and dizziness. [15]

Moderate TBI

Moderate TBI (GCS 9 to 13) accounts for approximately 10 percent of patients with head injuries. Mortality rates for patients with isolated moderate TBI is less than 20 percent, but long-term disability is as high as 50 percent. Overall, 40 percent of moderate TBI patients have a positive CT scan and 8 percent require neurosurgical intervention. [16] Approximately 10 percent of all moderate TBI patients will deteriorate due to secondary brain injury and progress to severe TBI.

Most patients with moderate TBI should be admitted because of the potential for deterioration ([Fig. 247-4](#)). Those with an initial GCS of 13 who return to normal, who remain intact after a 6-12h observation period, and who have a normal CT, can be discharged to family. Those with positive CT scans need neurosurgical consultation and admission to a monitored observation unit. If an institution has inadequate facilities to properly manage these patients, they should be transferred.

FIG. 247-4. Algorithm for the evaluation and treatment of moderate brain trauma.

Severe TBI

Severe TBI (GCS <9) accounts for approximately 10 percent of all emergency department patients with TBI. The mortality of severe TBI approaches 40 percent with deaths usually occurring within 48 h. Long-term disability is common, with less than 10 percent of patients making even a moderate recovery. The management of patients with severe TBI has three primary goals: to identify other life-threatening injuries, to prevent further secondary brain injury, and to identify treatable mass lesions. Management decisions are delineated in the algorithm, (Fig. 247-5).

FIG. 247-5. Algorithm for the evaluation and treatment of severe brain trauma.

EVALUATION AND MANAGEMENT

Prehospital

The care of the head-injured patient begins in the pre-hospital setting with EMS personnel. Assessing the history of the event and the patient's condition and mental status immediately after the injury is important. Securing the patient's airway and cervical spine, establishing IV access, and controlling bleeding are the initial priorities. Hypoxia and hypotension need to be identified and corrected rapidly on the scene. As discussed earlier, hypotension (SBP <90 mmHg) has been associated with a significant increase in mortality. Patients with isolated severe head trauma resuscitated with 250 cc of hypertonic (7.5%) saline in the prehospital setting had a significantly higher SBP on arrival to the emergency department and significantly decreased mortality rate when compared to those resuscitated with lacerated ringers alone.[17] A retrospective review of 169 consecutive TBIs found that patients with more severe TBIs tended to have higher admission and postoperative glucose values, and patients with glucose levels greater than 150 mg/dL had worse neurologic outcomes.[18] In animal models, hyperglycemia may aggravate ischemic neurologic injury. However, "separation of cause and effect is difficult because hyperglycemia constitutes a hormonally mediated response to more severe injury."[19] Therefore, it is recommended that glucose should not be administered without first checking a blood glucose finger stick in the comatose trauma patient.

Emergency Department

The ED physician should follow ATLS protocols for the evaluation and stabilization of all trauma patients. Airway control with cervical spine stabilization, breathing, and circulation are the first priorities. Only after the ABCs are secure can a neurologic and mental status examination be conducted to evaluate disability. Exposure of the patient of identify other life-threatening abnormalities can then be completed. Early recognition and treatment of hypoxemia, hypotension, and anemia are the hallmark to reducing morbidity and mortality from TBI.

HISTORY   A careful history is important for all patients with TBI. For the unconscious patient, the past medical history and the patient's baseline mental status must be obtained from the paramedics, bystanders, or the family. Important historical points include the mechanism of injury, the patient's condition before and after the trauma, the past medical history and the recent use of drugs or alcohol. Important information regarding the condition after the injury includes the length of the loss of consciousness, vomiting and if seizure activity occurred. A history of anticoagulant use or a coagulopathy must be determined for all patients. Potential for associated unidentified injuries conditions should be sought. These include entities such as hypothermia, inhalation injuries, and toxic exposures including carbon monoxide.

AIRWAY/BREATHING   Hypoxia, defined as a P_{O_2} <60 mmHg, increases mortality from TBI. All patients with severe TBI require intubation and ventilation with 100 percent O_2. Because cervical fractures are seen in 3 to 4 percent of patients with TBI, in-line cervical spine stabilization is essential. Orotracheal rapid sequence intubation (RSI) is preferred because when performed properly using appropriate agents the patient's physiology is optimized, increased ICP is prevented and it has the lowest complication rate. The ideal induction agent should both blunt the increase in ICP and yet not decrease the MAP (Table 247-2). Barbiturates have been shown to decrease ICP and decrease cerebral metabolic oxygen demand. Therefore, the use of a short-acting barbiturate as an induction agent and not for long-term barbiturate coma may be considered. Thiopental in a dose of 3 to 5 mg/kg has advantages of being both rapid in onset of action and short-acting. Unfortunately, thiopental is a cardiovascular depressant. Patients who are hypotensive should either receive a lower dose, 0.5 to 1 mg/kg or another inducting agent, such as etomidate (0.3 mg/kg). Ketamine should be avoided because it increases ICP. Short-acting paralytic agents are preferred to facilitate serial neurologic exams that can identify worsening brain injury. Although succinylcholine (1.5 mg/kg) can cause a rise in the ICP, this may be blunted by administering a defasciculating dose of vecuronium (0.01 mg/kg) two to three minutes prior to succinylcholine. These same guidelines should be followed for comatose patients, who are also susceptible to increases in ICP with laryngoscopy and intubation. Lidocaine should also be used as a pretreatment agent because of its potential to prevent hemodynamic changes (Table 247-2). Although nasotracheal intubation is not contraindicated in TBI, it should rarely be used for patients with TBI due to its higher complication rate, lower success rate, and potential for marked increase in ICP if not carried out perfectly. In the presence of a basilar skull fracture, nasotracheal intubation also leads to an increased risk of meningitis.

Pretreatment (given 2–3 min prior to paralysis)	
Agent	Purpose
Lidocaine 1.5 mg/kg IV	Hemodynamic stability
Fentanyl 3–5 microgram/kg IV	Hemodynamic stability and analgesia
Vecuronium (0.01 mg/kg) or pancuronium (0.01 mg/kg) IV	Defasciculating
Paralysis and induction agents	
Thiopental 3–5 mg/kg (normotensive) or 0.5–1 mg/kg (hypotensive)	Sedation
Succinylcholine 1.5 mg/kg	Paralysis

TABLE 247-2   Agents for Rapid Sequence Intubation of Patients with Severe TBI

CIRCULATION   Once the airway is secured, aggressive fluid resuscitation may be required to prevent hypotension and the resulting secondary brain injury. Studies have shown an increase in mortality from 27 to 50 percent for patients with isolated TBI who had a single episode of systolic blood pressure of less than 90 mmHg. Adequate fluid resuscitation has not been shown to increase ICP. Guidelines recommend that the MAP be maintained at 90 mmHg (systolic blood pressure of 120 to 140 mmHg) to achieve adequate cerebral perfusion.[20] Hypotension in the setting of trauma should generally be addressed with vigorous fluid and blood replacement. The use of pressors is potentially dangerous and seldom indicated. However, in the absence of shock from volume loss, pressors may be used in an effort to maintain

adequate cerebral perfusion. In these cases, monitoring should include cardiac output, continuous arterial blood pressure, and, optimally, intracranial pressure measurement. The pressors indicated for raising MAP to maintain cerebral perfusion are norepinephrine and phenylephrine. Norepinephrine dosages range from 2 to 80 µg/min and should be begun low and titrated slowly to the desired effect. Phenylephrine doses range from 40 to 180 µg/min and are similarly titrated.

Hypertension is a critical finding and must be taken as a Cushing's response in the setting of head injury. The finding of hypertension and bradycardia should initiate measures to decrease intracranial pressure. If hypertension exists independent of increased intracranial pressure, then the systemic pressure should be lowered by no more than 30 percent of the mean arterial blood pressure by using nipride. Pressor agents may be needed to maintain the MAP, although this has not been formally studied. Anemia is also associated with increased mortality. Therefore, external and internal bleeding need to be controlled quickly and the hematocrit should be kept above 30. Head injury alone rarely produces hypotension (except as a preterminal event). Exceptions to this include hypovolemic shock in infants due to epidural bleeding or subgaleal hematoma, or massive blood loss from scalp lacerations in any age group.

DISABILITY   **The Glasgow Coma Scale**   The initial neurologic examination of ATLS is to assess the level of consciousness using the AVPU system: *Alert*, responds to *Verbal* stimuli, responds to *Painfu_l_* stimuli or is *Unresponsive.* This same assessment provides most of the information needed to calculate the Glasgow Coma Scale. The GCS taken at any time does not replace an appropriate neurologic exam.

The Neurologic Exam   Other important aspects of the neurologic examination in the initial trauma evaluation include assessing pupils for size, reactivity, and anisocoria. Motor function, cranial nerve function, deep tendon reflexes, and evaluation of sensory changes are also useful to indicate the presence of an intracranial injury. Brainstem function in the unresponsive patient is assessed by observing respiratory pattern and eye movements. Oculovestibular (cold calorics) and oculocephalic (doll's eyes) responses are not checked until the cervical spine has been fully cleared.

Pupils are assessed for size and reactivity. A fixed and dilated pupil is highly suggestive of an ipsilateral hematoma with uncal herniation that requires rapid operative intervention. Direct ocular trauma should also be assessed. Bilateral fixed and dilated pupils suggest poor tissue perfusion, (i.e., hypoxemia) bilateral uncal herniation or drug effect, whereas bilateral pinpoint pupils suggest either opiate use or a pontine lesion.

Altered motor function can indicate brain, spinal cord or peripheral nerve injuries. Careful attention is paid to signs of increasing ICP and herniation. Movement in unresponsive patients is assessed by the application of painful stimuli. Decorticate posturing (abnormal upper extremity flexion and lower extremity extension) is indicative of an injury above the midbrain. Decerebrate posturing (abnormal arm extension and internal rotation with wrist and finger flexion and internal rotation and extension of the lower extremities) is a result of a more caudal injury and a worse outcome.

After the primary survey a secondary survey is needed to identify other significant injuries. Up to 60 percent of patients with severe TBI will have other major injuries.

DIAGNOSTIC RADIOGRAPHY FOR TBI   All patients with moderate to severe TBI require urgent head CT scan after stabilization. Delays in obtaining a CT scan can lead to a catastrophic delay in emergent neurosurgical interventions. Therefore, if the patient with moderate TBI is uncooperative or combative, intubation using RSI is often the best option. If this is undertaken, the best neurologic exam possible just prior should be performed, and may be valuable to subsequent neurosurgical consultation. Prior to the availability of CT scanning, skull films were the standard diagnostic test. Skull films will be positive in 5 percent of patients with mild TBI. Unfortunately, they often miss basilar skull fractures and do not reliably detect underlying intracranial pathology. CT scans are much more accurate and useful.

There is increasing agreement about the need to scan patients with a GCS of less than 14, but debate remains regarding the indicators for CT scanning for patients with a GCS of 15. Specific signs and symptoms can be indicative of intracranial lesions in these patients. These include a history of loss of consciousness, seizure, vomiting, alcohol use, or physical findings of large subgaleal swelling or amnesia. If any of these findings is present, patients shall have a less than 5 percent chance of having an intracranial lesion and a less than 1 percent chance of requiring neurosurgical intervention. Those with a GCS of 15 and none of these findings have not been shown to have adverse outcomes. Patients on anticoagulants or with coagulopathies are also at higher risk and should be scanned.

Control of the agitated patient with head injury is critical in the evaluation and stabilization of these cases. Haloperidol easily crosses the blood-brain barrier, has few adverse respiratory or cardiac effects, and does not interfere with the neurologic exam. However, contraindications to haloperidol include coma and severe toxic CNS depression. This limits its utility in severely inebriated patients and those patients whose mental status changes may deteriorate to coma. Haldol's slow onset of 10 to 30 min, even when given IV, diminishes it's utility in the more severely agitated patients.

Midazolam has sedative, hypnotic, anxiolytic, and amnestic effects. It easily crosses the blood brain barrier, reduces intracranial pressure and augments cerebral perfusion pressure. [22] Midazolam also causes skeletal muscle relaxation and is an effective anticonvulsant. However, it will not control psychotic symptoms. Its use is contraindicated in severe hypotension and may be limited by respiratory depression. Admission of a continuous infusion may allow maintenance of adequate sedation while preserving an intact airway. However, close monitoring is required for patients on midazolam infusion; airway protection by intubation is often indicated. Midazolam's rapid clearance allows for an adequate neurologic exam within minutes of discontinuation.

Propofol is an intravenous sedative hypnotic with onset of action less than 1 min with a duration of less than 10 min. Propofol decreases elevated intracranial pressure while not significantly decreasing cerebral perfusion pressure. [23] For conduction and maintenance of sedation, a variable rate infusion method is preferable over intermittent bolus doses. Patients will generally require maintenance rates of 20 to 75 µg/kg/h during the first 10 to 15 min. Dose may be decreased to 25 to 50 µg/kg/h and titrated to clinical response. Propofol is contraindicated with cardiovascular instability and hypotension. It is recommended for use in patients who are intubated and mechanically ventilated.

Treatment for Increased ICP

It is critical that intracranial pressure be maintained at less than 20 to 25 mmHg. Above this value results in a significant increase in morbidity and mortality. Several strategies may be used to achieve this goal. All patients with severe TBI and evidence of increased ICP should have the head of the bed elevated to 30 degrees, adequate volume resuscitation to a MAP of 90 mmHg, and maintenance of adequate arterial oxygenation. After these steps several other treatment modalities may be used to lower intracranial hypertension.

Hyperventilation has been widely used to reduce ICP but it is no longer recommended as a prophylactic intervention. [6] Because of the extreme sensitivity of the cerebral vasculature to CO_2 levels, hyperventilation leads to vasoconstriction that reduces ICP within 30 s. Unfortunately, hyperventilation and the resultant vasoconstriction can also cause cerebral ischemia. Hyperventilation should be reserved for head-injured patients with signs of increasing ICP (such as unilateral dilated pupil, motor posturing, and worsening mental status) despite other therapeutic measures (i.e., a last resort). If hyperventilation is used, it should be initiated as temporary measure and the P_{CO_2} should be monitored closely and returned to the 30 to 35 mmHg range as soon as possible. [6]

Osmotic agents such as mannitol reduce ICP by osmotic diuresis with an onset within 30 min and lasting approximately 6 to 8 h. Mannitol has the additional benefit of expanding volume, initially reducing hypotension, and improving the blood's oxygen-carrying capacity. The recommended dose is 0.25 g/kg to 1 g/kg. There is no dose-dependent effect seen with mannitol; therefore, some authors advocate the lower range of the suggested dose. However, due to the diuresis, over time there will be a net intravascular volume loss, requiring hemodynamic monitoring. The Brain Trauma Foundation recommends that CSF drainage is preferable to mannitol. In the ED, where an IC catheter may not be readily available, mannitol may be used.

In addition to the above measures, monitoring of ICP should be performed for all patients with evidence of increased ICP, herniation, and a GCS score of less than 8. A ventricular catheter offers the best method to directly monitor ICP and thus calculate CPP. Under this setting, any rise in ICP above 20 to 25 mm HG may be reduced by CSF drainage. This treatment has the most favorable risk-to-benefit ratio. If CSF drainage is not effective in reducing ICP, then mannitol should be administered, assuming adequate MAP. Barbiturates have been shown to reduce cerebral metabolic rate. However, the use of barbiturate coma is rarely indicated in the emergency department as its effect occurs relatively late. The recommended dose of pentobarital is 10 mg/kg over 30 min. Steroids have no proven role in treating patients with TBI. Studies addressing this issue have not demonstrated improved outcome with their use.

EMERGENCY DECOMPRESSION   When other methods to control the ICP have failed, patients with signs of herniation may need emergency decompression by trephination ("burr holes"). CT scanning before attempting trephination is recommended to localize the lesion and direct the decompression site. If CT scan is unavailable, or the patient is unstable for CT due to signs of rapidly progressive neurologic deterioration and herniation, then trephination should be considered.

As a final premorbid action for rapidly increasing intracranial pressure from traumatic hematoma expansion uncontrolled by medical therapy, emergency cranial surgical decompression may be attempted. If the cervical spine is stable, then optimally the patient's head is rotated so that the side with the dilated pupil is superior. The head should be stabilized and supported to prevent movement. A temporal burr hole should be attempted first by making a 4-cm vertical skin incision two finger-breadths anterior and three finger-breadths superior to the anterior tragus of the ear. When skull is reached, then a handheld drill should be inserted and drilled until the inner skull table is reached. A thin rim of bone should be left and scooped out under direct visualization with a curette.

If the temporal burr hole fails to yield blood or reverse signs of herniation then a frontal burr hole three finger-breadths from the midline and three finger-breadths from the hairline may be made. Should the second burr hole fail to improve the patient's condition, a final parietal burr hole can be placed four finger-breadths behind the frontal hole. Rarely, in cases with a high frontal injury, false lateralizing signs can occur due to Kernihan's notch. In these cases, the entire procedure should be repeated on the opposite side of the skull.

MANAGEMENT OF SPECIFIC INJURIES

Scalp Laceration

Because of a rich blood supply, loose connective, tissue and relatively loose attachment to the pericranium, scalp lacerations can lead to massive blood loss. During the resuscitation phase of trauma care, scalp hemorrhages should be controlled as rapidly as possible. If direct pressure is not effective, lidocaine with epinephrine can be infiltrated locally, and vessels can be clamped or ligated if still necessary. Early closure with irrigation and debridement is the best method to control bleeding. Wounds should be carefully examined prior to closure. Blood clots and debris should be cleaned away to examine for underlying fractures and galeal lacerations. Large galeal disruptions should be repaired, but small one can be left alone.

Skull Fracture

Skull fractures are usually categorized by location (basilar vs. the skull convexity), pattern (linear, depressed, or comminuted) and whether they are open or closed. Up to 50 percent of patients with skull fractures, including depressed fractures will not have significant loss of consciousness or any neurologic findings. This is why a careful physical exam and wound exploration is essential. Complicated skull fractures include those that are open or depressed, those that involve a sinus, and those that cause intracranial air (pneumocephalus).

LINEAR AND COMMINUTED FRACTURES   The management of linear and simple comminuted skull fractures is the same. Even open fractures (fractures with an overlying laceration) in and of themselves do not usually indicate admission or surgical exploration. However open fractures require careful cleaning and repair. Wounds should be explored gently so as not to drive bone fragments into the brain. A neurosurgeon should be consulted and a head CT scan performed to ensure that there is no underlying brain injury. Closure of these wounds should be undertaken only in consult with a neurosurgeon prior to CT scan. The use of prophylactic antibiotics following an open skull fracture is controversial.

Particular care should be taken in evaluating fractures that cross the middle meningeal artery or a major venous sinus. Occipital fractures also require aggressive evaluation, as they are associated with a 33 percent complication rate, including increased risk of subarachnoid hemorrhage. Fractures that are depressed beyond the thickness of the skull require operative repair. Depressed skull fractures are associated with an increased risk of intracranial injury, infections, and early seizures. CT scans are, therefore, indicated for all of these patients.

BASILAR SKULL FRACTURE   Basilar skull fractures occur in 3.5 to 24 percent of all patients with head injuries. The most common type of basilar skull fracture is longitudinal through the petrous portion of the temporal bone. This usually involves the external auditory canal and the tympanic membrane. These fractures are commonly associated with a torn dura leading to CSF leakage and a risk of traumatic meningitis. Signs and symptoms associated with basilar skull fractures include CSF otorrhea or rhinorrhea, mastoid ecchymosis (Battle's sign), periorbital ecchymoses (raccoon eyes), hemotympanum, vertigo, decreased hearing or deafness and seventh nerve palsy. Periorbital and mastoid ecchymoses are often absent on presentation to the ED, but develop gradually over the first hours after an injury. A nasal discharge that leaves a large clear ring when dripped onto a paper towel, or that is positive for glucose, indicates a basilar skull fracture with CSF leak. In general, patients with a skull fracture should be hospitalized. Approximately 20 percent of patients with CSF fistulas develop meningitis. A recent meta-analysis supports the use of prophylactic antibiotics by demonstrating a significant reduction in meningitis for patients receiving prophylactic antibiotics. [24] Administration of antibiotics should only be done in consultation with either a neurosurgeon or head and neck surgeon. Common organisms responsible for meningitis in these patients are *Pneumococcus*, *Streptococcus*, and *Haemophilus influenzae*. If prophylactic antibiotics are instituted, they should have broad coverage with good penetration into the meninges. A third-generation cephalosporin such as ceftriaxone at 1 to 2 g per day is a reasonable choice. Most CSF leaks will resolve spontaneously within a week.

Cerebral Contusion/Intracerebral Hemorrhage

Contusions are one of the most frequent types of TBI (Fig. 247-6). Contusions most commonly occur in the subfrontal cortex, the frontal and temporal lobes, and occasionally in the occipital lobes. The are often associated with a subarachnoid hemorrhage. Contusions may occur at the site of the blunt trauma or the opposite site of the brain, known as a "contrecoup" injury.
FIG. 247-6. Cerebral contusion with associated hemorrhage occurring subfromtally on the left, in the posterior temporal region.

Intracerebral hemorrhage can occur days after significant blunt trauma, often at the site of resolving contusions. This complication is more common with patients with a coagulopathy. CT scans in the immediate postinjury phase are often normal.

Subarachnoid Hemorrhage

Traumatic subarachnoid hemorrhage (tSAH) results from the disruption of subarachnoid vessels and presents with blood in the CSF (Table 247-3). In one large European head-injury study, one-third of all patients with moderate to severe head injuries demonstrated traumatic subarachnoid hemorrhage on early CT scans, [25] making tSAH the most common CT abnormality finding in patients with moderate to severe TBI. The overall incidence of tSAH is as high 40 percent when including CT abnormalities. When the CT scan is positive for tSAH, the amount of blood seen on the CT scan is inversely related to the presenting GCS and percent of positive outcomes. The outcome of patients with tSAH was significantly worse than that of patients with no SAH on first CT scan. Overall, 60 percent of the former group resulted in an unfavorable outcome defined as death, persistent vegetative state, or severe disability compared to only 30 percent in the latter group. Mortality in the early tSAH group was 42 percent compared to 14 percent in the no SAH group. [25] Recent data have demonstrated the use of nimodipine at 2 mg/h for 7 to 10 days followed by 360 mg daily until day 21 to significantly lower this unfavorable outcome by 55 percent compared to the placebo group. [26]

Type of Patient	% of TBI	Anatomic Location	CT Findings	Common Cause	Classic Symptoms
Epidural	Young, rare in the elderly and age <2	1	Potential space between skull and dura mater	Biconvex, football shaped hematoma	Skull fracture with tear of the middle meningeal artery	Immediate LOC with a "lucid" period prior to deterioration (only occurs in 20%)
Subdural	More risk for the elderly and alcoholics	25–30	Space between dura mater and arachnoid	Crescent or sickle-shaped hematoma	Acceleration-deceleration with tearing of the bridging veins	Acute, rapid LOC/lucid period possible. Chronic: altered MS and behavior with gradual decrease in consciousness
Subarachnoid	Any age group following blunt trauma	35–40	Subarachnoid	Blood in the basilar cisterns and hemispheric sulci and fissures	Acceleration-deceleration with tearing of the subarachnoid vessels	Mild to moderate TBI with meningeal signs and symptoms
Contusion/Intracerebral hemorrhage	Any age group following blunt trauma	20–40	Usually anterior temporal or posterior frontal lobe	May be normal initially with delayed "bloom"	Severe or penetrating trauma, shaken baby syndrome	Symptoms range from normal to unconscious

TABLE 247-3   Intracranial Hematomas

Patients with tSAH can present with mild to severe TBI. Those with isolated tSAH often present with a headache and photophobia and mild meningeal signs. A CT scan is generally diagnostic but care must be taken on reports of delayed intracranial hematomas, especially subdural hematomas, exist in the literature for patients who exhibited nonfocal neurologic exams with negative initial CT scans.[27] Unfortunately, delayed findings may not be detected for one to two months after initial insult. Generally, scans performed six to eight hours or more after injury will demonstrate tSAH. However, delays can occur in 3 to 5 percent of patients. Careful instructions and discharge in the care of a competent adult are therefore necessary to detect these delayed injuries. Referral for reexamination by a physician in 24 to 48 h is usually required for all patients with an initial negative CT scan. The disposition of any patient with tSAH requires immediate neurosurgical consultation and admission to an intensive care unit.

Epidural Hematoma
