U.S. citizens and residents who are exposed to rabies while traveling in countries where rabies is endemic may sometimes receive postexposure prophylaxis with regimens or biologics that are not used in the United States. If postexposure prophylaxis is begun outside the United States using a non-FDA-approved regimen or biologic of nerve tissue origin, it may be necessary to provide additional treatment when the patient reaches the United States. [19] State and local health departments should be contacted for specific advice in such cases. The major modification used abroad, usually in an attempt to reduce cost, is the substitution of various schedules for intradermal injection or the use of non-FDA-approved vaccines.

Pregnancy

Adverse pregnancy outcomes or fetal abnormalities have not been associated with rabies vaccination. [30,31] Because of the potential consequences of inadequately treated rabies exposure, and because adverse events have not been associated with rabies postexposure prophylaxis during pregnancy, pregnancy is not considered a contraindication to rabies postexposure prophylaxis or HRIG. [19] If there is substantial risk of exposure to rabies, preexposure prophylaxis may also be indicated during pregnancy.

Children

The risk of rabies and the management of postexposure prophylaxis in children have been reviewed. [26,32] In infants and children, the dose of rabies vaccine for preexposure and postexposure prophylaxis is the same as that recommended for adults (Table 141-3). The dose of HRIG for postexposure prophylaxis is based on body weight. For small children with multiple bites, the calculated dosage of HRIG may be insufficient to infiltrate all wounds. However, sterile saline can be used to dilute the volume twofold or threefold to permit thorough infiltration. [26]

CLINICAL DISEASE

Rabies virus causes acute encephalitis in all warm-blooded hosts, including humans, and the outcome is almost always fatal. While patients with rabies may manifest a variety of clinical symptoms and signs, the disease tends to follow a characteristic course (Table 141-4).

TABLE 141-4 Natural History of Clinical Rabies in Humans

Rabies infection is most commonly initiated by the bite of a rabid animal. Most commonly, the incubation period ranges from 20 to 90 days. [9] However, incubation periods have been reported as short as 4 days and as long as 19 years. Incubation periods exceeding one year have been well documented in the literature. [33] For patients who died from rabies in the United Sates between 1980 and 1996 and for whom a definite animal bite occurred, the median incubation period was 85 days (range: 53 to 150 days).[18] The incubation period has been reported to be shorter when the site of bite is on the head than when it is on an extremity. [9]

During the prodromal period, the symptoms and signs of rabies are often nonspecific. They include fever, sore throat, chills, malaise, anorexia, headache, nausea, vomiting, dyspnea, cough, and weakness. Early in the course some patients may report symptoms suggestive of rabies such as limb pain, limb weakness, and paresthesias at or near the presumed exposure site. Nonspecific neurologic symptoms may be reported including apprehension, anxiety, agitation, irritability, depression, and psychiatric disturbances.

The prodrome merges into the acute neurologic phase, which begins when the patient develops objective signs of central nervous system disease. Two major forms of acute neurologic disorder have been described: furious and paralytic. Furious rabies is noted in about 80 percent of patients and is characterized by hyperactivity, disorientation, hallucinations, and bizarre behavior. Periods of hyperactivity may alternate with periods of calm. Signs of autonomic dysfunction are frequently present and include hyperthermia, tachycardia, hypertension, and excessive salivation. About 50 percent of patients have classic hydrophobia in which attempts at drinking fluids result in severe spasms of the pharynx, larynx, and diaphragm. Paralytic rabies is noted in about 20 percent of patients and is characterized by paralysis, which may be maximal in the extremity that was bitten, diffuse, and symmetrical, or it may ascend in a pattern similar to Guillain-Barré syndrome. Accompanying signs may

include fever and nuchal rigidity.

Coma almost always occurs within 10 days of the onset of symptoms. In the series reported by Noah and colleagues, the median duration of illness was 19 days (range: 7 to 28 days).[18] All patients in the series died. Death occurs from a variety of complications including pituitary dysfunction, seizures, respiratory dysfunction with progressive hypoxia, cardiac dysfunction with dysrhythmias and arrest, autonomic dysfunction, renal failure, and secondary bacterial infections.

Rarely have patients recovered from rabies, but in all such cases the patient had received either postexposure or preexposure prophylaxis with duck embryo vaccine or suckling mouse brain vaccine before the onset of symptoms. Despite intensive therapy, no persons without postexposure prophylaxis have survived in the United States since 1980.

DIAGNOSIS AND TREATMENT

The diagnosis of rabies is frequently made postmortem. This occurs because of the rarity of the disease, the increasing numbers of persons without an obvious exposure, and clinical confusion with other disorders. Important clues to diagnosis include a history of an animal bite and the development of the pathognomonic signs of hydrophobia and aerophobia. Tetanus should not be confused with rabies, because in tetanus the mental status is usually normal and the cerebrospinal fluid is normal. Other diseases that may be confused with rabies include poliomyelitis, Guillain-Barré syndrome, transverse myelitis, postvaccinial encephalomyelitis, intracranial mass lesions, cerebrovascular accidents, and poisoning with atropine-like compounds.

During the incubation period of rabies, no diagnostic test is available for either animals or persons that will indicate infection. Routine laboratory tests are of limited value for the diagnosis of rabies. Specific tests are required to diagnose rabies. Because no single test is uniformly informative, a battery of tests is commonly recommended. Early in the course of illness, the most reliable diagnostic test is a nuchal skin biopsy with immunofluorescent rabies antibody staining. Once clinical symptoms develop, a brain biopsy is universally positive when properly stained, but the invasive nature of this test precludes routine use. RFFIT may be performed on serum to detect rabies antibodies. However, while serum antibody may be present as early as day 5 of clinical illness, it may be absent after 10 to 14 days or more. Rabies virus has been isolated antemortem from human saliva, brain tissue, cerebrospinal fluid, urine, and tracheal secretions. Recently, nested PCR of RNA extracted from saliva has been shown to be a sensitive test. However, further study is required before this test can replace virus isolation as a standard antemortem diagnostic test.

No specific therapy exists to treat rabies. Treatment is directed at the clinical complications of the disease. [9]

142 MALARIA

Jeffrey D. Band

With the increase in international travel and the continued shift of travel to tropical locales, it is not surprising that physicians are seeing more patients with infectious diseases acquired in the tropics. Malaria, a protozoan disease transmitted by the bite of the *Anopheles* mosquito, remains one of the most significant of these. Four species of the genus *Plasmodium* infect humans: *P. vivax, P. ovale, P. malariae,* and *P. falciparum.* Annually, over 250 million persons develop malaria, and more than 2.5 million persons die.[1] The incidence of malaria has been increasing in recent years despite worldwide aggressive attempts at control. Not only is the mosquito vector becoming less susceptible to a variety of insecticides, but *Plasmodium falciparum*—the parasite responsible for the most deadly form of malaria—is becoming increasingly resistant to antimalarial medications.

Malaria, especially disease due to *P. falciparum,* represents a medical emergency in any nonimmune host. Its early manifestations are largely nonspecific and can mimic other infectious diseases. Failure to diagnose infection rapidly can be disastrous. Likewise, failure to use specific antimalarial agents to which the individual strain is susceptible can result in early death. A diagnosis of malaria must be considered in any person returning from the tropics with an unexplained febrile illness. Questions regarding recent travel should become routine in emergency departments.

EPIDEMIOLOGY

Malaria transmission occurs in large areas of Central and South America, the Caribbean, sub-Saharan Africa, the Indian subcontinent, Southeast Asia, the Middle East, and Oceania. Certain species may predominate in a given geographic area.[2] For example, *P. vivax* is more common in the Indian subcontinent and in Central America, whereas *P. falciparum* is the most prevalent form in Africa, Haiti, and New Guinea.

The risk of contracting malaria, which varies considerably between regions, is largely dependent on the intensity of transmission in both urban and rural areas, and, for travelers, on the itinerary and time and type of travel. From 1990 to 1994, the Centers for Disease Control and Prevention reported 2580 cases of malaria among US civilians.[3] Of the more than 500 cases in 1994, a total of 303 (58 percent) were acquired in sub-Saharan Africa, 102 (20 percent) in Asia, 74 (14 percent) in the Caribbean and Central America, 24 (5 percent) in Oceania, and only 9 (2 percent) in South America. *Plasmodium vivax* accounted for 46 percent of all cases, and *P. falciparum* for another 46 percent. Mixed infections were uncommon, representing less than 1 percent of all cases. Thus, more than half of all cases of malaria, including the majority of cases due to *P. falciparum,* were acquired from travels in sub-Saharan Africa. Yet, for every traveler to sub-Saharan Africa, at least 10 travelers visit potential malarious areas of Asia and South America each year. Clearly, the intensity of exposure appears to be much higher in sub-Saharan Africa.

Resistance of *P. falciparum* to chloroquine continues to spread (Table 142-1).[4] In addition, strains of *P. falciparum* are resistant to other chemotherapeutic agents, including pyrimethamine-sulfadoxine, quinine, mefloquine, doxycycline, and new agents, including halofantrine and artesunate (the latter two agents are not available in the United States). Recently, strains of *P. vivax* have been isolated from patients who have failed chloroquine therapy.[5] Prior to 1990, no strains of *P. vivax, P. ovale,* or *P. malariae* were resistant to chloroquine.

TABLE 142-1   Geographic Distribution of Malaria, Including Resistant Strains

PATHOPHYSIOLOGY

The organism is transmitted primarily by the bite of an infected female anopheline mosquito. This vector is most frequently found in tropical and subtropical regions below 8200 ft (2500 m) above sea level. Plasmodial sporozoites are injected into the host's bloodstream during the mosquito's blood meal and are carried directly to the liver. The hepatic parenchymal cells are invaded, and asexual reproduction of the parasite begins (preerythrocytic schizogony or exoerythrocytic stage). As thousands of daughter merozoites are formed, the parenchymal liver cell ruptures, releasing daughter merozoites back into the circulation, where they rapidly invade erythrocytes (erythrocytic stage). In *P. vivax* and *P. ovale* infection, a portion of the intrahepatic forms are not released, remain dormant for months, and can later activate and cause clinical relapses.

The clinical manifestations of malaria first appear during the erythrocytic stage. Once merozoites enter this stage, they never reinvade the liver. Merozoites mature within the erythrocyte and take on various morphologic forms, including the early ring forms, trophozoites, and schizonts (which represent a mass of new merozoites). Eventually, the target erythrocyte lyses, and new merozoites invade uninfected red blood cells, continuing the infection and causing clinical manifestations. Lysogeny may become regular, occurring at 2- to 3-day intervals in established and untreated infections, producing the classic periodicity of symptoms.

After several cycles, a proportion of the merozoites develop into sexual forms (gametocytes). Upon ingestion by another feeding anopheline mosquito, male and female gametocytes undergo sexual reproduction and become infective sporozoites ready for their next host.

Each species of *Plasmodium* has specific characteristics, including typical morphologic forms and selective red blood cell tropism (Table 142-2). Many of these characteristics are responsible for important pathophysiologic consequences.

TABLE 142-2   Characteristics of Malaria-Causing *Plasmodium* Species

Malaria may also be transmitted by direct transfusion of infected blood or passed transplacentally from mother to fetus. In these cases, an exoerythrocytic phase is absent.

Disease ensues after an incubation period ranging from 8 days in the nonimmune and unprotected host to several weeks or more. Both incomplete suppression by partially active chemoprophylaxis and incomplete immunity can markedly prolong the incubation period to months or even years. Only the asexual intraerythrocytic parasite is responsible for the symptoms and pathophysiologic consequences. The hallmark of malaria is the recurring febrile paroxysm that corresponds to hemolysis of infected erythrocytes and release of antigenic products with activation of macrophages and production of cytokines.

Hemolysis can be high with *P. falciparum* infection, since parasitemia can be overwhelming and erythrocytes of all ages are susceptible. Parasitized erythrocytes lose flexibility and are removed in the microcirculation, with resultant obstruction and tissue anoxia of the lungs, kidneys, brain, and other vital organs. Noncardiac pulmonary edema, renal failure, and cerebral malaria may result. Sequestration accounts for the paucity of observed mature parasites in the peripheral smear of patients infected with *P. falciparum.*

In addition to prolonged high fever, hemolysis, and, in the case of infection with *P. falciparum,* obstruction to capillary flow, immunologic sequelae may also occur, resulting in glomerulonephritis, nephrotic syndrome, thrombocytopenia, and polyclonal antibody stimulation. Lastly, hypersplenism with resultant pancytopenia may occur, especially in cases of prolonged, untreated malaria.

CLINICAL FEATURES

Typically, patients develop a prodrome of malaise, myalgia, headache, and low-grade fevers, often accompanied by chills. [6] In some patients, headache, chest pains, cough, abdominal pain, arthralgias, or diarrhea may be prominent. The early manifestations are quite nonspecific and can easily become confused with a viral syndrome, influenza, hepatitis, and other less severe self-limited clinical entities. Illness usually progresses to severe chills followed by high-grade fevers accompanied by tachycardia, nausea, orthostatic dizziness, and extreme weakness. After several hours, the fever abates and the patient becomes diaphoretic and exhausted. Over time, the paroxysms of malaria—chills and fever followed by diaphoresis—may occur at nearly regular intervals that correspond to the length of the asexual erythrocytic cycles (Table 142-2). The classic paroxysms of malaria are often lacking in malaria due to *P. falciparum* or in persons who received some form of chemoprophylaxis.

The findings on physical examination are also not specific for malaria. Most patients appear acutely ill with high fevers, tachycardia, and tachypnea. Splenomegaly and tender abdomen are commonly present in advanced infection. The liver may or may not be enlarged. Features quite atypical for malaria include lymphadenopathy and a maculopapular skin rash.

Laboratory features include normochromic normocytic anemia with findings suggestive of hemolysis, a normal or mildly depressed total leukocyte count, thrombocytopenia, an elevated erythrocyte sedimentation rate, elevated lactose dehydrogenase, and mild abnormalities in liver and renal functions. Other laboratory abnormalities include hyponatremia, hypoglycemia, and a biologic false-positive VDRL.

Complications of malaria can occur rapidly in untreated infection, especially when the agent is *P. falciparum.*[7] Infections caused by any species of *Plasmodium* can result in hemolysis, splenic enlargement and, occasionally, splenic rupture. An immune-mediated glomerulonephritis is also common to all forms but tends to occur most often in *P. malariae* infection. With the ability to cause high parasitemia levels and sequestration with capillary sludging, *P. falciparum* infection can be fatal. Cerebral malaria—characterized by somnolence, coma, delirium, and seizures—is associated with mortality rates in excess of 20 percent. Reversible causes of encephalopathy must be excluded. The cerebrospinal fluid is usually normal, except for a slightly elevated opening pressure and protein concentration. A mild pleocytosis might also be present. Other life-threatening complications associated with *P. falciparum* infection include respiratory failure due to noncardiogenic acute pulmonary edema (similar to adult respiratory distress syndrome), renal failure (acute tubular necrosis), and severe metabolic abnormalities, including lactic acidosis and profound hypoglycemia. Any target organ is susceptible to the effects of severe tissue hypoxia from the cytoadherence between the parasitized erythrocyte and the vascular endothelium of the host.

The very young, the elderly, and pregnant women are at greatest risk for complications due to *P. falciparum.*

DIAGNOSIS

The definitive diagnosis is established by the visualization of parasites on Giemsa-stained thick and thin blood smears. In early infection, especially infection due to *P. falciparum,* in which parasitized erythrocytes are sequestered from the bloodstream, parasitemia may be undetectable. Also, parasitemia fluctuates over time: it generally is highest during chills and as the fever is on the rise. High fevers are schizonticidal. In highly suspicious cases, failure to detect parasitemia is not an indication to withhold therapy. Delay in the diagnosis and treatment of malaria can have disastrous results. If parasitemia is not seen in the stained thin smear, a thick smear that concentrates blood cells may provide the diagnosis[3] (Table 142-3). Extreme care in the preparation of slides is important, since debris may result in false-positive smears. If parasites are not visualized, repeated smears should be obtained at least twice daily for 2 to 3 days to exclude malaria completely. Newer molecular probes for rapid diagnosis and speciation of the invading pathogen are in development. [8,9] The two major questions to be answered by the blood smear are the degree of parasitemia present (correlates with prognosis) and whether *P. falciparum* is responsible for infection. Most patients with *P. falciparum* infection should be managed in the hospital setting, as should any patient with more than 3 percent parasitemia. Clues to the diagnosis of *P. falciparum* infection include the presence of small ring forms with double-chromatin knobs within the erythrocyte, multiply infected rings in individual red blood cells, a paucity of trophozoites and schizonts on smear, the pathognomonic crescent-shaped (banana-shaped) gametocyte, and parasitemia exceeding 4 percent. Repeated smears should be obtained daily to assess the efficacy of drug treatment.

1. Use scrupulously clean slides; manufacturers' precleaned slides may have residual debris.

2. Obtain a large drop of blood from the patient's finger by using a blood lancet.

3. Place the cleaned surface of the slide against the drop of blood; with a quick circular motion, make a film the size of a dime. Do not mix excessively or distortion will result. The thick smear should be of such depth that newsprint would be barely legible. (Let the smear air dry for 30 to 60 min.)

4. Obtain a small drop of blood from the patient's finger and, with a second clean slide, spread the blood gently over the slide. Air dry the thin film, fix it with methyl alcohol, and stain it with Giemsa stain.

5. If the thin smear is negative, examine the thick smear. Once air dried, the thick film should not be fixed prior to staining with Giemsa.

TABLE 142-3 Guidelines for Preparing Malaria Smears

TREATMENT

Therapeutic decisions are based on the severity of the illness, the agent, and whether the patient may be infected with chloroquine-resistant *P. falciparum*.[2,10] If *P. falciparum* infection can be excluded, most persons can be managed in the ambulatory setting. Close follow-up, including repeated smears, is necessary. Patients with significant hemolysis or who have underlying severe chronic medical problems that can be aggravated by high fevers or hemolysis are best hospitalized. Infected infants and pregnant women are also best managed in the hospital.

Chloroquine is the drug of choice for treatment of infection due to *P. vivax, P. ovale,* and *P. malariae.* Table 142-4 summarizes the treatment regimens for malaria. With treatment, the parasite load should decrease significantly within the first 24 to 48 h. No asexual forms of the parasite should be detectable 3 to 4 days after treatment is completed. Gametocytes, the sexual forms, which do not cause disease in the human host, may persist for several weeks after treatment and are not an indicator of treatment failure. Chloroquine has no effect on the exoerythrocytic parasites, which may be dormant in the liver with infection due to *P. vivax* and *P. ovale.* Unless terminal treatment is administered with primaquine, clinical relapses commonly occur. Primaquine should not be used in patients with glucose-6-phosphate dehydrogenase deficiency, because primaquine may induce massive hemolysis of erythrocytes. Table 142-5 summarizes the commonly described adverse effects and precautions or contraindications of the antimalarial medications. Despite treatment with both chloroquine and primaquine, infection or relapse may persist.

TABLE 142-4 Treatment Regimens for Malaria

TABLE 142-5 Adverse Effects, Precautions, and Contraindications of Antimalarial Drugs

Treatment of *P. falciparum* infection is generally best managed in a hospital setting, particularly if the level of parasitemia exceeds 3 percent. Unless one is certain that the patient could not have chloroquine-resistant *falciparum* infection (based on geographic exposure, Table 142-1), it is best to assume the infecting strain is resistant to chloroquine and to initiate treatment with a combination of quinine and doxycycline with or without pyrimethamine-sulfadoxine. Quinine may at times be in short supply, since only firms that specialize in generic drugs currently manufacture the product. Mefloquine is also an effective therapy for chloroquine-resistant *P. falciparum* (and the asexual erythrocyte stages of the other *Plasmodium* species). Halofantrine, a recently introduced antimalarial compound, may have a limited role for self-treatment of presumptive malaria acquired in Southeast Asia or if multiple drug-resistant malaria is suspected.

Persons presenting with complications caused by *P. falciparum* or with high parasitemia but unable to tolerate oral medications due to vomiting should receive intravenous medications. Supportive care is critical for these patients and includes close hemodynamic monitoring, use of judicious fluid replacement, correction of significant metabolic abnormalities, and additional support as needed (dialysis, mechanical ventilation, and so on). Exchange transfusions have been lifesaving in some patients with parasitemia in excess of 10 percent. Glucocorticoids have not been shown to be of benefit in the treatment of cerebral malaria and should not be used.[11] Quinidine is the intravenous drug of choice due not only to its widespread availability but also to its enhanced activity against *P. falciparum.* Parenteral quinine is available only from the Centers for Disease Control and Prevention.

Quinine and quinidine are potent inducers of insulin release and may cause severe hypoglycemia. Sudden changes in orientation, sweating, tremor, tachycardia, or anxiety should prompt measurement of plasma glucose concentration. Cinchona alkaloids are myocardial depressants, so cardiac monitoring is needed during administration. Terminal treatment with primaquine is not needed in patients with *P. falciparum* malaria, due to the absence of dormant asexual forms in the liver.

PREVENTION

Malaria is largely preventable through use of personal protective measures and appropriate chemoprophylaxis. A recent study confirmed that travelers to malarious areas frequently do not use antimosquito measures or take antimalarial drugs.[12] Between dusk and dawn, travelers should remain in well-screened areas, use mosquito nets if needed, and wear long-sleeved clothing. A pyrethrum-containing insect spray should be used during evening hours and before retiring to bed. Permethrin can be sprayed on clothing for additional protection, and an insect repellent containing *N,N*-diethyl-*m*-toluamide (DEET) applied to exposed skin.

Appropriate chemoprophylaxis depends on where one will be traveling. If potential exposure to infected mosquitoes is likely, prophylaxis is warranted even if such exposure will be brief. Table 142-6 summarizes the chemotherapeutic agents of choice.[2,4,13] The Centers for Disease Control and Prevention maintains a 24-h malaria hotline (888–232-3228), which provides up-to-date information on resistance patterns in countries. Chemoprophylaxis should generally be taken for 4 weeks following the last exposure. Studies exploring other chemoprophylactic options, such as proguanil combined with atovaquone or dapsone[10,14] and monotherapy with daily azithromycin,[15] appear promising.

TABLE 142-6   Recommended Chemoprophylactic Regimens for Prevention of Malaria*

Lastly, even with the religious use of antimosquito measures and chemoprophylaxis, malaria can be contracted or can recur. For reasons discussed earlier, malaria must be considered whenever fever occurs in someone who has traveled to a malarious area or who has received "successful" therapy in the past. Vaccines directed against various antigens of the malaria parasite are currently in trials, but the findings thus far have not been overwhelmingly encouraging.

143 COMMON PARASITIC INFECTIONS

Harold H. Osborn

Despite significant advances in medical knowledge and technology over the last half century, parasitic disease remains prevalent world-wide. It is estimated by the World Health Organization that 200 million people, living mostly in the rural tropics, suffer from schistosomiasis and that hookworm infects approximately a quarter of the world's population.[1] Such parasites as *Ascaris* and *Enterobius* each infect 1 billion people. *Ascaris* is said to infect 3 million people in North America; *Enterobius* infection rates among children in the United States vary from 10 to 45 percent.

Worldwide, malaria is the most prevalent infectious disease among humans, affecting over 500 million and killing over 2 million people each year. [2] In the United States, parasitic disease is becoming increasingly recognized. In addition to the persistence of endemic parasites in this country, three factors account for this trend: (1) immigration to the United States of infected individuals from the countries of Asia, Africa, and Latin America; (2) increased travel by Americans, particularly to the underdeveloped parts of the world; and (3) the rise of parasitic infections among immunosuppressed patients, especially those afflicted with HIV. [3]

Serologic surveys in the United States have demonstrated that 20 to 70 percent of the population have antibodies to *Toxoplasma* and over 90 percent have antibodies to *Pneumocystis carinii.* These two parasites can cause significant morbidity and mortality when they reactivate in immunosuppressed individuals and create opportunistic infections.

Finally, *Cryptosporidium* and *Giardia* are now recognized as causes of traveler's diarrhea and have become major causes of diarrhea in immunocompetent individuals in the United States. Person-to-person spread of these parasites has led to diarrheal illness in day care centers and other institutions, and contamination of municipal water supplies has led to major outbreaks. In 1993, 400,000 people in Milwaukee became ill after *Cryptosporidium* contaminated the drinking water, and 54 people died as a result.[4] It is estimated that 10 to 15 percent of the chronic diarrhea and wasting in AIDS patients is due to infection with *Cryptosporidium parvum.* Recently, surveys of water throughout the United States indicate that 50 percent of rivers and lakes may be contaminated with *Cryptosporidium.*[5] This parasite cannot be contained by chlorination, iodination, or ozonation of the water; it must be eliminated by filtration.

Outbreaks of diarrhea in the summer of 1996 due to the consumption of strawberries contaminated with *Cyclospora,* a coccidian, highlights the challenge of emerging parasitic diseases. Another problem in the 1990s was the increasing emergence of drug-resistant strains of various parasites. Malaria provides a notable example of drug resistance and two species (*Plasmodium falciparum* and *Plasmodium vivax*) now demonstrate resistance.[2] In addition, strains of leishmania are resistant to antimonial drugs in many areas, and reports of metronidazole-resistant trichomoniasis and giardiasis are increasingly common. [6]

The agents that cause parasitic diseases belong to three major groups: helminths (worms), protozoa, and arthropods. The multicellular helminths include nematodes (round worms), cestodes (flat worms), and trematodes (flukes). The protozoa are single-celled organisms that cause a variety of diseases ranging from malaria to amebiasis. Arthropods are classified as ectoparasites and are medically important as obligatory intermediate hosts and as mechanical vectors in many diseases. This chapter reviews diseases caused by helminths and protozoa. Malaria is discussed in Chap. 142, "Malaria."

HISTORY

The recognition of parasitic disease begins with the elicitation of a careful history. Specifically, the clinician should inquire about travel to or immigration from high-risk areas. Parasites flourish in warm, moist climates where sanitation is poor and where many of the people share a low socioeconomic status and have inadequate nutrition. Children are infected with parasites more frequently than adults because of their oral behavior, poor hygiene, and limited ability to ward off arthropod vectors.

Parasitic disease should be considered in any patient with unexplained fever, abdominal pain, diarrhea, skin ulcers, rash, or eosinophilia. The history should include dates of travel or immigration, destination or country of origin, living conditions, and activities. Certain specific areas of the world may implicate particular parasitic agents. Hmong tribesmen, who came to this country from Indochina in large numbers in 1979 and 1980, often harbor *Paragonimus westermani* (lung fluke), whereas visitors to Russia or the Rockies may return with *Giardia.* The history should also include questions about sexual orientation and contacts, drug use, and past illnesses as well as a complete review of systems. The use of pretravel medications, including antimalarial and antidiarrheal agents, should be elicited.

The presence of risk factors can provide a clue to specific parasitic diseases (Table 143-1). Cases of acute Chagas disease (trypanosomiasis) and babesiosis following blood transfusions have been described in the United States and Canada. Institutionalized patients may suffer from amebiasis and can become infected with *Hymenolepsis nana* (the most common tapeworm in the United States) or *Giardia.* Immunocompromised hosts (including those on steroids or antineoplastic agents) are susceptible to infection by *Strongyloides, Toxoplasma, Cryptosporidium,* and *P. carinii* and can develop a life-threatening hyper-infection syndrome with *Strongyloides stercoralis.* It is interesting to note that patients with AIDS, while susceptible to *Toxoplasma, Cryptosporidium, Pneumocystis, Isospora, Microsporidium,* and *Cyclospora,* are not any more susceptible to *Amoeba* and *Strongyloides* than immunocompetent individuals. Finally, the consumption of raw food has been associated with a variety of parasitic diseases, including fish, pork, and beef tapeworm.

Risk Factor	Parasite
Blood transfusion	*Plasmodium* species, *Trypanosoma, Babesia, Toxoplasma*
Intravenous drug use	*Plasmodium* species
Homosexuality	*Enterobius* (also seen after colonic irrigation therapy), *Giardia, Cryptosporidium*
Immunocompromised host	*Toxoplasma, Pneumocystis, Strongyloides, Cryptosporidium, Microsporidium, Isospora,* and *Cyclospora*
Hypogammaglobulinemia	*Giardia, Cryptosporidium*
Institutionalization	*Hymenolepsis nana, Entamoeba histolytica, Giardia*
Day-care centers	*Giardia, Cryptosporidium*
Livestock workers	*Cryptosporidium*
Pica	*Toxocara (visceral larva migrans),* hookworm (*Necator americanus*)
Consumption of raw food Sushi, sashimi, gefilte fish	*Diphyllobothrium, Anisakis*
Pork	*Taenia solium, Trichinella, Sarcocystis*
Beef	*Taenia saginata, Toxoplasma, Sarcocystis*

TABLE 143-1   Risk Factors for Parasitic Disease

PATHOPHYSIOLOGY

Parasites differ in their pathogenicity and in their capacity to produce invasive or systemic disease. The subclass coccidia, for example, includes both *Toxoplasma* and *Isospora*. However, *Isospora* is unable to invade the intestinal mucosa and thus produces only enterocolitis, whereas *Toxoplasma* crosses the intestine and produces severe systemic illness.

Sometimes various forms of the parasite differ in their ability to cause illness. The adult form of *Trichinella spiralis* remains in the intestine, while the larval form crosses and migrates to striated and cardiac muscle. Amebiasis can result in both intestinal and visceral infections. Pathogenicity may vary among strains within a genus. Infection with *Entamoeba* can result in an asymptomatic cyst carrier state or hepatic abscesses, depending on the strain involved.

Finally, organisms differ in their virulence. The infectious dose of *Giardia* and *Cryptosporidium* is on the order of 10^1 to 10^3 organisms. By contrast, the infectious dose of *Vibrio cholerae* and *Salmonella* is 10^5 to 10^8 organisms. This may be an important factor in the genesis of outbreaks in institutions and day-care centers.

CLINICAL FEATURES

Unfortunately, symptoms may be nonspecific, and the latency period between exposure and symptom appearance may be years. Symptoms can be acute or chronic, specific or vague. Parasitic disease can present with relatively common complaints, such as headache, fever, cough, and malaise, or with acute, life-threatening complications, such as seizures, hemoptysis, melena, and intestinal obstruction. A differential diagnosis can be attempted on the basis of history and knowledge of typical symptoms associated with various parasitic agents (Table 143-2).

TABLE 143-2 Symptoms of Parasitic Disease

DIAGNOSIS

Diarrhea is a common complaint that can be a manifestation of an inconsequential and self-limited problem or the hallmark of a serious chronic illness or infection, occasionally with life-threatening potential. Although a variety of systemic illnesses, toxins, drugs, and malabsorption syndromes can cause diarrhea, the infectious causes are of most immediate concern. Although viruses and bacteria are generally the most common causes of infectious diarrhea, parasites constitute a significant cause as well.

The majority of diarrhea-inducing infections are noninflammatory, usually arising in the upper small bowel from the action of an enterotoxin (e.g., *V. cholerae* or enterotoxigenic *Escherichia coli*) or other processes that alter the absorptive function of the villous tip (e.g., *Cryptosporidium, Giardia,* rotavirus, and Norwalk-like virus). In contrast, inflammatory diarrhea, which often presents as dysentery (bloody stools), arises in the colon from an invasive process, sometimes mediated by a cytotoxin (e.g., *Salmonella, Shigella, Campylobacter, Clostridium difficile,* and *Amoeba*).

If diarrhea has persisted for more than a few days, is bloody in nature, or is accompanied by substantial fever, dehydration, or weight loss, the patient should be evaluated more closely. Diarrheal illness lasting 10 days or longer and diarrhea in those with risk factors (see Table 143-1) should prompt a vigorous search for parasites.

Examination of a stool sample for fecal leukocytes has been advocated in these cases, but this procedure is controversial. The presence of fecal leukocytes has been considered a sign of inflammatory diarrhea and has been used to exclude toxigenic bacteria, viruses, and most parasites. However, when studied, the presence of fecal leukocytes has been shown to be neither sensitive nor specific for inflammatory causes. [7]

Examination of a stool specimen for ova and parasites is the best method of detecting intestinal parasites, including the cysts and trophozoites of protozoa and the larvae, eggs, and adults of helminths. Three specimens collected on different days should be examined, and the stool must be free of substances such as bismuth, barium, nonabsorbable antidiarrheal agents, and mineral oil. [8] Antimicrobial agents should be stopped at least 1 week prior to the stool collection. Fresh specimens are best, and specimens over an hour old should be preserved with formalin or polyvinyl alcohol. Multiple stool examinations are particularly important when dealing with formed stool, which usually contains fewer parasites than do diarrheal specimens. In patients with suspected giardiasis, 7 or 8 specimens may be necessary.

Occasionally *Giardia, Cryptosporidium,* and the larvae of *Strongyloides* may be detected by examining a duodenal aspirate or by having the patient swallow a string with a gelatin capsule (Entero-test). Recent studies suggest that detection of *Giardia* by examination of seven stool specimens is just as effective as examination of duodenal contents.

Special procedures for removing parasites include the following: warm water concentration through a filter for *Strongyloides* (Baermann test), sticky tape swab of the perianal area for *Enterobius* (Swube test), passage of urine through a nucleopore filter for *Schistosoma hematobium,* and use of an acid-fast stain to detect *Cryptosporidium, Isospora,* and *Cyclospora.*

The enzyme-linked immunosorbent assay (ELISA) technique can be used to make a serologic diagnosis of a variety of parasitic infections. In addition, the ELISA technique has been used to detect antigens of *Giardia* and *Cryptosporidia* in stool. Malaria-causing plasmodia, *Babesia,* microfilaria of *Wuchereria* and *Brugia,* and the trypanosomes that cause Chagas disease can be detected by Giemsa-stained thick and thin films of peripheral blood.

Finally, organisms that affect the central nervous system (CNS; e.g., *P. falciparum* which causes cerebral malaria, and *Acanthamoeba* or *Naegleria,* which cause amoebic meningoencephalitis) can be detected by culture or microscopic examination of centrifuged cerebrospinal fluid. *Pneumocystis* is detected by characteristic findings on chest x-ray, elevated lactate dehydrogenase (LDH) levels, and evidence of hypoxemia, and is confirmed by lung biopsy with special stains, while *Toxoplasma* is detected by characteristic findings on computed tomography (CT) scan in association with elevated serum antibody levels and is rarely confirmed by brain biopsy.

HELMINTHS

Nematodes (Roundworms)

Nematodes are cylindrical, unsegmented, elongated white worms. Their mode of entry into the human host varies from ingestion of eggs (*Ascaris* and *Enterobius*) to penetration of the skin (*Necator, Ancylostoma,* and *Strongyloides*) to inoculation by insect bite (*Wuchereria*).

ASCARIS *Ascaris lumbricoides* has a worldwide distribution, and its life span if left treated is 2 to 7 years. Larval invasion follows the ingestion of *Ascaris* eggs, and

during this stage the parasite migrates through the lungs. Clinical disease is due to pulmonary hypersensitivity or intestinal complications. Patients may have fever, cough, dyspnea, hemoptysis, and eosinophilia. Obstruction of the common bile duct and the intestine have been described. [9] The chest x-ray may reveal eosinophilic pneumonitis (Loeffler syndrome). The diagnosis is made by finding eggs or, occasionally, an adult worm in the stool. Serologic tests, including bentonite flocculation, ELISA, and indirect hemagglutination, may be helpful. Treatment is with mebendazole, albendazole, or pyrantel pamoate. Intestinal obstruction may necessitate surgery, especially in children.

ENTEROBIUS (PINWORM)   Adult *Enterobius* (pinworm) resides in the cecum, appendix, ileum, and ascending colon after its eggs are ingested. The gravid female migrates to the anus, especially at night, where it causes intense pruritus. Autoinfection with hand-to-mouth transmission is possible after scratching. A host of problems from vaginitis to enuresis have been attributed to *Enterobius* infection without good evidence. It is most prevalent in temperate climates during the winter and fall. The diagnosis is confirmed with a cellophane tape swab of the anus. All family members should be examined. Treatment is with pyrantel pamoate, albendazole, or mebendazole and should be repeated after 2 weeks.

NECATOR (HOOKWORM)   *Necator americanus* prevails in the southern United States and is often seen in immigrants from warmer climates. Infection is associated with the use of human fertilizer and the lack of shoes and latrines. Because each worm can withdraw 0.03 to 0.2 mL of blood a day, infection often leads to chronic anemia. Pica and geophagy are often seen in infected children. Patients may have cough, low-grade fever, abdominal pain, diarrhea, weakness, weight loss, heme-positive stools, and eosinophilia. The diagnosis is made by finding ova in the stool. In mild infections, multiple stool specimens or concentration techniques may be necessary. The parasite burden may be estimated using the Beaver stool or Kato slide smear method. Infections with less than 2100 eggs per gram of feces (<50 adult worms) are usually not hematologically important, whereas infections with over 11,000 eggs per gram result in significant anemia. Hookworm is best treated with mebendazole, albendazole, or pyrantel pamoate.

STRONGYLOIDES (THREADWORMS)   Adult threadworms reside in the mucosa of the small intestine. Because entry of the parasite is through the skin, penetration can lead to allergic manifestations, pruritus, and an erythematous rash. Migration throughout the lungs can produce cough, dyspnea, and pneumonia. The intestinal phase is manifested by abdominal pain, diarrhea with mucus and blood, and eosinophilia. Autoinfection can occur due to internal production of infective larvae. Larval migration in the skin produces larva currens. Fatalities may occur due to hyperinfection in elderly and immunocompromised patients (e.g., patients with leprosy, nephrotic syndrome, hepatic disease, or lymphoproliferative disorders and those on steroids). The diagnosis is confirmed by finding larvae in the stool. Occasionally, use of a formalin ether concentration method or duodenal aspiration may be necessary. Various stages of the parasite may be found in the sputum. An ELISA test is also available. An upper gastrointestinal series may reveal a deformed duodenal bulb, and *Strongyloides* may be confused with ulcer disease. Treatment is with thiabendazole or ivermectin.

TRICHURIS TRICHIURA (WHIPWORM)   Like *Ascaris, Trichuris trichiura* is found in rural communities in the southern United States. The infection is most often acquired in childhood because the ova are deposited in the soil where children play and defecate freely. The adult worm resides in the cecum. Patients complain of anorexia, insomnia, abdominal pain (including pain in the right upper quadrant), fever, flatulence, bloody diarrhea, weight loss, and pruritus and may have eosinophilia and microcytic hypochromic anemia. *Trichuris* can result in colitis or rectal prolapse in children. The diagnosis is made with the finding of ova in the stool. Mebendazole or albendazole is the treatment of choice.

TRICHINELLA SPIRALIS   Trichinosis is common in Mexico and the United States and results from the consumption of infected pork and, less commonly, bear and walrus meat. In the early stages of infection with *Trichinella spiralis,* the patient may present with acute myocarditis, nonsuppurative meningitis, bronchopneumonia, or catarrhal enteritis. The primary lesions are in striated muscle. Clinical symptoms depend on the site of invasion. Patients may present with nausea and vomiting, diarrhea, fever, urticaria, periorbital edema, (pathognomonic) splinter hemorrhages, myalgia, muscle spasm, stiff neck, headache, and psychiatric disturbances. Laboratory manifestations of trichinosis include leukocytosis, eosinophilia, elevated creatine phosphokinase and electrocardiographic changes. The diagnosis can be confirmed with latex agglutination, skin test, and a bentonite flocculation test. Biopsy of tender muscle may be helpful after the fourth week. Since *T. spiralis* encysts in striated muscle, stool examination is not helpful after the initial gastrointestinal phase in making the diagnosis. The differential diagnosis includes staphylococcal and salmonella food poisoning, shigellosis, and amebiasis. Mebendazole is indicated for treatment of the intestinal phase but may be ineffective after encystment. Steroids are indicated for severe infections, such as CNS disease and myocarditis, but are not advocated routinely because their use can increase the number of circulating larvae. Most cases are mild and never come to medical attention.

Trematodes (Flukes)

Trematodes are leaflike, symmetrical flatworms lacking a body cavity but possessing a ventral sucker to hold their position. They live in intermediate hosts such as snails, crabs, and fish and shed their eggs from the human host in the feces (*Schistosoma, Clonorchis,* and *Fasciola*), urine (*Schistosoma haematobium*), or sputum (*Paragonimus*).

SCHISTOSOMA   Schistosomes penetrate the skin, creating a papular pruritic rash. The adult form resides in the venous system. Symptoms of acute disease—fever, lymphadenopathy, and hepatosplenomegaly (so-called Katayama fever)—are rarely seen. More typically, patients present in the chronic stage with granulomas in the liver (portal hypertension) and bladder (obstructive hydroureter). Patients may present with diarrhea, abdominal pain, melena, hepatosplenomegaly, hematemesis, and, in the late stages, ascites and liver failure. With *S. haematobium,* dysuria and hematuria may be found. The diagnosis is suggested by a positive immunofluorescent antibody test result and confirmed by finding eggs in the feces or on rectal biopsy. Treatment is with praziquantel.

Cestodes (Flatworms)

The cestodes are flatworms commonly referred to as tapeworms. They have a scolex, or head, equipped with suckers, or hooks. Cestodes grow by segmentation, extending proglottides from the neck.

TAENIA   *Taenia solium* (pork tapeworm) is occasionally encountered in the United States in immigrants or visitors from Central America and the Middle East. *Taenia saginata* (beef tapeworm) is seen more often, especially in those who consume raw beef (e.g., steak tartare). Adult worms live in the small intestine. Infected patients can be asymptomatic or present with nausea and vomiting, headache, abdominal pain, pruritus, constipation, diarrhea, and intestinal obstruction. The larval stage of *T. solium* can cause clinical disease (cysticercosis), which can be serious and sometimes fatal. *Taenia* cysts may be found in subcutaneous tissue, the eye, the brain, and the heart and cause seizures and hydrocephalus. Radiographs of the soft tissues may reveal curvilinear calcifications indicative of cysts, and cysts can be seen in the meninges and brain parenchyma on CT scanning. The diagnosis is made by finding gravid proglottids in the stool. An ELISA or hemagglutination reaction may be helpful, but results of both can be falsely negative if the cysts are calcified. Treatment of the adult (intestinal) stage is with praziquantel. The larval (tissue) stage is treated with albendazole.

DIPHYLLOBOTHRIUM   *Diphyllobothrium* (fish tapeworm) has been reported in the Pacific northwest, Minnesota, Michigan, and other areas where raw fish (e.g., sushi and sashimi) and gefilte fish are consumed. *Diphyllobothrium* can compete with the host for vitamin B_{12}, and thus patients can present with pernicious anemia. Treatment is the same as for *Taenia.*

PROTOZOA

Amebas

Amebiasis, which is caused by *Entamoeba histolytica,* occurs worldwide and is associated with poor sanitation. Outbreaks have been reported in institutions for the mentally retarded and in the homosexual community. Amebae inhabit the cecum and large intestine, where they cause ulcers and diffuse inflammation, which can mimic ulcerative colitis. Rarely, an ameboma develops in the liver and presents as a liver abscess. Approximately half of all infected patients are asymptomatic. Symptoms include nausea and vomiting, anorexia, diarrhea, fever, abdominal pain, and leukocytosis. Protozoan infections, including amebiasis, do not produce eosinophilia. The diagnosis is established with stool testing, including testing of postcathartic stools and concentration and staining techniques. Stool specimens should be fixed in polyvinyl alcohol formalin, or merthiolate-iodine-formalin. Serologic tests (ELISA and indirect hemagglutination reaction) can be helpful in the presence of extraintestinal disease. Treatment is with metronidazole or tinidazole.

Giardia

Giardia is probably the most common intestinal parasite in the United States. It inhabits the duodenum and upper jejunum, where the alkaline pH creates a favorable

milieu. Cysts are ingested in fecally contaminated water or food or are passed by hand-to-mouth transmission. Waterborne outbreaks have become more common in the United States because the cysts are resistant to chlorination. Day-care centers have been increasingly implicated in promoting giardiasis.

Symptoms depend on the duration of infection at the time of presentation. Patients may complain of explosive, watery, or foul-smelling diarrhea, flatus, abdominal distention, fatigue, and fever or chronic diarrhea with weight loss or general debilitation. Stools should be examined for cysts and trophozoites with routine and concentration techniques. *Giardia* antigen can be detected in the stool with immunofluorescence or ELISA technique. Occasionally, duodenal aspiration, the string test (Entero-test), or small-bowel biopsy is necessary to make the diagnosis. The drug of choice for treatment is metronidazole.

Trypanosoma

American *Trypanosoma* (*T. cruzi*) causes Chagas' disease. Three strains of African *Trypanosoma* cause sleeping sickness. Chagas' disease is usually transmitted by the reduviid (kissing) bug, but infection can also follow breast-feeding and blood transfusion, as has occurred in the United States. A nodular swelling, or chagoma, develops at the site of inoculation following a bite. The acute phase of the disease can last 2 to 3 months, and patients present with fever, headache, anorexia, conjunctivitis, and myocarditis. Infants can develop meningocephalitis, and heart involvement can lead to congestive heart failure and ventricular aneurysms. The organism can attack the myenteric plexus of the gastrointestinal tract, resulting in megacolon. Chronic infection can result in a cardiomyopathy. Laboratory abnormalities include anemia, leukocytosis, an elevated sedimentation rate, and electrocardiographic changes. During the acute phase, trypomastigotes can be seen on a peripheral smear or cultured from the blood. In the chronic phase, the diagnosis is made with a complement fixation test, ELISA, or biopsy of the liver, spleen, or bone marrow. Treatment of acute Chagas' disease is with nifurtimox or benzindazole. Treatment of sleeping sickness is with suramin sodium.

Babesia

Babesia is a protozoan that, like *Plasmodium* species, possesses an erythrocytic phase. It is transmitted by *Ixodes* ticks and occasionally by blood transfusion. Babesiosis has been reported in the northeastern United States (especially Nantucket, MA, and Long Island, NY). Babesiosis in the northeast is caused by the murine species, *Babesia microtti,* and is transmitted by the deer tick, *Ixodes,* which also serves as a vector for Lyme disease. Patients may have intermittent fever, splenomegaly, hemolysis, and jaundice. Infection can be fatal in splenectomized patients, but its incidence is apparently not increased in immunocompromised patients. Diagnosis can be made on a Giemsa-stained peripheral smear. Occasionally, *Babesia* on smear can be confused with the ring forms of *P. falciparum* malaria. Babesiosis can simulate rickettsial diseases, such as Rocky Mountain spotted fever and Lyme disease. Treatment is with clindamycin and quinine.

Cryptosporidium

Cryptosporidium is a protozoan parasite of the subclass Coccidia, which also includes *Toxoplasma, Isospora, Cyclospora, Eimeria,* and *Sarcocystis. Cryptosporidium parvum* is the species that most commonly causes disease in human beings. Previously regarded only as a disease of immunodepressed individuals (especially those with AIDS), *Cryptosporidium* is now recognized as an important and increasingly common cause of diarrhea, including traveler's diarrhea, worldwide.

Like *Giardia, Cryptosporidium* is waterborne, as has been well documented in England and the United States, most recently in Milwaukee. Like *Giardia, Cryptosporidium* causes diarrhea by altering the microvillous tips of the cells lining the small intestine. It can infect other mammals, including cows, and waste water (raw sewage) and runoff from dairies and pastures may be the source of oocysts that contaminate reservoirs and pools.

The diarrhea of cryptosporidiosis, in both immunocompetent and immunocompromised patients, is profuse and watery (cholera-like), usually without blood, fecal leukocytes, and mucus. It is occasionally associated with crampy abdominal pain, nausea and vomiting, low-grade fever, and weight loss. Although the illness is self-limited in most immunocompetent individuals (lasting several days to 2 weeks), it can be relentless and debilitating in the immunocompromised, often resulting in severe dehydration, malabsorption, weight loss, and death. Rarely, *Cryptosporidium* can also cause respiratory and biliary tract disease.

The diagnosis is made by finding oocytes in the stool. Concentration of the stool specimen using formalin ether gives a higher yield. A modified Ziehl-Neelsen acid-fast stain is used to visualize the oocysts. A serum ELISA for antibodies to *Cryptosporidium* is available.

Treatment is mainly supportive (oral or intravenous hydration and antidiarrheal agents). Treatment of immunocompromised patients is difficult, and at present there is no accepted regimen. Paromomycin, a somatostatin-like agent, octreotide, and azithromycin have all been used with some success.

PROTOZOAN INFECTIONS IN IMMUNOCOMPROMISED HOSTS

Respiratory Tract

Pneumonia occurs commonly in immunocompromised patients and is often due to *P. carinii.* Because most normal children have antibodies to *P. carinii, P. carini* pneumonia probably represents a reactivation of a latent infection. The natural habitat and mode of transmission of *P. carini* are poorly understood. Patients present acutely with fever, dyspnea, a nonproductive cough, and scant rales. Arterial blood gas analysis may reveal hypoxia or an increased alveolar-arterial (A-a) gradient. The serum LDH level may be elevated. Early, the chest x-ray may be normal. Later, the classical appearance is of symmetrical interstitial infiltrates in the mid and lower lung zones. *Pneumocystis carini* occurs in premature and debilitated infants, AIDS patients, those receiving organ transplants, and those with inherited immunodeficiencies. Diagnosis is usually made by lung biopsy. The specimen should be stained with methenamine-silver nitrate or toluidine blue. Serologic tests are of limited value because many normal individuals have antibodies. Treatment is with trimethoprim-sulfamethoxazole or pentamidine isethionate. In patients with respiratory compromise (P_{O_2} <70 mmHg or A-a gradient >35 mmHg on room air) the addition of steroids has been shown to be beneficial.

Gastrointestinal Tract

Most patients with AIDS (50 to 98 percent) either present with or later develop diarrhea that is often life-threatening. Gastrointestinal disease in immunocompromised patients is often due to *Cryptosporidium, Isospora, Microsporidium,* and *Cyclospora.*

The diagnosis of *Cryptosporidium* is made with a modified Ziehl-Neelsen acid-fast stain or Kinyoun stain of the stool. Many antimicrobial and antidiarrheal agents have been tried without much success in the treatment of cryptosporidiosis. The high rate of recurrence and relapse of this disease is probably related to the underlying immunodeficiency. *Isospora belli* is another protozoan that can cause significant gastrointestinal disease. As with *Cryptosporidium,* infection with *Isospora* occurs after ingestion of oocysts in contaminated food or water and following sexual contact. Symptoms may vary from acute gastroenteritis in immunocompetent individuals to severe, protracted diarrhea in the immunocompromised. Characteristic oocysts can be detected in the stool with acid-fast stains. Treatment is with trimethoprim-sulfamethoxazole.

Microsporidium is an obligate intracellular protozoan that is becoming more commonly recognized as a pathogen in patients with AIDS and the immunocompetent. Most patients present with diarrhea and a wasting syndrome, but hepatitis, peritonitis, and keratitis have been described. Diagnosis by stool examination is difficult due to the small spore size. Immunologic detection of spores with polyclonal serum has been attempted. Definitive diagnosis usually requires intestinal biopsy and detection with transmission electron microscopy. Treatment is difficult. Patients who do not respond to standard antidiarrheal therapy can be tried on octreotide, albendazole, or metronidazole.

Central Nervous System

Toxoplasma, an intracellular parasite carried by cats and other intermediate hosts, can cause significant disease in immunocompromised patients. Infection can come from the ingestion of oocysts or undercooked meat, by placental transfer, following organ transplant, or during a blood transfusion. Acquired toxoplasmosis is usually asymptomatic. During acute infection, transient lymphadenopathy and splenomegaly may be present. Reactivation can result in encephalitis, chorioretinitis, myocarditis, and pneumonia. Symptoms of cerebral toxoplasmosis can include severe headache, seizures, confusion, and lethargy. Focal deficits may appear, and cerebellar, brainstem, and cranial nerve lesions may be seen. Making the diagnosis may be difficult. Ventricular fluid, brain tissue, or the buffy coat from a blood sample may be inoculated into test animals. The Sabin-Feldman dye test is fairly specific. An ELISA test for IgG and IgM antibodies to *Toxoplasma* is available. CT scanning may reveal characteristic intracerebral lesions with ring enhancement following the use of contrast. Magnetic resonance imaging is also used. Treatment is

with pyrimethamine plus sulfadiazine or spiramycin.

TREATMENT

Patients with potentially life-threatening infections (e.g., cerebral malaria, pneumocystic pneumonia, amebic meningoencephalitis, or CNS toxoplasmosis) should be started on antiparasitic treatment immediately in the emergency department (Table 143-3). Patients who are dehydrated from gastrointestinal losses or fever should receive intravenous hydration. Those who can take fluids orally can be rehydrated by mouth.

TABLE 143-3 Commonly Used Antiparasitic Drugs

DISPOSITION

Patients with diarrhea who appear severely ill, toxic, or dehydrated; those who cannot tolerate anything by mouth; and those with organ system involvement (e.g., lung, blood, or CNS) should be admitted for intravenous hydration, further diagnostic evaluation, and antiparasitic drug treatment as indicated. Patients who do not require hospitalization can be treated with antiparasitic agents if a specific diagnosis has been made and should be referred for follow-up. Those who can tolerate oral fluids can be reliably rehydrated with the World Health Organization oral rehydration solution. Such a solution can be prepared by adding 3.5 g sodium chloride (or ¾ teaspoon of table salt), 2.5 g sodium bicarbonate (or 2.9 g sodium citrate or 1 teaspoon of baking soda, 1.5 g potassium chloride (or 1 cup of orange juice or two bananas), and 20 g glucose (or 40 g sucrose or 4 tablespoons of sugar) to a liter (1.05 quart) of clean water. This makes a solution of approximately 90 mmol sodium, 20 mmol potassium, 80 mmol chloride, 30 mmol bicarbonate, and 111 mmol glucose per liter.

144 FOODBORNE AND WATERBORNE DISEASES

William T. Anderson

Foodborne and waterborne disease is the most widespread public health challenge facing contemporary medicine. The spectrum of illness is changing with the emergence of new pathogens and reemergence of old ones. Individual outbreaks of foodborne or waterborne illnesses have caused sickness in hundreds of thousands of people. The number of identified outbreaks has increased over the past 20 years. [1] The globalization of the food economy and explosion in international travel have facilitated the transmission of disease between continents. [1] Patients can present with uncommon pathogens and develop life-threatening complications or chronic illnesses. Emergency physicians need to understand the scope and magnitude of foodborne and waterborne illnesses. They should be able to recognize risk factors in the vast population of patients who present with diarrheal illness that compels a more aggressive investigation. Physicians should be cognizant of which pathogens can and cannot be tested for in their laboratory. Finally, emergency physicians should instruct patients on how to reduce their risk in the future. Specific etiologic agents and the general management of infectious diarrhea are covered elsewhere in this text.

Foodborne and waterborne illnesses encompass a variety of clinical and etiologic conditions. Waterborne illness is defined by the Centers for Disease Control and Prevention (CDC) as an illness that occurs after consumption or use of water intended for drinking or as illness associated with recreational water such as swimming pools, whirlpools, hot tubs, spas, water parks, and naturally occurring fresh and marine surface waters. [2] A foodborne-illness outbreak is the occurrence of two or more cases of a similar illness resulting from the ingestion of a common food. [3] Food or water may act as a vehicle for transmission of actively growing organisms or as a transfer medium for nonreplicating viruses, toxins, protozoa, bacteria, or chemical agents.

EPIDEMIOLOGY: FOODBORNE DISEASE

From 1988 to 1992, a total of 2423 outbreaks of foodborne diseases in the United States were reported to the CDC: 77,373 persons developed predominantly diarrheal illness. [3] This number represents only a small fraction of foodborne outbreaks. Most infections are undiagnosed or unreported. It has been estimated that foodborne illness affects 6 to 80 million people in the United States and causes 9000 deaths each year. [4] On a global scale, the prevalence of all diarrheal illnesses has been estimated to be 3 to 5 billion cases per year and is associated with 5 to 10 million deaths per year or approximately 27,000 deaths per day. [5]

The epidemiology of foodborne illnesses has evolved quickly over the past few decades in response to several influences. New pathogens such as *Escherichia coli* O157:H7,[6] enteroinvasive *Klebsiella pneumoniae,*[6] and *Cyclospora cayetanensis*[7] have been recognized as recent causes of foodborne illness. The expanding role of pathogens such as *Campylobacter jejuni, Listeria monocytogenes,* and *Yersinia enterocolitica,* previously unrecognized causes of foodborne illness, has brought them to the forefront.[7] A growing list of foods, previously thought to be safe, have been identified as new vehicles for transmission.

The evolution of foodborne epidemiology over the past few decades has been a reflection of changes in the food supply and population demographics. International trade has allowed people to come in contact with previously unfamiliar pathogens that are native to remote parts of the world. [4] Bacteria, viruses, parasites, and chemical contamination at the site of processing can be disseminated to a multitude of locations thousands of miles away. Low-dose contamination at a central processing site can cause widespread outbreaks that often are undetected. [4,8] Consolidation of the food industry has led to a larger market share and greater geographic distribution of products from a single supplier or distributor. [4] This increases the risk of larger outbreaks of disease. In 1994, a nationwide outbreak of over 224,000 illnesses of *Salmonella* serotype Enteritidis from one distributor occurred when ice cream premix was transported in tanker trucks that had not been completely sanitized after transporting nonpasteurized liquid eggs. No source for contamination was found in the manufacturing plant. [9]

The eating habits of the US population have changed, with a greater emphasis on incorporating fruits and vegetables in the diet. [1] To meet this increased demand, the volume of imported fresh fruits and vegetables has escalated. Imports can account for more than 75 percent of grocery-store fruit and vegetable stock. [1] Outbreaks of foodborne illness have occurred recently in produce such as fresh squeezed orange juice, raspberries, frozen strawberries, sliced tomatoes, and lettuce. [4]

Population dietary patterns have changed as a larger percentage of meals are consumed outside the home. [4] Nearly 80 percent of foodborne outbreaks in the United States from 1988 to 1992 occurred in cafeterias, restaurants, or delicatessens. [3] The number and array of food-service establishments that mass produce food has expanded. Many restaurants rely on transient personnel who have inadequate knowledge of food-handling techniques. [10] In the home, there has been a decline in basic food preparation skills. Many adults who prepare meals do not routinely wash their hands after handling raw meat or poultry. [10]

The number and the percentage of people with increased vulnerability to illness have changed. The United States will continue to experience a demographic shift to an older population base: 20 percent of the population will be over age 65 by the year 2040. [11] Patients with compromised immunity secondary to AIDS, immunosuppressants, chemotherapy, or chronic illnesses also represent an expanding segment of the population with heightened susceptibility to foodborne illness.[4,11]

Travelers are at an increased risk of foodborne illnesses secondary to exposure to new, previously unseen pathogens, increased exposure through meals at hotels and restaurants, and unpredictable standards for public health cleanliness and water-supply systems. [12] The relative risk of foodborne infection with viruses, bacteria, or parasites varies by country, but ranges from 20 to 50 percent for all travelers. [1] Enterotoxigenic *E. coli* is recognized as the major cause of travelers' diarrhea,[5] but other strains of *E. coli* are associated with travel, including enterohemorrhagic and enteroinvasive *E. coli*.[12] The prevalence of *Salmonella typhi* necessitates typhoid immunization for travelers to many countries. [12] *Salmonella* serotype Enteritidis outbreaks have occurred on airlines and railways from contaminated meals. [12] Other pathogens associated with international travel include *Brucella,* hepatitis A,[12] *Vibrio, Shigella, Campylobacter, Giardia lamblia,* and *Cryptosporidium*.[5]

Food-industry influences have contributed to the emergence of new pathogens in foodborne disease. The common use of antibiotics in animal food reservoirs and humans have facilitated an increase of antibiotic resistant strains of *Salmonella* and *Campylobacter jejuni*.[4] The disposal of the more than 1 billion tons of manure and associated pathogens that are an annual by-product of the farm industry is a growing dilemma and can contribute to the contamination of fruits and vegetables at harvest.[4]

National and international surveillance of foodborne illness is subject to constraints that limit reliable information and lead to inaccurate estimates of the magnitude of the problem. Globally, it is estimated that only 1 to 10 percent of the true incidents of foodborne illnesses are reported. [13] Some countries have estimated that foodborne illnesses may be 300 to 350 times more frequent than reported.[13]

There are a variety of reasons for this worldwide underestimation of illness. Many countries have failed to implement even a basic foodborne-disease surveillance system. Cholera is the only foodborne disease that must be reported internationally. [13] It is difficult to compare data from different countries because of the lack of uniform data collection. As well, many governments are reluctant to provide information on foodborne diseases, particularly if a country's economy is based on tourism or food exports.[13] In the majority of countries, foodborne-illness surveillance infrastructures or laboratories are nonexistent or function with inadequate resources making these countries vulnerable to outbreaks or epidemics of foodborne disease. [13]

EPIDEMIOLOGY: WATERBORNE DISEASE

There are 215,000 water systems in the United States classified as public systems that are regulated under the Safe Water Drinking Act and the Surface Water Treatment Rule.[2] These regulations require water utilities to disinfect surface water and groundwater by using parameters such as turbidity, coliform counts, and the presence of human enteric viruses and *Giardia lamblia* cysts as target organisms to assess efficacy of treatment.[2] The surveillance system for waterborne-disease outbreaks is similar to that for foodborne illnesses. Criteria for a waterborne outbreak is the presence of a similar illness in two or more people after the ingestion of drinking water or after exposure to water used for recreational purposes. Epidemiologic evidence must implicate water as the probable source of infection. [2]

The CDC identified 30 outbreaks of waterborne disease in the United States associated with drinking water causing illness in 405,366 people from 1993 to 1994. [2] A single outbreak of cryptosporidiosis, the largest waterborne-disease outbreak ever reported in the United States, accounted for 403,000 cases from which 4400 people were hospitalized. The outbreak was traced to a community water system. Surface water from Lake Michigan had been filtered and chlorinated, but a deterioration in the water quality and the decreased effectiveness of the coagulation-filtration process led to an inadequate removal of *Cryptosporidium parvum* oocysts. The treated water had met all state and federal quality standards that were then in effect. The outbreak was recognized by widespread absenteeism among employees of hospitals and among students and school teachers, a shortage of antidiarrheal drugs citywide, and a marked increase in the number of emergency department visits.[2] A single waterborne outbreak associated with *Salmonella*, infecting 625 people, occurred when municipal water-storage towers were inadequately protected from wild-bird droppings.[2]

PATHOPHYSIOLOGY

Normal physiologic defense mechanisms that exist to prevent disease from foodborne and waterborne pathogens include gastric acid, the normal flora of the gastrointestinal tract, intestinal motility, and mucous glycoproteins of the intestinal mucus. The effectiveness of each of these barriers can be altered by age, concomitant infections, chronic illnesses, medications, and the pathogen itself.

A gastric pH of 3 or less is generally found in most healthy adults and can effectively kill most foodborne pathogens. [14] A reduction in acidity can occur secondary to antacids, medications such as H_2 blockers, and proton-pump inhibitors. Chronic underlying medical conditions such as diabetes mellitus, pernicious anemia, and gastric surgery also reduce gastric pH. Hypochlorhydria has also been demonstrated in *Helicobacter pylori* infections.[14]

Nonpathogenic, indigenous intestinal bacteria inhibit colonization of pathogens by direct competition for nutrients and by the production of fatty acids or chemicals that are bactericidal. Alterations of intestinal flora occur commonly after antibiotic use, as well as secondary to radiation therapy, chemotherapy, and abdominal surgery.[14] Recent antibiotic use lowers resistance to *Salmonella* infections and has been implicated as a risk factor for infection with *E. coli* O157:H7.[14]

The normal motility of the intestinal tract provides an important defense mechanism by minimizing the contact between the mucosal surface and the pathogen. Bowel stasis permits multiplication and overgrowth of foodborne or waterborne pathogens and contributes to retrograde migration from the colon to the small intestine. Antiperistaltic agents, narcotics, and previous radiation therapy theoretically can prolong gut transit time and increase pathogen infectivity. [14]

Bacteria, such as enterotoxigenic *E. coli*, can increase their pathogenicity by adhering to the mucosal surface via surface pili or fimbria that bind to receptors on intestinal epithelial cells. [5] Direct invasion of the mucosal epithelial cells occurs with many foodborne pathogens such as *Shigella, Salmonella,* enteroinvasive *E. coli, Campylobacter,* and *Vibrio parahaemolyticus*.[5] Intracellular multiplication of these organisms is followed by epithelial cell death. Cytotoxins, such as the Shiga toxin of *Shigella dysentariae* or Shiga-like toxins produced by enterohemorrhagic *E. coli* O157:H7, enteropathogenic *E. coli*, and *V. parahaemolyticus* also cause cellular membrane disruption and cell lysis. [5] *Vibrio cholera* and enterotoxic *E. coli* produce protein toxins that alter fluid and electrolyte transfer across epithelial cell membranes and produce large volumes of fluid that exceed the absorptive capacity of the colon. The resultant, excessive diarrhea can lead to rapid dehydration. [5]

The most common pathogens causing foodborne illnesses are *Salmonella, Campylobacter, E. coli* O157, and the Norwalk viruses.[15] Viral gastroenteritis, caused by Norwalk viruses, rotaviruses, enteric adenoviruses, astroviruses, and calciviruses, accounts for the majority of cases of infectious diarrhea seen in the emergency department.[16] Usually transmitted person to person, food and water transmission is not uncommon and should be considered. [17] Viral infections of the gastrointestinal tract cause an enormous amount of diarrhea-related mortality and morbidity and is one of the leading causes of infant death worldwide. [18] Simultaneous infection with more than one viral pathogen is common.

Foodborne viruses are usually transmitted person to person by the fecal-oral route and are infectious in very low doses. Lack of confirmation of a viral etiology leads to an underreporting of viral foodborne outbreaks. [16] Viruses do not multiply or produce toxins, and food items simply act as transfer mediums.[17] Foods may be contaminated either at the source or at the time and place of preparation. Bivalve mollusks (oysters, clams, mussels, and cockles) have been implicated in the transmission of viruses. Their contamination usually occurs at the source in polluted shallow coastal waters. [17,19] Viral contaminants remain active when they are inadequately cooked or consumed raw, particularly in oysters. [17] The application of raw sewage or sludge to fruit and vegetable crops is another source of primary viral contamination.[17]

Viral contamination from infected food handlers occurs after harvesting as food items pass through several hands before reaching consumers. It is largely associated with cold food items that require much handling during preparation (salads and sandwiches) or ice. [17] Surfaces used in food preparation may become contaminated, as well. Food handlers may be asymptomatically shedding virus particles prior to the onset of illness or continue to shed virus particles up to 48 h after recovery. [17] Although unusual, airborne transmission of virus particles has been demonstrated in outbreaks of foodborne illness on cruise ships and in schools. [16] As in bacterial infections, waterborne transmission of virus is an effective mechanism of infectivity. Outbreaks have been associated with contamination of private wells, small water systems, and community water systems.[2,16] Seasonal outbreaks of Norwalk gastroenteritis have been associated with swimming in lakes and pools. [16]

Hepatitis A was the fourth leading cause of foodborne disease among outbreak-associated illness compiled by the CDC for 1988 to 1992. [3] It is the only reportable foodborne viral disease, and the true incidence of illness is underreported. [19] When food samples have become unavailable for testing, hepatitis A outbreaks are likely to be recognized weeks after contaminated food has been consumed. Most infections are the result of consumption of infected bivalves, but outbreaks associated with infected strawberries and raspberries have occurred. [16,17] Diarrhea is not commonly associated with hepatitis A.

Viruses can be eliminated at any step along the food-handling process. Heating is an effective means of inactivating hepatitis A virus particles in mollusks, and their exposure to temperatures of 85° to 90°C for at least 90 s is recommended. [17,19] Viruses are a small target for ionizing radiation. Enteric viruses are often acid resistant, and hepatitis A virus is quite resistant to drying. Viruses in water or on surfaces can be inactivated by chlorine, ozone, or ultraviolet light. [19]

DIAGNOSIS

Recognizing foodborne or waterborne illness can be extremely challenging for emergency physicians. Symptoms associated with foodborne illness are very common and nonspecific except for syndromes associated with chemical agents. Physical examination should be directed at identifying toxic or dehydrated patients, identifying the presence of blood in the stool, and excluding other diarrheal illnesses. A variety of diagnostic tests are available for confirmation of pathogens in suspected outbreaks, but routine testing of patients with infectious diarrhea for ova and parasites and stool cultures is not cost effective. [20] The majority of patients will have a self-limited illness that resolves by the time culture results are available. Diagnostic studies and cultures should be directed toward patients with blood or mucus in the stool, fever or other signs of toxicity, or significant historical risk factors for foodborne illness. When fecal leukocytes are present, the culture yield is higher for bacterial pathogens, but the absence of fecal leukocytes does not exclude a bacterial etiology and limits its diagnostic efficacy. [20]

Obtaining a complete history of an acute diarrheal illness is important. In a presumed foodborne illness, determining the exact time of exposure can help direct the evaluation to particular causative agents, although significant overlap exists between syndromes of foodborne illness (Table 144-1).[3] Extending a history beyond 3 or 4 days will provide only limited benefit in identifying pathogens—such as hepatitis A, *Cryptosporidium*, and *Salmonella*—with prolonged incubation periods.

TABLE 144-1   Etiologic Agents for Foodborne Diseases and Usual Incubation Periods

A history of two or more people within a household becoming ill simultaneously may indicate a foodborne etiology. If additional cases occur within 24 to 36 h, nonfoodborne sources, such as viruses, are more likely. Patients should be questioned about inadequate food-handling practices at home, such as preparation of food several hours prior to consumption, insufficient cooking or reheating of food, cross contamination between raw and cooked foods on common preparation surfaces, or people with poor personal hygiene handling the food. [21]

Patients should be questioned about other activities associated with an increased risk of foodborne disease, such as frequent restaurant meals, exposure to day-care centers, consumption of street-vended food or raw seafood, overseas travel, and camping with the ingestion of lake or steam water.

Host factors that reduce resistance and immunocompetence should be identified. The recent use of antibiotics and medications that reduce gastric acidity, such as H$_2$ blockers, proton-pump inhibitors, and antacids, should be identified. Identify patients with AIDS or other immunocompromised conditions.

The very young and the elderly have a higher incidence of infection and greater risk of complications from foodborne illnesses. Children younger than age 5 and adults older than age 65 have the highest attack rate for infection with *E. coli* and are at the greatest risk for hemolytic-uremic syndrome.[14] Isolation rates for *Salmonella* reported to the CDC and the risk for bacteremia were highest among children under age 9 and adults over age 80. [14] Residents of chronic care facilities are at increased risk for illness and death because of their close proximity, increased frequency of fecal incontinence, and a general debilitated state with multiple concurrent illnesses.[14]

A recent history of swimming in pools, water parks, lakes, and other recreational water facilities is important and should raise suspicion for cryptosporidiosis, although other pathogens such as enterohemorrhagic *E. coli* have been linked to water-park outbreaks. [2]

Stool cultures should minimally include the most frequent causes of foodborne illnesses: *Campylobacter, Salmonella,* and *Shigella.*[20] The frequency of *E. coli* O157:H7 foodborne illness has increased, and many laboratories routinely culture for it, as well. The Gram stain can identify *Campylobacter,* one of the most common causes of gastroenteritis, with a sensitivity of 66 to 99 percent and still has a role in the diagnosis of diarrheal disease. [20] Cultures for other organisms should be based on prevalence rates in the community or an increased index of suspicion based on history and physical examination. Emergency physicians should be cognizant of which pathogens are and, equally as important, are not routinely cultured for in their laboratories. Optimal sensitivity of the test requires more than a single specimen, preferably obtained in the emergency department, especially for ova and parasites. [20] Rectal swabs are not adequate for specimen collection.

Public health authorities usually become aware of and initiate investigations of potential foodborne or waterborne outbreaks when there is an increase in the frequency of pathogens reported to them by hospitals or a cluster of suspicious cases. Variations of this reporting structure do occur. Emergency physicians concerned about possible outbreaks should communicate with the infection control departments and microbiology laboratories in their hospitals.

CHRONIC SEQUELAE

Chronic secondary complications of foodborne illness occur in about 2 to 3 percent of patients. [22] The true incidence is probably higher because chronic sequelae may be difficult to link to the acute illness and may occur despite successful elimination of the primary organism. Frequently, the host and pathogen have common surface antigens. Host recognition of the foreign antigen initiates an autoimmune response. A low but consistent incidence (0.2 to 2.4 percent) of seronegative reactive arthritis has been noted following outbreaks of *Salmonella typhimurium, Shigella flexneri,* and *Campylobacter jejuni.*[22,23] Superantigens—protein virulence factors that can elicit extreme immune responses in the host—have been isolated from several foodborne bacteria and are thought to be associated with several autoimmune disorders, such as rheumatoid arthritis, multiple sclerosis, Graves disease, and psoriasis. [22] A link between *Campylobacter* and Guillain-Barré syndrome has been suspected for over a decade. It is estimated that possibly 40 percent of Guillain-Barré cases are secondary to primary infection, with *Campylobacter* usually developing 7 to 21 days after resolution of gastrointestinal symptoms. [22,23] Hemolytic-uremic syndrome (HUS), characterized by acute renal failure, thrombocytopenia, and microangiopathic hemolytic anemia, develops in some patients, particularly children, following acute colitis with *E. coli* O157:H7. HUS is caused by toxin-mediated damage to the glomerular epithelial cells and possibly the tubular epithelial cells and is the leading cause of acute renal failure in children. [22,23] Other organisms that have been linked to HUS include other strains of *E. coli, Citrobacter, Campylobacter, Shigella, Salmonella,* and *Yersinia.*[23] Many of the acute symptoms of ciguatera poisoning can persist as a waxing and waning chronic symptom complex that is often misdiagnosed as chronic fatigue syndrome, brain tumor, or multiple sclerosis. [23]

PREVENTION AND SURVEILLANCE

Traditional Surveillance

Effective foodborne-disease surveillance is critical to determine the frequency of cases, identify newly emerging pathogens, and isolate factors that contribute to the disease transmission.[11] Traditional surveillance systems for foodborne illnesses rely on clinical microbiology laboratories reporting identified pathogens or suspected outbreaks to state health departments, which then report them to the CDC. [24] This type of passive surveillance requires a person with a diarrheal illness to seek care from a physician who then in turn obtains a stool culture. The current underreporting of foodborne illnesses is a direct consequence of this interdependent chain of events where an elimination of even one step results in a case not being identified. [24] It is estimated that only 1 in 20 to 100 cases of *Salmonella* are reported to the CDC.[11]

FoodNet

FoodNet is a collaborative project of participating data collection sites in the CDC, US Department of Agriculture, and the US Food and Drug Administration (FDA) that became operational in 1995. It employs an active surveillance strategy for diarrheal illnesses and foodborne illnesses in sentinel populations monitored at over 300 clinical laboratories throughout the United States. [24] FoodNet investigators actively contact these laboratories for confirmed cases of *Salmonella, Shigella, Campylobacter, E. coli* O157:H7, *Listeria, Yersinia, Vibrio, Cyclospora,* and *Cryptosporidium.* They have built a comprehensive database of foodborne illness in these regions.[24] Physician practice patterns for ordering stool specimens have also been monitored. Population surveys create an approximation of the number of patients with diarrheal illness who seek medical care. [24] This information is centrally based at the CDC and facilitates timely recognition and response to foodborne outbreaks.

PulseNet

PulseNet, completed in May 1998, is a national computer network of public heath laboratories that perform DNA fingerprinting on two bacteria: *E. coli* O157:H7 and *Salmonella typhimurium.* Using a standardized methodology for pulsed-field gel electrophoresis (PFGE), designated network laboratories in the United States can rapidly determine whether foodborne illnesses in multiple locations are linked to a common pathogen and food source. Bacterial PFGE patterns are entered into a centralized national electronic database by the state or local health department. Matching patterns from different locations during a defined time period will trigger an

alert to a possible multilocation foodborne-illness outbreak. [8]

Prevention

The current system for ensuring food safety is complex, with authority divided between federal, state, and local governments. Currently in the United States, the FDA inspects food-processing plants and, along with the US Department of Agriculture, regulates the interstate commerce of these foods. Final delivery destinations, such as restaurants, supermarkets, and cafeterias, are regulated by local health departments. The movement of food from the farm or water sources follows a predictable process-specific pathway. Contamination can occur at one or more points in the process. Hazard Analysis and Critical Control Points (HACCP) is an applied methodology that identifies and controls the key steps in the process that are vulnerable to contamination. It requires cooperation between government regulatory agencies and the food industry and replaces the simple inspection of a final product. Industry-wide solutions can be implemented once contamination points are identified.[1,7,10,11]

Emergency physicians should advise infected patients of the potential risks they pose to family members or others, particularly if they are food handlers or health care workers.[15] A small number of factors in food handling are responsible for a large percentage of foodborne disease. [21] The most important steps that can be taken in the home to prevent foodborne disease is thorough cooking and eating cooked food promptly. Educate patients that food from animal sources such as meat, dairy, and eggs should be either pasteurized or completely cooked and not eaten undercooked or raw. Cross contamination from the juices or drippings from raw meat, poultry eggs, or shellfish with other foods must be avoided by washing hands or common preparation surfaces with soap and water. Prepared food should not be left for extended periods of time at temperatures that will promote bacteria growth.[4,21] The World Health Organization has established rules for the preparation of safe food in the home that can be accessed via the Internet at http://www.who.int/fsf/gldnrls.htm.

145 INFECTIONS FROM ANIMALS

John T. Meredith

The World Health Organization classifies zoonotic infections as those diseases and infections that are naturally transmitted between vertebrate animals and humans. [1] This broad class of diseases includes more than 200 specific diseases and syndromes covering an extremely variable range of clinical syndromes and medical therapy.[2] Zoonotic infections can be transmitted to humans by direct contact with an infected animal or infected animal product, by ingestion of contaminated water or food products, by inhalation, and through arthropod vectors. In North America and Western Europe, many of the serious zoonotic infections either have been eradicated or are beginning to come under control. Rabies, brucellosis, and echinococcosis will probably be eliminated from developed countries within the next 20 years.[3] Nevertheless, zoonotic infections with a relatively low incidence in North America often incur high morbidity and mortality. Pets are the principal reservoirs of zoonoses in North America. Zoonotic infections still represent a significant public health issue in most of the underdeveloped regions of the world, especially those undeveloped regions and countries dependent economically on agricultural animals. As such, the incidence of zoonotic infections is significant, with accompanying high morbidity and mortality. Another concern is the ever-increasing growth and mobility of the world's population. This increase in human mobility has resulted in the appearance of new zoonotic infections and the reemergence of previously eliminated zoonoses. Of significance is that more than 50 percent of the newly identified infectious agents since 1976 are associated with animals. [4] This trend of newly emerging zoonoses is likely to continue. Thus, diversity of presentation, human mobility, and zoonotic reemergence make the diagnosis and management of zoonotic infections a daunting task for emergency physicians.

RISK ASSESSMENT

Zoonotic infections are common in North America, with an estimated 4 million people infected annually. [5] These diseases are underdiagnosed, and the possibility of a zoonotic infection should be an integral part of the differential diagnosis of any patient who presents with an infectious syndrome. Specific occupations and avocations result in an increased risk of zoonotic acquisition by increased exposure to both domestic and nondomestic animals. Farmers, migrant workers, slaughterhouse workers, veterinarians, cattle ranchers, animal researchers and handlers, forestry workers, hunters, pet owners, and outdoor enthusiasts all have an inherent risk of acquiring a zoonotic infection. [6] The type of animal exposure is another important factor. Dressing, skinning, or handling an animal's skin; a history of animal bite or scratch; and ingestion of animal or dairy products all carry an associated risk of zoonotic infection. Recent travel and history of habitation, particularly in an underdeveloped country or rural area, represent particular risk factors for zoonotic infection. Other factors are a patient's immunologic status and the presence of comorbid or debilitating diseases. Patients with acquired immune-deficiency syndrome, diabetes, alcoholism, intravenous drug abuse, asplenism, cancer, and a history of chemotherapy all have an increased risk of acquiring a zoonotic infection. When assessing a patient who might have a zoonotic disease, information regarding occupation, avocation, place of residence, exposure to pets and to domesticated and wild animals, immunologic status, history of debilitating illness or drug and alcohol abuse, travel history, and arthropod exposure is very important to elicit (Table 145-1).[7]

Risk Category	Examples
Agricultural workers	Farmers, cattle ranchers, sheep ranchers, and migrant workers
Animal-processing workers	Slaughterhouse workers, animal-hide processors, and workers in any manufacturing plant that deals with animal products or by-products
Outdoor enthusiasts	Forestry workers, lumbermen, surveyors, park rangers, hunters, spelunkers, fishermen, and those who regularly engage in outdoor recreational activities
Pet owners	Those with a dog, cat, bird, rodent, rabbit, reptile, or fish
Professionals	Veterinarians, animal researchers, and animal handlers
Immunocompromised patients	Those with congenital immunodeficiencies, diabetes mellitus, alcoholism, renal failure, liver failure, cancer splenectomy or HIV

TABLE 145-1   Risk Factors for Zoonotic Infection

SYSTEMIC ZOONOSES INFECTIONS

Zoonotic infections are caused by an extremely diverse group of microorganisms. A myriad of classification approaches focus on the pathogen, animal vector, mode of transmission, geographic range, and clinical syndrome. For emergency physicians, the best approach is one of clinical syndrome presentation, but systemic zoonoses are most difficult to diagnose. Often, they present as an undifferentiated febrile illness with pyrexia, cephalgia, myalgia, malaise, and weakness. This presentation is very common in patients in an emergency department and can indicate pathology other than that of a zoonotic infection. The concern is how to differentiate a zoonotic infection from a benign febrile illness. In this regard, risk factors for acquiring a zoonotic infection are very important, as is recognizing the seasonal variation of most zoonotic infections. In the United States, most zoonoses show an increased incidence in the spring and summer. [8] However, systemic zoonotic infections should be included in the differential diagnosis of any seriously ill patient who presents with an undifferentiated fever. Specific zoonoses that can present as an undifferentiated febrile illness or septic presentation include *Aeromonas* spp, *Brucella canis, Capnocytophaga, Chlamydia psittaci, Leptospira* sp., *Francisella* sp., *Salmonella enteritidis, Streptococcus pyogenes, Yersinia pestis, Coxiella burnetii, Ehrlichia* sp., and *Rickettsia rickettsi* (Table 145-2).

TABLE 145-2   Systemic Zoonotic Infections

TICKBORNE ZOONOTIC INFECTIONS

Tickborne zoonoses deserve special consideration. More zoonotic diseases are transmitted by ticks then by any other vector. [9] Tickborne infections include bacterial, rickettsial, viral, and protozoan infections. As a subset of zoonotic infection, these diseases often go unrecognized in the initial evaluation of febrile patients. Because a high proportion of physicians in the United States know little about tickborne disease, they do not consider this diagnosis in febrile patients. [8] Additionally, not all patients who acquire a tickborne zoonotic infection recall a history of a tick bite. [10] Nevertheless, tickborne zoonoses represent a significant source of mortality and morbidity in the United States—approximately 13,000 cases each year. [11] An understanding of the geographic distribution of tickborne zoonoses is important in diagnosing this zoonotic subset (Table 145-3). The seasonal variation in tickborne zoonoses follows that of other zoonotic infections in North America, the highest incidence being incurred during spring and summer. Rocky Mountain spotted fever (RMSF), Lyme disease, relapsing fever, Colorado tick fever, tularemia, babesiosis, and ehrlichiosis often present with an undifferentiated febrile illness most characteristic of a viral infection, though often accompanied with a rash (Table 145-4).

Disease	Geographic Distribution
Lyme disease	Atlantic central and northcentral USA
Rocky Mountain spotted fever	Most of the continental USA although more prevalent in the southeast and southcentral USA
Ehrlichiosis	
Human granulocytic	Japan, Malaysia, and the USA Eastern, northeastern, and northcentral USA
Human monocytic	Mostly southern USA
Q fever	Worldwide
Relapsing fever	Worldwide
Tularemia	USA (except Hawaii) and Canada
Babesiosis	Coastal areas of MA, RI, and NY; also in MD, VA, MN, WI, GA, WA, and Mexico
Colorado tick fever	Western and northwestern USA and south-western Canada

TABLE 145-3   Tickborne Zoonotic Infections: Geographic Distribution

TABLE 145-4   Tickborne Zoonotic Infections

RMSF is the one of the most frequently reported rickettsial infections in the United States. [12] The causative organism is *Rickettsia rickettsii,* a pleomorphic, obligate intracellular parasite, and the vector is the *Dermacentor* sp. tick. Deer, rodents, horses, cattle, cats, and dogs can serve as zoonotic hosts. RMSF is classically described as a triad of fever, rash, and tick exposure in a majority of infected patients; but a history of tick exposure can only be recalled in approximately 50 percent of these patients. Additionally, RMSF is often misdiagnosed. [13] Other presenting signs and symptoms include malaise, myalgias, lymphadenopathy, abdominal pain, nausea, vomiting, diarrhea, hepatosplenomegaly, cephalgia, conjunctivitis, confusion, meningismus, renal failure, respiratory failure, and myocarditis. The rash of RMSF occurs on days 1 to 15 of the illness but is absent in up to 17 percent of patients. [14] Characteristically, this rash appears maculopapular, occurring on the extremities and around the wrist and ankles. The rash spreads centripetally up the trunk, involves the palms and soles, and can become petechial and, rarely, necrotic. The characteristic presentation of this rash may aid in the diagnosis of RMSF. Laboratory abnormalities are nonspecific and consist of a normal or decreased leukocyte count, thrombocytopenia, elevated liver function studies, and hyponatremia. Laboratory diagnosis is unreliable in the early course of RMSF. Diagnosis can be confirmed with a rise in antibody titer between acute and convalescent serum. Skin biopsy with immunofluorescent testing can also confirm diagnosis, but a negative skin test does not exclude infection. [15] Additionally, a culture of *R. rickettsii* may confirm diagnosis. Treatment is with a tetracycline or chloramphenicol (doxycycline 100 mg PO bid for 14 days or chloramphenicol 500 mg qid for 10 days).

Lyme disease is the leading vector-borne zoonotic infection in the United States. [16] Though most prevalent in the Northeast, all continental 48 states have reported Lyme disease. The responsible organism is *Borrelia burgdorferi,* a spirochete, and the vector is the *Ixodes* spp. tick. Small mammals and deer serve as the principal zoonotic hosts. Typically described in three distinct stages, the initial stage of illness often presents with a macular dermatitis: erythema migrans. This rash associated with early Lyme disease occurs 2 to 20 days at the site of the tick bite and is a result of a vasculitis. Erythema migrans, which is an erythematous plaque with central clearing, may persist for up to 1 month and recur in the secondary stage of Lyme disease. [17] Erythema migrans, though, occurs in only 60 to 80 percent of cases. [18] Untreated erythema migrans resolves spontaneously in 3 to 4 weeks. Nevertheless, erythema migrans may aid in the diagnosis of Lyme disease. [16,18] With the dissemination of the *Borrelia* spirochete, the secondary stage of illness—fever, adenopathy, and flulike symptoms—along with multiple annular dermatologic lesions may occur. The most common neurologic symptom is the development of cranial neuritis, and often facial nerve palsy that can be unilateral or bilateral. This palsy can occur concomitantly with the initial rash of erythema migrans. Other peripheral neuropathies can occur in addition to an asymmetric oligoarticular arthritis of the large joints, with a particular predilection to the knees. Chronic manifestations, the tertiary stage of illness, occur years after the initial infection and consist of chronic arthritis, myocarditis, subacute encephalopathy, axonal polyneuropathy, and leukoencephalopathy. These manifestations account for the tertiary stage of illness. [19] Diagnosis is principally a clinical one, though a two-step serologic test—enzyme immunoassay and Western immunoblot—may help to confirm it. *Borrelia burgdorferi* has been cultured, but that is extremely difficult. Treatment is with doxycycline (100 mg PO bid for 10 to 21 days) in the initial stage of illness. [9] Alternative antibiotic therapy includes amoxicillin, (500 mg PO tid for 10 to 21 days), cefuroxime (500 mg PO bid for 21 days), and clarithromycin (500 mg PO bid for 21 days). [16] Prophylactic treatment is not recommended, since fewer than 10 percent of the bites transmit the disease, and because prophylactic antibiotic administration may depress the immune response to the disease. A vaccine against Lyme disease is now available for high-risk individuals. This vaccine is made from the outer surface protein of *B. burgdorferi* using recombinant technology. As the tick feeds on an immunized host, antibodies are ingested destroying spirochetes in the gut of the engorging tick prior to the transmission to the host. A course of three injections of vaccine are required for maximal effectiveness in preventing asymptomatic infections.

Relapsing fever is frequently misdiagnosed and underreported. [20] The responsible organisms are *Borrelia* spirochetes, which can alter their surface antigens. The vectors are *Ornithodoros* ticks, and the principle zoonotic reservoirs are wild rodents. Often the initial presentation is that of a rash or pruritic eschar at the site of a tick bite. An average incubation period of 7 days precedes the onset of fever, chills, cephalgia, myalgia, arthralgia, abdominal pain, and general malaise. Characteristically, the febrile episodes are interspersed with afebrile periods. Leukocytosis, thrombocytopenia, and an elevated erythrocyte sedimentation rate are the typical laboratory findings. Diagnosis is confirmed with the appearance of spirochetes on Wrights- or Giemsa-stained peripheral blood smears. Treatment is with doxycycline or erythromycin (doxycycline 100 mg PO bid for 14 days or erythromycin 500 mg qid for 10 to 14 days). [21,22]

Colorado tick fever has an RNA virus as etiology. Endemic to the western mountainous regions of the United States, approximately 300 cases are reported annually. The principal vector is the tick of the *Dermacentor* sp., and the zoonotic reservoirs are deer, marmots, and porcupines. With an incubation period of 3 to 7 days, the onset of illness is characterized by fever, chills, cephalgia, myalgia, and photophobia. Often following the initial presentation is a macular or petechial rash. Rarely, complications occur. Diagnosis is most often clinical, with associated epidemiologic factors, but the virus can be isolated from blood or cerebrospinal fluid (CSF) by

inoculating suckling mice.[23] Treatment is supportive care, with infrequently, a long convalescence.

Tularemia, which has been characterized as "a plague-like disease of rodents,"[24] is caused by a gram-negative, nonmotile coccobacillus: *Francisella tularensis*. The zoonotic vectors are ticks of the *Dermacentor* sp. and the *Amblyomma* sp., and the principal zoonotic reservoirs are rabbits, hares, and deer.[11] However, tularemia can be contracted through open wounds while dressing an infected zoonotic host. The clinical presentation depends on the method of inoculation, with the ulceroglandular form being the most common. This particular form is often an ulcer at the site of the tick bite, with painful regional adenopathy. Other forms are a glandular form without ulcerations, and a typhoidal form consisting of fever, chills, cephalgia, and abdominal pain. The oropharyngeal form and pneumonic form are the result of deposition into the eyes or inhalation of *F. tularensis* bacterium. Laboratory findings are nonspecific, and the diagnosis can be determined by culture and enzyme-linked immunosorbent assay (ELISA). Treatment is with streptomycin [15 mg/kg intramuscularly (IM) daily for 10 to 14 days] or gentamicin (3 mg/kg/day in three divided doses daily for 10 to 14 days). A live attenuated vaccine is available for research workers and laboratory personnel.[25]

Babesiosis is a malaria-like disease with the etiologic agents being protozoan parasites: *Babesia microti* and *Babesia equi*.[26] The major zoonotic reservoirs are domesticated mammals, rodents, and deer. *Ixodes* ticks functions as the principal vector. Blood transfusions have been implicated in the transmission of babesiosis.[26] Clinically, the presentation is of generalized malaise, anorexia, fever, and chills often progressing to intermittent sweats, myalgia, and cephalgia. Splenectomy and immunologic impairment are thought to be risk factors for this zoonosis. Additionally, babesiosis can progress, resulting in hemolytic anemia. Laboratory tests often show evidence of hemolysis, liver dysfunction, anemia, thrombocytopenia, and renal failure. Interestingly, approximately 20 percent of the patients with babesiosis have a concurrent infection with Lyme disease. Diagnosis is made by finding intraerythrocytic ring forms on a Giemsa-stained peripheral blood smear, though false-negative results can occur when the level of parasitism is low. Treatment is with oral quinine (650 mg tid for 7 days) plus intravenous or oral clindamycin (600 mg tid for 7 days).[26]

Ehrlichiosis is a zoonotic disease with two principal presentations of *human granulocytic ehrlichiosis* and *human monocytic ehrlichiosis.* The etiologic agent responsible for the granulocytic form is thought be be similar to *Ehrlichia phagocytophila* and *Ehrlichia equi*.[27,28] The predominant form in the United States is the monocytic form caused by *Erlichia chaffeensis*. The ehrlichia bacteria are gram-negative pleomorphic coccobacilli that infect circulating leukocytes.[28] The zoonotic reservoirs are thought to be deer, dogs, and other mammals, with the vectors being *Ixodes* sp. and *Amblyomma* sp. ticks. Characteristic clinical presentation is that of fever, cephalgia, malaise, nausea, vomiting, abdominal pain, anorexia, and myalgia. In a minority of cases, a maculopapular or petechial rash is present involving the soles and palms. Renal failure, respiratory failure, and encephalitis can develop. Diagnosis is with serologic testing. Laboratory studies can demonstrate leukocytopenia, thrombocytopenia, and liver dysfunction. Treatment is with doxycycline, 100 mg PO bid for 7 to 14 days.[28]

Tick removal can present a vexing challenge to the emergency physician. The use of a burning match or any action resulting in crushing the tick should be avoided. These attempts at removal result in the tick regurgitating into the wound site. Additionally, they have the potential for incomplete removal of the tick. The most effective way to remove an imbedded tick is a two-step approach. First, viscous lidocaine is applied to kill the tick and anesthetize the bite site. Second, careful and gentle traction is applied to the tick's head with fine forceps. It is imperative that all parts of the tick be removed. Residual tick body parts can stimulate a granulomatous reaction and persistent infection.

ZOONOTIC ENCEPHALITIS AND MENINGITIS

Zoonotic encephalitis is most often transmitted hematologically as an arboviral infection with an arthropod vector and animal host. Often the vector is a mosquito or tick and the animal host is a small animal or bird. The one exception is rabies, which follows peripheral nerve tracts after inoculation from an infected animal's bite. Additionally, encephalitis may be seen in the nonviral zoonotic infections of *Bartonella henselae, Brucella canis,* borreliosis, *Coxiella burnetii, Ehrlichia* sp., listeriosis, leptospirosis, Lyme disease, RMSF, psittacosis, and toxoplasmosis.[11,29,30] The presentation is one of a prodromal illness with malaise, myalgia, fever and, occasionally, parotiditis. This prodromal phase advances to a sudden decline in mental status associated with headache and fever. Prompt recognition and therapy of encephalitis is important, given the high morbidity and mortality rates. However, it is significant to recognize that there are no pathognomonic signs and symptoms that distinguish the exact etiology of encephalitis. The CSF is often abnormal, showing a slightly elevated opening pressure, normal to slightly elevated protein concentration, normal glucose levels, and predominance of lymphocytes. The patient has an abnormal electroencephalogram with diffuse bilateral slowing interrupted by occasional spike activity. CSF viral cultures are frequently sterile, and the infectious agent is rarely isolated from the CSF.[31,32 and 33] ELISA of serum can be used to detect most arboviral infections causing encephalitis. Treatment is supportive and directed toward decreasing the intracranial pressure.

Zoonotic meningitis has an equally varied range of pathogens. Brucellosis, listeriosis, plague, salmonellosis, tularemia, leptospirosis, Lyme disease, ehrlichiosis, Q fever, RMSF, and psittacosis can all be etiologic agents. CSF is almost always abnormal as in zoonotic encephalitis but with a greater concentration of lymphocytes. Treatment is directed toward the specific organism cultured from the CSF. However, empiric antibiotic coverage should be administered immediately in any presumptive case of meningitis in an effort to reduce mortality and morbidity.

RESPIRATORY ZOONOTIC INFECTIONS

Respiratory zoonotic infections can be divided into two distinct syndromes of upper respiratory infections (pharyngitis) and lower respiratory infections (pneumonia). Recurrent culture-proven streptococcal pharyngitis in a household member can have a zoonotic source—often the household pet.[34] For complete eradication of this form of streptococcal pharyngitis from a family, the family pet, in addition to family members, may require a course of antistreptococcal antimicrobial therapy. Prolonged exudative pharyngitis raises the suspicion of a zoonotic origin or atypical pharyngitis, particularly if the exudative pharyngitis includes systemic symptoms and leukocytosis, and is refractory to standard antistreptococcal therapy. In this case, it is pertinent to inquire about animal exposure. Dogs and domesticated farm animals can be the source of *Streptococcus* sp., *Corynebacterium ulcerans, Yersinia* sp., and viral vesicular stomatitis. All of these zoonoses can present as an exudative pharyngitis.[5] Nondomesticated animals can be a source of exudative pharyngitis as a result of *Bordetella* sp., *Francisella tularensis, Streptobacillus moniformis,* and *Yersinia pestis*.[5] Both pet birds and wild birds carry *Chlamydia psittaci,* which can cause an atypical exudative pharyngitis in humans.

Zoonotic pneumonia presents as an atypical pneumonia with systemic symptoms. Most often the presentation consists of productive or nonproductive cough, fever, chills, headache, myalgias, and a nonspecific rash. These pneumonias are community acquired. Of concern to emergency physicians is that zoonotic pneumonia can often be rapidly lethal, as is the case in pneumonic plague. Zoonotic pneumonia should be considered in any case of gram-negative community-acquired pneumonia and in any case of atypical pneumonia with systemic symptomatology (Table 145-5).[35] A detailed history provides the data necessary for the consideration of zoonotic pneumonia. Inquiries about animal exposure, occupation, and recent travel are warranted for patients with an atypical pneumonia. Particular attention should be paid to slaughterhouse workers and those individuals exposed to ticks, birds, and other fowl. Additionally, a history of outdoor activity, recreational history, and food-contact history should be obtained.

TABLE 145-5   Zoonotic Pneumonias

Anthrax (*Bacillus anthracis*) is extremely rare in North America. The pulmonary form—inhalation anthrax—is acquired most often from handling unsterilized, imported animal hides or imported raw wool. Inhalation anthrax is universally fatal. Not a true pneumonia, inhalation anthrax is a mediastinitis without alveolar involvement.

Initial symptoms are flulike in character and progress to respiratory failure in 3 to 4 days, with a marked mediastinal and hilar edema. One of the serious concerns to emergency physicians is the potential use of *B. anthracis* as a biologic warfare agent. Though *B. anthracis* can be readily cultured, the delivery system that can generate 5 μ particles and disperse large volumes of culture material is not easily deployable in a large population center. Currently, active-duty US military personnel are being immunized against anthrax. Treatment is with either ciprofloxacin (750 mg PO bid for 7 to 10 days) or doxycycline (100 mg PO bid for 10 to 14 days). Penicillin or erythromycin can be used as alternative antibiotics. [36]

Brucellosis (*Brucella* sp.) occurs most often in slaughterhouse workers exposed to the aerosol of *Brucella* bacteria. The consumption of unpasteurized dairy products is another way of acquiring brucellosis. Pneumonia with frank pulmonary infiltrates as a result of brucellosis is uncommon. Often the presentation is one of an upper respiratory infection with a cough, hoarseness of voice, and wheezing. Typically, peritracheal and hilar lymph node involvement is seen. With long-standing resolution, calcified granulomas and lymph nodes are characteristic findings. [37] Doxycycline (100 mg PO bid for up to 6 weeks) combined with rifampin (10 mg/kg/day up to 600 mg per day) is effective therapy. [38]

Chlamydia psittaci is common to most birds and fowl. Psittacosis is also known as parrot fever, parrot disease, or ornithosis. Human acquisition is from the inhalation of dust from dried bird feces, feather dust, or aerosolized avian respiratory secretions. Psittacosis is characterized by an incubation period of 5 to 14 days followed by abrupt onset of fever chills, cephalgia, myalgia, and generalized malaise. Pneumonia is atypical, with a nonproductive cough and lobar or interstitial infiltrates on chest radiograph. Extrapulmonary manifestations involving the heart, central nervous system, liver, and kidney are common. Tetracyclines (doxycycline 100 mg PO bid for 10 to 14 days) are the drugs of choice for treatment, with erythromycin (250 mg PO qid for 10 to 14 days) for patients intolerant to tetracycline. [39,40]

Q fever (*Coxiella burnetii*) is unique because it is the only rickettsial infection acquired by aerosol inhalation rather than by an arthropod vector. Q fever is common among domesticated farm animals in the United States and is shed in urine, afterbirth products, and feces. Feed lots are often contaminated with *C. burnetii*, which is highly resistant to environmental degradation. The disease is often self-limiting, with variable pulmonary manifestations and extrapulmonary findings. In addition to pulmonary infiltrates, pericarditis, myocarditis, endocarditis, and granulomatous hepatitis can occur. Treatment is with doxycycline (100 mg PO bid for 10 to 14 days), with erythromycin (250 mg PO qid for 10 to 14 days) as an alternative antibiotic. [41]

Pasteurellosis (*Pasteurella multocida*) is endemic to the normal oral flora of cats and most dogs. Often associated with necrotizing cellulitis from bite wounds, bronchitis, bronchopneumonia, and suppurative pleural effusion can occur as a result of pulmonary infection. Treatment is with amoxicillin with clavulanate (500 mg/125 mg PO tid for 10 to 14 days), tetracycline (doxycycline 100 mg PO bid for 10 to 14 days), penicillin (penicillin V 500 mg PO qid for 10 days), or a third-generation cephalosporin. [42]

Rocky Mountain spotted fever (*Rickettsia rickettsi*), an arthropod-vectored rickettsial infection, can result in a pulmonary capillary vasculitis with associated bronchiolitis. [11] Often a nonproductive cough is present. The chest radiographic findings vary from a normal radiograph to one that shows diffuse interstitial infiltrates and pleural effusions. A secondary bacterial pneumonia is commonly associated with this rickettsial pneumonia. Treatment is with tetracycline or chloramphenicol. [43]

Plague (*Yersinia pestis*) is endemic to the United States and is most often found in rock squirrels and ground rodents of the Southwest. Cats can also be carriers of plague. The principal vector is the rodent flea. Humans and household pets can become infected when bitten by an infected flea. Often an eschar is found at the site of the flea bite, followed by the development of a bubo, an enlarged proximal lymph node. Sepsis and pneumonia from hematologic spread then follow the bubo formation. The pneumonic form is highly contagious and rapidly fatal if not aggressively treated. Additionally, the pulmonary plague can be disseminated from one person to another through aerosolization of respiratory secretions. Treatment is with gentamicin [2.0 mg/kg intravenous (IV) loading dose followed by 1.7 mg/kg IV tid for 10 to 14 days], streptomycin (1 gram IM bid for 10 to 14 days), or a combination of tetracycline and an aminoglycoside. [44]

Influenza accounts for the major viral zoonotic pneumonia. Influenza viruses of the Orthomyxoviridae family are classed as types A, B, and C, and "Thogoto-like" virus. Influenza types A, B, and C infect humans, but zoonotic infections are limited to influenza type A. [45] Migrating aquatic fowl are thought to be the natural animal reservoir for influenza type A. Horses and marine mammals can also serve as reservoirs for this zoonotic virus. Additionally, there is very strong epidemiologic and biologic evidence for transmission of influenza between specific species, such as between pigs and humans. [46] Antigenic drift of the viral surface proteins hemagglutinin and neuraminidase in conjunction with a zoonotic reservoir accounts for the frequent human pandemics of influenza. The most noted of these pandemics have been the Spanish influenza of 1918, the Asian influenza of 1957, and the Hong Kong influenza of 1968. It is estimated that 20 to 40 million deaths worldwide were attributed to the Spanish influenza pandemic. [46] Influenza pneumonia carries a high morbidity for all age groups. The mortality rate is greatest in those older than age 70. This age group accounts for 90 percent of the deaths from influenza. [47] Treatment of influenza pneumonia is supportive care. Though amantadine and rimantadine have shown to be effective against influenza A, these two antivirals are not effective against types B and C. Antibiotic therapy for superimposed bacterial pneumonia can contribute to the reduction of mortality and morbidity from influenza. Prevention is by annual vaccination and by preventing influenza introduction into domestic poultry and pigs.

Hantavirus, identified in 1977, is a viral zoonosis. The recognized etiologic agent in North America is the Sin Nombre virus, which belongs to the Bunyaviridae family of viruses. To date, at least 10 distinctive serotypes have been identified, each with a specific rodent vector, geographic distribution, and clinical manifestation. [47] The deer mouse (*Peromyscus maniculatus*) is the primary vector in the United States. [46] Infected rodents excrete Hantavirus in feces, urine, and saliva. Human infection occurs with the inhalation of dried, particulate feces contact with urine, or by a rodent bite. The majority of Hantavirus serotypes have a predilection for the kidney, and the most common worldwide presentation is that of acute renal failure with concurrent thrombocytopenia, ocular abnormalities, and flulike symptoms. In the United States, the presentation of this zoonosis is that of Hantavirus pulmonary syndrome, [47,48 and 49] which consists of an initial flulike prodromal illness of 3 to 4 days' duration, rapidly followed by pulmonary edema, hypoxia, hypotension, tachycardia, and metabolic acidosis. Dizziness, nausea, vomiting, absence of cough, and thrombocytopenia are common and may help to differentiate Hantavirus pulmonary syndrome from adult respiratory disease syndrome, bacterial pneumonia, and influenza pneumonia. [2] Hantavirus pulmonary syndrome carries a very high mortality rate of 50 to 70 percent. Diagnosis is with an immunofluorescent or immunoblot assay. Treatment consists of supportive care with attention to adequate oxygenation and possibly the use of an inhalation solution of ribavirin. [47,48 and 49]

GASTROINTESTINAL ZOONOTIC INFECTIONS

With a multitude of etiologies, gastroenteritis is one of the most common illnesses treated by emergency physicians. Many of the parasitic, bacterial, and viral organisms responsible for gastroenteritis share a zoonotic source in addition to a human source. In the evaluation of patients with suspected gastroenteritis, information regarding travel history and animal exposure is extremely important. Occupational exposure to cattle, horses, poultry, sheep, swine, or reptiles and even exposure to a household pet can be significant in determining a zoonotic origin. Dogs in particular are well known to have a 40 percent carriage rate for *Giardia lamblia* and a 30 percent carriage rate for the bacterial enteropathogens *Salmonella* sp. and *Yersinia* sp. [50]

Zoonotic gastroenteritis often presents with fever, headache, and abdominal pain often localizing to the right lower quadrant. Patients may have diarrhea or constipation. Laboratory findings may consist of electrolyte and acid-base abnormalities if diarrhea is severe. Leukocytosis may be seen if an interstitial invasion has occurred, and eosinophilia is often a finding with intestinal parasitic infestation. Most cases of zoonotic gastroenteritis are self-limiting and require only fluid hydration. However, specific pathogens may require specific therapy (Table 145-6).

Zoonosis	Animal Reservoir	Antibiotic Treatment
Brucellosis	Dogs and farm animals	Doxycycline or TMP-SMX
Campylobacter sp.	Dogs, cats, farm animals, poultry, and unpasteurized milk	Erythromycin or doxycycline
Giardia lamblia	Beavers, dogs, cats, and farm animals	Metronidazole, tinidazole, or quinacrine
Salmonella sp.	Reptiles (turtles), aquatic animals, dogs, cats, and horses (1 spl)	TMP-SMX or ciprofloxacin
Yersinia sp.	Rabbits, cats, and wild animals	Streptomycin, gentamicin, or doxycycline
Yersinia sp.	Dogs and cats	Gentamicin, chloramphenicol, TMP-SMX, doxycycline, or ciprofloxacin
Vibrio cholerae	Shellfish	Doxycycline, ciprofloxacin, or TMP-SMX (resistance to TMP-SMX)

Abbreviation: TMP-SMX, trimethoprim-sulfamethoxazole.

TABLE 145-6 Gastrointestinal Zoonotic Infections

DERMATOLOGIC ZOONOTIC INFECTIONS

Dermatologic findings are common in zoonotic infections, as the dermis is often the site of inoculation and may display focal findings. The common dermatologic infections of impetigo, ecthyma, and cellulitis can be transmitted zoonotically, as can human infestations with mites and lice. The dermatophytoses *Tinea verrucosum* and *Microsporum canis* account for the majority of zoonotic dermatophyte infections, with *M. canis* accounting for 15 percent of all human dermatophytoses.[51] Chancriform lesions (ulcerations at the site of inoculation) can result from zoonotic infection of bacterial, mycobacterial, fungal, or viral etiology. The most significant bacterial chancriform zoonotic lesions are *Bacillus anthracis* (anthrax), *Bartonella henselae* (cat-scratch disease), *Erysipelothrix rhusiopathiae* (erysipeloid), *Francisella tularensis* (tularemia), *Listeria monocytogenes* (listeriosis), *Mycobacterium marinum,* and *Pseudomonas mallei* (glanders).[5,30,52] The vast majority of these chancriform zoonotic infections occur in livestock workers, cattle ranchers, veterinarians, stable workers, horse trainers, slaughterhouse workers, poultry workers, and farmers. Significant zoonotic fungal chancriform infection is principally from *Blastomyces dermatitidis* (cutaneous blastomycosis) and *Sporothrix schenckii* (sporotrichosis). Dog and cat owners, along with veterinarians, are most at risk of contracting these two fungal zoonoses. [51] All of the chancriform zoonotic infections most commonly appear at the site of inoculation, often the hands or forearms.

Zoonotic dermatoses of viral etiology include *Vaccinia* sp. (cowpox), *Paravaccinia* sp. (pseudo-cowpox), and bovine papular stomatitis. These cutaneous viral zoonoses often occur on the hands and forearms of patients who work closely with cattle, sheep, goats, or horses.

Systemic zoonoses are also accompanied by dermatologic findings, usually a generalized maculopapular rash, which is common in bartonellosis, lymphocytic choriomeningitis, Colorado tick fever, leptospirosis, psittacosis, and rickettsial infections. However, the maculopapular rash associated with most zoonotic infections is nonspecific and does not facilitate the diagnosis. Those zoonotic infections with specific dermatologic findings aiding in the diagnosis are infections from *Aeromonas* sp., Lyme disease, RMSF *Vibric* sp., and viral hemorrhagic fevers (Table 145-7).[5,11]

Zoonoses	Characteristic Rash
Aeromonas sp.	Crepitant cellulitis with systemic toxicity
Lyme disease	Erythema migrans at the focus of the tick bite
Rocky Mountain spotted fever	Maculopapular rash on soles and palms, centripetal spread, and advance characteristic of petechial hemorrhage and necrosis
Viral hemorrhagic fever	Petechial and purpuric rash

TABLE 145-7   Specific Zoonotic Dermatologic Findings

ZOONOSES ACQUIRED FROM HOUSEHOLD PETS

It is estimated that there are more than 110 million dogs and cats, with 70 percent of all households in the United States having these pets. Additionally, up to 20 percent of all households have a pet bird, and more than 20 million homes have an aquarium. [53] There are more than 30 significant human diseases acquired from household pets.[30] Dogs and cats are the two most common household pets in North America and account for the majority of these zoonotic infections. Small rodents, pet birds, reptiles, and aquarium fish account for only a fraction of the zoonotic infections in the United States (Table 145-8).[53] Interestingly, though pet owners often have close contact with their pets, pet-acquired zoonoses are infrequent and not often recognized. Yet these infections have a very diverse etiology and encompass parasitic, bacterial, rickettsial, and fungal infections.

TABLE 145-8   Pet-Associated Zoonotic Infections

Parasitic infections are very common among household pets, predominantly dogs and cats. Up to 50 percent of dogs are infected with at least one intestinal parasite, and 15 percent of adult dogs actively excrete *Toxocara canis,* the source of toxocariasis, visceral larva migrans.[52] Despite its prevalence in dogs, human toxocariasis is infrequently diagnosed probably because infection is often subclinical. Typically, the only indication of infection is eosinophilia. Children may display fever, cough, and nonspecific rash, as well as an inability to gain weight. Rarely, pulmonary infiltrates, hepatosplenomegaly, and seizures may occur. Diagnosis is by either biopsy of infected tissue or by ELISA. Treatment in the symptomatic patient consists of oral diethylcarbamazine (2 mg/kg tid for 10 days) or albedazole (400 mg bid for 5 days). Corticosteroids can be used to control the allergic component.

Other intestinal parasites that may be transmitted to humans from household pets include *Ancylostoma caninum* (cutaneous larva migrans), *Echinococcus granulosus* (echinococcosis), and *Dipylidium caninum* (dipylidiasis or dog and cat tapeworm).[52] Cutaneous larva migrans is often a self-limiting, pruritic, erythematous serpiginous rash caused as the larva migrates through the skin and is often acquired from fecal-contaminated soil. Topical thiabendazole is effective therapy in shortening the disease course.[34,52] Though dogs and other carnivores are the definitive hosts for *E. granulosus,* echinococcosis is most common in areas of cattle and sheep ranching. This zoonosis involves multiple organ systems: liver, lung, muscle, bone, kidney, and brain. Typically, there is a unilocular cyst containing multiple larvae that enlarge over time. Diagnosis and treatment usually occur at the time of surgical resection. Aspiration of the cyst is contraindicated, because leakage of the cystic fluid can spread the infection and cause an anaphylactic reaction. [52] Dipylidiasis, a tapeworm common to both dogs and cats, is found worldwide. Human infection is rare; when infection does occur, however, it is often in children and presents with the nonspecific symptoms of diarrhea and pruritus ani. Occasionally, the cucumber-shaped proglottides are seen moving in the child's stool. Treatment is with oral niclosamide. Infection with *Dirofilaria immitis* (dog heartworm) is extremely rare in humans.[52]

Cats are the host of the intracellular protozoan *Toxoplasma gondii,* which causes toxoplasmosis. Human toxoplasmosis can occur in three ways: by ingestion of uncooked or raw meat, especially pork or mutton containing the *Toxoplasma* cysts; by ingestion of the oocysts from cat and wild-animal feces; and transplacentally.[30,34,52] Transplacental transmission can result in congenital abnormalities of retinochoroiditis, hydrocephalus, hepatosplenomegaly, and thrombocytopenia in 10 percent of the children infected. The majority of children transplacentally infected with toxoplasmosis display no significant abnormalities. Nevertheless, pregnant women should limit their contact to only indoor cats and avoid contact with cat feces. The encysted trophozoite can become reactivated in a

previously infected host if the host becomes immunocompromised.[54]

Bacterial zoonoses from household pets include, but are not limited to, brucellosis, leptospirosis, salmonellosis, and campylobacteriosis. Brucellosis (*Brucella canis*) is an uncommon infection in humans and is most often acquired from dogs. Pigs, cattle, and goats are less frequent transmitters. The typical human course for brucellosis is self-limited, with fever, headache, myalgias, and nonspecific laboratory findings. Tetracycline is the standard therapy in treating human brucellosis, with streptomycin added to tetracycline in the treatment of severe cases.[30,34] Leptospirosis (*Leptospira canicola*) infects almost all mammals, but dogs are the principal vector for humans. Humans become infected through exposure to body fluids, particularly urine, of an infected animal. The acute phase of leptospirosis is characterized by headache, malaise, myalgias, and fever. Nonspecific rash, meningitis, uveitis, myositis, and leptospiruria follow the acute phase. Doxycycline (100 mg PO bid for 10 to 14 days) and high dose penicillin (penicillin G 20 to 24 million units IV qd for 10 to 14 days) are the mainstays of treatment for leptospirosis. [34,52]

Campylobacteriosis (*Campylobacter jejuni*) is a major cause of infectious diarrhea in humans. This zoonotic infection also occurs in dogs, cats, pigs, poultry, cattle, and horses. Human infection from a pet is uncommon, but the presence of a puppy or kitten with a diarrheal illness in the house and human contacts experiencing diarrhea should raise the suspicion of pet-acquired campylobacteriosis. Though the disease is often self-limiting, treatment with erythromycin can facilitate resolution in protracted cases. Nontyphoidal salmonellosis is typically a self-limiting gastrointestinal illness prevalent among dogs. Human transmission is rare. Diarrhea in any pet should alert the pet owner to use increased personal hygiene and to dispose of the pet's feces properly. [30,34]

The ticks and fleas inhabiting dogs and cats can transmit the zoonotic infections of tularemia, plague, and Rocky Mountain spotted fever. Tularemia (*Francisella tularensis*) is a zoonotic infection occurring in humans exposed to infected animals or the vectors of ticks or deer flies. Endemic in the wild-animal population of the southeastern and north-central United States, cats are the primary reservoir of tularemia in human infections. Transmission is often by cat bite, tick bite, or scratch. Dogs do not directly transmit tularemia but do serve as carriers of the ticks that can transmit this zoonosis. Tularemia presents in four different forms, depending on the site of infection. The ulceroglandular form is the most common, followed by oculoglandular tularemia, oropharyngeal tularemia, and pneumonic tularemia. The infrequent but most serious pneumonic form is most common among laboratory workers and animal handlers. This form has the highest mortality. Treatment is with either streptomycin or tetracycline. [30,34,52]

Plague (*Yersinia pestis*) is endemic in the rodent population of the southwestern United States. Dogs and cats can also be sources of this zoonosis. Transmission occurs when bitten by fleas inhabiting an infected rodent, dog, or cat or by eating infected rodents. Plague has three forms: bubonic or suppurative lymphadenopathy (the most common), the pneumonic form, and the septicemic form. Because of the aggressive nature of *Y. pestis,* treatment should not be delayed. Aggressive treatment with gentamicin or streptomycin should be initiated at the first indication of infection. Doxycycline or chloramphenicol are effective alternative antibiotics.[30,43,52]

Rocky Mountain spotted fever (*Rickettsia rickettsi*) is a tick-transmitted, systemic zoonosis, with the tick *Dermacentor* sp. as principal vector and reservoir. Animal reservoirs consist of rodents, rabbits and, infrequently, dogs. Children incur two-thirds of the documented infections of RMSF. With a characteristic rash, this systemic zoonosis often presents with fever and headache. Treatment is with tetracycline or chloramphenicol in young children and pregnant women. [26,32,54]

Zoonotic fungal infections are occasionally acquired by humans. The most common of these infections is a dermatophytosis from *Microsporum canis*. It is estimated that up to 30 percent of human dermatophytoses have a zoonotic origin.[52] Treatment is often with topical antifungals or griseofulvin.

ZOONOSES TRANSMITTED FROM ANIMAL BITES

Well recognized is that up to 1 percent of all emergency department visits are a result of an animal bite. [55] The vast majority of these bites (70 to 93 percent) are from dogs. Conversely, cats account for 3 to 15 percent of all animal bites but carry the highest risk of infection. [55,56] Infection acquired from either a dog bite or a cat bite is typically mixed flora. *Staphylococcus* and *Streptococcus* species predominate, followed by *Corynebacterium* species and *Pasteurella multocida*.[56] Cat bites are notorious for *P. multocida* infection, with 50 to 70 percent of healthy cats having *Pasteurella* isolates.[30,56] Anaerobes account for infection in 41 percent of all animal bites. Appropriate wound care with meticulous irrigation and wound exploration for joint, tendon, vascular, and nerve involvement is a prerequisite. Antibiotic coverage is warranted for wounds at high risk of infection and can typically consist of one of the following antibiotics: amoxicillin with clavulanate (500 mg/125 mg PO tid for 10 to 14 days), ampicillin with sulbactam (1.5 to 3.0 g/0.5 to 1.0 g IV or IM qid for 7 to 10 days), ticarcillin disodium (3 g IV every 3 to 6 h for 7 to 10 days), or piperacillin and tazobactam (3.375 g IV qid for 7 to 10 days). In addition to antibiotic coverage, the current tetanus status should be addressed for every animal bite victim. [30,56]

Rabies deserves special consideration in reference to animal bites. Though rabies is relatively rare among pet dogs and cats, it is increasing in incidence among wild animals. In the United States, seven species account for 97 percent of laboratory-confirmed rabies. In decreasing frequency, these species are skunks (62 percent), bats (12 percent), raccoons (7 percent), cattle (6 percent), cats (4 percent), dogs (3 percent), and foxes (3 percent). [56] Any unprovoked bite, regardless if the animal is a stray or pet, or a bite sustained from a dog or cat without documented rabies immunization, is cause for alarm. Until there is documented proof that the animal is free of rabies, the animal in question is assumed to have rabies.

Of special note is that a history of animal vaccination does not exclude the possibility that rabies has been acquired by the biting animal. [52] The rabies status of an animal can be determined either by quarantining the animal for 10 days and observing it for behavioral changes or by postmortem examination of brain tissue. If it cannot be determined that the animal is free of rabies, then the bite victim should undergo rabies prophylaxis, which consists of human diploid cell vaccine and rabies immune globulin.[52]

ZOONOTIC INFECTIONS AND IMMUNOCOMPROMISED PATIENTS

Immunocompromised patients deserve special consideration and encompass a very large group: patients with congenital immunodeficiencies, diabetes mellitus, chronic renal failure, or liver failure; splenectomized patients; chronic alcoholics; cancer patients; and HIV-positive patients. Of all of these patients, those undergoing chemotherapy and those with AIDS have the greatest risk of acquiring a zoonotic infection. [7] It is estimated that 30 to 40 percent of immunocompromised patients may own pets.[57] *Salmonella* and *Campylobacter* are the two most common infections acquired by immunocompromised patients from their pets,[7] but the overall risk of transmission of *Salmonella* and *Campylobacter* from contact with pets is low. Additionally, *Mycobacterium marinum,* from aquatic pets, and *Bartonella,* from cats, are also commonly acquired by immunocompromised patients. Other acquired zoonotic infections that immunocompromised patients are susceptible to include *Toxoplasma gondii, Cryptosporidium, Giardia, Rhodococcus equi, Bartonella, Mycobacterium marinum,* and *Bordetella bronchiseptica* (Table 145-9). With the exception of *Bartonella* (cat-scratch disease), most of these zoonotic infections are acquired by immunocompromised patients from sources other than exposure to animals.[54] These sources are principally from contaminated food or water. Nevertheless, it is important for emergency physicians to inquire about animal exposure and zoonotic risk factors when evaluating immunocompromised patients. Consultation with an infectious disease specialist and a veterinarian may be warranted in evaluating immunocompromised patients in the emergency department.

146 SOFT TISSUE INFECTIONS

Steven G. Folstad

GAS GANGRENE

Gas gangrene or clostridial myonecrosis is a rapidly progressive and serious life- and limb-threatening soft tissue infection caused by one of the spore-forming clostridial species of organism. Severe myonecrosis with gas production and sepsis are the hallmarks of this disease, and early diagnosis and aggressive management are needed to prevent the high risk of mortality associated with this infection.

Epidemiology

Clostridium species are ubiquitous organisms found throughout our environment. It is estimated that a full 30 percent of traumatic injuries are contaminated with one or more of the *Clostridium* species. There is approximately 1000 cases of gas gangrene reported to the Centers for Disease Control and Prevention (CDC) each year in the United States.[1] The incidence of disease secondary to these organisms is decreasing, presumably due to better wound management and more effective antibiotic therapy. For example, the incidence of gas gangrene in battle-related injuries was 5 percent during World War I; this dropped to 0.2 percent during the Korean war and to 0.01 percent during the war in Vietnam.

Pathophysiology

There have been seven *Clostridium* species identified as causing gas gangrene. *Clostridium perfringens* is attributed to 80 to 95 percent of cases, with *C. septicum* being the second most common etiology.[2] The clostridial organisms are large, gram-positive, spore-forming anaerobic bacilli normally found in the soil, gastrointestinal tract, and female genitourinary tract. They produce several exotoxins that are responsible for the cellular destruction as well as the rapid progression and systemic toxicity of the disease. Bacteremia is rare. Secondary toxic effects may be caused by the release of myoglobin, creatine phosphokinase (CPK), and potassium from tissue breakdown.

There are two potential mechanisms for infection with clostridial organisms. The first and most common is through direct inoculation from an open wound. Similar to tetanus, clostridial species thrive best in contaminated wounds with crushed or ischemic edges that tend to offer a favorable anaerobic environment. The second mechanism for infection is via hematogenous spread. Nearly all these patients are relatively immunocompromised from some form of underlying disease such as diabetes mellitus, peripheral vascular disease, alcoholism, drug abuse, or hematologic or gastrointestinal malignancies. Almost a third of these cases of "spontaneous gas gangrene" are caused by *C. septicum*, with an even higher incidence in cases related to malignancies.

Clinical Features

The incubation period is short, usually less than 3 days. The most common presenting complaints in early gas gangrene are pain out of proportion to physical findings, as well as a sensation of "heaviness" of the affected part. On examination, the area may demonstrate a brawny edema with crepitance. The skin will develop a bronze or brownish discoloration with a malodorous serosanguineous discharge, and bullae may be present. Systemic manifestations include a low-grade fever with tachycardia out of proportion to the fever. The patient may be confused or irritable and have a rapid deterioration of the sensorium. Laboratory evaluation may reveal any or all of the following: metabolic acidosis, leukocytosis, anemia, thrombocytopenia, coagulopathy, myoglobinemia and myoglobinuria, and liver or kidney disfunction. Gram stain of the bullae often shows pleomorphic gram-positive bacilli with or without spores, red blood cells, but very few white blood cells. Radiologic studies may demonstrate gas within soft tissue fascial planes and possibly gas within the peritoneal or retroperitoneal space.

Diagnosis

Early diagnosis and treatment are essential in this life-threatening disorder. Familiarity with the disease and its clinical features is important to avoid overlooking the subtle early signs of its presentation. Any patient presenting with pain out of proportion to physical findings, with or without low-grade fever, and significant tachycardia, with or without a cutaneous injury, should be carefully evaluated for possible clostridial infection. Crepitus detectable on physical examination may be a later finding, and its absence does not rule out the diagnosis. Plain radiographs of the affected area may reveal gas within the involved muscle and surrounding soft tissue. A Gram stain of exudate or tissue showing gram-positive rods with a relative lack of leukocytes is considered diagnostic. Surgical exploration is also helpful in the diagnosis. In the early stages, the muscles are edematous and pale but still bleed when cut; in later stages, the muscles lose contractility and on dissection appear beefy red without bleeding and gas bubbles may be evident between the tissues.

The differential diagnosis of clostridial myonecrosis must encompass other gas-forming infections, including necrotizing fasciitis, streptococcal myositis, acute streptococcal hemolytic gangrene, crepitant cellulitis, and synergistic necrotizing cellulitis. The crepitance should be differentiated from other causes of subcutaneous emphysema such as pneumothorax, pneumomediastinum, and fractured larynx or trachea. The edema and pallor, with loss of distal pulses, seen in an affected extremity should be differentiated from vascular thrombosis conditions such as phlegmasia cerulea dolens.

Treatment

Treatment consists of four main phases:

1. *Resuscitation* should begin in the emergency department (ED) immediately on making a presumptive diagnosis. Aggressive fluid resuscitation using crystalloid, plasma, and packed cells is usually needed to replace red blood cells lost due to hemolysis and to correct hypotension due to shock. Volume status should be closely monitored using urine output and central venous pressure readings. Avoid the use of vasoconstrictors when possible due to the possibility of decreasing perfusion to already ischemic muscle.
2. *Antibiotic therapy* using penicillin G 10 to 40 million units per day in divided doses is recommended. Clindamycin, metronidazole, and chloramphenicol are alternative choices for the penicillin-allergic patient. Sodium penicillin is recommended over potassium penicillin to reduce the risk of worsening hyperkalemia in patients with hemolysis and tissue necrosis. Mixed infections with other anaerobes, gram-negative rods, and staphylococci are common. Therefore, multiple-antibiotic therapy using aminoglycosides, penicillinase-resistant penicillins, or vancomycin is recommended. Tetanus prophylaxis should be given as indicated.
3. *Surgical debridement* is a mainstay of therapy and may include fasciotomy, debridement, or amputation. The borders for debridement are guided by the appearance of the muscle.
4. *Hyperbaric oxygen (HBO) therapy* has been a widely used therapeutic modality since the early 1960s. Although there are no prospective human studies, retospective data suggest a twofold reduction in mortality in patients receiving concomitant HBO therapy. [3] The timing of its use in relation to surgical debridement remains somewhat controversial. Standard therapy consists of surgical debridement prior to HBO therapy, partly for confirmation of the diagnosis based on muscle appearance. Some argue that since elevated partial pressures of oxygen are bactericidal in tissues, as well as inhibitory to toxin production, preoperative HBO therapy may allow for sharper demarcation of necrotic tissue at debridement and less loss of tissue to amputation and decreased systemic toxicity. Typical HBO therapy at this time consists of 100% oxygen at 3 atm of pressure for 90 min immediately following surgery, with three dives in the first 24 h followed by two dives a day for 4 or 5 days.

Wound care at the time of initial evaluation and treatment is the most important factor in preventing clostridial infections. Debridement of crushed or dead tissue and copious irrigation prior to wound closure will help prevent the development of an environment favorable to clostridial growth. Prophylactic penicillin administration may be beneficial in preventing subsequent infection.

CELLULITIS

Cellulitis is a local soft tissue inflammatory reaction secondary to bacterial invasion of the skin. The classic symptoms of cellulitis have been attributed previously to bacterial invasion and subsequent proliferation within the local tissues; however, new evidence suggests that the majority of symptoms may instead be secondary to a complex set of immune and inflammatory reactions triggered by cells within the skin itself. [4]

Epidemiology

The term *cellulitis* represents a broad spectrum of disease in both location and severity. Unfortunatelly, general data on prevalence and incidence of disease are difficult to obtain and interpret. Cellulitis is a common disease in all EDs, affecting the elderly, the immunocompromised, and those with peripheral vascular disease at a much higher rate and severity.

Pathophysiology

Cellulitis is a local inflammation of the skin characterized by pain, induration, warmth, and erythema. It is caused by invasion of the tissues with bacteria, most commonly staphylococci or streptococci in adults and *Hemophilus influenzae* in children. In diabetic patients, additional consideration needs to be given to Enterobacteriaceae and rarely clostridia. Lymphangitis and lymphadenopathy are seen occasionally in previously healthy patients, but purely local inflammation is much more common. Systemic involvement with fever, leukocytosis, and bacteremia is seen most typically in patients with underlying immunosuppressive diseases. Traditional thought has been that the symptoms of cellulitis are related to the effects of the bacteria and their proliferation on local tissues. This has been poorly substantiated in that efforts at isolating these organisms from infected tissue have had a very poor yield. Needle aspiration of the leading edge of an area of cellulitis produces organisms in less that 10 percent of cultures, and even punch biopsy from the same area yields organisms in only around 20 percent of cultures. Only areas with suppuration or abscess formation have significantly higher yield. Recent studies now suggest that although bacterial invasion is what triggers the inflammation, the organisms are largely cleared from the site within the first 12 h, and the infiltration of lymphoid and reticular cells and their products is what produces the majority of symptoms. [4] Cells such as Langerhans cells and keratinocytes release the cytokines interleukin-1 and tumor necrosis factor that enhance infiltration of the skin by circulating lymphocytes and macrophages. The net effect of this is much more rapid clearing of bacteria but at the price of a significantly larger inflammatory response. Theoretically, the addition of anti-inflammatory agents to the treatment regime of cellulitis would be beneficial. Further study needs to be done to identify what specific role, if any, such agents should play.

Clinical Features

Patients with cellulitis typically present with localized tenderness, warmth, induration, and erythema. Specific note should be made on physical examination of evidence of lymphangitis or lymphadenitis because this may suggest more serious infection. The presence of high fever and chills suggests bacteremia, especially in patients with underlying medical disorders.

Diagnosis

In otherwise heathy patients, the clinical presentation is sufficient for diagnosing cellulitis. The high likelihood of typical organisms and the low yield of isolation techniques make further efforts unwarranted. In patients with underlying disease or signs of bacteremia, blood cultures and leukocyte counts are indicated. Local means of isolating the organism are controversial, but in the case of a toxic-appearing patient, they may be worthwhile. Differentiating deep venous thrombosis from cellulitis in the lower extremities is often difficult and may require Doppler studies or venogram.

Treatment

Simple cellulitis in otherwise healthy adult patients can be treated as on an outpatient basis with dicloxacillin (500 mg PO q6h), a macrolide (EES 500 mg PO q6h, azithromycin 500 mg PO initial dose then 250 mg PO qd × 4 d, clarithromycin 500 mg PO q12h), or amoxicillin-clavulanate (875/125 mg PO q12h), with all treatments lasting for 10 days except for azithromycin. The exception to this is cellulitis involving the head or neck, for which most patients should be admitted for intravenous antibiotics. Appropriate intravenous antibiotics include parenteral first-generation cephalosporins (cefazolin 1 g IV q6h) and penicillinase-resistant penicillins (nafcillin or oxacillin 2 g IV q4h). In diabetics, a perenteral second- or third-generation cephalosporin (ceftriaxone 1-2 g IV qd) should be used or imipenem (500 mg IV q6h) in severe cases. [5]

Disposition

Patients with evidence of bacteremia and those with underlying diseases such as diabetes mellitus, alcoholism, or other immunosuppressive disorders should be admitted for intravenous antibiotics. Empirical therapy may be started with the antibiotics listed earlier and changed as indicated by culture results.

All patients discharged on oral antibiotics should have close follow-up arranged with their local medical doctor to evaluate the success of treatment. Anti-inflammatory agents for the treatment of cellulitis are experimental at this time, and until further research identifies a specific role, they should be used with caution.

ERYSIPELAS

Epidemiology

There has been a dramatic increase in the incidence in erysipelas over the past 20 years, as well as a change in the locations that are infected most commonly. Previously, erysipelas involved the face more frequently, but now it is primarily an infection of the lower extremities. [6]

Pathophysiology

Erysipelas is a superficial cellulitis with lymphatic involvement that is caused primarily by group A *Streptococcus.* Atypical infections most commonly seen with other groups of streptococci are also noted. Infection is typically achieved through a portal of entry in the skin, with traumatic wounds, ulcers, and infected dermatoses of the lower extremities being the most common sites. Peripheral vascular disease, especially venous insufficiency, is a local risk factor for infection. Most often erysipelas occurs proximal to the portal of entry into the skin.

Clinical Features

The onset of symptoms is usually abrupt, with a sudden onset of high fever, chills, malaise, and nausea. Over the next 1 to 2 days a small area of erythema with a burning sensation develops. As the infection continues, a red, shiny, hot plaque forms. The plaque has a tense, painful induration that is sharply demarcated from the surrounding normal tissue. Lymphangitis and local lymphadenopathy are common. Purpura, bullae, and small areas of necrosis also are seen. Systemic symptoms continue until antibiotic therapy is initiated. On resolution of the infection, desquamation of the site typically occurs.

Diagnosis

The diagnosis is based primarily on physical findings. Leukocytosis with an increase in the neutrophil count is common. Performing a needle aspiration of the infection site is rarely successful at isolating an organism, but swabbing the portal of entry, when identifiable, may have a higher success rate. Blood cultures are positive in only around 5 percent of patients.[7] Serologic testing to determine ASO and anti-DNAase B titers may be more specific but is of little use acutely in the ED.

The differential diagnosis includes other forms of local cellulitis. Some believe that necrotizing fasciitis is a complication of erysipelas infections and should be considered in all cases.

Treatment

Penicillin G (1–2 million units IV q6h) may be used in nondiabetic patients for initial treatment due to the high incidence of streptococcal infection. Penicillinase-resistant penicillins (nafcillin or oxacillin 2 g IV q4h), parenteral second- or third-generation cephalosporins (ceftriaxone 1–2 g IV qd), or amoxicillin-clavulanate (875/125 mg PO q12h) should be used in diabetic patients and those with facial disease. Imipenem (500 mg IV q6h) is recommended in severe cases. Erythromycin, cephalosporins, or a macrolide should be used in patients with penicillin allergy. Essentially all patients with erysipelas should be admitted to the hospital for intravenous antibiotics.

CUTANEOUS ABSCESSES

The development of cutaneous abscesses most often is caused by a breakdown in the skin's normal protective barrier followed by contamination with local resident bacterial flora. In most cases involving otherwise immunocompetent patients, appropriate surgical incision and drainage are the only treatment required.

Epidemiology

Cutaneous abscesses are a common ED presentation, representing 1 to 2 percent of presenting complaints. There has been little recent investigation into the bacteriology or recommended treatment of simple cutaneous abscesses. This is probably secondary to the excellent outcome with simple incision and drainage regardless of the location or etiology.

Pathophysiology

Intact, healthy skin usually acts as an excellent barrier to bacterial invasion. Cutaneous factors such as constant desquamation of the epidermis continually shedding bacteria and the lower pH of 3 to 5 of the skin also contribute to the skin's protective function. Host cellular and humeral defenses further protect invading bacteria from developing subsequent infection. When favorable host factors are lacking, or in cases of overwhelming bacterial contamination, a break in the skin's integrity either superficially (abrasion, laceration, or thermal injury) or from deep inoculation (laceration, puncture, or bite) may lead to colonization and subsequent infection. Infection typically starts as a local superficial cellulitis. Many organisms that colonize normal skin can cause necrosis and liquefaction with subsequent accumulation of leukocytes and cellular debris. Loculation and subsequent walling off of these products of infection lead to abscess formation. As the infection progresses and the area of liquefaction increases, the abscess wall thins and ruptures spontaneously, draining either cutaneously or into an adjoining tissue compartment.

The bacterial etiology of soft tissue absceses often can be predicted by knowledge of the normal flora colonizing specific areas of the body. Environmental factors such as temperature, humidity, and the general hygiene of a patient play a role in the likelihood of infection, but only by increasing the number of bacteria colonizing the skin. In abscesses involving the scalp, trunk, and extremities, staphylococcal species are the most common infecting organism. *Staphylococcus aureus,* the least common of the staphylococcal species isolated on normal skin, is the most common species causing infection. *S. epidermis* and *S. hominis* are also seen frequently. Streptococci commonly colonize the oral and nasal mucosa and can be seen in abscesses involving the adjoining soft tissues. The intertriginous and perineal areas often are colonized by the gram-negative aerobes *Escherichia coli, Proteus mirabilis,* and *Klebsiella* species. Abscesses involving the axilla are most often infected with *P. mirabilis* for reasons that are not clear. Abscesses in the perirectal and genital areas are most commonly mixed anaerobic and aerobic in nature, with *Bacteroides* species being the most common anaerobe.

In abscesses secondary to foreign bodies, *S. aureus* is the most commonly isolated species. Bite injuries, especially by cats, are at risk for infection with *Pasteurella* multocida but also can involve *S. aureus*, as well as *Streptococcus viridans* and *Eikenella corrodens.* Human bites are less likely to involve *P. multocida* but have a high incidence of involvement with the anaerobe *Bacteroides fragilis* and the gram-positive *Corynebacterium jeikeium,* as well as the usual staphylococcal and streptococcal organisms. In infections associated with intravenous drug abuse, "mixed" infections prevail, with anaerobic bacteria predominating. [8] The most common anaerobic organism is the *Peptostreptococcus* species, with *Staphylococcus* and *Streptococcus* species being the predominating aerobic organisms. Interestingly, a significantly higher percentage of anaerobic infections have been noted in patients injecting cocaine. This has been attributed to the relative anaerobic enviroment created by the vasoconstrictive effect of the cocaine.

Clinical Features

Patients present with an area of swelling, tenderness, and erythema. Inspection of the area may reveal fluctuance, induration, or active drainage. Lymphadenitis, localized lymphadenopathy, or fever may indicate systemic involvement of the infection, but in otherwise healthy patients, cutaneous abscesses tend to remain localized. A careful history should be obtained, with special attention given to underlying immunocompromising illnesses, steroid or other immunosuppressive drug use, and alcoholism. Close inspection of the area for evidence of predisposing injury or foreign body is important. Radiography may be indicated to evaluate for certain radiopaque foreign bodies, and ultrasound may be useful in identifying nonradiopaque objects. Ultrasound can accurately identify many small foreign objects or at least a small fluid collection representing surrounding abscess. The limiting factor in the use of ultrasound is that because of the superficial location of most of these objects, a very high frequency ultrasound transducer is required (7.5–10 MHz). Specific abscesses that may be encountered in the ED are discussed below.

BARTHOLIN GLAND ABSCESSES   Bartholin gland abcesses are seen primarily in sexually active women. Another diagnosis should be considered in postmenopausal women. The Bartholin or vestibular glands are located at the 5 and 7 o'clock positions of the vaginal vestibule. The glands are secretory in nature, and obstruction of the ducts can cause retention of secretions leading to cyst and eventually abscess formation. The patient presents with a unilateral painful swelling of the labia and with a fluctuant 1- to 2-cm. mass at the location of Bartholin's gland. *Neisseria gonorrhoea* and *Chlamydia trachomatis* are often isolated in these abscesses, and cervical cultures are recommended in all patients with Bartholin's gland abscesses. Treatment is not recommended routinely, except in patients with a high clinical suspicion for sexually transmitted disease. Anaerobes, especially Bacteroides species, are also common, as are the gram-negative organisms typically colonizing the perineal region. Treatment involves incision and drainage along the vaginal mucosal surface. There is a very high incidence of reinfection if more

definitive steps are not taken to form a permanent fistulous tract. This can be done by using a Word catheter, a small catheter with a balloon on the distal end used to hold the abscess cavity open during healing, or by marsupializing the abscess walls.

PARONYCHIA AND FELONS   Paronychia and felons are discussed in Chap. 277, "Hand Infections."

HIDRADENITIS SUPPURATIVA   Hidradenitis suppurativa is a recurrent, chronic infection involving the apocrine sweat glands. Blockage of these glands by keratinous material leads to inflammation, local cellulitis, and subsequent abscess formation. Multiple areas of infection develop in different apocrine glands and coalesce to form chronic draining fistulous tracts. These tracts tend to occur in the axilla and groin, where the apocrine sweat glands predominate. Hidradenitis suppurative is more common in women and blacks, and there appears to be a genetic factor involved in its development. Obesity, shaving, and poor hygiene also contribute. The causative organism is usually *Staphylococcus*, but *Streptococcus* also can be involved. In the groin, gram-negative organisms and anaerobes also may be seen. Patients often will present with multiple lesions in different stages of development and healing but with an acute exacerbation in one or a few areas. ED treatment is directed primarily at incision and drainage of the acute infection with referral to a surgeon for further definitive treatment. This often requires wide excision of the affected area. Oral antibiotics should be used in patients with significant areas of cellulitis.

INFECTED SEBACEOUS CYSTS   Sebaceous glands occur diffusely throughout the body. Blockage of the duct of a sebaceous gland may lead to development of a glandular cyst that may exist for a long period of time without becoming infected. Once bacterial invasion occurs, abscess formation is common. These patients typically present with an erythematous, tender cutaneous nodule that is commonly fluctuant. Simple incision and drainage are the appropriate ED treatment. The cyst always contains a capsule that must be removed to prevent further infection. This is usually best done at a later follow-up visit when the initial inflamation has improved or resolved. Occasionally, the wall of the sac can be grasped with a forceps and removed at the time of drainage.

PERIRECTAL ABSCESSES   Most, if not all, perirectal infections are felt to arise from mucinous glands located within the anal crypts. Blockage of the ducts to these glands leads to bacterial invasion, infection, and commonly, abscess formation. The location of the subsequent abscess depends on the direction in which the infection spreads. The most common area of infection is the perianal abscess that is located superficially below the anal ring. Ischiorectal abscesses, supralevator abscesses, and intersphincteric abscesses all are caused by spread of infection into deeper perirectal tissues. Perirectal abscesses are more common in middle-aged males with other risk factors, including inflamatory bowel disease, diabetes, and other immunocompromising illnesses. The bacterial etiology of these infections is primarily the normal fecal flora. Mixed anaerobic and aerobic infections predominate, with *B. fragilis* being the primary anaerobe. Perirectal abscesses can represent serious, life-threatening infections, and only the most superficial should be treated with local anesthesia and incision and drainage in the ED.

PILONIDAL ABSCESSES   Pilonidal abscesses are located along the superior gluteal fold. It is thought that a pilonidal sinus forms along the gluteal fold possibly at the time of embryogenesis, although others believe it to be secondary to local soft tissue trauma. These sinuses are lined with squamous epithelium and hair. It is blockage of the sinus tract with hair and other keratinous material that leads to bacterial invasion and infection. The causative organisms typically are normal skin flora, with *Staphylococcus* species being the most common. Contamination with peritoneal and fecal organisms is also possible. Patients tend to develop symptoms in their late teens and early twenties, and without definitive surgical treatment, they tend to have recurrent infections, sometimes developing a chronic draining fistulous tract. Patients typically present to the ED with a tender, swollen, and fluctuant nodule located along the superior gluteal fold. Systemic symptoms are rare. The appropriate initial treatment includes incision and drainage using care to remove all excess hair and debris from the abscess cavity. The cavity should be packed with iodoform gauze, and the patient should return in 2 to 3 days for advancement of the packing. Antibiotics generally are not needed. Surgical referral is recommended for more definitive treatment.

STAPHYLOCOCCAL SOFT TISSUE ABSCESSES   *Staphylococcus* species are ubiquitous throughout the skin and have a particular affinity for hair follicles, where infection is common. Inflammation of a hair follicle caused by bacterial invasion is known as *folliculitis* and is best treated noninvasively with warm soaks. A deeper invasion into the soft tissue surrounding a hair follicle can lead to a localized abscess formation called a *furuncle* (boil). These are most commonly found on the face, neck, back, axilla, and inner thigh. Unless severe, warm compresses usually are adequate to promote spontaneous drainage. In the thick skin on the back of the neck, several furuncles may coalesce to form a large area of infection containing many interconnected sinus tracts and abscesses. This is known as a *carbuncle* and often requires surgical wide excision for complete resolution. Carbuncles are seen much more commonly in diabetics and may demonstrate signs of systemic involvement.

Diagnosis   Most simple cutaneous abscesses in otherwise healthy patients are local infections without need for further evaluation. Clinical presentation of a tender, swollen, often erythematous nodule strongly suggests infection. A palpable area of fluctance is typically enough for the diagnosis of abscess. Notice should be made of the admitting vital signs, with particular attention to temperature and heart rate. Fever or tachycardia suggests systemic involvement of the infection and may indicate the need for further laboratory testing. In patients with diabetes, alcoholism, and other immunocompromising conditions, the threshold for further diagnostic studies should be lower. A complete blood count and in certain situations (such as possible osteomyelitis) an erythrocyte sedimentation rate usually are all that are needed to evaluate for possible systemic involvement. Diabetic patients routinely should have blood glucose checked.

In simple abscesses involving otherwise healthy patients, a routine culture and sensitivity is not needed. If it is felt that antibiotic treatment is indicated, the causative organisms usually can be predicted by the general location of the abscess. If further certainty is required, a Gram stain of the abscess aspirate most often will lend the required information, and results can be obtained while the patient is still in the ED. Gram-positive cocci in clusters suggest infection with *S. aureus*, whereas many different organisms suggest a mixed anaerobic and aerobic infection. In patients in whom possible deep or chronic infection may complicate the course, early wound cultures with sensitivities may prove useful. Immunocompromised patients demonstrating systemic signs of infection also should have blood cultures drawn. In patients in whom foreign body involvement is a potential issue, plain radiographs or possibly ultrasound should be used to assist in identification.

Treatment   Incision and drainage are the only treatment necessary in most cases of superficial and localized abscesses. Often it is difficult to determine clinically if an area of fluctance is present within an area of induration and swelling. Needle aspiration of the most likely area of induration often can help in the diagnosis. When pus is encountered with aspiration, incision and drainage should be performed. When no pus is located, a trial of antibiotic therapy and warm compresses is appropriate initially. These patients should have a follow-up evaluation scheduled because many will need incision and drainage in the future.

Consideration must be given to the best location for abscess drainage. Abscesses well suited to ED treatment are those which are superficial, well localized, and not in close proximity to nerves or vascular structures. Fluctuant masses should be examined for pulsations or bruits if near vascular structures. Patient comfort is also an important consideration. Infiltration of a local anesthetic most often gives poor pain relief. The lower pH of infected tissue typically greatly reduces the effectiveness of a local anesthetic. Injecting additional fluid into an already swollen and tender area also increases pain. Regional or field blocks can be used effectively at times, and digital blocks to assist in the drainage of a large paronychia or felon are usually all that are needed. Patients with evidence of deeper tissue infection, as in many cases of perirectal abscess, and those in whom adequate analgesia cannot be obtained in the ED should be taken to the operating room for appropriate surgical drainage.

Nitrous oxide has been used with good success in many EDs for years. The parenteral use of rapid and ultra-short-acting sedatives and analgesics for conscious sedation in the ED has been shown to be both safe and effective when they are used appropriately. They are best suited for procedures that are very painful and short in duration. Incision and drainage seem ideal in this regard. Many agents have been used effectively, with the combination of fentanyl and midazolam being one of the more common and effective. Both these agents have a short time to peak effect (3-5 min for midazolam and <1 min for fentanyl) and a short duration of action (each 1 to $1\frac{1}{2}$ h), which allows the patient to be discharged at his or her presedation mental status baseline without a prolonged recovery period. Furthermore, the patient benefits from the analgesic effect of the fentanyl as well as the sedative, anxiolytic, and amnestic effects of the midazolam. Fentanyl, with less than 1 min to peak effect, is very well suited to titration for desired effect during the procedure. For further discussion, see Chap. 33.

Prior to any sedation or analgesia, the procedure should be explained to the patient, including any possible complications. With most superficial abscesses, the risks involved are relatively few. The possibility of severing a cutaneous nerve with residual local numbness, as well as the risk of injury to deeper nerves and blood vessels, should be discussed. The possibility of poor or delayed wound healing should be discussed in patients with diabetes or peripheral vascular disease. Some estimate should be made of the residual scarring that may be anticipated, especially in areas of cosmetic significance. As with all elective and invasive procedures, informed consent should be obtained in all patients. Although the risk of complications is low, informed consent prior to the procedure ensures that the patient has been appropriately educated concerning the risks and benefits, as well as optimizing medicolegal coverage for the clinician. Informed consent in patients receiving conscious sedation is also important and should cover the risk of respiratory depression requiring endotracheal intubation.

The patient should be positioned to ensure appropriate access to the abscess and in the most comfortable position possible. The area should be prepared with Betadine and draped in a sterile fashion. After appropriate anesthesia, the abscess should be opened widely over the area of greatest fluctance, using a No. 11 or 15 scalpel blade to ensure adequate drainage. As much pus as possible should be expressed by gentle compression. Hemostats are then used to break up any

loculated areas within the abscess cavity. The cavity is irrigated with saline and packed loosely with gauze tape to hold it open to promote drainage while the infection resolves. The packing should be left in place long enough for the cavity to heal from the inside out, preventing recollection of the abscess. Patients are discharged with instructions for warm compresses or soaks three to four times a day. A follow-up visit should be scheduled in 2 to 3 days for recheck and advancement or replacement of the packing. Wounds that continue to actively drain at the time of follow-up should have the packing replaced. Replacing the packing performs some degree of debridement of the abscess cavity, as well as providing fresh packing for absorption of pus and debris. Wounds that are not actively draining can have the packing advanced as needed to allow for internal healing while keeping the incision open to promote drainage.

The use of antibiotics in patients with cutaneous abscesses is somewhat controversial. The risk of systemic infection following local incision and drainage appears to be low. A recent ED study demonstrated that in 50 afebrile patients in whom blood cultures were drawn 2 and 10 min after incision and drainage of cutaneous abscesses, none of the cultures was found to be positive.[9] There are no good data suggesting that antibiotic treatment following incision and drainage speeds infection resolution in otherwise healthy patients. Generally, it is felt that in patients without underlying immunocompromising conditions or signs of systemic infection, antibiotics are not indicated following incision and drainage of superficial cutaneous abscesses. With a lack of hard scientific data pointing to clear-cut guidelines for antibiotic therapy, clinical judgment needs to be exercised. In patients with diabetes, alcoholism, or other underlying immunocompromising illnesses, or in those on immunosuppressant medications such as steroids or chemotherapeutics, the threshold for antibiotic use should be much lower. Furthermore, patients who present with signs of systemic disease such as fever and chills and those with cellulitis extending beyond the abscess borders also should be considered for antibiotic therapy. Abscesses involving the hands or face should be treated more aggressively with antibiotics because of the higher morbidity associated with prolonged infection or complications. The specific antibiotic used should be chosen according to the most likely pathogen involved. This can be somewhat predicted by the location of the infection. Duration of therapy should be directed to some degree by the severity of infection but typically should continue for 5 to 7 days.

Of separate concern are patients with underlying structural heart disease at risk for bacterial endocarditis. Certain structural cardiac conditions lead to a higher incidence of bacterial endocarditis. Futhermore, the severity of disease and morbidity are increased in patients with certain underlying cardiac diseases who develop bacterial endocarditis. The American Heart Association recently has updated its guidelines for patients at increased risk for developing bacterial endocarditis. [10] Table 146-1 outlines the cardiac conditions considered to be at high and moderate risk based on predicted outcomes if endocarditis does occur. Note that several types of patients frequently encountered in the ED, namely, patients after coronary artery bypass grafting, those with pacemakers, and those with mitral valve prolapse without valvular regurgitation, are not recommended for endocarditis prophylaxis. Despite the apparent low risk of transient bacteremia following incision and drainage of a simple cutaneous abscess, the American Heart Association recommends prophylactic antibiotics for those patients in the high- and moderate-risk catagories prior to the procedure. No mention is made of postprocedure treatment. The antibiotic selected should be directed at the most likely organism causing the abscess. Table 146-2 outlines suggested antibiotic treatment by organism for soft tissue infections and should be used for preprocedure prophylaxis for endocarditis. An intravenous or intramuscular antistaphylococcal penicillin, clindamycin, or first-generation cephalosporin is appropriate for patients not able to take oral medications. In patients with known methicillin-resistant *S. aureus* infection, vancomycin is recommended for prophylaxis.

TABLE 146-1   Cardiac Conditions at Risk for Endocarditis

TABLE 146-2   Antibiotic Recommendations for Soft Tissue Infections (Oral)

Disposition   Most patients can be discharged following incision and drainage of a cutaneous abscess. Again, clinical judgment plays an important part in this decision. Patients with severe underlying disease or those with immunocompromising conditions may benefit from admission and intravenous antibiotics. Furthermore, patients with signs of systemic infection or deeper infection such as osteomyelitis should be considered for admission. Appropriate follow-up within 2 to 3 days for those discharged is important.

SPOROTRICHOSIS

Sporotrichosis is a mycotic infection caused by the fungus *Sporothrix schenckii* commonly found on plants and vegetation and in soil. Infection is caused by traumatic inoculation and usually remains within the local soft tissues and lymphatics. Disseminated forms, although more rare, do occur.

Epidemiology

The organism responsible for sporotrichosis occurs worldwide and is found most commonly in soil, sphagnum moss, and decaying vegetable matter. Inoculation into the host most commonly occurs from a spine or barb on a plant puncturing the skin during handling. It is a common disease among florists, gardeners, and agricultural workers. Transmission from infected animals, especially cats, has been documented, and veterinarians and animal handlers are also at increased risk. The largest outbreak of sporotrichosis in the United States involved 15 states and 84 persons, all of whom handled conifer seedlings shipped in sphagnum moss contaminated with *S. schenckii*.[11]

Pathophysiology

S. schenckii is a thermally dimorphic fungus that changes from its mycelial form to its yeast form on entering a body-temperature environment. Local infection occurs in most cases, with disease limited to cutaneous or lymphocutaneous areas.[12] Osteoarticular involvement including osteomyelitis, septic arthritis, bursitis, and tenosynovitis occurs and may be related to a local cutaneous infection or secondary to hematogenous spread. Systemic forms, including pulmonary, meningeal, and disseminated forms, are much more rare.

Clinical Features

The incubation period averages 3 weeks from the time of initial inoculation but varies from a few days to several weeks. After the fungus enters the body through a break in the skin, three types of localized infections may occur. The fixed cutaneous type is characterized by lesions restricted to the site of inoculation and may appear as a crusted ulcer or verrucous plaque. Local cutaneous-type infections also remain local but present as a subcutaneous nodule or pustule. The surrounding skin becomes erythematous and may ulcerate, resulting in a chancre. Local lymphadenitis is common. The lymphocutaneous type is the third and most common type. It is characterized by an initial painless nodule or papule at the site of inoculation that later develops subcutaneous nodules with clear skip areas along local lymphatic channels. The local reactions in all three types of infections tend to be relatively painless but show no signs of improvement without treatment.

Diagnosis

History and physical findings are the key to diagnosis. Histopathologic stains are of little help because the organisms are scarce in tissues. Fungal cultures are the best way to isolate the fungus, and tissue biopsy cultures often are diagnostic. Routine laboratory tests are nonspecific, but an increased white blood cell count, eosinophil count, and erythrocyte sedimentation rate may be noted. The differential diagnosis includes tuberculosis, tularemia, cat-scratch disease, leishmaniasis, staphylococcal lymphangitis, and nocardiosis.

Treatment

The treatment of choice for cutaneous sporotrichosis until recently was potassium iodide (SSKI) 3 to 4 g three times a day to be continued for at least 1 month beyond resolution of clinical symptoms. This was a cumbersome treatment and was associated with a high incidence of side effects such as metallic taste, anorexia, and swelling of the salivary glands. Recently, itraconazole (100–200 mg qd for 3–6 months) has been shown to be a highly effective and much better tolerated treatment for localized as well as many systemic forms of sporotrichosis. [13] Fluconazole has been shown to be less effective than itraconazole and should be reserved for those few patients not tolerating itraconazole. Ketoconazole has shown even poorer results than fluconazole. Intravenous amphotericin B is effective, but adverse reactions usually limit its use to disseminated forms.

Disposition

Essentially all patients with a cutaneous form of sporotrichosis can be treated on an outpatient basis. Discharge instructions should include basic wound care for open lesions, and close follow-up with a local medical doctor should be arranged. Patients who are acutely ill or have evidence of systemic disease should be admitted to the hospital initially for possible treatment with intravenous amphotericin B.

147 REPORTABLE COMMUNICABLE DISEASES

Jane H. Brice

The Centers for Disease Control and Prevention (CDC) in Atlanta publishes a list of reportable communicable diseases that is updated and revised routinely. The most recent update as of this writing (1997) includes 52 nationally reportable diseases and is summarized in Table 147-1.[1] The requirement to report these diseases is mandated by state or territory laws and regulations, and therefore, the list differs for each state or territory.

TABLE 147-1   Nationally Reportable Communicable Diseases

The reliability of the national reporting system rests on health care providers, laboratories, and other public health personnel. Without consistent and timely reporting, it becomes very difficult to monitor trends in disease patterns, to detect unusual occurrences or pockets of disease, and to assess the effectiveness of public health interventions to eradicate or contain disease. Data reported by the 50 states, the District of Columbia, and the U.S. territories are summarized in the *Morbidity and Mortality Weekly Report,* which can be accessed on-line at *www.cdc.gov/epo/mmwr/mmwr.html*.

"The usefulness of public health surveillance data depends on its uniformity, simplicity, and timeliness."[1] What follows here is a summary of the case definitions for each of the specified nationally reportable diseases from the *Morbidity and Mortality Weekly (MMWR)* update on reportable diseases.[1] These case definitions establish uniform reporting criteria and are subject to revision. For the most up-to-date information, go to *www.cdc.gov/epo/mmwr/other/case_def/about.html*.

ACQUIRED IMMUNODEFICIENCY SYNDROME (AIDS)

AIDS is a chronic illness with varying manifestations. The CDC defines this syndrome[2,3] as all human immunodeficiency virus (HIV)-infected adolescents (³13 years) and adults with (1) a CD4 T-lymphocyte count of less than 200, (2) a CD4 T-lymphocyte percent of total lymphocyte of less than 14 percent, or (3) any of the following: pulmonary tuberculosis, recurrent pneumonia, invasive cervical cancer, or 23 other clinical conditions discussed elsewhere in this text and available on the MMWR Web site.[4]

ANTHRAX

Anthrax is an acute illness with one of several distinct clinical presentations. The cutaneous form is characterized by a skin lesion evolving over 2 to 6 days from a papule to a vesicle to a depressed black eschar. The inhalation form presents with a brief upper respiratory infection followed by hypoxia and dyspnea. On chest radiography, there will be evidence of mediastinal widening from adenopathy. The intestinal form is distinguished by severe abdominal pain and cramping followed by fever and sepsis. Finally, in the oropharyngeal form, a mucosal lesion in the oral cavity develops along with cervical adenopathy, edema, and fever.

The laboratory diagnosis is made by (1) isolation of *Bacillus anthracis* from a clinical specimen, (2) anthrax electrophoretic immunotransblot (EITB) reaction to the protective antigen and/or lethal factor bands in at least one serum specimen obtained after onset of symptoms, or (3) demonstration of *B. anthracis* through immunofluorescence.

BOTULISM

Foodborne   An acute illness of varying severity, foodborne botulism is manifested by diplopia, blurred vision, bulbar weakness, or symmetric paralysis that may be of rapid onset. Laboratory confirmation of this illness consists of demonstration of botulinum toxin in serum or stool or in food the subject recently consumed. A positive

Clostridium botulinum culture from stool also serves as confirmation of the diagnosis.

Infant   A constellation of symptoms in an infant under 1 year of age including constipation, poor feeding, and failure to thrive followed by progressive weakness, impaired respiration, and death should suggest infant botulism. Laboratory confirmation of the diagnosis is made in the same manner as described for foodborne botulism.

Wound   The symptoms for wound botulism mirror those found in the foodborne form. The laboratory diagnosis is made by finding botulinum toxin in serum or obtaining a positive culture from the wound.

BRUCELLOSIS

Infection with *Brucella* may be either of acute or insidious onset. Brucellosis is characterized by fever, night sweats, undue fatigue, anorexia, weight loss, headache, and arthralgias. The laboratory diagnosis may be made in several ways: (1) culture positive from a clinical specimen, (2) at least a fourfold increase in *Brucella* agglutination titers between the acute and convalescent phases in serum taken at least 2 weeks apart and studied in the same laboratory, or (3) positive immunofluorescence of *Brucella* in a clinical specimen.

CHANCROID

Chancroid is a sexually transmitted disease caused by the organism *Haemophilus ducreyi*. It is manifested by a painful genital ulcer with inflamed inguinal lymph nodes. Isolation of the organism from a clinical specimen confirms the diagnosis.

CHLAMYDIA TRACHOMATIS GENITAL INFECTIONS

Genital infection with *Chlamydia trachomatis* is sexually transmitted and may present in several different manners. There may be evidence of urethritis, epididymitis, cervicitis, or acute salpingitis, or the infection may be completely asymptomatic. It is therefore essential to test for *Chlamydia* whenever there is a suspicion of infection or when there is evidence of other sexually transmitted infection. *Chlamydia* also may cause conjunctivitis or pneumonia in newborns through perinatal transmission. Finally, *Chlamydia* causes lymphogranuloma venerum, which is discussed below. The diagnosis of *Chlamydia* is confirmed through either a positive culture or detection of the antigen or nucleic acid on immunofluorescence.

CHOLERA

Cholera infection is manifested by a diarrheal illness of varying severity. The presence of vomiting does not exclude the diagnosis. Isolation of the toxigenic *Vibrio cholerae* O1 or O139 from stool or emesis confirms the diagnosis. Serologic evidence of recent infection also may confirm a recent illness caused by cholera.

COCCIDIOIDOMYCOSIS

Infection with the fungus *Coccidioides immitis* may manifest in an acute or chronic illness and may, in some persons, be maintained in an asymptomatic state. This fungus is endemic in the southwestern United States. Those demonstrating symptoms usually complain of an influenza-like febrile respiratory illness. The disease may disseminate in approximately 0.5 percent.

Coccidioidomycosis should be considered in those with one or more of the following: (1) influenza-like signs and symptoms (fever, cough, chest pain, myalgia, arthralgia, and headache), (2) pneumonia or other pulmonary lesion on chest radiograph, (3) erythema nodosum or erythema multiforme rash, (4) involvement of bones, joints, or skin by dissemination, (5) meningitis, and (6) involvement of viscera or lymph nodes.

Laboratory confirmation is made through (1) culture, histopathology, or molecular evidence of *C. immitis,* (2) serologic tests including detection of IgM by immunodiffusion, enzyme immunoassay, latex agglutination, or tube precipitation or detection of rising titer of IgG by immunodiffusion, enzyme immunoassay, or complement fixation, or (3) coccidioidal skin-test conversion after onset of symptoms.

CRYPTOSPORIDIOSIS

Diarrhea, abdominal cramps, loss of appetite, low-grade fever, and nausea and vomiting are the cluster of signs and symptoms associated with cryptosporidiosis. The infection may be asymptomatic in some persons. The illness also can be prolonged and life threatening in immunocompromised patients. It is caused by the protozoa *Cryptosporidium parvum.*

In the laboratory, the diagnosis is confirmed by detecting oocysts in stool or demonstrating *Cryptosporidium* in intestinal fluid or small bowel biopsy specimens. Additionally, identifying *Cryptosporidium* antigen in stool by specific immunodiagnostic testing will confirm the diagnosis of cryptosporidiosis.

DIPHTHERIA

Diphtheria is characterized by upper respiratory symptoms including sore throat, low-grade fever, and an adherent membrane to tonsils, pharynx, and/or the nose. There is a cutaneous form of diphtheria that does not need to be reported to the CDC. Isolation of *Corynebacterium diphtheriae* from clinical specimens or a histopathologic diagnosis of diphtheria confirms the illness.

ENCEPHALITIS, ARBOVIRAL

Arboviral encephalitis is characterized by a febrile illness associated with any of the following neurologic signs and symptoms: headache, confusion, altered sensorium, nausea and vomiting, meningismus, cranial nerve palsy, paresis or paralysis, sensory deficit, altered reflexes, seizures, abnormal movements, or coma. The illness may be of varying severity and cannot be distinguished clinically from other central nervous system infections.

The diagnosis is made based on laboratory detection of (1) a fourfold or greater rise in serum antibody titer, (2) isolation of virus or finding viral antigen or genomic sequences in tissue, blood, cerebral spinal fluid, or other bodily fluids, or (3) IgM anitbody detected on enzyme immunoassay from serum or cerebral spinal fluid.

Eastern equine encephalitis, western equine encephalitis, California serogroup encephalitis, or St. Louis encephalitis are reportable to the CDC.

ESCHERICHIA COLI O157:H7

A diarrheal disease of variable severity, *E. coli* O157:H7 has gained national prominence through several food-borne outbreaks. The diarrhea of this disease is often bloody and associated with abdominal cramping. It may be complicated by hemolytic-uremic syndrome or thrombotic thrombocytopenic purpura. It also may be asymptomatic.

In the laboratory, isolation of the bacteria in a clinical specimen, or isolation of Shiga toxin–producing *E. coli* O157:NM from a clinical specimen (strains of O157:H7 that have lost the flagellar H antigen become nonmotile and are called *NM*) is diagnostic.

GONORRHEA

This sexually transmitted disease is characterized by varying manifestations including urethritis, cervicitis, or salpingitis. It may be asymptomatic in some persons or may become disseminated. Laboratory detection of *Neisseria gonorrhoeae* in clinical specimens confirms the diagnosis. Other methods of laboratory confirmation

include detection of antigen or nucleic acid in specimens or observation of gram-negative intracellular diplococci in a urethral smear obtained from a male patient.

HAEMOPHILUS INFLUENZAE INVASIVE DISEASE

Invasive disease caused by *H. influenzae* include meningitis, bacteremia, epiglottitis, or pneumonia. Laboratory isolation of *H. influenzae* from a normally sterile site such as blood, cerebral spinal fluid, or joint fluid is necessary to confirm the diagnosis.

HANSEN'S DISEASE (LEPROSY)

Hansen's disease is a chronic infection with *Mycobacterium leprae* involving the skin predominantly but which can include peripheral nerves and the mucosa of the upper airway as well. There are four clinical forms of Hansen's disease. Tuberculoid leprosy is characterized by one or a few well-demarcated, hypopigmented, and anesthetic skin lesions. Often these lesions have active, spreading edges and a clearing center. Peripheral nerve swelling or thickening also may be present. In the lepromatous form, a number of erythematous papules and nodules may be present or an infiltration of face, hands, and feet with lesions in a bilateral and symmetric pattern that progresses to thickening of the skin. The borderline or dimorphous form presents with skin lesions characteristic of both the tuberculoid and lepromatous forms. Finally, in the indeterminate form, early lesions, usually hypopigmented macules, are present that do not develop the more characteristic features of the tuberculoid or lepromatous forms.

Demonstration of acid-fast bacilli in skin or dermal nerves makes the diagnosis. Specimens should be obtained from a full-thickness skin biopsy of a lepromatous lesion, if possible.

HANTAVIRUS PULMONARY SYNDROME

Hantavirus pulmonary syndrome is a febrile illness characterized by bilateral interstitial pulmonary infiltrates and respiratory compromise resembling adult respiratory distress syndrome. There is typically a prodrome of fever, chills, myalgias, headache, and gastrointestinal distress. Common laboratory findings include one or more of the following: hemoconcentration, left shift in white blood cell count, neutrophilic leukocytosis, thrombocytopenia, or circulating immunoblasts.

Hantavirus should be considered in the setting of one or more of the following: (1) febrile illness [temperature greater than 38.3°C (101°F)] in a previously healthy individual with bilateral interstitial edema that may radiographically resemble adult respiratory distress syndrome and respiratory compromise requiring oxygen support developing within 72 h of hospitalization, or (2) unexplained respiratory illness resulting in death and autopsy examination demonstrating noncardiogenic pulmonary edema without identifiable cause.

Detection of hantavirus-specific IgM or rising titers of IgG, detection of hantavirus-specific ribonucleic acid sequences by polymerase chain reaction techniques in clinical specimens, and detection of hantavirus antigen by immunohistochemistry are all acceptable laboratory methods for confirming the diagnosis.

HEMOLYTIC-UREMIC SYNDROME, POSTDIARRHEAL

Hemolytic-uremic syndrome presents as acute onset of microangiopathic hemolytic anemia, renal injury, and low platelet count. Most cases occur within 3 weeks of an acute diarrheal illness. A low platelet count is typical early in the illness (within the first 7 days) but may have normalized by the time the patient seeks care. If the platelet count is not less than 150,000/μL within 7 days of the onset of the gastrointestinal illness, consider another diagnosis. Thrombotic thrombocytopenic purpura has similar features and is distinguished from hemolytic-uremic syndrome by the presence of fever and CNS involvement. Additionally, it may have a more gradual onset. Few cases of thrombotic thrombocytopenic purpura are associated with a diarrheal illness.

In the laboratory, both of the following findings will be present: (1) anemia of acute onset with microangiopathic changes (schistocytes, burr cells, or helmet cells on smear) and (2) acute renal failure with hematuria, proteinuria, or increased creatinine levels (50 percent over the patient's baseline values, or greater than 1.0 mg/dL for a child under 13 years of age, or greater than 1.5 mg/dL for persons over 13 years of age with previously normal renal function).

HEPATITIS

Hepatitis is characterized by acute and discrete onset of symptoms and jaundice or elevated serum aminotransferase levels. At present, hepatitis A, B, C, non-A and non-B, and delta are reportable. The laboratory diagnosis of each of the hepatitis viruses is listed below.

Hepatitis A. Detection of IgM to the hepatitis A virus (anti-HAV).

Hepatitis B. (1) Detection of IgM to hepatitis B core antigen (anti-HBc) or hepatitis B surface antigen (HBsAg) and (2) anti-HAV negative, if done.

Hepatitis C. Detection of antibody against hepatitis C antigen (anti-HCV), (2) serum aminotransferase levels greater than 2.5 times the upper limit of normal, (3) anti-HAV negative, if done, and (4) anti-HBc or HBsAg negative, if done.

Non-A, non-B hepatitis. (1) Serum aminotransferase levels greater than 2.5 times the upper limit of normal, (2) anti-HAV negative, and (3) anti-HBc and HBsAg negative.

Delta hepatitis. (1) HBsAg or anti-HBc positive and (2) detection of antibodies to hepatitis delta virus (not a reportable disease).

Persons with chronic hepatitis, those who are hepatitis B surface antigen positive, or those who are anti-hepatitis C virus positive should not be reported unless they have acute illness compatible with viral hepatitis at the time of the laboratory finding.

PERINATAL HEPATITIS B

In infants aged 1 to 24 months, infection with hepatitis B may range from an asymptomatic state to fulminant hepatitis. On laboratory investigation, the infant will be HBsAg-positive.

HIV INFECTION, PEDIATRIC

Pediatric (13 years of age) infection with human immunodeficiency virus (HIV) runs the gamut from asymptomatic to severely immunocompromised. Case definitions are broken into two age categories:[3]

1. Any child under 18 months of age born to an HIV-positive mother who has positive results on two separate tests (excluding cord blood) from one or more of the following: HIV culture, HIV polymerase chain reaction, or HIV p24 antigen, or who meets criteria for an acquired immunodeficiency deficiency syndrome (AIDS) diagnosis based on the 1987 AIDS surveillance case definition.
2. Any child 18 months of age or older born to an HIV-positive mother or any child infected by blood, blood products, or other known means of transmission who is HIV-positive by repeatedly positive enzyme immunoassay and confirmatory test or meets criteria set forth for children under 18 months of age.

LEGIONELLOSIS

Infection with *Legionella* causes two distinct illnesses: (1) legionnaires' disease, manifested by fever, myalgia, cough, and pneumonia, and (2) Pontiac fever, which is a milder illness without pneumonia. Laboratory confirmation of *Legionella* infection can be made by any of the following methods: (1) isolation of *Legionella* from respiratory secretions, lung tissue, pleural fluid, or other normally sterile site, (2) demonstration of fourfold or greater rise in reciprocal immunofluorescence antibody titer to greater than or equal to 128 against *Legionella pneumophila* serogroup 1 between paired acute and convalescent serum specimens, (3) detection of *L.*

pneumophila serogroup 1 in respiratory secretions, lung tissue, or pleural fluid by direct fluorescent antibody testing, or (4) detection of *L. pneumophila* serogroup 1 antigen in urine by radioimmunoassay or enzyme-linked immunosorbent assay.

LYME DISEASE

This tick-borne illness presents with systemic manifestations including those of the dermatologic, rheumatologic, neurologic, and cardiac systems. The best clinical marker is erythema migrans, the initial skin lesion that occurs in 60 to 80 percent of patients. Other acute symptoms include fatigue, fever, headache, mildly stiff neck, arthralgias, and myalgias. Late manifestations are variable and are best discussed by system:

1. *Musculoskeletal.* Recurrent brief and intermittent episodes (over weeks or months) of objective joint swelling in one or several joints, sometimes followed by chronic arthiritis.
2. *Central nervous system.* Any of the following (alone or in combination): lymphocytic meningitis, cranial neuritis (particularly Bell's palsy which is occasionally bilateral), radiculopathy, or rarely encephalomyelitis.
3. *Cardiovascular.* Acute onset of high-grade (second- or third-degree) AV block that resolves in days to weeks and is sometimes associated with myocarditis (note that palpitations, bradycardia, bundle-branch blocks, or myocarditis alone is not enough).

Isolation of the organism *Borrelia burgdorferi* from a clinical specimen or demonstration of antibody (IgM or IgG) against *B. burgdorferi* in serum or cerebral spinal fluid confirms the diagnosis. A two-test approach (enzyme-linked immunosorbent assay followed by Western blot) is recommended.

MALARIA

Malaria is caused by infection with one of the *Plasmodium* species. Most patients have fever. Other complaints include headache, chills, sweats, myalgias, nausea, vomiting, diarrhea, or cough. Untreated infection by *Plasmodium falciparum* can lead to coma, renal failure, pulmonary edema, and death. In the laboratory, malaria parasites can be seen on blood smear.

MEASLES (RUBEOLA)

Measles is an illness characterized by all the following (1) generalized rash lasting more than 3 days, (2) temperature greater than or equal to 38.3°C (101°F), and (3) cough, coryza, or conjunctivitis. The laboratory diagnosis can be made by any of the following: (1) positive serologic tests for measles IgM, (2) significant rise in measles antibody levels by any standard serologic assay, or (3) isolation of measles virus from clinical specimens.

MENINGOCOCCAL DISEASE

Meningococcal disease is most commonly evident as meningitis and/or meningococcemia. It may progress rapidly to purpura fulminans, shock, and death. Isolation of *Neisseria meningitidis* from a normally sterile site such as blood or cerebral spinal fluid confirms the diagnosis.

MUMPS

An illness with acute onset, mumps is characterized by unilateral or bilateral tender, self-limited swelling of parotid or other salivary gland for 2 or more days without other cause. The laboratory diagnosis is evident by (1) isolating mumps virus from a clinical specimen, (2) a significant rise between acute and convalescent titers in serum mumps IgG, or (3) finding mumps IgM in serum.

PERTUSSIS

Pertussis is an illness with cough lasting for 2 weeks or longer without other cause and with one of the following: (1) paroxysms of cough, (2) inspiratory whoop, or (3) posttussive vomiting. The laboratory confirmation is found in isolation of *Bordetella pertussis* from clinical specimens or a positive polymerase chain reaction for *B. pertussis.*

PLAGUE

An illness characterized by fever, chills, headache, malaise, prostration, and leukocytosis, plague manifests predominantly in one of the following clinical forms: (1) bubonic plague, manifested by regional lymphadenitis, (2) septicemic plague, in which there is septicemia without evident bubo, (3) pneumonic plague, where pneumonia results from either inhalation of infectious droplets (primary pneumonic plague) or hematologic spread from bubonic or septicemic cases (secondary pneumonic plague), or (4) pharyngeal plague, in which there is pharyngitis and cervical lymphadenitis resulting from exposure to larger infectious droplets or ingestion of infected tissues.

Presumptive laboratory diagnosis is made by (1) an increase in serum antibody titers to *Yersinia pestis* fraction 1 antigen without plague vaccination or (2) detection of fraction 1 antigen by fluorescent assay. Confirmatory laboratory diagnosis is produced by (1) isolation of *Y. pestis* in clinical specimens or (2) a fourfold or greater rise in serum antibody titer to *Y. pestis* fraction 1 antigen.

POLIOMYELITIS, PARALYTIC

Paralytic poliomyelitis is an illness of acute onset and apparent in the flaccid paralysis of one or more limbs with absent or diminished tendon reflexes in the affected limbs without other cause and without sensory or cognitive losses. Laboratory testing only serves to classify the case into categories set up by the CDC. The clinical case definition is sufficient for reporting.

PSITTACOSIS

Psittacosis is a disease found among bird handlers that presents with fever, chills, headache, photophobia, cough, and myalgia. In the laboratory, any of the following methods will confirm the diagnosis: (1) isolation of *Chlamydia psittaci* from respiratory secretions, (2) a fourfold or greater increase in antibodies against *C. psittaci* by complement fixation or microimmunofluorescence (MIF) to a reciprocal titer of at least 32 between paired acute and convalescent serum samples, or (3) detection of serum IgM to *C. psittaci* by MIF to a reciprocal titer of at least 16.

RABIES, ANIMAL

The laboratory diagnosis of animal rabies is the only necessary item for reporting. The diagnosis is usually made by a positive direct fluorescent antibody test (preferably performed on CNS tissue) or by isolation of rabies virus in cell culture or in a laboratory animal.

RABIES, HUMAN

In humans, rabies is an acute encephalomyelitis that almost always progresses to coma and death within 10 days of the first symptom. Laboratory confirmation of the illness can be made in any of the following manners (although the CDC strongly recommends confirming the diagnosis by *all* the suggested methods): (1) direct fluorescent antibody of viral antigen in clinical specimen (preferably the brain or the nerves surrounding hair follicles in the nape of the neck), (2) isolation in cell culture or in a laboratory animal of rabies virus from saliva, cerebrospinal fluid, or CNS tissue, or (3) identification of a rabies neutralizing antibody titer of greater than 5 in the serum or cerebrospinal fluid of an unvaccinated person.

ROCKY MOUNTAIN SPOTTED FEVER

This is a tick-borne illness of acute onset and characterized by headache, myalgia, fever, and petechial rash that appears on the palms and soles in two-thirds of patients. Laboratory diagnosis may be made by one of several methods: (1) a fourfold or greater rise in antibody titer to *Rickettsia rickettsi* antigen by immunofluorescence antibody, complement fixation, latex agglutination, microagglutination, or indirect hemagglutination antibody test in acute and convalescent specimens taken 4 weeks apart, (2) positive polymerase chain reaction to *R. rickettsii,* (3) positive immunofluorescence of skin lesion (biopsy) or organ tissue (autopsy), or (4) isolation of *R. rickettsii* from a clinical specimen.

RUBELLA

Rubella is characterized by all the following: (1) acute onset of generalized maculopapular rash, (2) temperature greater than 37.2°C (99°F), if measures, and (3) arthralgia/arthritis, lymphadenopathy, or conjunctivitis. Laboratory confirmation is obtained by (1) isolation of rubella virus, (2) significant rise in serum rubella IgG titers between the acute and convalescent phases by any standard serologic assay, or (3) positive serologic test for rubella IgM. It should be noted that rubella IgM tests are occasionally falsely positive in persons with other viral illnesses such as Epstein-Barr virus, cytomegalovirus, or parvovirus infection or in the presence of rheumatoid factor.

RUBELLA, CONGENITAL SYNDROME

The congenital syndrome of rubella is an illness of infancy resulting from rubella virus infection in utero. Infants present with signs and symptoms from the following categories: (1) cataracts/congenital glaucoma, congenital heart disease, hearing loss, and pigmentary retinopathy or (2) purpura, splenomegaly, jaundice, microcephaly, mental retardation, meningoencephalitis, and radiolucent bone disease. Laboratory detection is undertaken by any of the following methods: (1) isolation of rubella virus, (2) demonstration of rubella-specific IgM, or (3) infant rubella antibody levels persistently high for longer than expected from passive maternal antibody transfer. Infant antibodies should decrease by a twofold dilution each month of life.

SALMONELLOSIS

Infection with *Salmonella* causes diarrhea, abdominal pain, and occasionally nausea and vomiting of variable severity. Infections may be asymptomatic or may cause extraintestinal disease. Isolation of *Salmonella* from a clinical specimen confirms the diagnosis.

SHIGELLOSIS

Shigellosis presents with diarrhea, nausea, abdominal cramping, and tenesmus of varying severity or may be asymptomatic. Isolation of *Shigella* from a clinical specimen confirms the diagnosis.

STREPTOCOCCAL DISEASE, INVASIVE, GROUP A

Invasive group A streptococcal disease is associated with any of several clinical syndromes, including (1) pneumonia, (2) bacteremia associated with cutaneous infection (cellulitis, erysipelas, or infection of a surgical or nonsurgical wound), (3) deep soft tissue infection (myositis or necrotizing fasciitis), (4) meningitis, (5) peritonitis, (6) osteomyelitis, (7) septic arthritis, (8) postpartum sepsis (puerperal fever), (9) neonatal sepsis, or (10) nonfocal bacteremia. Laboratory isolation of group A streptococci (*Streptococcus pyogenes*) by culture from a normally sterile site makes the diagnosis.

STREPTOCOCCUS PNEUMONIAE DRUG-RESISTANT INVASIVE DISEASE

Drug-resistant, invasive *S. pneumoniae* is associated with many clinical syndromes depending on the site of infection. Isolation of the organism from a normally sterile site and finding a "nonsusceptible" isolate form the crux of the diagnosis.

STREPTOCOCCAL TOXIC SHOCK SYNDROME

Streptococcal toxic shock syndrome (STSS) is a severe, rapidly progressive illness associated with either invasive or noninvasive group A streptococcal infection. This syndrome may occur with infection at any site but is most often associated with a cutaneous lesion. To be considered as STSS, all the following manifestations must be present within 48 h of hospitalization:

1. Hypotension: systolic blood pressure less than 90 mmHg for adults or less than the fifth percentile by age for children under 16 years of age.
2. Multiorgan involvement with two or more of the following:
   a. Renal: Creatinine greater than 2 mg/dL for adults, or twice the upper limit of normal for age, or twice the baseline value for persons with underlying renal dysfunction.
   b. Coagulopathy: Platelets less than 100,000/μL or disseminated intravascular coagulopathy.
   c. Hepatic: Total bilirubin, alanine aminotransferase, or aspartate aminotransferase twice the upper limit of normal for age or twice normal baseline values for those persons with underlying liver disease.
   d. Respiratory: Adult respiratory distress syndrome.
   e. Dermatologic: Generalized erythematous macular rash that may desquamate.
   f. Musculoskeletal: Soft tissue necrosis including necrotizing fasciitis, myositis, or gangrene.

The laboratory diagnosis is made by isolating group A *Streptococcus* in a normally sterile site.

SYPHILIS

The manifestations of syphilitic illness vary with the time period between infection and detection. Primary syphilis is recognized by the one or more chancres, usually on the genitalia. Secondary syphilis is identified by the presence of localized or diffuse mucocutaneous lesions. The primary chancre may still be present. Laboratory diagnosis for primary or secondary syphilis rests on demonstrating *Treponema pallidum* by dark-field microscopy, direct fluorescent antibody (DFA-TP), or equivalent method.

Latent syphilis has no clinical symptoms. The early latent period occurs in those infected within the previous 12 months, and the late latent period refers to those infected for greater than 1 year. Persons in whom the period of infection cannot be documented and in whom there are no clinical symptoms are referred to as being latent of unknown duration. Laboratory diagnosis of latent syphilis can be made in one of the following ways: (1) no past diagnosis of syphilis and a reactive nontreponemal test (VDRL or RPR) and a reactive treponemal test (FTA-ABS or MHA-TP) or (2) history of syphilis therapy and current test titer with fourfold increase from last nontreponemal test titer.

Neurosyphilis is evident by the presence of CNS findings in the setting of a reactive serologic test for syphilis and a reactive VDRL in cerebrospinal fluid. Late syphilis with clinical manifestations other than neurosyphilis is manifested by inflammatory lesions of the cardiovascular system, bone, and skin. Rarely, lesions of the upper or lower respiratory tracts, mouth, eye, abdominal organs, reproductive organs, lymph nodes, or skeletal muscles occur. Evidence of late syphilis is seen after more than 15 years of untreated infection.

Syphilitic stillbirth is fetal death after at least a 20-week gestation or in a fetus weighing greater than 500 g in which the mother had untreated or inadequately treated syphilis at delivery. This should be reported as congenital syphilis.

SYPHILIS, CONGENITAL

Infection in utero with *T. pallidum* causes an illness of varying severity in children. Those under 2 years of age may present with hepatosplenomegaly, rash, condyloma lata, snuffles, jaundice (nonviral hepatitis), pseudoparalysis, anemia, or edema from nephrotic syndrome and/or malnutrition. Older children may have the

stigmata of syphilis: interstitial keratitis, nerve deafness, anterior bowing of the shins, frontal bossing, mulberry molars, Hutchinson teeth, saddle nose, rhagades, or Clutton joints.

Identification of *T. pallidum* by dark-field microscopy, fluorescent antibody, or other specific stains in specimens from lesions, placenta, cord blood, or autopsy material confirms the diagnosis.

TETANUS

Tetanus has an acute onset and is characterized by hypertonia and/or painful muscular contractions typically of the muscles of the neck and jaw without other cause. Since there are no serologic tests available to confirm the suspicion of tetanus, a clinically compatible case is sufficient for diagnosis.

TOXIC SHOCK SYNDROME

Toxic shock syndrome is an illness manifested by

1. Temperature greater than or equal to 38.8°C (102°F)
2. Diffuse macular erythroderma
3. Desquamation, particularly affecting the palms and soles, 1 to 2 weeks following onset of illness
4. Hypotension, as defined by
    a. Systolic blood pressure less than or equal to 90 mmHg for adults or less than the fifth percentile by age for those persons under 16 years of age
    b. Orthostatic decrease in diastolic blood pressure greater than or equal to 15 mmHg from lying to sitting
    c. Orthostatic syncope or dizziness
5. Multisystem involvement (three or more):
    a. Gastrointestinal: vomiting or diarrhea at outset
    b. Muscular: Severe myalgia or creatinine phosphokinase twice the upper limit of normal
    c. Mucous membranes: Vaginal, oropharyngeal, or conjunctival hyperemia
    d. Renal: Blood urea nitrogen or creatinine twice the upper limit of normal or urinary sediment with pyuria in the absence of urinary tract infection
    e. Hepatic: Total bilirubin, alanine transferase, or aspartate transferase twice the upper limit of normal
    f. Hematologic: Platelets less than 100,000/μL
    g. Central nervous system: Disorientation or alteration in consciousness without focal neurologic signs when fever and hypotension are absent

Although the diagnosis is primarily a clinical one, laboratory evaluation should include no rise in Rocky Mountain spotted fever, leptospirosis, or measles titers, if obtained, and negative blood, throat, and cerebrospinal fluid cultures. Blood cultures positive for *Staphylococcus aureus* is not inconsistent with the diagnosis of toxic shock syndrome.

TRICHINOSIS

Trichinosis presents with variable manifestations. Most commonly a person will complain of fever, myalgia, and periorbital edema. Eosinophilia may be present on white blood cell differential. Trichinosis is caused by ingestion of *Trichinella* larvae in meat most commonly. On laboratory evaluation, *Trichinella* larvae may be found in tissue obtained by muscle biopsy, or the serologic test for *Trichinella* will be positive.

TUBERCULOSIS

Tuberculosis is a chronic infection characterized pathologically by formation of granulomas. Caused by *Mycobacterium tuberculosis,* the most common site of infection is the lungs, although other organs may be involved. The following criteria must be met for a reportable case of tuberculosis: (1) a positive tuberculin skin test, (2) other signs and symptoms compatible with tuberculosis (abnormal chest radiograph or clinical evidence of current disease), (3) treatment with two or more antituberculosis medications, and (4) completed diagnostic evaluation. Laboratory confirmation can be made by any of the following methods: (1) isolation of *M. tuberculosis* from a clinical specimen, (2) detection of *M. tuberculosis* from a clinical specimen by nucleic acid amplification test, or (3) acid-fast bacilli in a clinical specimen when culture has not or cannot be obtained.

TYPHOID FEVER

The insidious onset of fever, headache, malaise, anorexia, relative bradycardia, constipation or diarrhea, and cough are characteristic of typhoid fever. Caused by the bacteria *Salmonella typhi,* typhoid fever may be relatively mild or even asymptomatic. Isolation of *S. typhi* in blood, stool, or other clinical specimen seals the diagnosis.

YELLOW FEVER

This mosquito-borne viral illness presents with acute onset of fever, headache, myalgias, and conjunctival injection. This is followed by brief remission and recurrence of the preceding symptoms along with hepatitis, albuminuria, jaundice, and in some cases renal failure, shock, and generalized hemorrhages. Laboratory diagnosis of yellow fever is made on finding (1) a fourfold or greater rise in yellow fever titer in patients with no recent history of yellow fever vaccination and in whom cross-reaction to other flaviviruses has been excluded or (2) yellow fever virus antigen or genome in tissue, blood, or other body fluids.

148 OCCUPATIONAL EXPOSURES, INFECTION CONTROL, AND STANDARD PRECAUTIONS

Kathy J. Rinnert

The estimated 9.7 million people who receive care in emergency departments (EDs) each year in the United States represent a range of humanity that includes all age, racial, ethnic, and socioeconomic groups.[1] The diverse patient population and unpredictable ED work environment combine to create special hazards for health care personnel and increase their risk of occupational exposure to infectious agents.

This chapter examines standard precautions, infection control practices, and occupational exposures for health care providers in the prehospital setting and the ED. Routes of infectious disease exposure, infectious disease precautions, and use of personal protective equipment (PPE) are also discussed. Finally, occupational exposures commonly encountered in the ED are reviewed.

OCCUPATIONAL RISKS AND EXPOSURES

The Occupational Safety and Health Administration (OSHA) estimates that approximately 5.6 million workers are at risk for contact with blood and other body fluids during the performance of their work duties.[2] Of these, 4.4 million health care workers are at risk of exposure to potentially infectious materials. OSHA defines health care workers to include nurses, physicians, dentists and dental workers, laboratory and blood bank technologists, medical examiners, phlebotomists, ED personnel, intensive care and operating room technicians, orderlies, housekeeping personnel, and laundry workers. OSHA defines an additional 1.2 million non–health care workers also at risk for infectious exposure to include those in law enforcement; fire, rescue, and emergency medical services; correctional facilities; research laboratories; and the funeral industry.

OSHA defines *occupational exposure* as a "reasonably anticipated skin, eye, mucous membrane, or parenteral contact with blood or other potentially infectious materials that may result from the performance of the employee's duties."[2] OSHA defines *blood* as "human blood, blood products, or blood components." *Other potentially infectious materials* are defined as "human body fluids, such as saliva, semen, and vaginal secretions; cerebrospinal, synovial, pleural, pericardial, peritoneal, and amniotic fluids; any body fluids visibly contaminated with blood; unfixed human tissue or organs; HIV- or HBV [hepatitis B virus] containing cell or tissue cultures, culture mediums, or other solutions; and all body fluids where it is difficult or impossible to differentiate between body fluids." Health care workers should treat all bodily secretions, fluids, and tissues as potentially infectious substances.

Sources of exposure for blood-borne, airborne or droplet, and contact-related pathogens are multiple and varied. Low compliance with barrier precautions for blood-borne diseases has been demonstrated in hospital workers, emergency medical personnel, and air medical crews.[3,4,5,6 and 7] Activities that expose medical personnel to blood-borne diseases include placement of venous access, phlebotomy, needle recapping, specimen handling, administration of injected medications, lumbar puncture, chest tube insertion, airway suctioning, placement of nasogastric and orogastric tubes, intubation, placement of urinary catheters, and hemorrhage control. Health care activities that bring workers into close physical proximity to patients or their environment expose workers to airborne or droplet-dispersed organisms. Dressing changes, wound debridement, and wound irrigation may expose health care workers to contaminated materials or infectious agents. Workplace activities that may expose health care personnel to contact-dispersed organisms or parasites include cleaning patient care areas or equipment, changing linens, caring for incontinent and diapered patients, and physical examination. A seemingly innocuous physical examination (including integument, scalp, eyes, oropharynx, respiratory tract, and wounds) is not an activity without risk depending on the nature of the infectious agent or exposure source.

Many infectious diseases can be transmitted via blood or body fluid contamination, including HIV; hepatitis A virus (HAV), HBV, hepatitis C virus (HCV), and hepatitis D virus (HDV); cytomegalovirus; tetanus; tuberculosis (TB); herpes virus; malaria; Rocky Mountain spotted fever; and Creutzfeldt-Jakob disease. Some of these diseases are fatal (e.g., HIV), some are seriously debilitating and chronic (e.g., hepatitis), and some require protracted multidrug regimens due to drug resistance (e.g., TB).

Disease transmission may also occur by exposure to airborne nuclei, particle droplets, or contact (direct or indirect). Diseases spread by airborne droplet nuclei include measles, varicella and tuberculosis. Diseases transmitted by large particle droplets include *Haemophilus influenzae* type B, *Neisseria meningitidis*, pertussis, adenovirus, influenza, mumps, and rubella. Diseases spread by patient contact (direct contact) or by contact with items within the patient's environment (indirect contact) include *Clostridium difficile*, pediculosis, and scabies. Contact isolation may also apply to those patients with gastrointestinal, respiratory, skin, or wound colonization or infection with multidrug-resistant bacteria determined to be of special clinical and epidemiologic significance. Examples include methicillin-resistant *Staphylococcus aureus* and vancomycin-resistant enterococcus. The Hospital Infection Control Practices Advisory Committee of the Centers for Disease Control and Prevention (CDC) has developed a listing of selected infections and conditions that may be encountered in the ED, along with recommended occupational exposure precautions.[8,9]

While the geographic distribution and population incidence of most infectious diseases are well known, this does not imply that infectivity is limited to specific ethnic groups, races, or subsets of the population.[10,11,12,13,14 and 15] As the world population becomes increasingly mobile, patients with geographically isolated diseases may migrate to regions where the disease incidence may be low or nonexistent. In addition, many infectious diseases display heterogeneous and varying symptom complexes, including prolonged latent or asymptomatic stages.[16] Therefore, providing health care to an apparently healthy, asymptomatic patient does not preclude the possibility of disease infectivity and exposure. Since health care workers cannot readily identify those who are infected or risky, it is prudent to employ infection control practices and utilize PPE during all patient care activities. It is on this premise that the concept of standard precautions is based.

Portals for infectious disease entry are percutaneous, mucous membrane (oral, ocular, nasal, or rectal), respiratory, and dermal.

Percutaneous exposures are the most commonly reported and pose the highest risk for the contraction of blood-borne disease. It is estimated that only 10 percent of such injuries are reported.[17] Needle sticks or cuts by sharp objects account for the majority. Needle sticks by hollow needles have a higher rate of infection with HBV and HIV than do those by solid needles. It is postulated that this is due to the larger inoculum transferred to the worker within the bore of a hollow needle. Workplace activities that put personnel at risk for percutaneous injuries include phlebotomy, initiation of intravenous access, manipulation of access devices, suturing, and medication injection. Since the majority of these activities are nursing functions, it is not surprising that many studies document nurses as the most likely recipients of

needle-stick injury.[17,18]

Mucous membrane exposures are the second most commonly reported occupational exposure and result from splatters, splashes, and sprays of blood and body fluids. Risk is entailed by such health care tasks as wound management (hemorrhage control, exploration, cleansing, irrigation, and debridement), airway suctioning, nasogastric or orogastric tube placement, intubation, and handling specimen containers of blood or body fluids.

Respiratory exposures result from the inhalation of airborne or droplet particulate materials. Health care workers risk respiratory exposure when they are confined with an expectorating, coughing, or sneezing patient for prolonged periods or in a poorly ventilated environment.

Dermal exposure involves skin contact with patients (direct contact) or environmental surfaces or objects that are contaminated with infectious materials (indirect contact). Risk of infection is increased if the place of worker contact is a large surface area or if the dermis is not intact (abraded, chapped, or excoriated). The emergence of drug-resistant organisms, such as methicillin-resistant *S. aureus* and vancomycin-resistant enterococci, pose additional exposure risk. Transmission of these diseases may be related to contact with infected patients, medical equipment used on them, or both. Workplace activities that place the health care worker at risk include patient examination, turning or moving patients, and changing linens or wound dressings. Parasites of the integument (e.g., scabies, lice, etc.) are also agents of dermal exposure. Other dermal exposures include hypersensitivity reactions of health care workers that may occur with prolonged or repeated exposure to specific inert substances (e.g., latex).

The risk of infection in an exposed health care provider depends on the route (portal) of exposure, the concentration (number of organisms) of pathogen in the infectious material, the infectious characteristics (virility) of the pathogen, the volume (dose) of infectious material, and the immunocompetence (susceptibility) of the exposed individual. Infectious characteristics may vary as the pathogen mutates, becoming resistant to treatment agents (e.g., antibiotics, antivirals, antifungals, etc.) or the host's immune defenses. The potential for infection may be incrementally higher as the route of exposure changes; that is, percutaneous exposures have greater potential for infection than do mucous membrane exposures, respiratory exposures, or dermal exposures.

As the number of organisms of the infectious agent increases, the rate of infectivity increases. For example, a percutaneous exposure to HBV carries a higher risk of infection than does a similar exposure to HIV. This higher rate of disease transmission is probably due to the higher concentration of virus in the blood of infected persons. It is reported that the concentration of virus in a HBV-infected individual is 100,000,000 free virus particles per cubic centimeter of blood, imparting a 6- to 30- percent risk of infection after a single percutaneous exposure. In contrast, there are 1000 free virus particles per cubic centimeter of blood in an HIV-infected patient, which imparts a 0.5 percent risk of infection following a percutaneous exposure. As the infectious disease state progresses, the concentration of microorganisms varies, depending on the immunocompetence or treatment status of the host. The CDC considers blood or blood-containing body fluids to be the "single most important source of HIV and HBV in the workplace setting." The strength (virility) of the infectious agent and the length (time) of exposure may also contribute to the transmission of blood-borne diseases, but the effect of these factors on infectivity is unclear.

INFECTION CONTROL

Infection control practices are designed to prevent transmission of microbial agents and to provide a wide margin of safety for health care workers. These practices were developed for hospital employees and other workers in health care facilities as a result of epidemiologic knowledge of blood-borne exposures and transmission rates.[3,4,5 and 6] Emergency personnel should utilize these practices to minimize infection due to contact with contaminated body secretions, devices, objects, or surfaces. Infection control practices include hand washing; use of personal protective equipment (PPE); cleaning, disinfecting, and sterilizing patient care equipment and environmental surfaces; decontamination and laundering of soiled uniforms, clothing, and patients' linens; disposal of needles, sharps, and infectious waste; and patient placement. Infection control measures that are simple, part of the routine work environment, and uniform across all situations have the greatest likelihood of compliance.

Basic infection control principles serve as a starting point for the prevention of infectious disease transmission. These principles are implemented in concert with other practices to prevent or mitigate exposure to transmissible infectious diseases. A complete infection control program includes administrative controls, equipment engineering, work practice controls, education of the work force, and medical management.

Administrative controls are designed to organize, define, and direct infection control activities. The most important of these activities is the development of a written infection control (exposure) plan. This plan defines all policies, procedures, and activities related to the education, prevention, and management of infectious diseases in the work force. Jobs and specific work tasks are identified and evaluated for potential exposure to infectious diseases. Initial and recurrent training in infectious disease hazards and risk activities must be provided to all health care workers. Risk reduction training and activities must be documented and monitored for adequate compliance. Other administrative controls include written policies and procedures for all infection control activities. Infection control monitoring, compliance, evaluation, modification, and quality improvement are to be clearly defined in policy and procedure documents.

Equipment engineering serves to reduce employee exposure by removing the hazard or isolating the health care provider from exposure. Examples of such equipment include self-sheathing needles, needleless drug administration devices, sharps containers, pocket masks, disposable airway equipment, syringe splash guards, and PPE. PPE is "specialized clothing or equipment which does not permit blood or potentially infectious substances to pass through or reach worker clothing, skin, eyes, mouth, or other mucous membranes under normal conditions of use."[2]

PPE includes such items as examination gloves, face masks, eye protection, face shields, and impervious gowns and aprons. The American Society for Testing and Materials has published specifications for examination gloves and protective clothing materials (gowns and shoe, sleeve, and leg covers). [19,20,21,22,23,24 and 25] In addition, the National Fire Protection Association (NFPA) specifies the minimum documentation, design and performance criteria, and test methods for emergency medical clothing.[26,27] Package labeling for PPE must describe components of the medical garment and indicate compliance with NFPA standards. Several sources make recommendations on the types of PPE to be worn during specific patient care activities. [7,28,29]

The most common barrier devices for infection control and prevention of blood exposures in the ED include examination gloves, eye and face protection, and disposable resuscitation equipment. Disposable, single-use examination gloves are standard in all health care settings. They are utilized when patient care activities involve potential exposure to blood, blood-containing body fluids, or other potentially infectious materials or contact with mucous membranes, tissues, or nonintact skin. Adequate supplies of gloves should be available to allow glove changes if significant contamination or loss of integrity (tears or punctures) occurs. Health care providers should avoid handling personal or common-use items (e.g., telephone, door handles, drinking cups, and combs) while wearing gloves to prevent environmental contamination. Gloves should fit tightly and extend above the wrist to provide maximal barrier protection for the wrist and lower forearm. Choice of glove ultimately depends upon individual preference and task performance needs. The potential for hypersensitivity reactions to glove component materials (latex, powder, etc.) must be taken into account when furnishing PPE for health care workers.

Emergency medical personnel who operate in the out-of-hospital environment (emergency medical services, air medical services, and interfacility transport services) may be exposed to situations where broken glass or sharp metal is exposed. In such cases, gloves with additional protective characteristics are needed. Structural firefighters' gloves are optimal and can be used during rescue and extrication activities. Firefighters' gloves can be replaced by examination gloves when patient care activities commence.

Face masks, eye protection, face shields, and gowns should be present in all EDs and emergency response vehicles. These barrier devices are used when anticipated exposure includes the possibility of splashes, sprays, arterial bleeding, or exsanguinating hemorrhage or when airway management techniques are undertaken. Face masks and eye protection should be worn simultaneously or a face shield employed to protect the ocular, oral, and nasal mucous membranes. Impervious aprons or gowns are appropriate if massive exposures are anticipated. Appropriately sized and adequate numbers of barrier devices should be available if gross contamination or loss of barrier integrity occurs. Additional uniform or work clothing and shower facilities should be available if contamination of clothing or dermal surfaces occurs.

Disposable resuscitation equipment should be readily available for all patient encounters requiring rescue breathing. Most bag-valve-masks, oxygen reservoirs, and tubing are meant to be discarded after each use. Reusable equipment must be cleaned and disinfected after each use. Disinfecting procedures for all reusable equipment (laryngoscope blade and handle, pocket mask, gurney, and patient care area) should be documented in policy and performed after each use.

Pocket masks are designed to isolate the health care provider from contact with blood, saliva, respiratory secretions, and vomitus. These masks vary in type and can

be cleaned and disinfected for reuse or discarded after a single use. All personnel who may be called upon to render resuscitative efforts should have ready access to pocket masks.

Work practice controls modify the performance of a task to minimize exposure to blood and blood-containing body fluids and infectious materials. Work practice controls necessitate delineated policies concerning proper disposal of needles and sharps containers (i.e., avoid shearing, bending, recapping, or breaking); proper disposal of contaminated linens, clothing, and infectious waste; appropriate disinfection techniques for reusable equipment; and restriction of employee activities (e.g., avoidance of eating, drinking, smoking, and application of cosmetics) while in work areas that entail a reasonable likelihood of exposure to blood and body fluids.

Education of the work force on topics of infectious disease transmission, epidemiology, disease symptoms, portals of exposure, control methods, administrative compliance mechanisms, appropriate use and cleaning of medical equipment, use of PPE (barrier precautions), and medical management of infectious disease is necessary. In addition, there must be an awareness of the types of PPE to utilize and methods of risk reduction. Health care providers must also be aware that utilization of these devices does not totally eliminate infection risk. [30],[31] Members of the work force are more likely to comply with infection control guidelines when they understand the purpose and reasoning that underlie recommendations for the use of PPE and specific risk reduction practices. Mandatory compliance with the utilization of PPE must be established in departmental or hospital policy and enforced in daily practice.

Medical directors and administrators of EDs should classify their work force (e.g., clerical personnel, coders, billers, supervisors, nurses, doctors, physicians' assistants, nurse practitioners, emergency medical technicians, paramedics, electrocardiogram technicians, radiography technicians, etc.), identify risky activities (e.g., hemorrhage control, intravenous access, phlebotomy, suctioning, intubation, etc.), and devise infection control plans. EDs should ensure initial and repeated infection control training programs; establish engineering and workplace controls; and administer postexposure medical evaluation, counseling, prophylaxis, and referral for health care workers with infectious disease exposures.

Medical management practices include preventive vaccinations, acute postexposure medical evaluation, infectious disease counseling, disease prophylaxis, and medical follow-up. Vaccines should be readily available to all health care personnel who may be exposed to infectious disease. OSHA mandates vaccines at initial employee training and within 10 days of employment for all personnel at risk of exposure. [2] In addition, mechanisms for postexposure medical management should be well defined and readily available to health care providers 24 h/day. Once a blood exposure has occurred, policies and procedures for exposure management must be understood and followed by all employees. An exposure incident is a "specific eye, mouth, or other mucous membrane, nonintact skin, or parenteral contact with blood or other potentially infectious materials." [2] An established reporting policy for exposed personnel should include medical assessment, prophylaxis, and follow-up appropriate to the type and source of the exposure. [28],[32] As with any medical evaluation, the confidentiality of the source patient and employee must be strictly maintained. [33]

LEGISLATIVE REGULATIONS

OSHA has drafted federal regulations that prescribe safeguards to protect workers and reduce risk of exposure to blood-borne diseases. [34] These standards were first published in Title 29, Code of Federal Regulations, part 1910.1030, in December 1991. [35] Title 29 (the blood-borne standard) requires employers of one or more individuals "who can reasonably be expected to come into contact with blood or specified body fluids during the performance of their duties" to develop programs for the mitigation of blood-borne disease transmission: (1) development of a written exposure control plan, (2) utilization of engineering controls to reduce risk by removing the hazard or isolating the worker from exposure, (3) utilization of work practice controls to standardize and maximize the safety with which work tasks are performed, (4) identification of mechanisms for compliance with Title 29 standards, and (5) communication of workplace hazards to those with potential for blood-borne disease exposures. Workplace education should include information about the agents of infectious disease, epidemiology, methods of disease transmission, disease signs and symptoms, risky work tasks, risk reduction strategies, and postexposure management. Such education must occur at initial employment, with repeated training provided at specified intervals.

INFECTION PRECAUTIONS

In 1987, the CDC recommended the use of blood and body substance precautions for all patients through a system called universal precautions. The initial precautions applied to all body substances. These recommendations were revised in 1988 to include only those body fluids associated epidemiologically with transmission of blood-borne pathogens. [36] Exposures related to oropharyngeal or respiratory secretions (airborne or droplet), parasitic infectious exposures, and contact exposures were not considered in the revised precautions. Confusion resulted, with hospitals adopting some but not all aspects of universal precautions or body substance isolation. Such confusion has led to lack of uniformity in infectious disease precautions from facility to facility. The focus of universal precautions and body substance isolation is on blood and blood-containing fluids, and the recommendations inadequately address infections transmitted by air or droplet. Confusion, lack of uniform application of infection control precautions, and the emergence of antibiotic-resistant organisms have promoted the development of a new system that is simple, is easy to apply, and pertains to all methods of infectious disease transmission.

In 1996, the Hospital Infection Control Practices Advisory Committee of the CDC devised a new system of isolation precautions to address all methods of disease transmission and to bring uniformity to hospital infection control practices. The new guidelines contain two tiers of precautions: standard and transmission-based. Standard precautions combine the major features of body substance isolation and universal precautions. Transmission-based precautions are designed for patients with documented or suspected transmissible pathogens for which additional protection beyond standard precautions is required. Transmission-based precautions are of three types: airborne, droplet, and contact. They are to be utilized in addition to, not in place of, standard precautions. [37] Unlike universal precautions, which list specific body fluids that may transmit blood-borne pathogens, or body substance isolation, which considers all body fluids to pose risk for transmission of blood-borne pathogens, standard precautions assume a broader approach to health care and patient protection, by including agents transmitted by routes other than blood.

Standard Precautions

Standard precautions should be exercised when caring for *all* patients and include hand washing, gloves, mask and eye protection or face shield, gowns, handling of patient care equipment and linens, environmental controls, workplace controls, and patient placement.

Hand washing is to be performed after touching blood, body fluids, secretions, excretions, and contaminated items *whether or not* gloves are worn. Hands should be washed immediately after gloves are removed, between patient contacts, and when otherwise indicated to avoid the transfer of organisms to other patients or environments. It may be necessary to wash hands between procedures on the same patient to prevent cross-contamination of various body sites. Plain soap and water are recommended for routine use. Washing with an antimicrobial agent or waterless antiseptic may be utilized for control of outbreaks or hyperendemic infections.

Clean, nonsterile gloves are to be used when touching blood, body fluids, secretions, excretions, and contaminated items. Clean gloves should be used before touching nonintact skin and mucous membranes. Gloves should be changed between tasks and procedures following contact with material that may contain a high concentration of microorganisms. Gloves should be removed and hands washed before touching noncontaminated items, environmental surfaces, or other patients.

Face masks, eye protection, and face shields should be fluid resistant and are worn to protect mucous membranes of the eyes, nose, and mouth during patient care activities and the performance of procedures likely to generate splashes or sprays of blood, body fluids, secretions, excretions, and infectious materials. Masks that become significantly soiled, moistened by the user's exhaled vapor, or contaminated by fluids should be immediately replaced, since loss of protective function occurs if the barrier device is completely saturated.

Clean, nonsterile gowns should be fluid resistant and used to protect the worker's skin and clothing during patient care activities and the performance of activities likely to generate splashes or sprays of blood, body fluids, secretions, and excretions. The gown selected should be appropriate for the type and volume of fluid likely to be encountered. Soiled gowns should be replaced as soon as possible, since barrier protection is lost if the garment is saturated with contamination. Sleeve protectors, booties, and leggings should be used if a large volume of contamination or infectious material difficult to contain is anticipated.

Patient care equipment and linens soiled with blood, body fluids, secretions, and excretions should be handled to prevent skin and mucous membrane exposure, contamination of clothing, and transfer of microorganisms to other patients and environments. Reusable items should be cleaned and reprocessed to eliminate infectivity. Single-use items should be discarded properly.

Environmental controls relate to hospital procedures for the decontamination of objects in patient care areas. Environmental surfaces, beds, bed rails, bedside equipment, and frequently touched surfaces should be cleaned and disinfected between patient use.

Workplace controls (work practice controls) include proper disposal techniques for needles, scalpels, and other sharp instruments. Proper handling of these devices should stress the avoidance of recapping, excessive handling, and manipulation. Proper disposal should emphasize the use of self-sheathing devices, use of puncture-resistant containers, and routine replacement of sharps containers prior to overflowing. Patients who contaminate the environment or those who cannot assist in their own hygiene should be placed in a private room if available.

Airborne Precautions

In addition to standard precautions, airborne precautions are utilized for patients known to be or suspected of being infected with microorganisms transmitted by airborne droplet nuclei. Airborne precautions also apply to small particle residue (5 μm or smaller) of evaporated droplets containing microorganisms that remain suspended in the air and can be dispersed widely by air currents over a long distance. Examples of infectious agents spread by this method are found in Table 148-1.

Rubeola (measles)

Varicella (including disseminated zoster)

Tuberculosis

Source: Modified from Centers for Disease Control and Prevention.[a]

TABLE 148-1   Airborne-Spread Infectious Diseases

As with standard precautions, utilization of previously described techniques for hand washing, gloves, face mask and eye protection or face shield, gowns, equipment and linen, environmental controls, and workplace controls applies. The placement of patients in the ED requires a room with (1) monitored negative air pressure in relation to surrounding areas, (2) 6 to 12 air changes per hour, and (3) discharge of the room air to the outdoors or high-efficiency filtration of the air before it is circulated to other areas in the hospital. The door to the patient's room must be kept closed, and the patient must remain in the room. Movement and transportation of the patient should be limited. If movement is unavoidable, the patient should wear respiratory protection to avoid contamination of other areas within the hospital. Health care providers entering the room must wear respiratory protection, such as a personalized, fitted mask with efficient filters (approved particulate respirator).

Droplet Precautions

In addition to standard precautions, droplet precautions are employed for patients known to have or suspected of having serious illnesses transmitted by large particle droplets (>5 μm in size) that can be generated by the patient during talking, sneezing, or coughing or during the performance of procedures. Examples of infectious agents spread by this method are listed in Table 148-2.

Invasive *Haemophilus influenzae* type B (including meningitis, pneumonia, epiglottis, sepsis)

Invasive *Neisseria meningitidis* (including meningitis, pneumonia, sepsis)

Serious bacterial respiratory infections:
  Diphtheria (pharyngeal)
  Mycoplasma pneumonia
  Pertussis
  Pneumonic plague
  Streptococcal pharyngitis, pneumonia, scarlet fever

Serious viral infections:
  Adenovirus
  Influenza
  Mumps
  Parvovirus B19
  Rubella

Source: Modified from Centers for Disease Control and Prevention.[a]

TABLE 148-2   Droplet-Spread Infectious Diseases

As with standard precautions, utilization of previously described techniques for hand washing, glove, face mask and eye protection or face shield, gown, equipment and linen, environmental controls, and workplace controls applies. Patients should be placed in a private room. Special air handling and ventilation are not required, and the door may remain open. If a private room is not available, the patient may be placed in a room with other patients who have active infections with the same microorganism (i.e., cohorting). When this is not achievable, maintain spatial separation of at least 3 ft between the infected patient and other patients and visitors. Patient transportation should be limited to essential procedures only. Patients who must be moved to other areas of the hospital for testing and procedures should don face masks to minimize the dispersal of droplets. Health care personnel should observe standard precautions and wear face masks when working within 3 ft of the patient.

Contact Precautions

In addition to standard precautions, contact precautions should be utilized with patients known to have or suspected of having serious illnesses easily transmitted by direct patient contact or by contact with items in the patient's environment. Examples of such infectious diseases are seen in Table 148-3.

Multidrug-resistant infections or colonization (gastrointestinal, respiratory, skin, wound sites)

Enteric infections with low infective dose or prolonged environmental survival:
  Clostridium difficile
  Enterohemorrhagic *Escherichia coli* 0157:H7
  Shigella
  Hepatitis A
  Rotavirus

Respiratory syncytial virus

Parainfluenza virus

Enteroviral infections

Skin infections that are highly contagious or that may occur on dry skin:
  Diphtheria (cutaneous)
  Herpes simplex virus (neonatal or mucocutaneous)
  Impetigo
  Major, noncontained abscesses, cellulitis, decubiti
  Pediculosis
  Scabies
  Staphylococcal furunculosis
  Herpes zoster (disseminated or in an immunocompromised host)

Viral hemorrhagic conjunctivitis

Viral hemorrhagic infections (Ebola, Lassa, Marburg)

Source: Modified from Centers for Disease Control and Prevention.[a]

TABLE 148-3   Contact Spread Infectious Diseases

As with standard precautions, utilization of previously described techniques for hand washing, glove, face mask and eye protection or face shield, gown, equipment and linen, environmental controls, and workplace controls applies. If the examination and care of a patient result in contact with infective materials and a high concentration of microorganisms (wound drainage or fecal material), changing of gloves is required. Hand washing with an antimicrobial agent or waterless antiseptic is required after removal of gloves. After glove removal and hand washing, workers should avoid contact with potentially contaminated environmental surfaces or items in the patient's room.

In addition to wearing a gown as described in the standard precautions, one should wear a clean, nonsterile gown upon entering a patient's room if one anticipates substantial contact with the patient or if the patient is incontinent or has diarrhea, a colostomy, an ileostomy, or wound drainage not contained by dressings. The gown should be removed prior to leaving the patient's room, and care should be taken to avoid contact with potentially contaminated environmental surfaces.

Transportation and movement should be limited to essential purposes only. If the patient must be moved to another treatment area, one should ensure that contamination spread is minimized by large, bulky dressings.

Medical equipment (e.g., blood pressure cuffs, stethoscopes, bedside commodes, etc.) should be dedicated to a single patient (or cohort of similarly infected patients) to avoid sharing between noninfected patients. Health care personnel who use personal medical equipment (e.g., stethoscopes) should thoroughly clean these items between using them on different patients if the possibility of contamination exists.

Specific workplace activities and medical devices may significantly mitigate the occupational exposures experienced by health care personnel. These task-related and device-related recommendations are found in Table 148-4 and Table 148-5, respectively.

TABLE 148-4   Task-Specific Recommendations for Use of PPE

TABLE 148-5   Task-Specific Recommendations for Use of Medical Safety Devices

COMMON OCCUPATIONAL EXPOSURES

Hepatitis

Hepatitis is most commonly caused by a virus. More than 90 percent of cases of viral hepatitis in humans are caused by five viruses: HAV, HBV, HCV (or classic non-A, non-B hepatitis virus), HDV (or delta agent), and hepatitis E virus [(HEV) or epidemic non-A, non-B hepatitis virus].

These five viruses are each very different and share only a common tropism for the liver, with the hepatocyte representing the dominant site for viral replication and acute or chronic hepatitis as the major clinical manifestation of infection. The viruses can be divided into two distinct groups based upon the existence of a lipid-containing outer envelope. [38] HBV, HCV, and HDV all possess a lipid-containing outer viral envelope. HAV and HEV, lacking a lipid envelope, are stable when secreted from infected hepatocytes into bile and thus gain entry into the gastrointestinal tract. These viruses are spread by the fecal-oral route and can cause extensive single-source outbreaks of disease. HAV and HEV do not cause persistent infection, nor have they been identified as the causative agents of chronic viral hepatitis. In contrast, HBV, HCV, and HDV, because of their lipid envelope, are probably inactivated by bile. Therefore, these viruses are not shed into the gastrointestinal tract in biologically significant amounts. These viruses are transmitted by several routes, including virus shed from mucous membranes or by percutaneous exposure. HBV, HCV, and HDV may each cause persistent infection, and all three have been identified as etiologic agents in chronic viral hepatitis and cirrhosis. Persistent infections caused by HBV and HCV may ultimately result in the development of primary hepatocellular carcinoma.

HAV is a single-stranded RNA virus within the genus *Hepatovirus* of the family Picornaviridae. HAV is worldwide in its distribution, with the highest prevalence of infection in geographical regions with substandard water and sanitation. It is estimated that there are between 125,000 and 200,000 infections per year in the United States, where risk factors associated with disease acquisition include living in the same household with a hepatitis patient (»25 percent of patients), close contact with young children attending day-care centers (»18 percent), sexual activity with oral-anal contact (»11 percent), and foreign travel to areas where hepatitis A is endemic (»4 percent). [35] It is noteworthy that approximately 40 percent of patients report no apparent risk factor. While most cases of hepatitis A can be explained by fecal-oral transmission, association with injected drug use has been reported by 2 percent of patients. [38] While this association may reflect the general living conditions and poor sanitation that may be associated with injected drug users, acute infection with HAV is associated with a substantial viremia that may persist for several weeks. Percutaneous transmission of the virus may be possible if individuals share non-sterile needles during the prodromal phase.

Recently developed formalin-killed whole virus vaccines are highly effective in the prevention of hepatitis A. Two such vaccines are being used in the United States: Havrix (Smith-Kline Beecham) and Vaqta (Merck and Company.) [46] These vaccines are given as a single primary immunization with a booster dose at 6 to 12 months. Immunizations should target individuals with increased risk of acquiring hepatitis A or those who are at increased risk of fatal, fulminant disease, including children in communities where hepatitis A is endemic, travelers to developing nations, male homosexuals, and injected drug users. People with underlying liver disease, particularly those over 50, are at increased risk of fulminant hepatitis A and should be immunized. Preventive measures for health care providers include the use of standard precautions with the addition of contact precautions when caring for patients who are incontinent or diapered.

HBV is a partially double-stranded, circular DNA virus of the family Hepadnaviridae. HBV is worldwide in its distribution and is an important cause of acute and chronic hepatitis. Approximately 300,000 new cases of HBV B are reported in the United States each year. It is estimated that 300 million people worldwide are chronic carriers, with approximately 1 million of them in the United States. [41] Ninety-five percent of adult cases resolve spontaneously, while 5 percent of patients

develop chronic hepatitis B. In contrast, neonates develop the chronic form in 90 percent of cases. [42] Percutaneous exposure to blood, sexual transmission, and perinatal transmission account for most HBV infections in humans. In 1972, mandatory screening for HBV began on donor blood; as a result, the risk of posttransfusion transmission of HBV is extremely low.

Active prophylaxis against HBV infection has been available since 1982. These highly effective, recombinant vaccines are available in two commercial products: Recombivax HB (Merck and Company) and Engerix-B (Smith Kline Beecham). These vaccines are given as a series of three intramuscular injections at 0, 1, and 6 months. As of this writing, neonatal and infant HBV vaccination has been suspended until a mercury-free vehicle is developed. While the need for booster vaccination is unclear, it has been suggested that revaccination occur after an interval of 10 years. Current recommendations are to vaccinate all newborn infants and all adolescents and adults in high-risk groups. Passive immunity is available using hepatitis B immunoglobulin (HBIG), which is prepared from the pooled serum of patients with spontaneous recovery from acute HBV. HBIG is given simultaneously with HBV vaccine to adults not immune to HBV who have experienced percutaneous or sexual exposures and newborns whose mothers are hepatitis B surface antigen (HBsAg) positive. Highest efficacy is found when HBIG is administered within 12 h of exposure to HBV. Completion of the HBV vaccine series at 1 and 6 months must be performed to ensure long-term (>10 years) immunity. The CDC currently recommends a postvaccination titer be obtained within 1 to 6 months of completing the vaccine series.

Health care workers who are exposed to blood or body fluids in their daily work are at increased risk for acquiring HBV. In the CDC study of HBV infections in sentinel counties, health care providers accounted for only 1 percent of cases, compared to heterosexual contact with multiple partners (27 percent), injected drug use (14 percent), and homosexual contacts (11 percent). The risk of acquiring HBV after an accidental needle stick from a patient with HBV varies from 20 percent if the patient is HBsAg positive to 66 percent if the patient is both HBsAg and hepatitis B e antigen positive. [42] Preventive measures for health care providers include the use of standard precautions and HBV vaccination. Postexposure medical examination, counseling, treatment (HBIG and HBV vaccine), and follow-up are required.

HCV is an enveloped, single-stranded RNA virus of the flavivirus family. It was discovered in 1988 and identified as the agent responsible for most cases of non-A, non-B hepatitis. HCV is the most common chronic blood-borne infection in the United States and a major cause of chronic liver disease worldwide. Throughout the 1980s, an average of 230,000 new infections occurred each year in the United States. [43] Between 1989 and 1996, the annual number of infections declined by more than 80 percent, to 36,000. [45] The Third National Health and Nutrition Examination Survey, conducted between 1988 and 1994, estimates that 3.9 million Americans (1.8 percent) have been infected with HCV. [44] While most acute infections are asymptomatic, serious sequelae result from this infection. Persistent infection develops in most HCV-infected patients (>85 percent). Chronic hepatitis develops in approximately 60 to 70 percent of HCV-infected patients and may progress to cirrhosis (10 to 20 percent) and hepatocellular carcinoma (1 to 5 percent). [45,46] Factors that may influence the severity and progression of disease in patients with chronic HCV infection include alcohol-induced liver disease, older age at the time of infection, male gender, and immunodeficiency.

The most common and the efficient route of transmission of HCV is parenteral. Before the first immunoassays for detecting antibodies to HCV were introduced in 1990, transfusion of blood and blood products accounted for approximately 90 percent of infections. Measures such as deferral of high-risk donors and widespread use of hepatitis antibody testing have decreased the risk of contracting HCV to 1 in 100,000 U transfused. In contrast, injected drug usage has consistently accounted for a substantial portion of HCV infections and currently accounts for 60 percent of HCV transmissions in the United States. [47]

The prevalence of HCV infection among health care workers is no greater than in the general population, averaging 1 to 2 percent, which is 10 times lower than the prevalence of HBV. [48,49,50,51 and 52] The average incidence of anti-HCV seroconversion after unintentional needle sticks or sharps exposure from an HCV-positive source is 1.8 percent (range, 0 to 7 percent). [53] Since no vaccine currently exists, preventive measures must focus on counseling, screening high-risk populations (injected drug users, recipients of blood clotting factor concentrates before 1987, recipients of blood and solid organ transplants before 1992, and chronic hemodialysis patients), and use of infection control practices. Preventive measures for health care providers include the use of standard precautions.

HDV is a single-stranded, circular RNA virus. The genome of HDV is contained within an envelope provided by HBV. Although HBV surface proteins are required for HDV viral assembly, they are not needed for viral replication. HDV infection can occur simultaneously with HBV infection (coinfection) or as a superinfection of patients with chronic HBV infection. While coinfection increases the initial severity of the acute HBV infection, the progression to an HBV carrier state occurs less frequently. HDV superinfection tends to increase the frequency and severity of clinical sequelae of chronic HBV infection. Currently, no evidence links HDV with progression to hepatocellular carcinoma.

The prevalence of HDV is unclear; serologic markers of HDV in an HBV coinfection become unmeasurable within 1 to 5 years. There is similar difficulty in testing for HDV superinfection. HDV infections are rare in the United States. In countries with increased HBV endemicity, such as Greece, Italy, Jordan, and Egypt, as many as 50 percent of chronic HBV-infected patients may exhibit superinfection with HDV. [54]

HDV is transmitted primarily by parenteral contact with blood. Sexual and vertical transmission of HDV is reported, but it is less efficient than with HBV. Prevention of HDV depends on prevention of HBV infection (immunization) and reducing exposure to blood (reduction of high-risk behaviors). No vaccine for HDV currently exists. Preventive measures for health care providers include the use of standard precautions.

HEV is a nonenveloped, single-stranded RNA virus provisionally classified in the Caliciviridae family. HEV is the major etiologic agent of enterically transmitted non-A, non-B hepatitis worldwide. The virus is endemic and epidemic in developing countries that lack the infrastructure to ensure adequate sanitation and water purification. HEV is spread primarily by the fecal-oral route. The clinical infection mimics HAV, and infections usually resolve without sequelae. The case fatality rate is low except in pregnant women, in whom it may approach 20 percent. [55] No vaccine for HEV currently exists. Preventive measures for health care providers include the use of standard precautions with the addition of contact precautions when caring for patients who are incontinent or diapered.

Hepatitis G virus (HGV), characterized in 1996, is a flavivirus. It is estimated that there are 900 to 2000 infections each year in the United States, the majority being asymptomatic or minimally symptomatic. Transmission has been documented through blood transfusions and vertical transmission from mother to infant in the perinatal period. [56] Coinfection with HBV and HCV is common, probably reflecting similar modes of transmission. HGV is the only identifiable agent in 0.3 percent of community-acquired acute hepatitis. [57] No vaccine for HGV currently exists. Preventive measures for health care providers include the use of standard precautions.

Human Immunodeficiency Virus

HIV is an enveloped genome of two identical, single-stranded RNA molecules. HIV, classified as a retrovirus in the subfamily lentivirus, replicates in activated CD4 T lymphocytes. There are two types of human lentiviruses: HIV-1, the predominant HIV type in most parts of the world, and HIV-2, primarily found in West Africa. [58] As of December 1996, the Joint United Nations Programme on HIV/AIDS estimated that there were a total of 27 million adults and 2.6 million children with HIV infection. Of these cases, 62 percent occurred in sub-Saharan Africa and 23 percent in South and Southeast Asia. [59] As of 1996, there were at least five African nations with adult prevalence of HIV greater than 10 percent. In 1996, there were over 32,000 deaths in the United States due to HIV and/or AIDS, ranking it the eighth leading cause of death in the nation. [60] The capacity of HIV to recombine and generate mosaic genotypes confounds treatment efforts and vaccine development. The virus mutates at varying rates over time in various individuals, and data suggest that the host's ongoing immune response is a driving force for genetic variation.

More than 70 percent of HIV infections are due to unprotected heterosexual intercourse. Other important modes of transmission include unprotected homosexual intercourse, injected drug use, mother-infant vertical transmission, and blood transfusions. Blood screening, use of a voluntary donor pool, and more rational use of blood products has greatly reduced transfusions as a means of infection.

Percutaneous injury with exposure to HIV-infected blood in health care workers accounts for 80 percent of occupational exposures. [17] The average risk of HIV infection from all types of percutaneous exposures to HIV-infected blood is 0.3 percent. [61] Risk of infection is increased for deep injury, injury by a device previously placed in the source patient's artery or vein, visible blood on the device causing the injury, and death of the source patient as a result of AIDS within 60 days postexposure. The risks of acquiring HIV after mucous membrane and skin exposure to HIV-infected blood are approximately 0.1 percent and less than 0.1 percent respectively. [17] As previously mentioned, large-volume exposures, increased viral titer in the source patient, large surface area of contact, and loss of integrity in mucous membranes or skin may increase the risks of acquiring HIV. Chemoprophylaxis should be recommended to exposed workers after occupational exposures associated with highest risk for HIV transmission. The US Public Health Service has published guidelines for the management of health care workers exposed to HIV with recommendations for postexposure prophylaxis (Table 148-6, Table 148-7, and Table 148-8). [62] Chemoprophylaxis should begin as soon as possible after the exposure, ideally within 1 to 2 h. Animal studies show that antiretrovirals are not effective if started later than 24 to 36 h after the exposure event. No vaccine for HIV currently exists. Preventive measures for health care providers include the use of standard precautions. Postexposure medical examination, counseling, treatment (antivirals based on risk

evaluation), and follow-up should be readily available to health care personnel.

Tuberculosis

TB is a global epidemic that is expected to result in an estimated 90 million new cases and 30 million deaths during the current decade. [65] Four subspecies of mycobacteria exist, each of which can cause tubercular disease: *Mycobacterium africanum, Mycobacterium bovis, Mycobacterium microti,* and *Mycobacterium tuberculosis.* Mycobacteria are slow-growing, aerobic rods with lipid-laden cell walls, which account for its acid-fast-staining characteristics. *Mycobacterium tuberculosis* is the primary cause of TB in humans. [64] According to the World Health Organization Global Tuberculosis Programme, *M. tuberculosis* kills more adults in the world each year then any other single pathogen. [65] During 1997, approximately 19,900 (7.4 cases per 100,000) cases of TB were reported in the United States. [66] This represents a 7 percent decrease from 1996 and a 26 percent decrease from 1992. [66] In 1997, six states (California, Florida, Illinois, New Jersey, New York, and Texas) reported 57 percent of all TB cases in the United States. [67] From 1992 to 1997, a substantial decline in the number of TB cases has been noted among US-born persons in all age groups. During this same time, the number of cases among foreign-born persons has increased by approximately 6 percent. Approximately 7.6 percent of isolates in 1997 were resistant to at least one antibacterial, isoniazid, and 1.3 percent were resistant to two agents, isoniazid and rifampin (multidrug-resistant TB). [66] Outbreaks of multidrug-resistant TB, particularly among HIV-infected persons, contributed to the resurgence of TB in the late 1980s and early 1990s.

Transmission of TB occurs through inhalation of aerosolized bacilli. Fewer than 1 to 10 bacilli can cause infection, but only about 20 percent of exposed individuals become infected. [68] Infectious individuals expel large droplets by coughing or sneezing. Large droplets are usually trapped in the upper airways of exposed individuals, where mechanical barriers prevent access to the alveoli. Some droplets partially evaporate into smaller droplet nuclei (1 to 5 μm), which remain suspended in the environment for extended periods and are easily carried by air currents. Small droplet nuclei, containing 1 to 3 tubercle bacilli, have an approximately 50 percent chance of reaching the alveoli after inhalation. [68]

Control measures for TB have included the widespread use of bacille Calmette-Guérin (BCG) vaccine and the provision of unsupervised pharmacologic therapy. While the BCG vaccine has the highest coverage of any vaccine in the World Health Organization Expanded Programme on Immunization, randomized and placebo-controlled trials have shown efficacy ranges from 0 to 80 percent. [65] Since evidence exists that the vaccine confers protection against serious forms of childhood TB (disseminated and meningeal TB), which have high rates of morbidity and mortality, the vaccine will continue to be a component of childhood immunization strategies in developing countries. BCG has never been recommended in the United States because of its low efficacy and due to the dermal hypersensitivity it induces with purified protein derivative. Preventive measures advocated by the CDC include environmental controls (negative-pressure ventilation and ultraviolet radiation) in health care settings, application of directly observed therapy, and vaccine development. Occupational exposures for health care providers can be mitigated through use of standard and airborne precautions.

Mumps

Mumps is a systemic disease caused by the mumps virus, which belongs to the paromyxovirus family. Humans are the only known host. Although infection and swelling of the parotid gland (parotitis) is a hallmark of the disease, involvement of the central nervous system and testes occur frequently. Incidence of mumps has decreased steadily since the introduction of live mumps vaccine in 1967, with routine use of the preparation beginning in 1977. In 1995, 906 cases were reported, representing a 99 percent decrease from the 185,691 cases reported in 1968. [69]

Mumps is transmitted by infectious droplets rather than by true airborne spread. While isolation of patients is the mainstay of outbreak control, this mechanism is not effective in preventing subsequent cases. Primary prevention by immunization is preferred. A monovalent mumps vaccine (Mumpsvax, Merck and Company) available in the United States is a live virus-vaccine (Jeryl-Lynn strain) that is prepared in egg culture. This vaccine is 97 percent effective in producing measurable antibody in susceptible individuals to whom the vaccine is administered. Various tri- and bivalent preparations are available as combination vaccines for mumps, measles, and

rubella. Current recommendations for infectious disease (including mumps, measles, and rubella) vaccinations are published in the Red Book by the Committee on Infectious Diseases of the American Academy of Pediatrics.[70] Adults who may be at increased risk for exposure to and transmission of mumps should be considered for vaccination. These persons include international travelers, persons attending colleges or post-high school educational institutions, and persons who work in health care facilities. Preventive measures for health care providers include use of standard and droplet precautions as well as vaccination if immunization status is unclear.

Measles

Rubeola, or measles, is caused by the measles virus, a paromyxovirus. Worldwide, measles is the most common cause of death among children that is preventable by use of a vaccine.[71] Incidence of measles has decreased steadily since the introduction of measles vaccine in 1963. In the United States, measles incidence is at the lowest level ever measured, with 488 and 135 cases reported in 1996 and 1997, respectively.[72] International importations and cases directly linked to international importations accounted for more than half of the cases reported during these years. This indicates that further reduction of measles incidence in the United States requires international cooperation and improved global control of measles. Obstacles to measles eradication in the United States include increasing numbers of susceptible children and infants who are not immunized and circulation of measles virus from other geographic regions of the world. Measles vaccination levels among the school-aged population in the United States, currently at 98 percent, must be maintained.

Transmission of the measles virus occurs by aerosolization of respiratory secretions. While isolation of patients is the mainstay of outbreak control, this mechanism is not effective in preventing subsequent cases. Primary prevention by immunization is preferred. A monovalent measles vaccine (Attenuvax, Merck and Company) available in the United States is a live virus vaccine that is prepared in egg culture. Various tri- and bivalent preparations are available as combination vaccines for mumps, measles, and rubella. Adults who may be at increased risk for exposure to and transmission of measles should be considered for vaccination. For persons born during or after 1957 who work in health care facilities, adequate vaccination consists of two doses of measles-mumps-rubella vaccine (M-M-RII, Merck and Company) or other live measles-containing vaccine separated by at least 28 days. Preventive measures for health care providers include use of standard and airborne precautions as well as vaccination if immunization status is unclear.

Rubella

Rubella, or German measles, is an exanthematous illness caused by a togavirus. Some of the most important consequences of rubella are miscarriages, stillbirths, fetal anomalies, and therapeutic abortions that result when rubella infection occurs during early pregnancy. When maternal infection occurs during the first 12 weeks of pregnancy, the probability of fetal infection with serious residual defects is 80 percent. When maternal infection occurs at 13 to 14 weeks' gestation, the probability of defects is 67 percent. The probability of fetal anomalies decreases to 25 percent by 26 weeks' gestation.[73] Before rubella vaccine was licensed in 1969, there were over 50,000 cases per year in the United States. In 1988, 225 cases were reported, the lowest since reporting began.[69] Outbreaks in unvaccinated adult populations (e.g., in prisons, colleges, and workplaces) led to more than 1000 cases being reported in 1990 and 1991.

Transmission of rubella is by respiratory droplets. While isolation of patients is the mainstay of outbreak control, this mechanism is not effective in preventing subsequent cases. Primary prevention by immunization is preferred. A monovalent rubella vaccine (Meruvax, Merck and Company) available in the United States is a live-virus vaccine that is prepared in human diploid cells. Various tri- and bivalent preparations are available as combination vaccines for mumps, measles, and rubella. Persons generally can be presumed to possess immunity to rubella if they have received one dose of measles-mumps-rubella or other live rubella vaccine on or after their first birthday, possess laboratory evidence of rubella immunity, or were born before 1957. Adults with unclear serologic evidence of immunity should receive one dose of rubella-containing vaccine. Preventive measures for health care providers include use of standard and droplet precautions as well as vaccination if immunization status is unclear.

Varicella and Herpes Zoster

Varicella zoster virus (VZV) is a double-stranded DNA virus of the Herpesviridae family. Varicella (chickenpox) is the primary manifestation of VZV infection. Once VZV infection has occurred, the virus is permanently established in the dorsal root and trigeminal ganglia, persists in latent form, and recurs when reactivated as herpes zoster (shingles). More than 90 percent of humans become infected with VZV.[74] In the United States, there are over 3.5 million cases of chickenpox and 300,000 cases of herpes zoster per year.[75,76] Chickenpox is highly contagious and poses a serious nosocomial and occupational infection risk.

Varicella (chickenpox) transmission occurs by contact, droplet, airborne, and transplacental routes.[74] Transmission associated with herpes zoster (shingles) occurs with direct contact with vesicular lesions. Airborne transmission of herpes zoster may also occur, especially if the source patient is immunosuppressed.[77,78] VZV infections may be prevented or modified via passive immunoprophylaxis with varicella zoster immunoglobulin (VZIG).[79] Types of exposures to varicella or zoster for which VZIG is indicated (i.e., susceptible people exposed to infected persons) includes residents in the same household, playmates with face-to-face indoor contact, hospitalized patients whose beds are adjacent to or in large wards (varicella), hospitalized patients with face-to-face contact (varicella), hospitalized patients visited by persons deemed to be contagious (varicella), physical contact with persons deemed to be contagious (zoster), and newborn infants with onset of varicella in the mother 5 days antepartum or 48 h postpartum.[80] VZIG is given as an intramuscular injection and should be administered within 48 h of exposure and not more than 96 h after exposure. In 1995, a live attenuated varicella vaccine (Oka, Merck and Company) was approved. The vaccine is recommended by the American Academy of Pediatrics for all susceptible children by their thirteenth birthday. The vaccine is also approved for healthy persons 13 years of age or older who have no previous infection or immunization history. These patients require two doses of varicella vaccine administered 4 to 8 weeks apart.[81] Preventive measures for health care providers include use of standard, airborne, and contact precautions. Health care providers who are susceptible to varicella should not enter the room if other immune care givers are available.

Influenza

Influenza viruses are divided into three types: A, B, and C. Influenza types A and B are responsible for epidemics of respiratory illness that occur every winter. Type A viruses are divided into subtypes based on two surface antigens: hemagglutinin (H) and neuraminidase (N). Three subtypes of H (H1, H2, and H3) and two subtypes of N (N1 and N2) are found among influenza A viruses. Currently circulating subtypes of influenza A are A(H1N1) and A(H3N2).

Two features of influenza virus replication and evolution account for its prominent place among emerging and reemerging diseases. First is the rapid and unpredictable antigenic change (antigenic drift) in the surface proteins, H and N. Antigenic drift occurs as a virus becomes established within the human population, rendering individuals susceptible to new viral strains that are resistant to antibodies formed to previously circulating viruses. Annual epidemics occur because sufficient numbers of individuals in the population are susceptible to the antigenically drifted virus. The second reason for the prominence of the influenza virus is the emergence of novel influenza viruses in humans (antigenic shift). Antigenic shift occurs when animal influenza viruses normally infecting only avian or swine reservoirs are transmitted to humans. This may occur either by direct transmission of an animal strain to humans or by genetic reassortment between influenza viruses of human and animal etiology. Antigenic shift is the appearance of a new influenza virus with novel H and N proteins that are immunologically distinct from those of the influenza viruses previously circulating in the human population. A pandemic occurs when human-to-human transmission of these novel viruses occurs and leads to disease in a large, immunologically susceptible human population.[82] During the twentieth century, three well-known pandemics resulted in high rates of morbidity and mortality in the United States and worldwide: the "Spanish" influenza (1918), killing 20 million worldwide and approximately 500,000 in the United States; the "Asian" influenza (1957), killing 70,000 in the United States; and the "Hong Kong" influenza (1968), killing 34,000 in the United States.[83] Influenza A and B viruses continually undergo antigenic drift. Only influenza A viruses exhibit antigenic shift, accounting for occasional pandemics.

Influenza virus is spread primarily by small particle aerosols of virus-laden respiratory secretions expelled into the air by coughing, sneezing, and talking. Direct contact with secretions also enables transmission of the virus. Two measures are available to reduce the impact of influenza: immunoprophylaxis with inactivated (killed virus) vaccine and chemoprophylaxis with an influenza-specific antiviral agent. Annual vaccination prior to the influenza season is the most effective means of reducing morbidity and mortality rates. Immunization programs focus on individuals at high risk for complications of influenza infection and individuals who may transmit the virus to high-risk populations. High-risk individuals include persons age 65 years and older; residents of chronic care and nursing home facilities; adults and children of any age with chronic disorders of the pulmonary or cardiovascular systems (including asthma); adults and children with chronic metabolic diseases (including diabetes mellitus), renal dysfunction, hemoglobinopathies, or immunosuppression; children and teenagers receiving long-term aspirin therapy (at risk for developing Reye's syndrome after influenza); and women who will be in the second or third trimester of pregnancy during influenza season.[82] Individuals who should receive vaccinations to reduce transmission to high-risk groups include prehospital personnel, nurses, physicians, hospital and clinic personnel who have contact with patients, staff of nursing home and chronic care facilities, home health care providers, and household contacts of those in high-risk populations. A trivalent vaccine is prepared on an annual basis to protect for two strains of influenza A and one strain of influenza B. Typically, one intramuscular injection is sufficient to ensure

immunity. Two doses administered 1 month apart may be needed for previously unvaccinated children under age 9 years. [84]

Prophylactic use of the antiviral agents amantadine-hydrochloride and rimantadine-hydrochloride are 70 to 90 percent effective in preventing infection by influenza A virus when administered during the influenza season. Antivirals are useful in individuals who have not been vaccinated or have contraindications to vaccination. Vaccinations or chemoprophylaxis should be obtained for ED personnel on an annual basis. Additional preventive measures include use of standard, airborne, and contact precautions.

Scabies

Scabies is a highly contagious, pruritic skin disorder caused by an arachnid, *Sarcoptes scabiei* var. *hominis.* The human scabies mite is endemic in many developing countries, where the prevalence ranges from 20 to 100 percent. In some areas of Central and South America, the scabies infestation rate among young children is close to 100 percent.[85] Human scabies is transmitted primarily by direct personal or sexual contact with infected individuals. Although less common, transmission may occur by contact with contaminated bedding and clothing. The mite has been found to survive for 2 to 3 days on inanimate objects. The scabies mite is motionless at room temperature and lacks the ability to jump or fly from person to person.[86]

The average person infected with scabies harbors 10 to 15 live adult female mites at any given time. [87] In patients with Norwegian scabies, an atypical, crusted form of scabies, mite populations are in the thousands to millions. [88] This form is often seen in physically or mentally handicapped, immunocompromised, or institutionalized persons. Some sources advise testing patients who exhibit Norwegian scabies for HIV. [89] Preventive measures for health care providers include use of standard and contact precautions in patients with pruritic eruptions.

Pediculosis

Pediculosis is a dermal infestation caused by a parasitic insect (lice). Lice are sucking insects belonging to the family Pediculidae. Infestations in various body regions (e.g., head, thorax, and groin) are caused by the head louse (*Pediculus humanus capitis*), the body louse (*Pediculus humanus corporis*), and the crab louse (*Phthirus pubis*). There are three stages in the life cycle of the louse: the nit, the nymph, and the adult. Nits are louse eggs found firmly attached to hair shafts and take about 1 week to hatch. Nymphs mature to adults in 7 days and survive by feeding on human blood. Adult lice are about the size of a sesame seed and can live up to 30 days on an infested individual. Adult forms also feed on blood and may survive up to 2 days on inanimate objects.

Lice are transmitted by direct contact with infected individuals or common use of infected bedding, clothing, or combs, brushes, or headgear. Worldwide, as many as 6 to 12 million people are infected each year. Preschool- and elementary school-age children and their household contacts are infested most often. Prevention of occupational exposures in health care providers includes use of standard and contact precautions.

Latex Allergy

Latex is a milky cytosol secreted by lactifer cells from the rubber tree, *Hevea brasiliensis.*[90] Trees harvested in Malaysia account for the majority of latex used in the manufacture of medical products. The cytosol contains *cis*-1,4 polyisoprene, which is immunologically inert. A manufacturing process called sulfur heat vulcanization results in the cross-linking of chains of polyisoprene, yielding a polymer that exhibits excellent tensile strength, elasticity, and barrier capacity. [90] Such desirable characteristics have lead to the use of rubber latex in the manufacture of many medical products, including gloves (for surgery, examination, and housekeeping and cleaning), intravascular devices (balloon catheters, intravenous tubing, and ports), airway devices (nasopharyngeal airways, endotracheal tubes, and oxygen masks), tourniquets, blood pressure cuffs, electrocardiogram leads, tape, and dressings.

Immune reactions to latex products may take three forms: irritant, contact dermatitis (type IV), and IgE (type I). Irritant reactions are nonimmune in nature and result in dry dermal erythema limited to the site of contact. Contact dermatitis occurs as a result of dermal exposure to chemicals used in the manufacturing of latex products. Thiurams and thiazoles are the most common chemicals to induce this type IV response.[91] This reaction, which may extend beyond the site of contact, results in a dry dermal erythema, pruritus, weeping, and vesiculation. Such loss of skin integrity permits the access of latex proteins to the immune system and may result in an IgE-mediated response. IgE (type I) response is an immunologic reaction to protein allergens contained in latex. Clinical manifestations of such reactions include urticaria, asthma, rhinitis, angioedema, laryngeal edema, and anaphylaxis. IgE reactions may occur as a result of mucosal, dermal, contact, or inhalational exposure. Cornstarch powder, which serves as a lubricant to ease the donning of latex gloves, binds and aerosolizes protein allergens, leading to inhalation exposure.

At highest risk of developing IgE-mediated latex allergy are individuals with high exposure to latex and those who are atopic. Workers in industries that make rubber products (e.g., tire manufacturers and doll makers) and those who use rubber products (e.g., housekeepers, hairdressers, and health care workers) are at high risk of developing this allergy. [90] While anyone can develop latex allergy, specific patient populations are at higher risk. Individuals likely to develop latex allergy include those with a history of multiple allergies (including dermal, respiratory, oral, or facial reactions to latex or rubber products); asthma (reactive airways disease), eczema, multiple food allergies (especially to bananas, avocados, and other tropical fruit), frequent surgical or dental procedures, multiple urogenital procedures (e.g., bladder, vaginal, and rectal), spina bifida and related conditions of spinal dysraphism, congenital urinary anomalies, or sensitivity to ethylene oxide (a sterilization agent).

Since September 1998, the US Food and Drug Administration has promulgated uniform labeling for all medical products. [90] Many latex-free medical products exist on the market and may be substituted for currently used products. Prevention of disease in health care workers is critical and requires the use of synthetic or low-allergen powder-free gloves.[90] The National Institute for Occupational Safety and Health and the CDC have published several documents that describe the hazards of latex allergy and suggest steps health care providers may take to protect themselves. [92,93] Health care institutions recognize latex allergy as a threat to the work force. As a result of the growing number of reports of anaphylaxis and other allergic reactions to latex, many institutions have drafted policies to increase awareness of latex allergies, identify individuals (patients and staff) who may be at risk, and outline steps to reduce latex exposures. [94,95] Emergency personnel may take the following steps to protect themselves from latex exposure and allergy in the workplace: use nonlatex gloves for workplace activities that do not involve contact with infectious materials; use synthetic or low-allergen powder-free gloves when handling infectious materials; avoid oil-based hand lotions or creams when wearing latex gloves (to prevent glove deterioration); wash hands with mild soap and dry thoroughly upon removal of latex gloves; frequently clean work areas and equipment contaminated with latex-containing dust; obtain education and training regarding latex allergy; and recognize the symptoms of latex allergy. Health care providers should be aware that hypoallergenic latex gloves do not reduce the risk of latex allergy but do reduce reactions to chemical additives in latex.

149 ANTIBIOTICS IN THE EMERGENCY DEPARTMENT

James H. Bryan
Kenneth C. Dirk
Jonathan Jui

INTRODUCTION

When prescribing antibiotics and using this chapter:

1. Ask the patient about any allergies to medications.
2. Use your judgment about these recommendations especially with regard to drug interactions and side effects.
3. Unless otherwise indicated, the dosages listed here are for adults with normal renal and hepatic function.
4. Hospital admission and parenteral therapy should be considered for any patient who is severely ill, immunocompromised or who may not be compliant with oral medications/follow-up.
5. When needed, multiple drug therapy is noted and indicated by the words **PLUS** or **PLUS/MINUS**.
6. The first-line therapies listed in this chapter are based upon efficacy and cost. If a first-line medication fails, consider switching to a broader-spectrum (and often more expensive) therapy.
7. When using IV vancomycin or an antipseudomonal aminoglycoside, serum levels should be monitored.
8. Frequently used abbreviations: bid, twice a day; DRSP, drug-resistant *Streptococcus pneumoniae;* IM, intramuscularly; IV, intravenously; MRSA, methicillin-resistant Staphylococcus aureus; PO, orrally; qid, four times a day; qd, every day; tid, three times a day.

PREGNANCY RISK CATEGORIES

Pregnancy risks for all medications listed in the chapter are denoted after each drug dosage. The risk category is contained in brackets, e.g., [B].

Category A: Controlled studies have failed to demonstrate fetal risk during the first trimester.

Category B: Animal studies have not demonstrated a risk, but there are no controlled studies in women; or, animal studies have shown an adverse effect that was not confirmed in controlled studies in women in the first trimester, and there is no risk in later trimesters.

Category C: Animal studies have shown adverse effects and there are no studies in women; or, no animal or human studies are available. Use only if the potential benefit outweighs the risk to the fetus.

Category D: There is positive evidence of human fetal risk. Use only in life threatening situations or for serious illnesses where no alternative medications are effective.

Category X: Contraindicated. Fetal risk outweighs potential benefit.

Medications that Should Be Used with Caution or Are Contraindicated in Pregnancy

- acyclovir (Zovirax): **Category C**— may cause chromosomal breaks at very high concentrations. No data available on risk in breast feeding.
- erythromycin estolate (Ilosone): **Category B** relative to fetus but contraindicated due to maternal risk of cholestatic hepatitis. No risk in breast feeding. All other erythromycin preparations are considered safe in pregnancy and breast feeding.
- lindane (Kwell): **Category C**— less toxic alternatives exist. Considered safe in breast feeding
- metronidazole (Flagyl): **Category B**— contraindicated in first trimester; use in later trimesters if benefits outweigh the risk. Discontinue breast feeding during use—recommend single dose therapy with resumption of breast feeding 12–24 hours after use.
- nitrofurantoin (Macrodantin, Macrobid): **Category B**— contraindicated in third trimester because of possibility of hemolytic anemia. Avoid during breast feeding if infant at risk for G6PD deficiency; otherwise considered safe.
- Quinolones: ciprofloxacin (Cipro), norfloxacin (Noroxin), ofloxacin (Floxin), levofloxacin (Levaquin): **Category C**— may cause arthropathy in fetuses, although recent review does not substantiate this risk.
- sulfonamides: **Category B** in first and second trimesters; **Category D** in third trimester due to possible kernicterus. Avoid during breast feeding in premature infants and infants with hyperbilirubinemia or G6PD deficiency. Considered safe in full term infants without medical problems.
- tetracyclines/doxycycline (Vibramycin): **Category D**— may stain teeth and bone.
- trimethoprim/sulfamethoxazole (Bactrim, Septra): **Category C** in first and second trimesters; **Category D** in third trimester. See sulfonamides, above. Trimethoprim interferes with folic acid metabolism and should be used in the first and second trimesters only if the potential benefits outweigh the risks.

Considered Relatively Safe in Pregnancy

- cephalosporins: **Category B**
- penicillins: **Category B**
- erythromycins (except estolate preparations): **Category B**
- clotrimazole (topical): **Category B**

EAR/NOSE/THROAT

Acute Necrotizing Ulcerative Gingivitis (ANUG)

1. Penicillin V potassium (Pen-VEE K) 500 mg PO qid [B]
2. Tetracycline (Achromycin) 500 mg PO qid [D]
3. Doxycycline (Vibramycin) 100 mg PO bid [D]

Course: 7–10 days
Organisms: spirochetes, fusobacterium

Dental Infections/Periapical and Periodontal Abscesses

1. Clindamycin (Cleocin) 300 mg PO qid [B]
2. Erythromycin 500 mg PO qid [B, except estolate contraindicated]
3. Amoxicillin/clavulanic acid (Augmentin) 875/125 mg PO bid **OR** 500/125 mg PO tid [B]

Course: 7–10 days
Organisms: oral flora

Epiglottitis

A. CHILDREN

1. Cefuroxime (Ceftin) 50 mg/kg IV q8h [B]
2. Cefotaxime (Claforan) 50 mg/kg IV q8h [B]
3. Ceftriaxone (Rocephin) 50 mg/kg IV qd [B]

Organisms: *H. influenzae, S. pyogenes, S. pneumoniae, S. aureus*

B. ADULTS

1. Cefuroxime (Ceftin) 1 g IV q8h [B]
2. Cefotaxime (Claforan) 2 g IV q8h [B]
3. Ceftriaxone (Rocephin) 2 g IV qd [B]

Organisms: group A *Strep, H. influenzae*

Ludwig's Angina

Note: *Requires admission to the hospital, usually to the ICU, for airway monitoring and management.*
Regimen A (*Note* **two** *drug therapy*)
Penicillin G 4 million units IV q4h [B]
(Administer over 1 h. Rapid infusion may cause seizures.)
PLUS
Metronidazole (Flagyl) 15 mg/kg IV loading dose, maximal dose 1000 mg, then 7.5 mg/kg IV q6h (max 500 mg/dose) [B, contraindicated in 1st trimester]

Regimen B
Cefoxitin (Mefoxin) 2 g IV q8h [B]
Clindamycin (Cleocin) 600 mg IV q8h (if penicillin allergic) [B]
Ticarcillin/clavulanic acid (Timentin) 3.1 g IV q6h [B]
Piperacillin/tazobactam (Zosyn) 3.375 g IV q6h [B]
Ampicillin/sulbactam (Unasyn) 3 g IV q6h [B]
Organisms: *Streptococcus* sp., *Bacteroides* sp., *Eikenella corrodens*, polymicrobic

Otitis Externa

1. Neomycin, polymyxin B, and 1% hydrocortisone otic solution (Cortisporin otic) 4 drops in affected ear tid–qid [C]; dispense 10 mL
   OR (for severe infection)
2. Ofloxacin 0.3% otic solution (Floxin) 10 drops in affected ear bid (use 5 drops bid if child <12 years old) [C]; dispense 10 mL

If refractory:

1. Ciprofloxacin 0.2% and hydrocortisone 1% otic suspension (Cipro HC otic) 3 drops in affected ear bid × 7 days [C]; dispense 10 mL
   OR
2. Dicloxacillin 500 mg PO qid for *S. aureus* [B]

Course: 10 days (except 7 days for Cipro or Dicloxacillin as noted)
Organisms: *Pseudomonas*, Enterobacteriaceae, *S. aureus, Proteus* sp.

Notes:

1. Use Cortisporin otic suspension (not solution) if TM perforated.
2. Cotton wicks placed in the canals aid absorption especially if the canal closes completely due to edema.
3. Consider malignant otitis externa, especially in immunocompromised patients or diabetics. Patients usually appear ill and require admission.

Otitis Media

A. CHILDREN AGE 10 OR UNDER

1. Amoxicillin (Amoxil) 80–90 mg/kg/day PO divided bid or tid [B]
   Easy dose: 40 mg/kg/dose PO bid OR **30 mg/kg/dose PO tid**
   Maximum dose 750 mg/dose bid **OR** 500 mg/dose tid
   Available in suspensions of 125 mg and 250 mg/5 mL
2. TMP/SMX (Bactrim, Septra) 6–12 mg/kg/day TMP and 30–60 mg/kg/day SMX PO divided bid [C; D in 3rd trimester]
   Easy dose: 1 mL/kg/day PO divided bid = 8 mg/kg/day TMP and **40 mg/kg/day SMX**
   Maximum: 20 mL/dose
   Suspension of TMP 40 mg and SMX 200 mg/5 mL
3. Azithromycin (Zithromax) 10 mg/kg PO initial dose, then 5 mg/kg/day for 4 days [B]
   Maximum: 500 mg on day 1 and 250 mg on days 2–5
   Available in suspensions of 100 mg and 200 mg/5 mL
4. Erythromycin/sulfisoxazole (Pediazole) 50 mg/kg/day erythromycin and 150 mg/kg/day sulfa PO divided tid or qid [C; D in 3rd trimester]
   Easy dose: 1.25 mL/kg/day PO divided tid or **qid**
   Maximum: 10 mL/dose
   Suspension of erythromycin 200 mg and sulfisoxazole 600 mg/5 mL
5. Ceftriaxone (Rocephin) 50 mg/kg IM single dose [B]
   Maximum: 1 g/dose

If severe or refractory:

1. Amoxicillin/clavulanate (Augmentin) 80–90 mg/kg/day as amoxicillin, PO divided bid or tid [B]
   Easy dose: 40 mg/kg/dose as amoxicillin PO bid OR **30 mg/kg/dose as amoxicillin PO tid**
   Maximum: 750 mg/dose as amoxicillin bid **OR** 500 mg/dose as amoxicillin tid
   Available in suspensions of 125 mg and 250 mg amoxicillin/5 mL
2. Cefuroxime axetil (Ceftin) 20–30 mg/kg/day PO divided bid [B]
   Easy dose: 20 mg/kg/day = 10 mg/kg/dose PO bid
   Maximum: 250 mg/dose
   Available in suspension of 125 mg/5 mL
3. Cefpodoxime (Vantin) 10 mg/kg/day PO in 1 dose [B] (probably effective but data limited)

Maximum: 400 mg/dose
Available in suspensions of 50 mg and 100 mg/5 mL
4. Cefprozil (Cefzil) 15 mg/kg/dose PO bid [B] (probably effective but data limited)
Maximum: 250 mg/dose
Available in suspensions of 125 mg or 250 mg/5 mL
5. Ceftriaxone, 50 mg/kg IV or IM QD for 3 days

B. ADULTS AND CHILDREN OVER AGE 10

1. Amoxicillin (Amoxil) 500 mg PO tid [B]
2. TMP/SMX DS (Bactrim DS, Septra DS) 1 tablet PO bid [C; D in 3rd trimester]
3. Azithromycin (Zithromax) 500 mg PO initial dose, then 250 mg PO for 4 days [B]
4. Amoxicillin/clavulanate (Augmentin) 500 mg PO tid or 875 mg PO bid [B]
5. Cefuroxime axetil (Ceftin) 250–500 mg PO bid [B]
6. Ceftriaxone (Rocephin) 1 g IM/IV single dose [B]

Course: 10 days (except azithromycin and ceftriaxone as noted)
Organisms: *S. pneumoniae* (30–35%), non-typeable *Haemophilus influenzae* (20–25%), *Moraxella (Branhamella) catarrhalis* (10–15%), group A *Strep*, *Staphylococcus aureus* (1–2%) and viral (35%)

Parotitis/Sialoadenitis

1. Dicloxacillin 500 mg PO qid [B]
2. Cephradine (Velosef) 500 mg PO qid [B]
3. Cephalexin (Keflex) 500 mg PO qid [B]
4. Amoxicillin/clavulanic acid (Augmentin) 875/125 mg PO bid **OR** 500/125 mg PO tid [B]
5. Clindamycin (Cleocin) 150–450 mg PO qid [B]
6. Vancomycin (Vancocin) 15 mg/kg IV q12h (for severe penicillin allergy; max 1 g/dose; monitor serum levels) [C]

Course: 7–10 days
Organisms: *Staphylococcus aureus*, anaerobes

Periorbital and Orbital Cellulitis

See Skin and Soft Tissue Infections.

Sinusitis, Acute

A. CHILDREN

Uncomplicated

1. Amoxicillin (Amoxil) 80–90 mg/kg/day PO divided bid or tid [B]
   Easy dose: 40 mg/kg/dose PO bid OR **30 mg/kg/dose PO tid**
   Maximum: 750 mg/dose bid **OR** 500 mg/dose tid
   Available in suspensions of 125 mg and 250 mg/5 mL
2. TMP/SMX (Bactrim, Septra) 6–12 mg/kg/day TMP and 30–60 mg/kg/day SMX PO divided bid [C; D in 3rd trimester]
   Easy dose: 1 mL/kg/day PO divided bid = 8 mg/kg/day TMP and 40 mg/kg/day SMX
   Maximum: 20 mL/dose
   Suspension of TMP 40 mg and SMX 200 mg/5 mL
3. Erythromycin/sulfisoxazole (Pediazole) 50 mg/kg/day erythromycin and 150 mg/kg/day sulfa PO divided tid or qid [C; D in 3rd trimester]
   Easy dose: 1.25 mL/kg/day PO divided tid or qid
   Maximum: 10 mL/dose
   Suspension of erythromycin 200 mg and sulfisoxazole 600 mg/5 mL

If severe or refractory:

1. Amoxicillin/clavulanate (Augmentin) 80–90 mg/kg/day as amoxicillin, PO, divided bid or tid [B]
   Easy dose: 40 mg/kg/dose as amoxicillin, PO bid OR **30 mg/kg/dose as amoxicillin, PO tid**
   Maximum dose: 750 mg/dose as amoxicillin, PO bid **OR** 500 mg/dose as amoxicillin, PO tid
   Available in suspensions of 125 mg and 250 mg amoxicillin/5 mL
2. Cefuroxime axetil (Ceftin) 20–30 mg/kg/day PO divided bid [B]
   Easy dose: 20 mg/kg/day = 10 mg/kg/dose PO bid
   Maximum: 250 mg/dose
   Available in suspension of 125 mg/5 mL
3. Cefpodoxime (Vantin) 10 mg/kg/day PO in 1 dose [B]
   Maximum: 400 mg/dose
   Available in suspensions of 50 mg and 100 mg/5 mL
4. Cefprozil (Cefzil) 15 mg/kg/dose PO bid [B]
   Maximum: 250 mg/dose
   Available in suspensions of 125 mg or 250 mg/5 mL
5. Clarithromycin (Biaxin) 7.5 mg/kg/dose PO bid (for severe penicillin allergy) [C]
   Maximum: 500 mg/dose
   Available in suspensions of 125 mg or 250 mg/5 mL

B. ADULTS, SINUSITIS
Notes:

1. Many ENT consultants consider decongestants an equally important component of therapy, but this is not supported by the literature.

Sprays:

a. 0.25% phenylephrine (Neo-Synephrine) nasal spray tid to qid for 3 days only [C]
b. Oxymetazoline 0.05% (Afrin) nasal spray bid for 3 days only [C]

Oral:

Pseudoephedrine (Sudafed) 30–60 mg PO qid [C]

2. Consider adding antihistamines if an allergic component is suspected.

a. Diphenhydramine (Benadryl) 25–50 mg PO qid [B, contraindicated in 1st trimester]
    b. Cetirizine (Zyrtec) 10 mg PO qd [B]
    c. Fexofenadine (Allegra) 60 mg PO bid [C]

Uncomplicated

1. TMP/SMX DS (Bactrim DS, Septra DS) 1 tablet PO bid [C; D in 3rd trimester]
2. Azithromycin (Zithromax) 500 mg PO initial dose, then 250 mg PO qd for 4 days [B]
3. Clarithromycin (Biaxin) 250–500 mg PO bid [C]

If severe or refractory:

1. Amoxicillin/clavulanate (Augmentin) 500 mg PO tid or 875 mg PO bid [B]
2. Cefuroxime axetil (Ceftin) 500 mg PO bid [B]
3. Cefpodoxime (Vantin) 200 mg PO bid [B]
4. Cefprozil (Cefzil) 250 mg PO bid [B] **OR** (if severe penicillin allergy or suspect DRSP)
5. Levofloxacin (Levaquin) 500 mg PO qd (if severe penicillin allergy or suspect DRSP; [C])

Course: 7 to 21 days (except azithromycin as noted)
Organisms: *S. pneumoniae, H. influenzae*, group A *Streptococcus, M. catarrhalis*, anaerobes

Tonsillitis/Pharyngitis

A. CHILDREN AGE 10 AND UNDER

Note: If patient exhibits signs or symptoms of severe swelling/edema (e.g., voice change, unable to swallow saliva), consider adding prednisone (1–2 mg/kg PO × 5 days) to the antibiotic regimen.

1. Penicillin V potassium (Pen VEE-K) 25–50 mg/kg/day PO divided tid–qid [B]
    Easy dose: 45 mg/kg/day = 15 mg/kg/dose PO tid
    Maximum: 500 mg/dose
    Available in suspensions of 125 mg and 250 mg/5 mL
2. Amoxicillin (Amoxil) 20–50 mg/kg/day PO divided tid [B]
    Easy dose: 30 mg/kg/day = 10 mg/kg/dose PO tid
    Maximum: 250 mg/dose
    Available in suspensions of 125 mg and 250 mg/5 mL
3. Erythromycin ethyl succinate (EES) 30–50 mg/kg/day PO divided qid [B]
    Easy dose: 40 mg/kg/day = 10 mg/kg/dose PO qid
    Maximum: 500 mg/dose
    Available in suspensions of 200 mg and 400 mg/5 mL
4. Azithromycin (Zithromax) 10 mg/kg PO initial dose, then 5 mg/kg/day for 4 days [B]
    Maximum: 500 mg day 1 and 250 mg days 2–5
    Available in suspensions of 100 mg and 200 mg/5 mL
5. Benzathine penicillin G (Bicillin L-A)—single dose therapy [B]
    In children less than 60 lb: 600,000 units IM
    In children greater than 60 lb: 1.2 million units IM

If severe or refractory:

1. Clindamycin 8–20 mg/kg/day PO divided qid (for penicillin allergic) [B]
    Easy dose: 5 mg/kg/dose PO qid
    Maximum: 300 mg/dose
    Available in suspension of 75 mg/5 mL
2. Cefuroxime axetil (Ceftin) 20–30 mg/kg/day PO divided bid [B]
    Easy dose: 20 mg/kg/day = 10 mg/kg/dose PO bid
    Maximum: 250 mg/dose
    Available in suspension of 125 mg/5 mL
3. Cefpodoxime (Vantin) 5 mg/kg/dose PO bid [B]
    Maximum: 200 mg/dose
    Available in suspensions of 50 mg and 100 mg/5 mL
4. Amoxicillin/clavulanate (Augmentin) 20–40 mg/kg/day (as amoxicillin) PO divided tid [B]
    Easy dose: 30 mg/kg/day = 10 mg/kg/dose PO tid
    Maximum: 500 mg per dose
    Available in suspensions of 125 mg and 250 mg amoxicillin/5 mL

B. ADULTS AND CHILDREN OVER AGE 10
Notes:

1. Sexual history essential to help rule out gonococcus (see Genital Tract Infections—Gonorrhea). Lab tests include latex agglutination (rapid strep test), Gram stain and/or culture.
    If prepubertal, treat for group A *Streptococcus* only.
2. If patient exhibits signs or symptoms of severe swelling/edema (e.g., voice change, unable to swallow saliva), consider adding prednisone (40 mg PO qd × 5 days) to the antibiotic regimen.

1. Penicillin V potassium (Pen-VEE K) 250–500 mg PO tid–qid [B]
2. Erythromycin 250 mg PO qid **OR** 500 mg bid [B, except estolate contraindicated]
3. Erythromycin ethyl succinate (EES) 400 mg PO qid **OR** 30–50 mg/kg/day PO divided qid [B]
4. Azithromycin (Zithromax) 500 mg PO initial dose, then 250 mg PO qd for 4 days [B]
5. Clarithromycin (Biaxin) 250–500 mg PO bid [C]

In refractory cases:

1. Clindamycin (Cleocin) 300 mg PO qid [B]
2. Cefuroxime axetil (Ceftin) 250 mg PO bid [B]
3. Cefpodoxime (Vantin) 200 mg PO bid [B]
4. Amoxicillin/clavulanate (Augmentin) 500 mg PO tid or 875 mg PO bid [B]

Course: 10 days (except azithromycin as noted).
Organisms: *Streptococcus* sp., *Mycoplasma pneumoniae, Chlamydia pneumoniae*, rhinovirus and Epstein-Barr virus

EYE

Blepharitis

Erythromycin ophthalmic ointment (Ilotycin)—apply to lid margins bid–tid [B]; dispense 3.5 g tube
Course: 14 days
Organisms: *S. aureus, S. epidermidis*

Conjunctivitis: Adult and Children

Notes:

1. Sulfacetamide may sting or burn when applied. This often decreases compliance.
2. Ophthalmic ointment is thick and impairs vision when first applied. Although drops require more frequent dosing, patients usually tolerate drops better while awake. Ointment is best used at bedtime.
3. If conjunctivitis is secondary to an imbedded organic material (mascara brush, tree branch), or in contact lens wearers, consider antipseudomonal coverage.
4. Slit lamp exam important to rule out herpes as organism. If herpes or gonococcus suspected, immediate ophthalmologic consultation is indicated.

1. Erythromycin ophthalmic ointment (Ilotycin)—apply to lid of affected eye bid–tid [B]; dispense 3.5 g tube
2. Sulfacetamide (10%) ophthalmic solution or ointment (Bleph-10, Sodium Sulamyd) [C]
   Solution. apply 1–2 drops to affected eye q2h; dispense 5 mL
   Ointment: apply to lid of affected eye qid; dispense 3.5 g
3. Tobramycin (0.3%) ophthalmic solution or ointment (Tobrex) [B]
   Solution: apply 1–2 drops to affected eye q 2–4 h; dispense 5 mL
   Ointment: apply to lid of affected eye q4h; dispense 3.5 g

For *Pseudomonas* coverage (see Note 3, below)

1. Ciprofloxacin (0.3%) ophthalmic solution (Cipro): 2 drops to affected eye q2h while awake for 2 days, then q4h for 5 days [C]

Course: 7 days
Organisms: *S. aureus, S. pneumoniae, E. coli, Proteus* sp., *Pseudomonas*

Conjunctivitis: Neonatal

(Gram stain and culture necessary)

1. Chlamydia trachomatis (occurs days 3–10)
   Erythromycin 50 mg/kg/day divided qid PO for 14 days
2. Neisseria gonorrhea (occurs days 2–4)
   Ceftriaxone 50 mg/kg IV or IM

Corneal Abrasion

1. Treat same as conjunctivitis, above, except consider antipseudomonal coverage (ciprofloxacin or tobramycin) for abrasions due to organic foreign bodies and contact lenses.
2. Patching of the eye is no longer considered necessary and should be based on patient comfort issues (i.e., discomfort of foreign body sensation versus discomfort of eye patch).
3. If eye is to be patched, use ointment instead of solution.
4. Consider short-acting cycloplegics (e.g., cyclopentolate 1–2 drops to affected eye [C]) if eye is to be patched.
5. A short course of acetaminophen with codeine or hydrocodone is appropriate for pain control.
6. Up to date tetanus prophylaxis is recommended for patients with corneal abrasions.

Course: 3 days

GASTROINTESTINAL

Ascariasis, Giardiasis. See Parasites.

***Clostridium difficile*/Pseudomembranous Colitis**

Regimen A
Metronidazole (Flagyl) 500 mg PO tid [B; contraindicated 1st trimester]
PLUS (to bind toxin)
Cholestyramine (Questran) 4 gm PO tid

Regimen B
Vancomycin (Vancocin) 125–250 mg PO tid [C] (cholestyramine binds vancomycin; do not use)
Course: 10–14 days

Diverticulitis

Note: Treatments listed are for outpatient therapy in patients that appear nontoxic and are without evidence of bowel perforation. If patients appear toxic, are unable to tolerate PO, or perforation is suspected, admission is required.
Regimen A (*Note* **two** *drug therapy*)
TMP/SMX DS (Bactrim DS, Septra DS) 1 tablet PO bid [C; D in 3rd trimester] **OR**
Ciprofloxacin (Cipro) 500–750 mg PO bid [C]
PLUS
Metronidazole (Flagyl) 500 mg PO qid [B, contraindicated 1st trimester]

Regimen B
Amoxicillin/clavulanic acid (Augmentin) 500/125 mg PO tid **OR** 875/125 mg PO bid [B]
Course: 10–14 days
Organisms: *Enterobacter, Bacteroides,* enterococci

Gastroenteritis

Base treatment on the presence of fecal leukocytes or clinical picture:

1. Ciprofloxacin (Cipro) 500 mg PO bid [C]
2. TMP/SMX DS (Bactrim DS, Septra DS) 1 tablet PO bid [C; D in 3rd trimester]
   PLUS (to cover *Campylobacter*)
   Erythromycin 500 mg PO qid [B, except estolate contraindicated]
3. Amoxicillin/clavulanate (Augmentin) 500 mg PO tid
   PLUS (to cover *Campylobacter*)
   Erythromycin 500 mg PO qid [B, except estolate contraindicated]

Course: 3–5 days
Organisms: *Shigella, Salmonella, Campylobacter,* enteroinvasive *E. coli, Yersinia*

***Helicobacter pylori* (associated with non-NSAID induced duodenal or gastric ulcers)**

Regimen A (*Note* **four** *drug therapy*)
Bismuth subsalicylate (Pepto-Bismol) 2 tabs PO qid with meals and at bedtime [D]
PLUS
Metronidazole (Flagyl) 500 mg PO bid **OR** 250 mg PO qid with meals and at bedtime [B, contraindicated 1st trimester]
PLUS
Tetracycline (Achromycin) 500 mg PO qid before meals and at bedtime [D] (doxycycline has lower efficacy; do not substitute)
PLUS
Omeprazole (Prilosec) 20 mg PO bid before meals [C]

Regimen B (*Note* **three** *drug therapy*)
Metronidazole (Flagyl) 500 mg PO bid **OR** 250 mg PO qid with meals and at bedtime [B, contraindicated 1st trimester] **OR**
Amoxicillin (Amoxil) 1 g PO bid **OR** 500 mg PO qid [B]
PLUS
Omeprazole (Prilosec) 20 mg PO bid before meals [C]
PLUS
Clarithromycin (Biaxin) 500 mg PO bid with meals [C]
Course: 7–14 days (90% eradication with 7 days of therapy)
Organism: *Helicobacter pylori*
Note: Usual definition of cure: negative serology urea breath test 1–3 months or longer after treatment.

Spontaneous Bacterial Peritonitis (SBP)

1. Cefotaxime 2 g IV q8h (q4h if life-threatening) [B]
2. Ticarcillin/clavulanic acid (Timentin) 3.1 g IV q6h [B]
3. Piperacillin/tazobactam (Zosyn) 3.375 g IV q6h [B]
4. Ampicillin/sulbactam (Unasyn) 3 g IV q6h [B]

Organisms: Enterobacteriaceae, *S. pneumoniae,* enterococci, anaerobes

GENITOURINARY TRACT INFECTIONS (EXCLUDING SEXUALLY TRANSMITTED DISEASES)

Cystitis

A. CHILDREN AGE 10 AND UNDER

1. TMP/SMX (Bactrim, Septra) 6–12 mg/kg/day TMP and 30–60 mg/kg/day SMX PO divided bid [C; D in 3rd trimester]
   Easy dose: 1 mL/kg/day PO divided bid = 8 mg/kg/day TMP and 40 mg/kg/day SMX
   Maximum: 20 mL/dose
   Suspension of TMP 40 mg and SMX 200 mg/5 mL
2. Amoxicillin (Amoxil) 20–40 mg/kg/day PO divided t.i.d. [B]
   Easy dose: 30 mg/kg/day = 10 mg/kg/dose PO tid
   Maximum: 250 mg/dose
   Available in suspensions of 125 mg and 250 mg/5 mL
3. Amoxicillin/clavulanate (Augmentin) 20–40 mg/kg/day (as amoxicillin) PO divided tid [B]
   Easy dose: 30 mg/kg/day = 10 mg/kg/dose PO tid
   Maximum: 500 mg/dose
   Available in suspensions of 125 mg and 250 mg amoxicillin/5 mL
4. Cefuroxime axetil (Ceftin) 20–30 mg/kg/day PO divided bid [B]
   Easy dose: 20 mg/kg/day = 10 mg/kg/dose PO bid
   Maximum: 250 mg/dose
   Available in suspension of 125 mg/5 mL
5. Cefixime (Suprax) 8 mg/kg/day PO in 1 dose [B]
   Maximum: 400 mg/day
   Suspension 100 mg/5 mL

B. ADULTS AND CHILDREN OLDER THAN 10
Notes:

1. If patient has significant bladder pain, add phenazopyridine (Pyridium) 200 mg PO tid after meals for 2 days [B] (will turn the urine red/orange color)
2. **For uncomplicated cystitis in adult females** (non-pregnant, non-diabetic) with symptoms of short duration, consider short course therapy:
   a. TMP/SMX DS (Bactrim DS, Septra DS) 1 tablet PO bid for 3 days [C; D in 3rd trimester]
   b. Ciprofloxacin (Cipro) 500 mg PO bid for 3 days [C]
   c. Ofloxacin (Floxin) 200 mg PO bid for 3 days [C]
   d. Norfloxacin (Noroxin) 400 mg PO bid for 3 days [C]
   e. Fosfomycin (Monurol) 3 g PO single dose [B]

1. TMP/SMX DS (Bactrim DS, Septra DS) 1 tablet PO bid [C; D in 3rd trimester]
2. Ciprofloxacin (Cipro) 500 mg PO bid [C]
3. Ofloxacin (Floxin) 200 mg PO bid [C]
4. Norfloxacin (Noroxin) 400 mg PO bid [C]
5. Levofloxacin (Levaquin) 500 mg PO qd [C]
6. Amoxicillin/clavulanic acid (Augmentin) 250 mg PO tid [B]
7. Cefuroxime axetil (Ceftin) 250 mg PO bid [B]
8. Ceftibuten (Cedax) 400 mg PO qd [B]

Course: 7 to 10 days (See Notes below)
Organisms: *E. coli,* enterococci, *Staph* sp.

Endometritis

A. EARLY POSTPARTUM [1ST 48 H]
(*Note* **three** *drug therapy*)

1. Cefoxitin (Mefoxin) 2 g IV q 6–8 h [B]
2. Ticarcillin/clavulanic acid (Timentin) 3.1 g IV q6h [B]
3. Imipenem (Primaxin) 500–1000 mg IV q6h [C]
4. Ampicillin/sulbactam (Unasyn) 3.0 g IV q6h [B]
5. Piperacillin/tazobactam (Zosyn) 3.375 g IV q6h [B]
   PLUS

1. Doxycycline (Vibramycin) 100 mg IV or PO q12h [D]
2. Clindamycin (Cleocin) 450–900 mg IV q8h [B]
   PLUS

1. Gentamicin (Garamycin) 2 mg/kg IV loading dose, then 1.7 mg/kg IV q8h (monitor serum levels) [D]
2. Ceftriaxone (Rocephin) 2 g IV qd [B]
3. Cefotaxime (Claforan) 2 g IV q8h [B]

Organisms: *Prevotella bivia* and other Bacteroides sp., group B streptococci, *Enterococci, E. coli, Chlamydia trachomatis, Gardnerella vaginalis*

B. LATE POSTPARTUM (48 H TO 6 WEEKS)
Doxycycline (Vibramycin) 100 mg PO or IV bid (discontinue nursing) [D]
Course: 14 days
Organisms: *C. trachomatis, M. hominis*

Epididymitis and Orchitis

A. YOUNGER PATIENTS (LESS THAN 35 YEARS OF AGE)
Treat for gonorrhea and chlamydia—*See Sexually Transmitted Diseases.*

B. OLDER PATIENTS (GREATER THAN 35 YEARS OF AGE)

1. Ciprofloxacin (Cipro) 500 mg PO bid [C]
2. TMP/SMX DS (Bactrim DS, Septra DS) 1 tablet PO bid [C; D in 3rd trimester]
3. Ofloxacin (Floxin) 200 mg PO bid [C]

Course: 10–14 days
Organisms: *E. coli, Proteus* sp.

Prostatitis—Acute

A. YOUNGER PATIENTS (LESS THAN 35 YEARS OF AGE)
Treat for gonorrhea and chlamydia—*See Sexually Transmitted Diseases.*

B. OLDER PATIENTS (GREATER THAN 35 YEARS OF AGE OR HISTORY OF INSERTIVE ANAL INTERCOURSE)

1. Ciprofloxacin (Cipro) 500 mg PO bid [C]
2. TMP/SMX DS (Bactrim DS, Septra DS) one tablet PO bid [C; D in 3rd trimester]
3. Ofloxacin (Floxin) 200 mg PO bid [C]

Course: 14–28 days
Organisms: *E. coli, Enterobacter, Klebsiella, Proteus*

Prostatitis—Chronic

Chronic prostatitis involves similar organisms as acute prostatitis. If patient has already had treatment, a longer course of a different antibiotic is warranted. Referral to urologist recommended as chronic therapy may be needed. **Course:** 1–3 months.

Pyelonephritis

A. UNCOMPLICATED
Young, otherwise healthy patients with pyelonephritis may be treated as outpatients. Use the same medications as listed in Cystitis, except exclude TMP/SMX from treatment regimen (due to resistance). Consider initiating therapy with a single dose of parenteral medication as listed below for complicated pyelonephritis. **Course:** 14 days.

B. COMPLICATED
Admission is recommended for patients with pyelonephritis complicated by elderly, pregnant, renal insufficiency, or structural abnormality (including a single kidney), immunocompromised (e.g., diabetics, HIV, transplant, chemotherapy), intractable nausea/vomiting, sickle cell anemia, renal calculi, toxic appearance, unremitting fever.

1. Ceftriaxone (Rocephin) 2 g IV qd [B]
2. Cefotaxime (Claforan) 1 g IV q12h [B]
3. Ciprofloxacin 400 mg IV q12h [C]
4. Levofloxacin (Levaquin) 500 mg IV qd [C]
5. Ampicillin 2 g IV q4h [B] **PLUS** gentamicin (Garamycin) 2 mg/kg IV loading dose, then 1.7 mg/kg IV q8h **OR** 5.1 mg/kg IV QD (monitor serum levels) [D]
6. Ampicillin/sulbactam (Unasyn) 3.0 g IV q6h [B]
7. Ticarcillin/clavulanic acid (Timentin) 3.1 g IV q6h [B]
8. Piperacillin/tazobactam (Zosyn) 3.375 g IV q6h [B]
9. Imipenem (Primaxin) 500–1000 mg IV q6h [C]

Organisms: *E. coli, Enterococcus,* Enterobacteriaceae

Sterile Pyuria

(*Pyuria without bacteria or with negative culture. Consider evaluation for tuberculosis as possible etiology.*)

1. Doxycycline 100 mg PO bid [D]
2. Tetracycline 500 mg PO qid [D]
3. Erythromycin 500 mg PO qid [B, except estolate contraindicated]
4. Ofloxacin (Floxin) 200 mg PO bid [C]
5. Levofloxacin (Levaquin) 250 mg PO qd [C]
6. Azithromycin (Zithromax) 500 mg PO initial dose, then 250 mg PO qd for 4 days [B]

Course: 7 days (except azithromycin as noted)
Organisms: *C. trachomatis, Ureaplasma urealyticum,* tuberculosis

HEART

Endocarditis (Culture Results Unavailable)

Note: If patient condition permits, cultures should be obtained before initiating antimicrobial therapy

Infective endocarditis—native valve
Regimen A (*Note* **three** *drug therapy*)
Penicillin G 3.5 million units IV q4h [B] **OR**
Ampicillin 2 g IV q4h [B]
PLUS
Nafcillin 2 g IV q4h [B]
PLUS
Gentamicin (Garamycin) 2 mg/kg IV loading dose, then 1.7 mg/kg IV q8h (monitor serum levels) [D]

Regimen B (*Note* **two** *drug therapy*)
Vancomycin (Vancocin) 15 mg/kg IV q12h (max 1 g/dose; monitor serum levels) [C]
PLUS
Gentamicin (Garamycin) 2 mg/kg IV loading dose, then 1.7 mg/kg IV q8h (monitor serum levels) [D]
Organisms: *Strep viridans, Strep* sp., enterococci, *Staph sp.*

Infective endocarditis—prosthetic valve (*Note* **three** *drug therapy*)
Vancomycin (Vancocin) 15 mg/kg IV q12h (max 1 g/dose; monitor serum levels) [C]
PLUS
Gentamicin (Garamycin) 2 mg/kg IV loading dose, then 1.7 mg/kg IV q8h (monitor serum levels) [D]
PLUS
Rifampin (Rimactane) 600 mg PO qd [C]
Organisms: *Staph epidermidis, Staph aureus, Strep viridans,* enterococci

1. **Infective endocarditis—intravenous drug abusers** (*Note* **two** *drug therapy*)
   Nafcillin 2 gram IV q4h [B] (preferred)
   OR if penicillin allergic or suspect MRSA
   Vancomycin (Vancocin) 15 mg/kg IV q12h (max 1 g/dose; monitor serum levels) [C]
   PLUS
   Gentamicin (Garamycin) 2 mg/kg IV loading dose, then 1.7 mg/kg IV q8h (monitor serum levels) [D]

Organisms: *S. aureus,* gram-negative bacilli

Endocarditis Prophylaxis

Prophylaxis is **recommended** for patients with

1. **High risk conditions:** prosthetic valves, previous history of endocarditis, congenital heart disease (e.g., transposition or tetralogy), pulmonic shunts/conduits
   OR
2. **Moderate risk conditions:** cardiomyopathy, mitral prolapse with regurgitation
   AND undergoing the following procedures: Dental procedures (excluding filling cavities, suture removal, orthodontic removal or adjustment, or dental x-rays), rigid bronchoscopy, sclerotherapy of esophageal varices, dilation of esophageal strictures, biliary tract or intestinal surgery, prostatic surgery, cystoscopy, and urethral dilatation.

   In general, prophylaxis is **not recommended** for

1. **Low risk conditions:** ASD or repaired ASD/VSD, PDA beyond 6 months old, mitral valve prolapse without regurgitation/insufficiency, history of CABG, history of rheumatic fever without valve dysfunction, cardiac pacemakers or AICDs.
   OR
2. **Patients undergoing the following procedures:** Intubation, TEE*, flexible bronchoscopy*, EGD without biopsy*, uninfected D&C/TAB, uninfected IUD insertion/removal, uninfected Foley cath placement, cardiac catheterization, angioplasty, coronary stent placement, or skin biopsy. (* *Consider prophylaxis in high-risk patients.*)

A. ADULTS AND CHILDREN OVER AGE 10

1. Amoxicillin (Amoxil) 2 g PO 1 h before procedure [B]
2. Clindamycin (Cleocin) 600 mg PO 1 h before procedure [B]
3. Cephalexin (Keflex) 2 g PO 1 h before procedure [B]
4. Azithromycin (Zithromax) 500 mg PO 1 h before procedure [B]

If unable to take PO

1. Ampicillin 2 g IV/IM 30 min before procedure [B]
2. Clindamycin (Cleocin) 600 mg IV 30 min before procedure [B]
3. Cefazolin (Ancef) 1 g IV/IM 30 min before procedure [B]

B. CHILDREN AGE 10 AND UNDER
Note: Do not exceed adult dose

1. Amoxicillin (Amoxil) 50 mg/kg PO 1 h before procedure [B]
2. Clindamycin (Cleocin) 20 mg/kg PO 1 h before procedure [B]
3. Cephalexin (Keflex) 50 mg/kg PO 1 h before procedure [B]

4. Azithromycin (Zithromax) 15 mg/kg PO 1 h before procedure [B]

If unable to take PO

1. Ampicillin 50 mg/kg IV/IM 30 min before procedure [B]
2. Clindamycin (Cleocin) 20 mg/kg IV 30 min before procedure [B]
3. Cefazolin (Ancef) 25 mg/kg IV/IM 30 min before procedure [B]

MENINGITIS/ENCEPHALITIS

Encephalitis

Herpes simplex virus (HSV) encephalitis
Requires admission to hospital
Acyclovir (Zovirax) 10 mg/kg IV q8h (infused over 1 h) [C]

Meningitis

Notes:

1. If meningitis is suspected, do not delay antibiotics while obtaining lumbar puncture or cultures.
2. Some regions have a high incidence of **drug-resistant Streptococcus pneumoniae (DRSP)** [susceptible MIC £0.1 µg/mL; intermediate >0.1 to £1.0; resistant ³2.0]. If prevalence of DRSP is high (i.e., >2% isolates intermediate or resistant MIC), add vancomycin to regimen.
3. Some authorities recommend dexamethasone in children or adults with positive Gram stain or coma. **Dexamethasone dose: 0.4 mg/kg IV q12h for 4 doses** [C] with first dose given prior to antibiotics (if patient's condition permits, efficacy is improved if given 15–20 min before antibiotics).

A. NEONATAL AND INFANTS (UP TO 8 WEEKS OF AGE)
(*Note* **two or three** *drug therapy*)
Note: Ceftriaxone is no longer recommended in neonates because of the potential for biliary sludge pseudolithiasis.

Cefotaxime (Claforan) 75 mg/kg IV or IM q6h [B]
PLUS (to cover group B *Strep* and *Listeria*)
Ampicillin 50 mg/kg IV or IM q6h [B]
PLUS/MINUS (to cover DRSP—see Notes, above)
Vancomycin (Vancocin) 15 mg/kg IV q6h (monitor serum levels) [C]
Organisms: group B *Strep, E. coli, Listeria, Klebsiella, Enterobacter, S. aureus, H. influenzae*

B. INFANT/CHILD

1. Cefotaxime (Claforan) 75 mg/kg IV or IM q6h [B] **OR**
2. Ceftriaxone (Rocephin) 50 mg/kg IV or IM q12h (max 2 g/dose) [B]
   PLUS/MINUS (to cover DRSP—see Notes, above)

1. Vancomycin (Vancocin) 15 mg/kg IV q6h (max 1 g/dose; monitor serum levels) [C]

Organisms: *H. influenzae, S. pneumoniae, N. meningitidis*

C. PEDIATRIC PATIENTS WITH A SEVERE PENICILLIN ALLERGY
Regimen A (*Note* **two** *drug therapy*)
Vancomycin (Vancocin) 15 mg/kg IV q6h (max 1 g/dose; monitor serum levels) [C]
PLUS
TMP/SMX (Bactrim, Septra) 5 mg/kg IV q12h based on TMP [C; D in 3rd trimester]

Regimen B (*Note* **three** *drug therapy*)
Vancomycin (Vancocin) 15 mg/kg IV q6h (max 1 g/dose; monitor serum levels) [C]
PLUS
Gentamicin (Garamycin) 2 mg/kg IV loading dose, then 1.7 mg/kg IV q8h (monitor serum levels) [D]
PLUS
Rifampin (Rimactane) 10–20 mg/kg IV qd (max 600 mg/dose) [C]

D. ADULT (18–50 YEARS OF AGE)

1. Ceftriaxone (Rocephin) 2 g IV q12h [B] **OR**
2. Cefotaxime (Claforan) 2 g IV q8h [B]
   PLUS/MINUS (to cover DRSP—see Notes, above)
   Vancomycin (Vancocin) 15 mg/kg IV q6h (max 1 g/dose; monitor serum levels) [C]

Organisms: *S. pneumoniae, N. meningitidis*

E. ADULT (>50 YEARS OF AGE, OR IMMUNOCOMPROMISED
(*Note* **two or three** *drug therapy*)

1. Ceftriaxone (Rocephin) 2 g IV q12h [B] **OR**
2. Cefotaxime (Claforan) 2 gm IV q8h [B]
   PLUS
   Ampicillin 2 g IV q4h [B]
   PLUS/MINUS (to cover DRSP—see Notes, above)
   Vancomycin (Vancocin) 15 mg/kg IV q6h (max 1 g/dose; monitor serum levels) [C]

Organisms: *S. pneumoniae, N. meningitidis, Listeria,* aerobic gram-negative bacilli

F. ADULT PATIENTS WITH A SEVERE PENICILLIN ALLERGY
Regimen A (*Note* **two** *drug therapy*)
Vancomycin (Vancocin) 15 mg/kg IV q6h (max 1 g/dose; monitor serum levels) [C]
PLUS
TMP/SMX (Bactrim, Septra) 5 mg/kg IV q12h based on TMP [C; D in 3rd trimester]
Regimen B (*Note* **three** *drug therapy*)
Vancomycin (Vancocin) 15 mg/kg IV q6h (max 1 g/dose; monitor serum levels) [C]
PLUS
Gentamicin (Garamycin) 2 mg/kg IV loading dose, then 1.7 mg/kg IV q8h (monitor serum levels) [D]

PLUS
Rifampin (Rimactane) 10–20 mg/kg IV qd (max 600 mg/dose) [C]

G. MENINGOCOCCAL PROPHYLAXIS (CLOSE CONTACTS)

1. Ciprofloxacin (Cipro) 500 mg PO single dose (must be >18 years) [C]
2. Rifampin 600 mg q12h for 4 doses (pediatric dose: 10 mg/kg PO q12h for 4 doses) [C]
3. Ceftriaxone (Rocephin) 250 mg IM single dose (pediatric dose <15 years: 125 mg IM single dose) [B]

OCCUPATIONAL HIV EXPOSURE

FIG. 149-1. Determining the need for HIV post-exposure prophylaxis (PEP) after an occupational exposure.*

PARASITES

Ascariasis

1. Albendazole (Albenza) 400 mg PO single dose [C]
2. Mebendazole (Vermox) 100 mg PO bid for 3 days [C]
3. Pyrantel pamoate (Antiminth) 11 mg/kg PO single dose (max 1 g) [not recommended in pregnancy]

Organism: *Ascariasis lumbricoides*

Giardiasis

1. Metronidazole (Flagyl) 250 mg PO tid for 5 days [B, contraindicated 1st trimester]
2. Furazolidone (Furoxone) 1.5 mg/kg PO qid for 10 days (consider in children; max 100 mg/dose) [C]
3. Paromomycin (Humatin) 10 mg/kg PO tid for 7 days (max 500 mg/dose) [not absorbed from GI tract so may be useful in pregnancy; not FDA approved for this use]

Course: 5 days
Organism: *Giardia lamblia*

Lice, Body

No pharmacologic treatment is required. Body lice live in clothing and only leave for a blood meal. If possible discard clothing, otherwise treat clothing with 1% malathion powder or 10% DDT powder. Untreated nits viable for 1 month. Clothing of sexual partners and other close contacts should also be discarded or treated.
Organism: *Pediculosis humanus corporis.*

Lice, Head and Pubic (Crabs)

Notes:

1. Lindane (Kwell) is cheaper but less effective and potentially toxic (seizures, aplastic anemia).
2. Lindane is not recommended in patients with extensive dermatitis, children under 2 years old or in pregnant/lactating women; it should **not** be applied following a bath.
3. Bedding and clothing should be washed and dried using heat cycle or removed from body contact for at least 72 h.
4. Sexual partners and other close contacts should also be treated.

1. Permethrin cream 5% (Elimite) [B]
   Wash hair, apply as a liquid and leave on for 10 min, wash off, and comb. Re-treat in 1 week. Also available OTC as Permethrin 1% creme rinse (Nix).
   Dispense 60 mL
2. Pyrethrins with piperonyl butoxide (RID) [C]
   Apply as for permethrin cream, above
   Dispense 60 mL
3. Lindane 1% shampoo (Kwell) [B]
   Apply to hair for 4 min, wash off (see Notes, below)
   Dispense 1–2 ounces
4. Ivermectin (Stromectol) 200 µg/kg PO single dose (adults or pediatrics) [C]

Organism: *Pediculosis humanus capitus, Phthirus pubis*

Pinworms

1. Mebendazole (Vermox) 100 mg PO single dose; repeat dose in 2 weeks [C]
2. Pyrantel pamoate (Antiminth, Pin-X) 11 mg/kg PO single dose (max 1 g); repeat every 2 weeks × 2 [not recommended in pregnancy]
3. Albendazole (Albenza) 400 mg PO single dose; repeat dose in 2 weeks [C]

Organism: *Enterobius vermicularis*

Scabies

Notes:

1. Bedding and clothing should be washed and dried using heat cycle or removed from body contact for at least 72 h.

2. Sexual partners and other close contacts should also be treated.

1. Permethrin cream 5% (Elimite)
   Apply to skin from neck down, leave on 8–14 h, wash off; re-treat in 1 week [B]
   Dispense 60 g
2. Crotamiton 10% (Eurax)
   Apply to skin from neck down for 2 nights and wash off 24 h after second application [C]
   Dispense 60 mL
3. Ivermectin (Stromectol) 200 µg/kg PO single dose (adults or pediatrics) [C]

Organism: *Sarcoptes scabiei* (skin mite)

PRESURGICAL ANTIBIOTICS

Appendicitis (Not Perforated)

Note: Must be given within 2 h of surgery to be effective.

1. Cefoxitin (Mefoxin) 2 g IV [B] **OR**
2. Cefotetan (Cefotan) 2 g IV [B]

Organisms: enteric gram negative bacilli, anaerobes

Bowel Perforation/Peritonitis

(*Note* **two** *drug therapy,* **except** *Regimen D*)
Regimen A
Cefoxitin (Mefoxin) 2 g IV [B] **OR**
Cefotetan (Cefotan) 2 g IV [B]
PLUS/MINUS
Gentamicin (Garamycin) 2 mg/kg IV [D]

Regimen B
Clindamycin (Cleocin) 600 mg IV [B]
PLUS
Gentamicin (Garamycin) 2 mg/kg IV [D] **OR**
Aztreonam (Azactam) 2 g IV [B]

Regimen C
Cefotaxime (Claforan) 2 g IV [B]
Ceftriaxone (Rocephin) 1–2 g IV [B]
Ceftizoxime (Cefizox) 2 g IV [B]
Cefoperazone (Cefobid) 2 g IV [B]
Ceftazidime (Fortaz) 2 g IV [B]
PLUS
Metronidazole (Flagyl) 1 g IV [B, contraindicated 1st trimester] **OR**
Clindamycin (Cleocin) 600 mg IV [B]

Regimen D
Imipenem (Primaxin) 500 mg IV [C]
Organisms: enteric gram negative bacilli, anaerobes, enterococci

Cholecystitis/cholangitis

Regimen A
Ticarcillin/clavulanic acid (Timentin) 3.1 g IV [B]
Ampicillin/sulbactam (Unasyn) 3 g IV [B]
Piperacillin/tazobactam (Zosyn) 3.375 g IV [B]
Imipenem (Primaxin) 500–1000 mg IV [C]
Meropenem (Merrem) 1 g IV [B]

Regimen B (*Note* **two** *drug therapy*)
Cefotaxime (Claforan) 2 g IV [B]
Ceftriaxone (Rocephin) 1–2 g IV [B]
Ceftizoxime (Cefizox) 2 g IV [B]
Cefoperazone (Cefobid) 2 g IV [B]
Ceftazidime (Fortaz) 2 g IV [B]
PLUS
Metronidazole (Flagy1) 1 g IV [B, contraindicated 1st trimester] **OR**
Clindamycin (Cleocin) 600 mg IV [B]

Regimen C (*Note* **one or two** *drug therapy*)
Ticarcillin (Ticar) 3–4 g IV [B] **OR**
Piperacillin (Pipracil) 3–4 g IV [B]
PLUS/MINUS
Metronidazole (Flagyl) 1 g IV [B, contraindicated 1st trimester]

Regimen D (*Note* **two** *drug therapy*)
Aztreonam (Azactam) 2 g IV [B]
PLUS
Clindamycin (Cleocin) 600 mg IV [B]
Organisms: Enterobacteriaceae, enterococci, *Bacteroides, Clostridium*

Open Fractures

(*Note* **two** *drug therapy for* **severe** *fractures*)

1. Cefazolin (Ancef) 1–2 g IV [B]
2. Vancomycin 15 mg/kg IV (max 1 g) [C]
3. Clindamycin (Cleocin) 600 mg IV [B]

PLUS (*for severe fractures—grade II and above*)

1. Gentamicin (Garamycin) 2 mg/kg IV [D]

Organisms: *S. aureus, S. epidermidis,* gram negative rods

Penetrating Abdominal Wounds

See Presurgical Antibiotics, Bowel Perforation/Peritonitis.

RESPIRATORY TRACT INFECTIONS

Bronchitis

A. ADULTS (NON-SMOKERS, NO UNDERLYING DISEASE OR HISTORY OF RESPIRATORY PROBLEMS)
Notes: Antibiotics are rarely necessary. Treat with inhaled beta-agonist therapy (e.g., albuterol, metaproterenol). If no improvement after 1 week, consider treatment

1. Erythromycin 500 mg PO qid [B, except estolate contraindicated]
2. Erythromycin ethyl succinate (EES) 400 mg PO qid [B]
3. Azithromycin (Zithromax) 500 mg PO initial dose, then 250 mg PO qd for 4 days [B]
4. Clarithromycin (Biaxin) 250–500 mg PO bid [C]
5. Doxycycline (Vibramycin) 100 mg PO bid [D]

(Chlamydia pneumonia (TWAR) has resistance to erythromycin. Consider azithromycin or clarithromycin.)
Course: 7–10 days (except azithromycin as noted)
Organisms: usually viral, *Mycoplasma pneumoniae, S. pneumoniae, Chlamydia pneumoniae* (TWAR)

B. ADULTS (SMOKER OR CHRONIC ILLNESS)
Note: In addition to antibiotics, treat with an inhaled b-agonist (e.g., albuterol, metaproterenol)

1. TMP/SMX DS (Bactrim DS, Septra DS) 1 tablet PO bid [B; D in 3rd trimester]
2. Doxycycline (Vibramycin) 100 mg PO bid [D]
3. Azithromycin (Zithromax) 500 mg PO initial dose, then 250 mg PO qd for 4 days [B]
4. Clarithromycin (Biaxin) 250–500 mg PO bid [C]
5. Amoxicillin/clavulanate (Augmentin) 250–500 mg PO tid [B]
6. Levofloxacin (Levaquin) 250–500 mg PO qd [C]
7. Sparfloxacin (Zagam) 400 mg PO initial dose, then 200 mg PO qd [C]
8. Cefuroxime axetil (Ceftin) 250–500 mg PO bid [B]
9. Cefpodoxime proxetil (Vantin) 200 mg PO bid [B]

Course: 10 days (except azithromycin as noted)
Organisms: *H. influenzae, M. catarrhalis, S. pneumonia, Klebsiella* sp., anaerobes, *E. coli*

Pertussis

Notes:

1. Consider diagnosis in afebrile patients, including adults, with persistent cough.
2. Treatment of household contacts recommended.
3. Differential diagnoses include gastroesophageal reflux, asthma, and postnasal drip.

A. PEDIATRIC

1. Erythromycin estolate (Ilosone) 40 mg/kg/day PO divided bid–tid for 7 days [contraindicated in pregnancy]
   Easy dose: 20 mg/kg/dose PO bid for 7 days
   Maximum: 250–500 mg per dose
   Liquids: 125 mg and 250 mg/5 cc
2. Erythromycin ethyl succinate (EES) 30–50 mg/kg/day PO divided qid for 14 days [B]
   Easy dose: 10 mg/kg/dose PO qid for 14 days
   Maximum: 250–500 mg per dose
   Liquids: 200 mg and 400 mg/5 cc
3. TMP/SMX (Bactrim, Septra) 10 mg/kg/day TMP & 50 mg/kg/day SMX PO divided bid for 14 days [C; D in 3rd trimester]
   Easy dose: 1.25 cc/kg/day PO divided bid for 14 days
   Maximum: 20 cc per dose
   Suspension of TMP 40 mg and SMX 200 mg/5 cc

B. ADULTS

1. Erythromycin estolate (Ilosone) 500 mg PO qid for 7 days [contradicted in pregnancy]
2. TMP/SMX DS (Bactrim DS, Septra DS) 1 tablet PO bid for 14 days [B; D in 3rd trimester]

Organisms: *Bordetellal pertussis, Bordetella parapertussis*

Pneumonia

A. NEONATES (<1 MONTH)
(*Note* **two** *drug therapy*) Ceftriaxone is no longer recommended in neonates because of the potential for biliary sludge pseudolithiasis.

1. Ampicillin 50 mg/kg IV q6h [B] **OR**
2. Nafcillin 50 mg/kg IV q6h [B]
   OR (if suspect **MRSA**)
3. Vancomycin (Vancocin) 10 mg/kg IV q6h (max 1 g; monitor serum levels) [C]
   PLUS

1. Gentamicin (Garamycin) 2 mg/kg IV loading dose, then 1.7 mg/kg IV q8h (monitor serum levels) [D] **OR**
2. Cefotaxime (Claforan) 50 mg/kg IV q6h [B]

Organisms: group B *Strep, Listeria,* coliforms, *Staph. aureus, Pseudomonas, Chlamydia*

B. PEDIATRIC (1 MONTH–18 YEARS)

INPATIENT THERAPY
(*Note* **two** *drug therapy*)
Erythromycin 10 mg/kg IV q6h (max 1 g/dose) [B, except estolate contraindicated]
PLUS
Cefuroxime 50 mg/kg IV q8h (max 1 g/dose) [B]
OUTPATIENT THERAPY
Note: Consider initiating outpatient therapy with a single dose of the parenteral antibiotics listed above for inpatient therapy.

1. Erythromycin 30–50 mg/kg/day PO divided qid
   Easy dose: 10 mg/kg/dose PO qid
   Maximum: 250–500 mg/dose
   Liquids:
   Erythromycin ethyl succinate (EES) 200 mg and 400 mg/5 mL [B]
   Erythromycin estolate (Ilosone) 125 mg and 250 mg/5 mL (contraindicated in pregnancy)
2. Clarithromycin (Biaxin) 7.5 mg/kg/dose PO bid [C]
   Maximum: 250–500 mg/dose
   Suspensions: 125 mg and 250 mg/5 mL
3. Erythromycin/sulfisoxazole (Pediazole) 50 mg/kg/day erythro and 150 mg/kg/day sulfa PO divided tid **OR** qid [C; D in 3rd trimester]
   Easy dose: 1.25 mL/kg/day PO divided qid
   Maximum: 10 mL/dose
   Suspension of erythromycin 200 mg and sulfisoxazole 600 mg/5 mL

Course: 10–14 days
Organisms: *S. pneumoniae, H. influenzae* (1–24 months), *Chlamydia pneumoniae, Mycoplasma pneumoniae,* RSV (1–24 months), viral

C. ADULTS (60 YEARS OLD OR LESS, COMMUNITY ACQUIRED, NO COMORBIDITY)

INPATIENT THERAPY
Regimen A
(*Note* **two or three** *drug therapy*)
Cefotaxime (Claforan) 2 g IV q8h [B] **OR**
Ceftriaxone (Rocephin) 2 g IV qd [B]
PLUS
Erythromycin 5 mg/kg/dose IV qid (max 1 g/dose) [B, except estolate contraindicated] **OR**
Azithromycin (Zithromax) 500 mg IV qd [B]
PLUS/MINUS (if suspect drug-resistant *Strep. pneumoniae*)
Vancomycin (Vancocin) 15 mg/kg IV q6h (max 1 g/dose; monitor serum levels) [C]

Regimen B (*Note* **one or two** *drug therapy*)
Levofloxacin (Levaquin) 500 mg IV qd [C]
PLUS/MINUS (if aspiration suspected)
Clindamycin 600 mg IV q8h [B]
OUTPATIENT THERAPY
Notes:

1. Initial antibiotic selection may differ in areas with community-wide erythromycin (macrolide) resistant *S. pneumoniae.*
2. Erythromycin variably effective against *H. influenzae.*
3. Consider initiating outpatient therapy with a single dose of the parenteral antibiotics listed above for inpatient therapy.

1. Azithromycin (Zithromax) 500 mg PO initial dose, then 250 mg PO qd for 4 days [B]
2. Clarithromycin (Biaxin) 250–500 mg PO bid [C]
3. Erythromycin 500 mg PO qid **OR** erythromycin ethylsuccinate (EES) 400 mg PO bid [B, except estolate contraindicated]
4. Levofloxacin (Levaquin) 500 mg PO qd [C]
5. Doxycycline (Vibramycin) 100 mg PO bid [D]

Course: 10–14 days (except azithromycin as noted) (levofloxacin preferred in areas with *S. pneumoniae* macrolide resistance)
Organisms: *S. pneumoniae, Mycoplasma pneumoniae, Chlamydia pneumoniae* (TWAR), *Legionella* sp., *H. influenzae*

D. ADULTS (OLDER THAN 60 YEARS OF AGE, SMOKER, CHRONIC ILLNESS, ALCOHOLIC)

INPATIENT THERAPY
Note: Treat as for adults (60 years old, community acquired, no comorbidity), above.

OUTPATIENT THERAPY
Note: Consider initiating outpatient therapy with a single dose of the parenteral antibiotics listed above for inpatient therapy.
Regimen A
Azithromycin (Zithromax) 500 mg PO initial dose then 250 mg PO qd for 4 days [B]
Clarithromycin (Biaxin) 250–500 mg PO bid [C]

Regimen B (if suspect Drug Resistant *S. pneumoniae*)
Levofloxacin (Levaquin) 500 mg PO qd [C]
Sparfloxacin (Zagam) 400 mg PO initial dose, then 200 mg PO qd [C]
Grepafloxacin (Raxar) 600 mg PO qd [C]

Regimen C (if suspect aspiration)
Amoxicillin/clavulanate (Augmentin) 500 mg PO tid [B]
Course: 10–14 days (except azithromycin as noted)
Organisms: *S. pneumoniae, H. influenzae, M. catarrhalis, Legionella* sp., *Chlamydia pneumoniae,* coliforms

Pulmonary Tuberculosis

(*Chest x-ray positive, active disease*) Many regional variations and conflicting recommendations exist. Unless local/regional sensitivities are well established, consider initiating treatment with **four drug therapy.**

A. CHILDREN
Notes:

1. Patients with positive chest x-rays (active disease) **must be isolated.**

2. All cases **must be reported** to the local health department.
3. Antituberculosis medications have inherent toxicities and side effects: INH (hepatitis, peripheral neuropathy), rifampin (hepatotoxicity, flu-like syndrome, discoloration of body fluids/staining of contact lenses), PZA (arthralgias, hyperuricemia, hepatitis), ethambutol (optic neuritis), and streptomycin (ototoxicity). Close monitoring is essential.
4. Consider adding pyridoxine (vitamin B_6) 25–50 mg PO qd [A] to decrease NIH-induced neuropathy.

Isoniazid (INH) 10–20 mg/kg/day PO (max 300 mg/day) [C]
PLUS
Rifampin (Rimactane) 10–20 mg/kg/day PO (max 600 mg/day) [C]
PLUS
Pyrazinamide (PZA) 15–30 mg/kg/day PO (max 2 g/day) [C]
PLUS
Ethambutol (Myambutol) 15–25 mg/kg/day PO (max 2.5 g/day) [B]
OR
Streptomycin 20–40 mg/kg/day (max 1 g/day) [D]

B. ADULTS

Isoniazid (INH) 5 mg/kg/day PO (max 300 mg/day) [C]
PLUS
Rifampin (Rimactane) 10 mg/kg/day PO (max 600 mg/day) [C]
PLUS
Pyrazinamide (PZA) 15–30 mg/kg/day PO (max 2 g/day) [C]
PLUS
Ethambutol (Myambutol) 15–25 mg/kg/day PO (max 2.5 g/day) [B]
OR
Streptomycin 15 mg/kg/day (max 1 g/day) [D]

Course: Treatment regimens vary. Initiate therapy with all drugs simultaneously, and arrange appropriate follow-up.

SEPSIS

Note: If patient condition permits, cultures should be obtained prior to antibiotic administration.

A. NEONATAL (UP TO 8 WEEKS OF AGE, NORMAL HOST)
(*Note* **two** *drug therapy*)

Note: Ceftriaxone is no longer recommended in neonates due to the potential for biliary sludge pseudolithiasis.
Cefotaxime (Claforan) 50 mg/kg IV/IM q8h (q12h if < 1 week old) [B]
PLUS (to cover group B *Strep* and *Listeria*)
Ampicillin 25 mg/kg IV/IM q6h (q8h if < 1 week old) [B]
Organisms: group B *Strep, E. coli, Listeria, Klebsiella, Enterobacter, S. aureus, H. influenzae*

B. INFANT/CHILD (NORMAL HOST)

1. Cefotaxime (Claforan) 50 mg/kg IV/IM q8h [B] **OR**
2. Ceftriaxone (Rocephin) 100 mg/kg IV or IM q24h [B]

Organisms: *H. influenzae, S. pneumoniae, N. meningitidis, S. aureus*

C. PEDIATRIC (IMMUNOCOMPROMISED)
Regimen A
(*Note* **two or three** *drug therapy*)
Ceftazidime (Fortaz) 50 mg/kg IV q8h [B]
Mezlocillin (Mezlin) 50–75 mg/kg IV q 4–6 h [B]
Ticarcillin (Ticar) 50 mg/kg IV q 4–6 h [B]
Piperacillin (Pipracil) 50 mg/kg IV q 4–6 h [B]
Ticarcillin/clavulanic acid (Timentin) 50 mg/kg IV q6h [B]
Piperacillin/tazobactam (Zosyn) 100 mg/kg IV q8h [B]
PLUS
Gentamicin (Garamycin) 2 mg/kg IV loading dose, then 1.7 mg/kg IV q8h (monitor serum levels) [D] **OR**
Tobramycin (Nebcin) 2 mg/kg IV loading dose, then 1.7 mg/kg IV q8h (monitor serum levels) [D] **OR**
Amikacin (Amikin) 5 mg/kg IV q8h (monitor serum levels) [D]
PLUS/MINUS (if indwelling intravascular device present)
Vancomycin (Vancocin) 10 mg/kg IV q6h (max 1 g/dose; monitor serum levels) [C]

Regimen B
(*Note* **one or two** *drug therapy*)
Imipenem (Primaxin) 30 mg/kg IV q8h [C] **OR**
Meropenem 40 mg/kg IV q8h [B]
PLUS/MINUS (if indwelling intravascular device present)
Vancomycin (Vancocin) 10 mg/kg IV q6h (max 1 g/dose; monitor serum levels) [C]
Organisms: Enterobacteriaceae, *Pseudomonas* sp., *S. aureus, S. epidermidis, S. viridans, Corynebacterium* sp.

D. PEDIATRIC PATIENTS WITH A SEVERE PENICILLIN ALLERGY
(*Note* **two** *drug therapy*)

Vancomycin (Vancocin) 10 mg/kg IV q6h (max 1 g/dose; monitor serum levels) [C]
PLUS

1. Gentamicin (Garamycin) 2 mg/kg IV loading dose, then 1.7 mg/kg IV q8h (monitor serum levels) [D] **OR**
2. Aztreonam (Azactam) 30 mg/kg IV q8h [B]

E. ADULT (NORMAL HOST)
Regimen A
Ticarcillin/clavulanic acid (Timentin) 3.1 g IV q6h [B]
Piperacillin/tazobactam (Zosyn) 3.375 g IV q6h [B]
Imipenem (Primaxin) 500–1000 mg IV q8h [C]
Meropenem 1 g IV q8h [B]

Regimen B
(*Note* **two** *drug therapy*)

Cefotaxime (Claforan) 2 g IV q8h [B] **OR**
Ceftriaxone (Rocephin) 2 g IV q12h [B]
PLUS
Metronidazole (Flagyl) 15 mg/kg IV loading dose, max dose 1000 mg then 7.5 mg/kg IV q6h (max 500 mg/dose) [B; contraindicated 1st trimester] **OR**
Clindamycin (Cleocin) 900 mg IV q8h [B]

Regimen C
(*Note* **two** *drug therapy*)
Ciprofloxacin (Cipro) 400 mg IV q12h [C]
Ofloxacin (Floxin) 400 mg IV q12h [C]
Levofloxacin (Levaquin) 500 mg IV qd [C]
PLUS
Clindamycin (Cleocin) 900 mg IV q8h [B]
Organisms: gram positive cocci, gram negative cocci, anaerobes

F. ADULT (IMMUNOCOMPROMISED)
Regimen A
(*Note* **two or three** *drug therapy*)
Ceftazidime (Fortaz) 2 g IV q8h [B]
Mezlocillin (Mezlin) 3 g IV q6h [B]
Ticarcillin (Ticar) 3–4 g IV q4h [B]
Piperacillin (Pipracil) 3–4 g IV q4h [B]
Ticarcillin/clavulanic acid (Timentin) 3.1 g IV q6h [B]
Piperacillin/tazobactam (Zosyn) 3.375 g IV q6h [B]
PLUS
Gentamicin (Garamycin) 2 mg/kg IV loading dose, then 1.7 mg/kg IV q8h (monitor serum levels) [D] **OR**
Tobramycin (Nebcin) 2 mg/kg IV loading dose, then 1.7 mg/kg IV q8h (monitor serum levels) [D] **OR**
Amikacin (Amikin) 7.5 mg/kg IV q12h (monitor serum levels) [D] **OR**
Aztreonam (Azactam) 1–2 g IV q8h [B]
PLUS/MINUS (if indwelling intravascular device present)
Vancomycin (Vancocin) 15 mg/kg IV q12h (max 1 g/dose; monitor serum levels) [C]

Regimen B
(*Note* **one or two** *drug therapy*)
Imipenem (Primaxin) 500–1000 mg IV q8h [C] **OR**
Meropenem 1 g IV q8h [B]
PLUS/MINUS (if indwelling intravascular device present)
Vancomycin (Vancocin) 15 mg/kg IV q12h (max 1 g/dose; monitor serum levels) [C]
Organisms: Enterobacteriaceae, *Pseudomonas, S. aureus, S. epidermidis, S. viridans, Corynebacterium* sp.

G. ADULT PATIENTS WITH A SEVERE PENICILLIN ALLERGY
(*Note* **two** *drug therapy*)

1. Vancomycin (Vancocin) 15 mg/kg IV q12h (max 1 g/dose; monitor serum levels) [C]
   PLUS

1. Gentamicin (Garamycin) 2 mg/kg IV loading dose, then 1.7 mg/kg IV q8h (monitor serum levels) [D] **OR**
2. Aztreonam (Azactam) 1–2 g IV q8h [B]

H. INTRAVENOUS DRUG ABUSERS
(*Note* **two** *drug therapy*)

1. Nafcillin 2 g IV q4h [B]
   OR (especially if catheter-induced sepsis)
2. Vancomycin (Vancocin) 15 mg/kg IV q12h (max 1 g/dose; monitor serum levels) [C]
   PLUS

1. Gentamicin (Garamycin) 2 mg/kg IV loading dose, then 1.7 mg/kg IV q8h (monitor serum levels) [D]

Organisms: *S. aureus, Pseudomonas,* enterococci

SEXUAL ASSAULT PROPHYLAXIS

Sexually Transmitted Disease Prophylaxis

(*Note* **two** *drug therapy to treat* **gonorrhea and chlamydia**)
Gonorrhea treatment
Notes:

1. Azithromycin (Zithromax) 2 g PO single dose is considered effective for *N. gonorrhoeae* and *Chlamydia*, but GI discomfort is common.
2. May consider prophylaxis for *T. vaginalis* with metronidazole (Flagyl) 2 g PO single dose [B, contraindicated 1st trimester]
3. Recommend initial testing for GC, *Chlamydia*, HIV, syphilis, and pregnancy.
4. Ofloxacin (Floxin) and ciprofloxacin (Cipro) do not have activity against incubating syphilis.

1. Ceftriaxone (Rocephin) 125 mg IM single dose [B]
2. Cefotaxime (Claforan) 500 mg IM single dose [B]
3. Cefixime (Suprax) 400 mg PO single dose [B] (not for pharyngeal infection)
4. Ciprofloxacin (Cipro) 500 mg PO single dose [C]
5. Ofloxacin (Floxin) 400 mg PO single dose [C]
6. Spectinomycin (Trobicin) 2 g IM single dose [B]
   PLUS (for *Chlamydia* coverage)

1. Azithromycin (Zithromax) 1 g PO single dose [B] **OR**
2. Doxycycline (Vibramycin) 100 mg PO bid for 7 days [D]

Pregnancy Prophylaxis

Notes:

1. Consider only if patient is not already pregnant.
2. Must be taken within 72 h of unprotected sex to be effective.

3. May cause severe nausea.

1. Ovral (50 µg ethinyl estradiol + 0.5 mg norgestrel) 2 tablets PO initially, then 2 tablets PO 12 h later [X]   **OR**
2. Lo/Ovral (30 µg ethinyl estradiol + 0.3 mg norgestrel) 4 tablets PO initially, then 4 tablets PO 12 h later [X]
3. Levonogestrel (Plan B) 0.75 mg 1 tablet PO initially then 1 tablet PO 12 h later
4. Leven, Nordette (30 µg ethinyl estradiol + 0.15 mg levonorgestrel) 4 tablets PO initially, then 4 tablets PO 12 h later.

SEXUALLY TRANSMITTED DISEASES

Female Genital Infections

Note: Pregnancy test advised prior to initiation of therapy in many cases.

CERVICITIS

A. Chlamydia, Gonorrhea, Herpes Simplex, Syphilis   *See General Genital Infections*.

PELVIC INFLAMMATORY DISEASE (PID)

A. Outpatient Management
Regimen A
(*Note* **two** *drug therapy*)
Ofloxacin (Floxin) 400 mg PO bid [C]
PLUS
Metronidazole (Flagyl) 500 mg PO bid [B, contraindicated 1st trimester] **OR**
Clindamycin (Cleocin) 450 mg PO qid [B]

Regimen B
(*Note* **two or three** *drug therapy*)
Ceftiaxone (Rocephin) 250 mg IM once [B] **OR**
Cefoxitin (Mefoxin) 2 g IM [B], plus probenecid 1 g PO single dose [B]
PLUS
Doxycycline (Vibramycin) 100 mg PO bid for 14 days [D]
PLUS/MINUS (if resistant to therapy)

Metronidazole (Flagyl) 500 mg PO bid [B, contraindicated 1st trimester] **OR**
Clindamycin (Cleocin) 450 mg PO qid [B]
Course: 14 days

B. Inpatient Management
Notes: Hospital admission often advisable for parenteral antibiotics especially in cases with pregnancy, peritonitis, suspected abscess, clarification of diagnosis, immunodeficiency, and failure of outpatient therapy.

Regimen A
(*Note* **two** *drug therapy*)
Cefoxitin (Mefoxin) 2 g IV q6h [B] **OR**
Cefotetan (Cefotan) 2 g IV q12h [B]
PLUS
Doxycycline (Vibramycin) 100 mg PO bid for 14 days [D]
OR (if pregnant)
Azithromycin (Zithromax) 500 mg IV qd for 2 days, then 250 mg IV qd for 7 more days [B]

Regimen B
(*Note* **two** *drug therapy*)
Clindamycin (Cleocin) 900 mg IV q8h [B]
PLUS
Gentamicin (Garamycin) 2 mg/kg IV or IM loading dose, then 1.7 mg/kg IV/IM q8h (monitor serum levels) [D]
Course: After afebrile for 24 h on IV antibiotics, switch to doxycycline 100 mg PO bid for 14 days [D]. Also, if treating tubo-ovarian abscess, add metronidazole (Flagyl) 500 mg PO bid [B, contraindicated 1st trimester] **OR** clindamycin (Cleocin) 450 mg PO qid for 14 days [B].
Organisms: *N. gonorrhoeae, Chlamydia trachomatis, Mycoplasma hominis,* Enterobacteriaceae, anaerobes

VAGINITIS

Note: 1998 CDC Sexually Transmitted Diseases Treatment Guidelines report that treating partners is unnecessary.

A. Bacterial Vaginosis
Nonpregnant

1. Metronidazole (Flagyl) 500 mg PO bid for 7 days [B, contraindicated 1st trimester]
2. Clindamycin cream (2%) [Cleocin] one applicator (5 g) intravaginally qhs for 7 days [B]
3. Metronidazole gel (0.75%) [Metrogel Vaginal] one applicator (5 g) intravaginally bid for 5 days [B, contraindicated 1st trimester]
4. Clindamycin (Cleocin) 300 mg PO bid for 7 days [B]

Pregnant
Note: Metronidazole contraindicated 1st trimester. Begin treatment in 2nd trimester with

1. Metronidazole (Flagyl) 250 mg PO tid for 7 days [B, contraindicated 1st trimester] **OR**
2. Clindamycin (Cleocin) 300 mg PO bid for 7 days [B]

Organisms: polymicrobic: *Gardnerella vaginalis, Bacteroides, Mycoplasma hominis, Mobiluncus, Peptococcus*

B. Herpes Simplex
See General Genital Infections.

C. Trichomonas
Note: Partners must be treated and should be advised to avoid sex until full course of therapy is completed and both partners are asymptomatic.
Nonpregnant

1. Metronidazole (Flagyl) 2 g PO single dose [B, contraindicated 1st trimester] **OR**

2. Metronidazole 500 mg PO bid for 7 days [B, contraindicated 1st trimester]

Pregnant
Clotrimazole (Gyne-Lotrimin, Mycelex-7) 100 mg intravaginally qhs for 14 days (decreases symptoms, but cure rate only 20%) [B]

D. Vaginal Candidiasis/Yeast
Note:

1. All available over the counter (OTC) except fluconazole.
2. For relapses or treatment failures not resolved in one week, consider fluconazole (Diflucan) 150 mg PO on days 1, 5, 9, and 13. [C]
3. Creams and suppositories are oil-based and may weaken condoms or diaphragms.

1. Fluconazole (Diflucan) 150 mg PO single dose [C, not recommended in pregnancy]
2. Miconazole vaginal suppositories (Monistat 3) 200 mg intravaginally qhs for 3 days [generally accepted in pregnancy]
3. Miconazole 2% vaginal cream (Monistat 7): one applicator (5 g) per vagina qhs for 7 days [generally accepted as safe in pregnancy]
4. Clotrimazole vaginal suppositories (Gyne-Lotrimin, Mycelex-7) 100 mg tablet intravaginally qhs for 7 days **OR** two 100 mg tabs intravaginally for 3 days [B]
5. Clotrimazole 1% vaginal cream (Gyne-Lotrimin, Mycelex-7): one applicator (5 g) per vagina qhs for 7 days [B]
6. Butoconazole (Femstat) 2% cream one applicator (5 g per vagina qhs for 3 days [C]

Course: As listed, however 7 days of treatment are recommended for those medications used during pregnancy.

Male Genital Infections

EPIDIDYMITIS/PROSTATITIS

A. Younger Patients (less than 35 years of age)
Treat for gonorrhea and chlamydia—See General Genital Infections.

B. Older Patients (greater than 35 years of age):
See Genitourinary Tract Infections.

HERPES SIMPLEX
See General Genital Infections.

SYPHILIS
See General Genital Infections.

URETHRAL DISCHARGE/URETHRITIS
Note: Urethral swab Gram stains (which are notoriously inaccurate) may help determine the diagnosis although most centers treat empirically and may or may not send GC and *Chlamydia* culture/antigen tests for confirmation.

A. Gonorrhea and Chlamydia
See General Genital Infections.

B. Trichomonas
Note: Partners must be treated and should be advised to avoid sex until full course of therapy is completed and both partners are asymptomatic.
Metronidazole (Flagyl) 2 g PO single dose [B, contraindicated 1st trimester]
Organisms: *N. gonorrhoeae, C. trachomatis, Ureaplasma urealyticum, T. vaginalis, Mycoplasma hominis*

General Genital Infections (Male and Female)

GENITAL WARTS

1. Liquid nitrogen application to warts.
2. Referral to dermatology or primary care physician for other forms of therapy.
3. Obtain VDRL/RPR.

Organism: human papillomavirus

GONORRHEA/CHLAMYDIA
Notes:

1. Up to 50% of GC positive patients have *Chlamydia trachomatis* as well.
2. Patients may need a repeat culture 4–7 days after treatment if they remain symptomatic.
3. With the emergence of penicillinase-producing *N. gonorrhoeae* (PPNG), there will be regional differences in selecting the *primary* antibiotic.
4. All patients with gonorrhea should have a serologic test for syphilis (VDRL/RPR). Consider testing for HIV.
5. Single dose ofloxacin (400 mg) [C] or azithromycin (2 g) [B] cover both chlamydia and gonorrhea.

A. Uncomplicated Urethral, Endocervical or Rectal
(*Note* **two** *drug therapy to treat* **gonorrhea and chlamydia**)
Gonorrhea treatment

1. Cefixime (Suprax) 400 mg PO single dose [B]
2. Ceftriaxone (Rocephin) 125 mg IM single dose [B]
3. Ciprofloxacin (Cipro) 500 mg PO single dose [C]
4. Ofloxacin (Floxin) 400 mg PO single dose [C]
5. Spectinomycin (Trobicin) 2 g IM single dose (if allergic to cephalosporins and quinolones) [B]
   PLUS (for chlamydia treatment)

Non-pregnant (chlamydia treatment)

1. Azithromycin (Zithromax) 1 g PO single dose [B]
2. Doxycycline (Vibramycin) 100 mg PO bid for 7 days [D]
3. Erythromycin 500 mg PO qid for 7 days [B, except estolate contraindicated]
4. Ofloxacin (Floxin) 300 mg PO bid for 7 days [C]

Pregnant (chlamydia treatment)

1. Erythromycin 500 mg PO qid for 7 days OR 250 mg PO qid for 14 days [B, except estolate contraindicated]
2. Amoxicillin (Amoxil) 500 mg PO tid for 7 days [B]

3. Azithromycin (Zithromax) 1 g PO single dose [B, preliminary data indicate probably safe and effective, but data insufficient to recommend routine use]

B. Pharyngeal
Note: Chlamydia coinfection of pharynx is unusual, but coinfection of genitals may occur; therefore it is recommended to treat both GC and chlamydia.

1. Ceftriaxone (Rocephin) 125 mg IM single dose [B]
2. Ciprofloxacin (Cipro) 500 mg PO single dose [C]
3. Ofloxacin (Floxin) 400 mg PO single dose [C]
   PLUS (for chlamydia treatment)

1. Azithromycin (Zithromax) 1 g PO single dose [B] **OR**
2. Doxycycline (Vibramycin) 100 mg PO bid for 7 days [D]

HERPES SIMPLEX—GENITAL

A. Primary Episode

1. Acyclovir (Zovirax) 400 mg PO tid **OR** 200 mg PO 5 times a day [C]
2. Famciclovir (Famvir) 250 mg PO tid [B]
3. Valacyclovir (Valtrex) 1000 mg PO bid [B]

Course: 7–10 days.

B. Recurrent Episodes
Treatment beneficial only if instituted within 2 days of onset of lesions.

1. Acyclovir (Zovirax) 800 mg PO bid **OR** 400 mg PO tid **OR** 200 mg PO 5 times/day [C]
2. Famciclovir (Famvir) 125 mg PO bid [B]
3. Valacyclovir (Valtrex) 500 mg PO bid [B]

Course: 5 days

C. Chronic Suppression

1. Acyclovir (Zovirax) 400 mg PO bid [C]
2. Famciclovir (Famvir) 250 mg PO bid [B]
3. Valacyclovir (Valtrex) 500 PO qd **OR** 250 mg PO bid [B]

PUBIC LICE (CRABS) AND SCABIES
See Parasites.

SYPHILIS (PRIMARY, SECONDARY, LATENT <1 YEAR)
Notes:

1. Consider HIV testing.
2. Treatment failures may occur with any regimen. Patients should be reexamined in 3 and 6 months.
3. Three weekly injections of benzathine penicillin are recommended for treatment failures, latent infections >1 year, and for HIV-infected patients.

1. Benzathine penicillin G (Bicillin L-A) strongly preferred, use alternatives only if penicillin allergy (consider desensitization in patients with a penicillin allergy) [B]
   a. a. Children: 50,000 units/kg IM single dose (max 2.4 million units)
   b. b. Adults: 2.4 million units IM single dose

If penicillin allergic:

1. Doxycycline (Vibramycin) 100 mg PO bid for 14 days [D] **OR**
2. Tetracycline 500 mg PO qid for 14 days [D]

Organism: *Treponema pallidum*

SKIN AND SOFT TISSUE INFECTIONS

Note: Consider tetanus status in all patients.

Bites

Note: Consider initiating outpatient therapy with a single dose of IV medication listed under inpatient therapy.

A. CAT (OUTPATIENT THERAPY)
Notes:

1. Cat bites have a high infection rate (30–50%) and frequently require IV antibiotic therapy. Close follow-up is mandatory.
2. Consider x-ray to rule out broken cat tooth.

1. Amoxicillin/clavulanate (Augmentin) 500/125 mg PO tid **OR** 875/125 mg PO bid [B] **OR**
2. Cefuroxime axetil (Ceftin) 500 mg PO bid [B]

If penicillin allergic
(*Note* **two** *drug therapy*)

1. Clindamycin 300–450 mg PO qid [B]
   PLUS (for *Eikenella* coverage)

1. Ciprofloxacin (Cipro) 500 mg PO bid [C] **OR**
2. TMP/SMX DS (Septra DS, Bactrim DS) 1 tablet PO bid [C; D in 3rd trimester] **OR**
3. Doxycycline (Vibramycin) 100 mg PO bid [D]

Course: 7–10 days
Organisms: *Pasteurella* sp., streptococci, staphylococci, *moraxella, neisseria, fusobacterium, bacteroides, porphyromonas, prevotella, erysiphelothrix.*

B. DOG (OUTPATIENT THERAPY)
Note: Consider need for rabies therapy.

1. Amoxicillin/clavulanate (Augmentin) 500/125 mg PO tid **OR** 875/125 mg PO bid [B]

If penicillin allergic (*Note* **two** *drug therapy*)

1. Clindamycin 300–450 mg PO qid [B]
   PLUS (*for capnocytophaga (DF2) coverage*)

1. Ciprofloxacin (Cipro) 500 mg PO bid [C] **OR**
2. TMP/SMX DS (Septra DS, Bactrim DS) 1 tablet PO bid [C; D in 3rd trimester] **OR**
3. Doxycycline (Vibramycin) 100 mg PO bid [D]

Course: 7–10 days
Organisms: *Pasteurella multocida,* staphylococcus, streptococcus, *fusobacterium* sp, *bacteroides* sp, EF4, *Capnocytophaga cynodegmi* (formerly DF2), EF4

C. HUMAN (OUTPATIENT THERAPY)

1. Amoxicillin/clavulanate (Augmentin) 500/125 mg PO tid **OR** 875/125 mg PO bid [B]
2. Cephradine (Velosef) [B] **OR** Cephalexin (Keflex) [B] 500 mg PO qid **PLUS** penicillin 500 mg PO qid [B]
3. Penicillin 500 mg PO qid [B] **PLUS** dicloxacillin 500 mg PO qid [B]

If penicillin allergic
(*Note* **two** *drug therapy*)

1. Clindamycin 300–450 mg PO qid [B]
   PLUS (for *Eikenella* coverage)

1. Ciprofloxacin (Cipro) 500 mg PO bid [C]
2. TMP/SMX DS (Septra DS, Bactrim DS) 1 tablet PO bid [C; D in 3rd trimester]

Course: 7–10 days
Organisms: *S. viridans, Eikenella corrodens, Staph* sp., *Corynebacterium,* anaerobes (*Peptostreptococcus, Bacteroides*)

D. BITES (HUMAN, DOG, AND CAT)—INPATIENT THERAPY

1. Ampicillin/sulbactam (Unasyn) 1.5 g IV q6h [B]
2. Cefoxitin (Mefoxin) 2 g IV q8h [B]
3. Ticarcillin/clavulanate (Timentin) 3.1 g IV q6h [B]
4. Piperacillin/tazobactam (Zosyn) 3.375 g IV q6h [B]

If penicillin allergic
(*Note* **two** *drug therapy*)

1. Clindamycin (Cleocin) 900 mg IV q8h [B]
   PLUS

1. Ciprofloxacin (Cipro) 400 mg IV q12h [C]
2. TMP/SMX (Bactrim, Septra) 5 mg/kg IV q12h based on TMP [C;D in 3rd trimester]

Breast Infections

A. Mastitis
Note: Continue nursing to decrease duration of symptoms.

1. Cephradine (Velosef) 500 mg PO qid [B]
2. Cephalexin (Keflex) 500 mg PO qid [B]
3. Dicloxacillin 500 mg PO qid [B]
4. Clindamycin (Cleocin) 300 mg PO qid [B]

Course: 10–14 days
Organism: *Staphylococcus aureus*

B. Breast Abscess
Notes:

1. Incision and drainage usually required.
2. Discontinue nursing.
3. Treat mild cases with oral regimen as listed for Mastitis, above.

1. Cefazolin (Ancef) 1 gram IV q 8 hours [B]
2. Nafcillin 2 grams IV q 4 hours [B]
3. Vancomycin (Vancocin) 15 mg/kg IV q 12 hours (max 1 gram/dose; monitor serum levels) [C]

Organism: *Staphylococcus aureus*

Cellulitis

A. UNCOMPLICATED

Note: Consider initiating outpatient therapy with cefazolin (Ancef) 1–2 g IV/IM. [B]; if cellulitis is severe, schedule wound check in 24 h.

1. Cephradine (Velosef) 500 mg PO qid [B]
2. Cephalexin (Keflex) 500 mg PO qid [B]
3. Dicloxacillin 500 mg PO qid [B]
4. Cefadroxil (Duricef) 500 mg PO bid [B]

5. Clindamycin (Cleocin) 300 mg PO qid [B]

Course: 10–14 days
Organisms: *Staph.* and *Strep.* sp.

Infected Lacerations

A. Non-Contaminated   Most infected lacerations are due to Staphylococcal and Streptococcal species and should be treated the same as Cellulitis. Lacerations contaminated by fresh or brackish water have a high incidence of infections by *Aeromonas* and should be treated as outlined below.

B. Contaminated (fresh or brackish water)

1. TMP/SMX DS (Bactrim DS, Septra DS) 1 tablet PO bid]C; D in 3rd trimester]
2. Ciprofloxacin (Cipro) 500 mg PO bid [C]
3. Ofloxacin (Floxin) 200 mg PO bid [C]
4. Norfloxacin (Noroxin) 400 mg PO bid [C]
5. Levofloxacin (Levaquin) 500 mg PO QD [C]

Course: 10–14 days
Organism: *Aeromonas hydrophilia*

B. COMPLICATED: CHRONIC, PERINEAL, OR INFECTIONS IN DIABETICS
Notes:

1. Consider initiating therapy with a long acting cephalosporin, e.g., cefonicid (Monocid) or ceftriaxone (Rocephin) 1–2 g IM/IV.
2. If cellulitis is moderate or severe, schedule a wound check in 24 h to assess need for admission.

1. Ciprofloxacin (Cipro) 500 mg PO bid [C] **PLUS** clindamycin (Cleocin) 300 mg PO qid [B]
2. Amoxicillin/clavulanate (Augmentin) 500 mg PO tid [B]

Course: 10–14 days
Organisms: gram negative rods, anaerobes, *S. aureus, Strep* sp.

Necrotizing Fasciitis

Regimen A (for "flesh-eating bacteria, gas gangrene, non-groin infections)

Clindamycin (Cleocin) 900 mg IV q 8 hours [B]
PLUS
Penicillin G 4 million Units IV q 4 hours [B]
OR (if penicillin allergic)
Vancomycin (Vancocin) 15 mg/kg IV q 12 hours (max 1 gram/dose; monitor serum levels) [C]
Organisms: Group A, C, G streptococci, *Clostridium* sp., polymicrobic anaerobes and aerobes

Regimen B (for Fournier's gangrene)
Metronidazole (Flagyl) 15 mg/kg IV loading dose (maximum 1 gram) then 7.5 mg/kg IV q 6 hours (max 500 mg/dose) [B; contraindicated 1st trimester]
PLUS
Ticarcillin/clavulanic acid (Timentin) 3.1 gm IV q 6 hours [B] **OR**
Ampicillin/sulbactam (Unasyn) 3 mGM IV q 6 hours [B] **OR**
Piperacillin/tazobactam (Zosyn) 3.375 gm IV q 6 hours [B]
Organisms: *E. coli, Klebsiella,* enterococci, *Bacteroides, Fusobacterium, Clostridium,* polymicrobic anaerobes and aerobes

Fungal Infections

Note: Many antifungal agents are contraindicated in patients taking terfenadine (Seldane) or Cisapride (Propulsid), as this combination may produce life-threatening dysrhythmias. Specific agents implicated at this time include ketoconazole, itraconazole, and fluconazole (at doses of 400 mg/day), but the provider is urged to consult the PDR prior to prescribing these agents.

A. CANDIDA (CUTANEOUS)

1. Clotrimazole 1% cream (Lotrimin, Mycelex)—apply to rash tid–qid [B]
2. Miconazole 2% cream (Monistat-Derm)—apply to rash tid–qid [generally accepted as safe in pregnancy]
3. Nystatin cream (Mycostatin)—apply to rash tid–qid [A]
4. Amphotericin B 3% cream (Fungizone)—apply to rash tid–qid [B]

Course: 14 days

B. CANDIDA (ORAL THRUSH) (NOT AIDS PATIENTS)

1. Fluconazole (Diflucan) 200 mg PO single dose or 100 mg/day for 5 days [C]
2. Itraconazole (Sporanox) oral solution 200 mg (20 mL) PO qd without food for 7 days [C]
3. Nystatin (Mycostatin) 500,000 U swish and swallow qid **OR** two 500,000 U tabs PO tid [B]
   Infant dose: 1 mL each buccal mucosa qid [B]
4. Clotrimazole (Mycelex) 10 mg troche–dissolve in mouth 5 times/day [B]

Course: 14 days (except fluconazole and itraconazole as listed)

C. TINEA CAPITIS

1. Terbinafine (Lamisil) 250 mg PO qd for 2–3 weeks [B]
2. Itraconazole (Sporanox) 3–5 mg/kg per dose PO qd for 30 days [C]
3. Ketoconazole (Nizoral) 200 mg PO qd for 30 days [C]
   Children: 3.3–6.6 mg/kg PO qd for 30 days [C] (monitor for hepatotoxicity)

D. TINEA CRURIS (JOCK ITCH), PEDIS (ATHLETES FOOT), OR CORPORIS

1. Clotrimazole 1% cream (Lotrimin, Mycelex)—apply to rash bid [B]
2. Miconazole 2% cream (Monistat-Derm)—apply to rash bid [generally accepted as safe in pregnancy]
3. Ketoconazole 2% cream (Nizoral)—apply to rash qd [C]

Course: 2–3 weeks or 1 week after itching gone

For severe or refractory infections

1. Ketoconazole (Nizoral) 200 mg PO qd for 4 weeks minimum [C] (monitor for hepatotoxicity) **OR**
2. Fluconazole (Diflucan) 150 mg PO once per week for 1–4 weeks (not FDA approved for this indication) [C]

E. TINEA UNGUIUM (ONYCHOMYCOSIS)

Fingernails

1. Terbinafine (Lamisil) 250 mg PO qd for 6 weeks [B]
2. Itraconazole (Sporanox) 200 mg PO bid for 1 week/month for 2 months [C]

Toenails

1. Terbinafine (Lamisil) 250 mg PO qd for 12 weeks [B]
2. Itraconazole (Sporanox) 200 mg PO qd for 3 months [C]

F. TINEA VERSICOLOR

1. Fluconazole (Diflucan) 400 mg PO single dose [C]
2. Ketoconazole (Nizoral) 400 mg PO single dose **OR** 200 mg PO QD for 7 days (monitor for hepatotoxicity; not FDA approved for this use) [C]
3. Ketoconazole 2% cream (Nizoral) apply to rash qd for 2 weeks [C]
4. Itraconazole (Sporanox) 400 mg PO qd for 3–7 days [C]
5. Selenium sulfide (Selsun) 2.5% lotion—apply as lather, leave for 10 minutes, then wash off. Apply qd for 7 days [C]

Herpes Simplex

A. BELL'S PALSY
(*Treatment considered optional by some authorities*)
Acyclovir (Zovirax) 400 mg PO 5 times a day for 10 days [C]
PLUS/MINUS
Prednisone 30 mg PO bid for 5 days [C]

B. GENITAL
See Sexually Transmitted Diseases, General Genital Infections.

Herpes Zoster (Shingles)

A. NORMAL HOST

Notes:

1. Above recommendations most effective if started within 3 days of onset of rash.
2. Patients with lesions in multiple dermatomes may require admission and IV therapy (see dose under *Immunocompromised host*, below).

1. Acyclovir (Zovirax) 800 mg PO 5 times a day for 7–10 days [C]
2. Famciclovir (Famvir) 500 mg PO tid for 7 days [B]
3. Valacyclovir (Valtrex) 1000 mg PO tid for 7 days [B], plus/minus prednisone 30 mg PO bid for 5–7 days.

B. IMMUNOCOMPROMISED HOST

Acyclovir (Zovirax) 10–12 mg/kg IV q8h; decrease to 7.5 mg/kg in elderly patients (each dose infused over 1 h) [C]

Impetigo

1. Dicloxacillin 12–25 mg/kg/day PO divided qid [B]
   Easy dose: 20 mg/kg/day = 5 mg/kg/dose PO qid
   Maximum: 500 mg/dose
   Available in suspension of 62.5 mg/5 mL
2. Cephalexin (Keflex) 25–50 mg/kg/day PO divided qid [B]
   Easy dose: 40 mg/kg/day = 10 mg/kg/dose PO qid
   Maximum: 500 mg/dose
   Available in suspensions of 125 mg and 250 mg/5 mL
3. Cephradine (Velosef) 25–100 mg/kg/day PO divided qid [B]
   Easy dose: 40–80 mg/kg/day = 10–20 mg/kg/dose PO qid
   Maximum: 500 mg/dose
   Available in suspensions of 125 mg and 250 mg/5 mL
4. Mupirocin 2% ointment (Bactroban)—apply to lesion tid for 3–5 days [B]
5. Erythromycin ethyl succinate (EES) 30–50 mg/kg/day PO divided qid [B]
   Easy dose: 40 mg/kg/day = 10 mg/kg/dose PO qid
   Maximum: 500 mg/dose
   Available in suspensions of 200 mg and 400 mg/5 mL
6. Azithromycin (Zithromax) 10 mg/kg PO initial dose, then 5 mg/kg/day for 4 days [B]
   Maximum: 500 mg on day 1 and 250 mg on days 2–5
   Available in suspensions of 100 mg and 200 mg/5 mL
7. Clarithromycin (Biaxin) 7.5 mg/kg/dose PO bid [C]
   Maximum: 500 mg
   Available in suspensions of 125 mg and 250 mg/5 mL

Course: 10 days (except mupirocin and azithromycin as noted)
Organisms: group A *Strep* (honey-crusted lesions); *S. aureus* (bullous lesions)

Orbital (Postseptal) and Periorbital (Preseptal) Cellulitis

Notes:

1. Periorbital cellulitis is confined to the space anterior to the septum (i.e., eyelids).

2. The infection in orbital cellulitis is posterior to the septum and is characterized by proptosis, ophthalmoplegia, and visual loss.
3. All cases of orbital cellulitis and all but the mildest cases of periorbital cellulitis should be admitted.
4. In the absence of trauma, most cases of orbital and periorbital cellulitis are due to extension of sinus infections.

INPATIENT THERAPY: ORBITAL AND PERIORBITAL CELLULITIS
A. Pediatrics
Regimen A
(*Note* **two** *drug therapy*)
Ceftriaxone (Rocephin) 100 mg/kg IV qd [B]
Cefotaxime (Claforan) 40 mg/kg IV q6h [B]
Cefuroxime (Zinacef, Ceftin) 30 mg/kg IV q8h [B]
PLUS
Clindamycin (Cleocin) 10 mg/kg IV q6h [B]

Regimen B (if severe penicillin allergy): (*Note* **three** *drug therapy*)
Vancomycin (Vancocin) 10 mg/kg IV q6h (max 1 g/dose; monitor serum levels) [C]
PLUS
Aztreonam (Azactam) 30 mg/kg IV q8h [B]
PLUS
Clindamycin (Cleocin) 10 mg/kg IV q6h [B]

Regimen C
(*Note* **single** *drug therapy*)
Ampicillin/sulbactam (Unasyn) 50 mg/kg IV q6h [B]
Ticarcillin/clavulanic acid (Timentin) 50 mg/kg IV q6h [B]
Piperacillin/tazobactam (Zosyn) 100 mg/kg IV q8h [B]

B. Adults   Regimen A
Ampicillin/sulbactam (Unasyn) 3 g IV q6h [B]
Ticarcillin/clavulanic acid (Timentin) 3.1 g IV q6h [B]
Piperacillin/tazobactam (Zosyn) 3.375 g IV q6h [B]

Regimen B (if severe penicillin allergy): (*Note* **two** *drug therapy*)
Vancomycin (Vancocin) 15 mg/kg IV q12h (max 1 g/dose; monitor serum levels) [C]
PLUS
Clindamycin (Cleocin) 450–900 mg IV q8h [B]

OUTPATIENT THERAPY: PERIORBITAL CELLULITIS ONLY
Note: Only mild cases of periorbital cellulitis should be treated on an outpatient basis, and these require follow-up within 24 h. Initiate therapy with a dose of IV antibiotic listed above for inpatient treatment.

A. Children Less Than 5 Years Old

1. Amoxicillin/clavulanate (Augmentin) 80–90 mg/kg/day (as amoxicillin) PO divided bid or tid [B]
   Easy dose: 40 mg/kg/dose PO bid OR **30 mg/kg/dose PO tid**
   Maximum: 750 mg/dose bid or 500 mg/dose tid
   Available in suspensions of 125 mg and 250 mg amoxicillin/5 mL
2. Cefuroxime axetil (Ceftin) 20–30 mg/kg/day PO divided bid. [B]
   Easy dose: 20 mg/kg/day = 10 mg/kg/dose PO bid
   Maximum: 250 mg/dose
   Available in suspension of 125 mg/5 mL
   OR (if severe penicillin allergy)
3. Clarithromycin (Biaxin) 7.5 mg/kg/dose PO bid [C]
   Maximum: 500 mg
   Available in suspensions of 125 mg and 250 mg/5 mL

OUTPATIENT THERAPY: PERIORBITAL CELLULITIS ONLY
B. Adults and Children Age 5 Years and Older

1. Cephradine (Velosef) 500 mg PO qid
2. Cephalexin (Keflex) 500 mg PO qid
3. Dicloxacillin 500 mg PO qid
4. Cefadroxil (Duricef) 500 mg PO bid
5. Clindamycin (Cleocin) 300 mg PO qid
6. Amoxicillin/clavulanate (Augmentin) 500/125 mg PO tid OR 875/125 mg PO bid [B]

Course: 10–14 days
Organisms: *H. influenzae* (pediatrics), *Staphylococcus aureus, S. epidermidis, Streptococcus pneumoniae, Streptococcus* sp., *M. catarrhalis*, anaerobes

Varicella Zoster (Chickenpox)

Note: Start therapy within 24 h after onset of rash.

A. NORMAL HOST
Notes:

1. Children 2–12 years old are not routinely treated.
2. Acyclovir (Zovirax) 800 mg PO qid or 20 mg/kg/dose, for adults and children >12 years old for 5 days [C]
3. If pregnancy in 3rd trimester or evidence of pneumonia, consider admission and IV therapy (see dose under *Immunocompromised host*, below).

B. IMMUNOCOMPROMISED HOST
Acyclovir (Zovirax) 10–12 mg/kg IV q8h; decrease to 7.5 mg/kg in elderly patients (each dose infused over 1 h) [C]

TICK-BORNE DISEASES

Lyme Disease

A. STAGE I (EARLY)—ERYTHEMA CHRONICUM MIGRANS

1. Doxycycline (Vibramycin) 100 mg PO bid [D]

If pregnant

1. Amoxicillin (Amoxil) 500 mg PO tid [B]
2. Cefuroxime axetil (Ceftin) 500 mg PO bid [B]
3. Clarithromycin (Biaxin) 500 mg PO bid [C]

In children <8 years old

1. Amoxicillin (Amoxil) 20–50 mg/kg/day PO divided tid [B]
   Easy dose: 30 mg/kg/day = 10 mg/kg/dose PO tid
   Maximum: 250 mg/dose
   Available in suspensions of 125 mg and 250 mg/5 mL
2. Cefuroxime axetil (Ceftin) 20–30 mg/kg/day PO divided bid [B]
   Easy dose: 20 mg/kg/day = 10 mg/kg/dose PO bid
   Maximum: 250 mg/dose
   Available in suspension of 125 mg/5 mL
3. Clarithromycin (Biaxin) 7.5 mg/kg/dose PO bid (*for severe penicillin allergy*) [C]
   Maximum: 500 mg/dose
   Available in suspensions of 125 mg or 250 mg/5 mL

Course: 21 days

B. STAGE II OR III—ARTHRITIC, NEUROLOGIC, CARDIAC SYMPTOMS

1. Ceftriaxone (Rocephin) 2 g IV qd for 21 days [B]
2. Consider doxycycline (Vibramycin) 100 mg PO bid [D] **OR** amoxicillin (Amoxil) 500 mg PO tid [B] in very mild cases

Course: 30 days.
Organism: *Borrelia burgdorferi* transmitted via ixodid ticks

Rocky Mountain Spotted Fever

1. Doxycycline (Vibramycin) 100 mg PO bid [D]
2. Chloramphenicol (Chloromycetin) 500 mg PO qid [C]

In children <8 years old and pregnant women

1. Chloramphenicol (Chloromycetin) 50 mg/kg/day PO divided qid [C]

Course: 7 days minimum or until 2 days after fever resolution
Organism: *Rickettsia rickettsi* transmitted via ixodid ticks

ADVERSE EFFECTS AND PRESCRIBING HINTS

Cephalosporins

- **Cephalexin/Cephradine:** Take with meals. May cause nausea and diarrhea.

Erythromycins

- May cause stomatitis, nausea, diarrhea, transient hearing loss with large doses.
- Erythromycin estolate may cause cholestatic hepatitis in adults; this risk increases in pregnancy.
- May interfere with hepatic metabolism of other medications, especially warfarin, phenytoin, valproate, carbamazepine, theophylline, and digoxin.
- Do not prescribe concurrently with terfenadine (Seldane).
- **Erythromycin base:** Take on empty stomach.
- **Non-base erythromycin (e.g., EES):** Take with meals.

Metronidazole

- May cause nausea, vomiting, headache, metallic taste, disulfiram (Antabuse)-like reaction with alcohol.
- Do not use in first trimester of pregnancy.
- It can alter metabolism of warfarin, phenytoin, and phenobarbital.

Penicillins

- May cause nausea and diarrhea (about 10%) and candidal vaginitis in women (about 40%).
- Skin rashes may appear with all penicillins especially in patient with mononucleosis (>50%).
- **Amoxicillin:** Take with meals.
- **Ampicillin:** Take on empty stomach.
- **Dicloxacillin:** Take on empty stomach.
- **Penicillin:** Take on an empty stomach. IV Penicillin is most often supplied as the potassium salt. Monitor for hyperkalemia when giving high doses of penicillin G.
- **Amoxicillin/clavulanate:** Take with meals to reduce GI side effects.

Quinolones

- Contraindicated in patients under 18 years of age or pregnant/nursing mothers (see Table 149-1).
- Avoid antacids.
- May cause increase in theophylline levels, increases warfarin levels; alters phenytoin levels ($\uparrow$ or $^-$).

TABLE 149-1 Functional Classification of Quinolones

Tetracyclines

- Avoid dairy products and antacids.
- Do not use in children less than 8 years old or pregnant/nursing mothers.
- May lead to photosensitivity, nausea, cramps or diarrhea.
- **Tetracycline:** Take on empty stomach.

Trimethoprim/Sulfamethoxazole (TMP/SMX)

- May take on empty stomach or with meals.
- May cause rash, nausea, or vomiting.
- May cause acute hemolytic anemia in patients with G6PD deficiency.
- Blood dyscrasias (e.g., thrombocytopenia, megaloblastic anemia, neutropenia) are dose-related.
- TMP/SMX is pregnancy category C in trimesters 1 and 2, and category D in 3rd trimester. Trimethoprim interferes with folic acid metabolism and therefore should be used in the 1st and 2nd trimesters only if the potential benefit outweighs the potential risk. TMP/SMX is contraindicated in the 3rd trimester because it can cause kernicterus.
- Increases phenytoin levels.

DRUG INTERACTIONS

In this section, we have attempted to identify some of the most common or potentially dangerous drug interactions. This list is in no way all-inclusive, and the prescriber is reminded to utilize the PDR and other sources for more complete listings.

Ciprofloxacin–Norfloxacin

- Theophylline—increased theophylline levels due to decreased metabolism.
- Warfarin (Coumadin)—although many consider this interaction weak, warfarin levels may increase due to decreased metabolism.
- Alters phenytoin levels ($\uparrow$ or $^-$)

Erythromycin

- Terfenadine (Seldane)—concomitant use may produce cardiac dysrhythmias/sudden death.
- Theophylline—increased theophylline levels due to decreased metabolism.
- Warfarin (Coumadin)—increased warfarin levels due to decreased metabolism.
- Increases phenytoin and valproate levels.

Ketoconazole–Fluconazole–Itraconazole

- Terfenadine (Seldane)—concomitant use may produce cardiac dysrhythmias/sudden death.
- Warfarin (Coumadin)—increased warfarin levels due to decreased metabolism.
- Cisapride (Propulsid)—concomitant use may produce cardiac dysrhythmias/sudden death.

Rifampin

- Theophylline—decreased theophylline levels due to increased metabolism.
- Warfarin (Coumadin)—decreased warfarin levels due to increased metabolism.

Warfarin (Coumadin)

Many antibiotics interfere with Warfarin (Coumadin) metabolism and should be used, if at all, with extreme caution in patients on anticoagulation therapy. These antibiotics include

- ciprofloxacin (many consider this interaction negligible)—potentiates warfarin activity
- dicloxacillin and nafcillin—inhibit warfarin activity
- erythromycin—potentiates warfarin activity
- fluconazole—potentiates warfarin activity
- ketoconazole—potentiates warfarin activity
- metronidazole—potentiates warfarin activity
- miconazole—potentiates warfarin activity
- rifampin—inhibits warfarin activity
- tetracycline/doxycycline—potentiates warfarin activity
- trimethoprim/sulfamethoxazole (Bactrim, Septra)—potentiates warfarin activity

Antiobiotics compatible with warfarin include most oral cephalosporins, penicillins (except dicloxacillin and nafcillin), and clindamycin. Consider ciprofloxacin with monitoring of PT/INR.

Immunosuppressants

Multiple drugs interact with immunosuppressant medications, especially with cyclosporin. Review interactions or contact the transplant physician prior to prescribing new antibiotics to patients on immunosuppressive therapy.

Anticonvulsants

Multiple antibiotics interfere with metabolism of anticonvulsants, especially with phenytoin. Review potential drug interactions before prescribing new antibiotics to

patients on anticonvulsant therapy.

CEPH DU JOUR

Robert A. Brownstein

Viral illnesses are among the most common reasons that people come to an emergency department. Although some may be trivial, such as the common cold, others are life threatening, such as viral encephalitis, hemorrhagic fever viruses, and HIV, and still others are capable of causing chronic diseases and may contribute to the development of certain malignancies. Effective therapies for some viruses are now available, with more drugs and vaccines undergoing clinical trials. Influenzaviruses and the herpesvirus family are discussed in this chapter.

INFLUENZA A AND B

Influenza viruses are single-stranded RNA viruses of the orthomyxovirus family. There are three types—A B, and C—as determined by their genetic material. Type C does not cause significant human disease and does not warrant further discussion. The virions have surface glycoproteins that contain either hemagglutinin or neuraminidase activity. Different subtypes of influenza (i.e., influenza A-H1N1 versus influenza A-H2N2) have large differences between the hemagglutinin (H) or neuraminidase (N) molecules, whereas different strains of the same subtype have minor differences in the H or N molecules.

Antigenic drift is minor mutations in the RNA genome of either the H or N molecule causing a change in antigenicity. Influenza A has much more frequent drift than B, and H more than N, so that influenza A and H molecules show virtually annual changes accounting for decreased antigenicity and facilitating annual epidemics.

Antigenic shift occurs by genetic reassortment within a host infected by two different influenzaviruses, producing a new virus with little or no antigenic similarity to the old viruses. The population lacks immunity against the new virus, but has high levels of immunity against the old virus, giving the new virus a competitive advantage. This type of shift has occurred three times with hemagglutinin and twice with neuraminidase in this century (thus, we have H1, 2, and 3, and N1 and 2). Antigenic shifts are responsible for the flu pandemics, such as in 1918.

Epidemiology

Flu occurs worldwide, in the winter months in the northern and southern hemispheres, and sporadically year round in the tropics. In the United States, flu generally occurs from November to April. Influenza is spread by droplets generated by coughing. During epidemics, attack rates are in the 20 to 30 percent range, and may be as high as 50 percent during pandemics.[1] The Centers for Disease Control and Prevention and local health departments track influenza activity monthly. Influenza A attack rates are higher for children than for adults or the elderly, but the disease carries a higher mortality rate for young adults and especially for the elderly. Influenza B produces a similar illness with high attack rates for children and lower attack rates for adults, probably because of preexisting immunity due to a lower rate of antigenic drift.

After exposure, the incubation period is usually about 2 days. Viral shedding (contagiousness) starts approximately 24 h before the onset of symptoms, rises to peak levels within 48 h, and then declines over the next 3 to 7 days. In young children. viral shedding is prolonged.

Pathophysiology

Following exposure, the virus enters the columnar cells of the respiratory tract epithelium. Host defenses at this point include mucociliary clearance, nonspecific proteins and, if present, specific immunoglobulin A (IgA) molecules. The invaded epithelial cells release large numbers of virions before cell death; thus, large numbers of virions are available for spread with respiratory secretions. Influenza viral particles are rarely found outside the respiratory tract.

Clinical Features

Classic flu symptoms include fever of 38.6° to 39.8°C (101° to 103°F), with chills or rigor, headache, myalgia, and generalized malaise. Respiratory symptoms include dry cough, rhinorrhea, and sore throat, frequently with bilateral tender, enlarged cervical lymph nodes. The onset of symptoms is typically rapid and dramatic; many patients recall the exact time of onset. Ocular symptoms include eye pain, light sensitivity, tearing, and pain with lateral gaze. Myalgias and arthralgias, but not arthritis, are extremely common. The myalgias often affect back muscles in adults and calf muscles in children. Almost half of affected children have gastrointestinal symptoms, but these are unusual in adults. The elderly do not usually have classic symptoms and may have with only fever, malaise, confusion, and nasal congestion.

The fever generally lasts 2 to 4 days, followed by rapid recovery from most of the systemic symptoms. Cough, fatigue, and occasionally depression may last for several weeks following recovery.

Diagnosis

Traditionally, diagnosis has been through the use of viral cultures or serologic tests, which do not yield results for several days. These tests are not useful in individual patients except to confirm diagnosis after recovery from acute illness, but they do provide useful epidemiologic data. Some studies have shown that a clinical diagnosis of flu during a known outbreak has an accuracy of approximately 85 percent,[2,3] but bacteremia should also be considered in patients with rigor and myalgias. Newer rapid antigen tests are becoming available that may change the approach to flulike illnesses. These tests will enable rapid diagnosis and institution of antiviral agents, and may decrease the empiric use of antibiotics. One commercially available test requires a little more than 1 h to perform and lists a sensitivity of 50 to 70 percent, with a specificity of 93 to 100 percent.[4]

Complications

The complications of acute influenza infection include primary influenza pneumonitis, secondary bacterial pneumonia, croup, exacerbation of chronic obstructive

pulmonary disease, and Reye's syndrome. Other rare complications include Guillain-Barré syndrome, myocarditis, and pericarditis.

Primary influenza pneumonitis occurs most commonly in those with preexisting cardiac or pulmonary disease, but in most large outbreaks it has been seen in previously healthy young adults. The initial symptoms are typical flulike symptoms with progression to cough and dyspnea. There is significant hypoxia. Radiologic findings are bilateral infiltrates similar to Adult Respiratory Distress Syndrome (ARDS). Bacterial cultures and Gram stains are negative, and antibiotics do not help. Treatment is primarily supportive. Most clinicians would support the use of anti-influenza agents, but there are no good studies demonstrating efficacy. The mortality rate of influenza pneumonitis remains high.

Secondary pneumonia is clinically similar to pneumonia occurring without antecedent flu. This complication presents 1 to 2 weeks after the flu, with a brief well period in between. Secondary pneumonia is most common in the elderly and in those with diabetes mellitus or preexisting cardiopulmonary disease. Treatment is initially with broad-spectrum antibiotics and pulmonary support, with narrowing of antibiotic coverage when culture results become available.

Reye's syndrome has been associated with influenza B and varicella zoster infections and with the use of aspirin. [5] It occurs primarily in children between the ages of 2 and 16 years and begins with vomiting and progresses to altered mental status or coma. There is hepatomegaly due to fatty infiltration of the liver. There are elevated levels of liver enzymes (alanine aminotransferase and aspartate aminotransferase), elevated ammonia levels, and an elevated prothrombin time. Hypoglycemia is common. The case fatality rate is from 10 to 40 percent. The American Academy of Pediatrics has recommended that aspirin not be used for fevers caused by influenza or varicella. [6,7]

Treatment

Two antiviral drugs—amantadine and rimantadine—are currently approved for the treatment of influenza A. Neither has activity against influenza B. For maximal effectiveness, both need to be started within 48 h of onset of symptoms and can reduce the duration of systemic symptoms by 1 to 2 days. The dose is 100 mg bid for 5 days for both drugs. Amantadine is cleared renally, and the dose needs to be adjusted in the elderly and in renal insufficiency. The recommended dose for persons older than age 65 is 100 mg qd. Amantadine causes an increase in seizure activity in patients with a preexisting seizure disorder. Rimantadine is cleared hepatically, and a 50 percent dose reduction is recommended in severe liver dysfunction. Rimantadine has a significantly lower incidence of central nervous system (CNS) side effects than does amantadine. Neither drug should be used during pregnancy. Both amantadine and rimantadine can be used in children older than the age of 1 year, although only rimantadine is officially approved for prophylaxis in children. Amantadine costs approximately $20 for a course of therapy versus about $140 for a course of rimantadine in adults. A new medication—zanamavir—appears promising in clinical trials and has activity against both influenza A and B. [8]

Prophylaxis

The flu vaccine is formulated annually and contains two strains of influenza A and one of influenza B. It is 70 to 90 percent effective in preventing illness in those under age 65. For patients over age 65 and not in chronic care facilities, it is 30 to 70 percent effective in preventing hospitalizations due to flu and pneumonia. For those in chronic care facilities, it is 50 to 60 percent effective in preventing hospitalizations due to flu and pneumonia, and approximately 80 percent effective in preventing excessive numbers of deaths due to flu and pneumonia. [9] The vaccine is recommended for all persons over age 65; for residents of chronic care facilities; for adults and children with chronic cardiopulmonary disease; for persons with diabetes mellitus and other chronic metabolic diseases, renal disease, or hemoglobinopathies; and for the immunosuppressed and health care workers. Children and teenagers who require aspirin therapy should be immunized because of the risk of Reye syndrome. Women who will be pregnant during flu season should be immunized. The vaccine is safe for pregnant and lactating women. A whole virus vaccine is used in adults, whereas a split virus vaccine is used in children younger than age 12. The only contraindication to immunization is known allergy to egg protein or other vaccine components.

Amantadine and rimantadine are as effective as the vaccine in preventing flu, when used at the same doses as just described but for a prolonged duration. Consideration should be given to instituting chemoprophylaxis in a chronic care facility where flu has been definitively diagnosed, regardless of vaccination status of patients. The medicines should be given for at least 14 days, and then until the outbreak has subsided for a full week. For those at high risk who can not be vaccinated, a 6- to 8-week course of chemoprophylaxis during peak flu season is indicated. Postexposure prophylaxis consists of immunization followed by 14 days of chemoprophylaxis. [8]

HERPESVIRUSES

The herpesviruses are a ubiquitous class of enveloped DNA viruses that cause an expanding list of human illness. The herpesviruses all have the ability to dwell in the host as a lifelong latent infection and may cause clinical disease or recurrent disease at a time distant from the primary infection. Some have been shown to be carcinogenic. Each herpesvirus has distinguishing clinical characteristics and will be discussed individually. Human herpesviruses 6 and 7, both which cause roseola, and human herpesvirus 8, implicated in Kaposi sarcoma, are not discussed in this chapter. As a class, the herpesviruses are transmitted by close contact, since they are unable to survive in the environment and are unable to penetrate intact skin. The varicella zoster virus (VZV) can be spread via aerosolized particles as well as by close contact. Most transmission of the herpes simplex virus (HSV) and of Epstein-Barr virus (EBV) occurs during asymptomatic shedding. Viruses discussed below are HSV, VZV, EBV, and cytomegalovirus (CMV).

HERPES SIMPLEX VIRUSES 1 AND 2

Epidemiology

HSV has been found in all populations throughout the world. Transmission is via contact of infected secretions (saliva or genital) with mucous membranes or with open skin. There is serologic evidence of exposure to HSV-1 in most persons by the time of puberty, and the rates are higher among lower socioeconomic classes. HSV-2 is spread primarily sexually, and its rates are variable among different adult populations, depending on sexual behavior.

Pathophysiology

After exposure, the virus replicates locally in the epithelial cells, causing lysis of the infected cells and producing an inflammatory response. This response results in the characteristic rash of HSV, which is indistinguishable from the rash of VZV. The rash consists of small thin-walled vesicles on an erythematous base. Continued replication may result in viremia in immunocompromised hosts and rarely in normal hosts. Following primary infection, the virus becomes latent in a sensory nerve ganglion.

Clinical Features

ORAL HSV   HSV-1 primarily causes oral lesions, but may cause genital infection. HSV-2 causes identical lesions, but primarily genital, and may cause oral lesions. The primary oral infection of HSV-1 is often mild or asymptomatic. In children under age 5, it may present as a pharyngitis or gingivostomatitis associated with fever and cervical lymphadenopathy. The lesions are distributed throughout the mouth, unlike the limited posterior involvement of herpangina. Admission of the young may be necessary due to poor oral intake and dehydration. In teenagers and young adults, there may simply be a posterior pharyngitis or tonsillitis. The primary lesions generally last 1 to 2 weeks. The diagnosis is largely clinical. Viral cultures take days to weeks to be performed and thus are of little use in an emergency department setting. The use of intravenous (IV) acyclovir at a dose of 5 mg/kg has been recommended for severe gingivostomatitis that requires admission and IV hydration. [10] Oral acyclovir has been shown to shorten the duration of symptoms in children if begun within the first 72 h of symptoms. No treatment other than oral hygiene is required for mild or moderate disease.

Recurrent oral lesions occur in 60 to 90 percent of infected individuals and are usually milder and generally occur on the lower lip at the outer vermilion border, but considerable variation exists, with individuals usually having recurrences at the same site as prior recurrences. The recurrences are often triggered by local trauma, sunburn, or stress. The outbreaks are frequently preceded by prodromal symptoms of local adenopathy and pain or tingling. The lesions usually follow the prodrome within the first 48 h and may last for up to 10 days, but are usually crusted over by 48 h. Treatment of recurrent oral herpes labialis with oral acyclovir 400 mg five times per day in adults shortens duration of symptoms. Topical acyclovir is ineffective. Topical pencyclovir applied every 2 h for 4 days shortens duration of symptoms [11] and has recently been approved for this indication. In patients with severe or frequent recurrences, prophylaxis with oral acyclovir can reduce outbreaks

by 50 to 75 percent.[10]

GENITAL HSV   HSV-1 and 2 cause identical genital infections, with HSV-2 causing the majority. These are covered in detail in the section on sexually transmitted diseases. A few items of importance are presented here. Recurrent genital lesions carry a small threat of intrauterine infection in pregnant patients, as does primary genital HSV (1 or 2),[12] and initiation of oral acyclovir and consultation with an obstetrician or perinatologist and follow-up within 72 h are recommended. Cesarean section is recommended for all women with active lesions present when labor commences, whether primary or recurrent.[13] Primary lesions carry a higher risk of transmission to the neonate.[14]

OCULAR HSV   HSV infections of the eye can lead to corneal blindness and are usually caused by HSV. An ulcerative keratitis is the most common manifestation. Herpetic vesicles can be seen on the conjunctiva or on the lid margin as a blepharitis. There is a regional adenopathy. Fluorescein staining may show a diagnostic dendritic ulceration of the cornea. Due to the threat of permanent vision loss, consultation with an ophthalmologist is mandatory and antiviral therapy should be begun immediately. Superficial keratitis usually heals completely in several weeks. Recurrent ocular infections may involve the deeper structures, with a high risk of visual loss, and, if deeper structures are involved, immediate consultation with an ophthalmologist and the administration of IV acyclovir is appropriate. Following the acute treatment, long-term treatment with acyclovir can reduce recurrences of ocular HSV.[15]

ENCEPHALITIS   Herpes simplex encephalitis, which is usually caused by HSV-1, is rare, but is one of the most common types of viral encephalitis in the United States. The mechanism of entry into the CNS is not definitely known, but is believed to be along neural routes. The temporal lobes are the major targets, and temporal abnormalities seen by computed tomography (CT), magnetic resonance imaging (MRI), or electroencephalography, though not always present, increase the likelihood of HSV encephalitis.

Clinically, there may be a preceding viral-like illness or the onset may be sudden. There may be no cutaneous manifestation of an HSV infection. There may be headache, fever, and altered mental status, indicated by speech disturbances or focal seizures. Temporal lobe seizures may present as olfactory hallucinations. The cerebrospinal fluid (CSF) findings are nonspecific showing an elevated white blood cell count, with mononuclear predominance. Cultures are usually negative for HSV. Conclusive diagnosis is made by biopsy, with either culture or direct antibody testing. HSV DNA identified in the CSF by polymerase chain reaction has been used, but the sensitivity and specificity have not been well defined and a negative result does not rule out HSV encephalitis. For untreated persons, the mortality rate is close to 70 percent. Treatment should be initiated in the emergency department if the diagnosis is suspected. Treatment is with IV acyclovir at 10 mg/kg/q8.

BELL'S PALSY   HSV may affect the peripheral branches of the cranial nerves. HSV-1 is a frequent cause of Bell's palsy, which has classically been described as an idiopathic palsy of the peripheral branch of cranial nerve VII (CN VII). It occurs equally among men and women and occurs most frequently in the middle aged and has been reported in children. CN VII controls motor function of the facial muscles and the stapedius muscle, taste sensation of the anterior two-thirds of the tongue, and lacrimal gland secretory function. Clinical features include facial hemiplegia or hemiparesis, taste disturbance in greater than 50 percent of the cases, decreased blinking, variably dry eyes, or increased tearing, jaw or face pain, as well as numbness of the face and or neck in 60 percent of patients.[16] The diagnosis is made by definite findings of peripheral nerve VII involvement and exclusion of other treatable causes. The motor control of the muscles of the forehead are from bilateral motor cortices to the CN VII motor nuclei, so central CN VII lesions spare the forehead, but cause unilateral weakness of the lower face. A peripheral lesion results in paralysis of the forehead, along with the face. Attempting to close the eye on the affected side results in an upward gaze (Bell's phenomenon). Paralysis of the stapedius muscle results in hyperaccusis on the affected side.

Ruling out of other conditions is important in making the diagnosis. The results of a detailed examination of the cranial nerves should be normal except for the aforementioned findings associated with CN VII. The findings on examination of the ear, tympanic membrane, mastoid, and parotid gland should be normal in order to make a diagnosis of Bell's palsy. A CN VII palsy in association with otitis media, mastoiditis, or parotitis is a potential ear, nose, and throat (ENT) emergency and should prompt immediate consultation. The presence of vesicles on the tympanic membrane or in the ear canal is diagnostic of the Ramsay Hunt syndrome and is discussed in the section on VZV. A history of chronic ear infections, prior ear surgery, or tumor or recent head trauma excludes a diagnosis of Bell's palsy. If the presentation and examination are consistent with Bell's palsy, imaging of the CNS (CT or MRI) is not indicated, but if there are atypical features, recent trauma, or doubt, then imaging is recommended along with ENT consultation. The differential diagnosis includes stroke, tumor, atypical Guillain-Barré syndrome, and Lyme disease, especially if in endemic areas and if bilateral.

Treatment consists of prednisone for anti-inflammatory effect at 60 mg PO qd or 1 mg/kg/day for 5 days and then tapered over the next 5 days, along with acyclovir 400 mg five times per day for 10 days and follow-up with either ENT or neurologic consultation.[17] The prognosis is generally good for total recovery, but patients with total paralysis are at increased risk of long-term or permanent paralysis and should be seen in follow-up within 2 to 3 days, and patients with incomplete paralysis instructed to return if the weakness becomes total paralysis. Among patients with incomplete paralysis, 6 percent will have residual weakness at 1 year. Among the patients with complete paralysis at 1 year, 84 percent had total or good recovery, with 16 percent having poor to fair recovery.[18]

Eye care is important in preventing damage due to impaired blinking and decreased tearing. Artificial tears should be used frequently during the day at any sign of dryness or every 2 h. At night, a lubricating ointment with or without an eye patch should be used. Care of the eye is the most important therapeutic intervention that can be made by emergency physicians.

HERPETIC WHITLOW   Herpetic whitlow is a primary or recurrent HSV infection of the finger. HSV-1 is seen in children who autoinnoculate their fingers by putting them in their mouths during an episode of oral herpes. HSV-1 is also seen in health care workers who are exposed to infected oral secretions. HSV-2 is more common among adults due to digital/genital contact in the community. The disease is usually limited to a single digit. Herpetic whitlow is frequently painful and accompanied by axillary adenopathy. Vesicles, which may be recognizable early in the course of the disease, coalesce and may appear to contain pus, but actually contain necrotic epithelial cells causing the purulent appearance. Healing occurs spontaneously over 2 to 3 weeks if local wound care and pain control are used. Whitlow may be misdiagnosed as a paronychia and incised, which may delay healing or allow a secondary infection to occur. When incised, no purulent material will be expressed. For patients with frequent painful recurrences suppressive therapy with acyclovir may be effective.[10]

IMMUNOCOMPROMISE   Immunocompromised patients (those with organ transplants, HIV, etc.) are at increased risk of disseminated or severe typical and atypical HSV disease, usually resulting from reactivation of latent virus. HSV infection in immunocompromised patients may cause esophagitis, proctitis, colitis, and pneumonitis, as well as encephalitis. Definitive diagnosis is difficult without a biopsy of the affected tissue, because these patients generally all have latent HSV and are frequently shedding HSV in their secretions. Any evidence of disseminated or CNS disease mandates admission and IV acyclovir. The decision to admit or treat the immunocompromised on an outpatient basis with mucocutaneous HSV is based on severity of disease, reliability of the patient, and ability of the patient to stay hydrated; is made on a case-by-case basis; and should be made in conjunction with the patient's primary care provider. Additionally, patients with large areas of skin involvement by burns or eczema are at risk of severe or fatal infection although, most commonly, resolution will occur without treatment. Consultation and consideration for admission for these patients are recommended.

ANTIVIRAL DRUGS   There are three agents widely available for HSV: acyclovir (Zovirax and generic), famciclovir (Famvir), and valacyclovir (Valtrex). Only acyclovir is available in oral and IV forms, whereas the others are available only in an oral form. Famciclovir and valacyclovir are more active in vitro, but all have similar clinical efficacy.[7] Oral dosing regimens and comparative retail prices are listed in Table 150-1 (listed are retail prices for consumers from a single national chain in July 1998; current prices may vary considerably). Valacyclovir and famciclovir are pregnancy category B, used only if benefits to the patient outweigh the risk to the fetus. Acyclovir is pregnancy category C, but is generally considered safe in pregnancy. All three medications are indicated for recurrent genital HSV and shingles. Only acyclovir and valacyclovir are indicated for primary genital HSV. Acyclovir is also indicated in primary varicella (chicken pox). IV acyclovir is indicated for CNS or disseminated disease. Other uses of these drugs, such as in treating whitlow or severe oral disease, are off label and not well studied.

Disease	ANTIVIRAL DRUGS		
	Acyclovir (oral)	Valacyclovir	Famciclovir
Primary genital herpes Price*	200 mg 5X/day for 10 days $36.33	1 g bid for 10 days $88.00	Not indicated —
Recurrent genital herpes Price*	200 mg 5X/day for 5 days $18.00	500 mg bid for 5 days $35.00	125 mg bid for 5 days $32.00
Chickenpox Price*	800 mg qid for 5 days $64.00	Not indicated —	Not indicated —
Herpes zoster Price*	800 mg 5X/day for 10 days $129.00	1 g tid for 7 days $83.00	500 mg tid for 7 days $124.00

*Prices based on retail price to consumer at a single national chain in July 1998; current local prices may vary considerably.

TABLE 150-1   Oral Dosing Regimens and Comparative Retail Prices for Antiviral Drugs

HERPES ZOSTER: CHICKENPOX

Epidemiology

Herpes zoster virus (VZV and human herpesvirus 3) is the cause of chickenpox as a primary infection, which may reactivate later in life as zoster (shingles). Prior to the use of the varicella vaccine, 90 percent of primary infection occurred among children at age 10 years or younger, with the majority of these in children younger than age 3. Only approximately 10 percent of individuals over age 15 remain susceptible to VZV. Chickenpox is endemic, occurring year round, but there are annual epidemics in late winter and early spring. After exposure, attack rates are close to 80 percent among susceptible household contacts. The route of spread is presumed to be respiratory. Patients are infectious for approximately 48 h before the appearance of the rash until the vesicles are crusted over, and for about 4 to 5 days after the appearance of the rash.

Pathophysiology

After exposure, viral replication occurs at an unknown site, followed by a viremia. Viral replication in the skin results in degenerative changes in epithelial cells, leading to multinucleated giant cells in vesicles. The rash usually appears 14 to 15 days after exposure. The rash then fades, and the virus becomes latent in a dorsal root ganglion.

Clinical Features

In children, there is typically a prodrome of 1 to 2 days of low-grade fever and malaise, followed by the appearance of lesions on the face and trunk. The lesions initially are maculopapular and then vesicles with clear fluid on an erythematous base. The fluid quickly becomes turbid due to the accumulation of cellular debris. As the lesions continue to age, they scab over. The rash spreads centripetally to involve the extremities. Over the next several days, new lesions appear in crops. A hallmark of chickenpox is the presence of lesions in various stages. Accompanying the rash is fever up to 39.8°C (103°F), malaise, pruritus, and anorexia. The mortality rate among children is less than 2/100,000 cases and death is generally due to encephalitis. Varicella encephalitis is characterized by chickenpox accompanied by an altered level of consciousness, fever, vomiting, headaches, and seizures. Cerebellar ataxia is a more benign CNS complication characterized by ataxia, vomiting, tremor, and altered speech, with complete resolution within a month. Another serious potential complication is Reye syndrome, so parents should be instructed to avoid aspirin and aspirin-containing products.

In adults, the mortality rate of primary varicella infection approaches 30/100,000 cases, and the disease process is more severe and prolonged. Encephalitis may occur, but a more common life-threatening complication is VZV pneumonitis,[19] which presents with cough, tachypnea, and dyspnea approximately 4 days after the onset of illness. Chest x-rays reveal a diffuse pneumonitis. Women in the second or third trimesters of pregnancy are at higher risk of severe pneumonitis. Women in the immediate perinatal period are at increased risk of severe disease, as are neonates. Chickenpox during pregnancy can cause fetal anomalies.[7]

Treatment

Acyclovir is the only medication approved for active chickenpox. For previously healthy children, its benefit is small and, generally, care is supportive, with attention to skin care, including bathing and the use of antipruritic drugs. The American Academy of Pediatrics does not recommend the use of acyclovir in uncomplicated chickenpox in previously healthy children who are younger than age 12. Oral acyclovir is recommended for patients older than age 12 and those with chronic illnesses or on chronic salicylate therapy. For children, the dosage is 20 mg/kg PO qid for 5 days (maximal single dose, 800 mg); adults are given 800 mg PO qid for 5 days. For maximal benefit, acyclovir should be started within 24 h of development of the rash. All patients with varicella encephalitis or pneumonitis should be admitted for IV acyclovir. Treatment of pregnant or peripartum women who develop chickenpox should be discussed with an obstetrician or perinatologist, as some physicians will elect to admit for IV acyclovir. Neonates who develop chickenpox or whose mothers develop postpartum chickenpox should be admitted for IV acyclovir. Immunocompromised patients tend to have more severe disease and should be admitted for IV acyclovir.

Varicella zoster immune globulin (VZIG) is available to confer passive immunity to exposed susceptible adults or immunocompromised children and pregnant women. VZIG should also be given to any neonate with chickenpox or whose mother developed chickenpox within 5 days before delivery or 48 h after delivery.[7]

Varicella vaccine is now recommended for children who are age 1 year or older. It is also recommended for adults with either a reliable history of never having chickenpox or with serologic evidence of susceptibility. The vaccine is a live attenuated cell-free vaccine. Because it is a live vaccine, it is contraindicated in immunocompromised patients, household contacts of immunocompromised patients, and pregnant or lactating women.

HERPES ZOSTER: SHINGLES

Herpes zoster (shingles) is the reactivation of latent VZV infection. There is a lifetime incidence of almost 20 percent, with the majority of cases being among the elderly. It occurs only in people who have had chicken pox. After a single occurrence in an immunocompetent host, there is a 4 percent likelihood of a second occurrence.

The lesions of shingles are identical to those of chickenpox, but are limited to a single dermatome in distribution. Thoracic and lumbar dermatomes are most common. The cranial nerves may be affected as well, with the potential complications of herpes zoster ophthalmicus (HZO) and Ramsay Hunt syndrome. What triggers the reactivation is unknown. The disease begins with a prodrome of pain in the affected area for 1 to 3 days, followed by the outbreak of a maculopapular rash that quickly progresses to a vesicular rash. The course of the disease is usually around 2 weeks, but may persist for a full month.

HZO is due to involvement of the ophthalmic branch of CN V and is a vision-threatening condition. The Hutchinson sign (lesions on the tip of the nose) may be seen before ocular involvement is recognized, but its absence does not rule out HZO.[20] Ocular involvement can be seen in the presence of only a slight rash on the forehead. HZO induces a keratitis and may be followed by involvement of deeper structures. There is usually facial pain, regional adenopathy, and occasionally a red eye preceding the appearance of the rash. A dendriform corneal ulcer can often be identified with fluorescein staining. The presence of a skin rash helps differentiate HZO from ocular HSV. HZO or suspected HZO mandates an ophthalmologic consultation due to the threat to vision.

CN VII can also be affected. Involvement of the maxillary or mandibular branches can result in intraoral lesions. Involvement of the geniculate ganglion of CN VII results in Ramsay Hunt syndrome, which clinically presents as a facial palsy resembling Bell palsy with a unilateral motor weakness, loss of taste on the anterior two-thirds of the tongue, and vesicles in the ear canal or on the tympanic membrane (the only sites of CN VII cutaneous innervation). Ramsay Hunt syndrome has also been described as an infrequent cause of altered mental status in the elderly.[21] This is treated in the same fashion as Bell palsy. Immunocompromised patients should be admitted for IV acyclovir.

The most common complication of shingles is postherpetic neuralgia (PHN). This is uncommon in younger patients, but increases in frequency with age. The pain at times may be so severe as to be debilitating. Occasionally, the anterior horn cells become involved, causing a transient local weakness or paralysis, with these patients being particularly prone to severe pain. PHN occurs in 10 to 20 percent of all patients after an episode of acute zoster, but in up to 70 percent of patients aged 70 years or older. It generally resolves in 1 to 2 months, but may last greater than a year in some patients.

The treatment of zoster in the normal host is aimed at decreasing the risk of PHN, as the antivirals have a clinically small, but statistically significant, effect on the duration of the acute disease. Treatment should begin as soon as possible, and within 72 h of onset of disease for maximal benefit. The present literature shows that all three currently available antiherpes agents are more effective than placebo at reducing the duration of PHN, but not at reducing its incidence. [22],[23] and [24] There is a suggestion that both famciclovir and valacyclovir may be more effective than acyclovir, but this has not been shown to be clinically significant. [25] Corticosteroids have not been shown to be effective, but have been shown to improve quality-of-life indices in affected elderly, and a 21-day taper beginning at 60 mg PO qd should be considered in patients older than age 50 if no contraindications exist. [26],[27]

Initial treatment of patients with PHN is typically systemic analgesia, often narcotics. Patients should be referred back to their primary care provider, because first-line agents often fail, and a trial of amitriptyline or carbamazepine may be tried as second-line therapy.

Immunocompromised patients have an increased risk of disseminated disease. This can be recognized clinically by evidence of the rash involving more than a single dermatome or crossing the midline. Disseminated disease may occur in patients with skin lesions limited to a single dermatome. Patients with disseminated disease may develop pneumonitis, hepatitis, meningoencephalitis, or other organ system involvement and should be admitted for IV acyclovir. Immunocompromised patients with shingles without evidence of dissemination can be treated as outpatients with oral acyclovir at the standard dosing, with instructions to return if the rash spreads or if they develop respiratory symptoms, headaches, or other signs of organ system disease. Close follow-up with their primary care provider is recommended.

EPSTEIN-BARR VIRUS: INFECTIOUS MONONUCLEOSIS

Human herpesvirus 4, known as Epstein-Barr virus (EBV), is the primary cause of the infectious mononucleosis syndrome. EBV is found in humans throughout the world. Serologic testing reveals that 90 to 95 percent of the adult population has developed antibodies to EBV. [28] Approximately half of the population will seroconvert as young children, with a second peak incidence during the teen and young adult years.

EBV is spread by close contact between individuals shedding the virus and a susceptible individual. EBV is not able to survive outside the human host for any significant amount of time, and spread via fomites has not been demonstrated. Transmission among teenagers is often via the exchange of saliva during kissing. Adults may asymptomatically shed EBV for up to 18 months after clinical recovery, and EBV may be demonstrated in the throats of up to 20 percent of all adults. In immunocompromised persons, up to 50 percent may demonstrate EBV.

After infection, there is a 1- to 2-month incubation period during which viral replication occurs in B lymphocytes in the reticuloendothelial system. The presence of EBV induces the production of specific anti-EBV antibodies, as well as the production of the heterophil antibodies. Heterophil antibodies react with antigens on the red cells of sheep, horses, and cows. Heterophil antibodies are not specific for EBV and can be produced by infection with CMV or toxoplasmosis, as well as other infections. Heterophil antibodies are rarely produced in infants.

Following the asymptomatic incubation, EBV can produce a wide array of illnesses. Classic infectious mononucleosis is manifested by fever, exudative pharyngitis, lymphadenopathy, splenomegaly, and an atypical lymphocytosis. Infants and young children frequently have asymptomatic infections. A prodrome of malaise, fatigue, and fever may be present for several days before the onset of the symptoms in classic mononucleosis. An elevated liver transaminase level is uniformly found in mononucleosis. Hepatomegaly and jaundice are unusual in children and young adults, but common in older adults. A severe sore throat is a common presenting complaint, and the appearance may be of a severe bilateral exudative tonsillitis/pharyngitis. Bilateral tender cervical adenopathy is virtually universal. At some point in the illness, approximately half of the patients will have palpable splenomegaly. Splenomegaly is most prominent during week 2 of illness and then resolves over the next 1 to 2 weeks. The majority of patients have an uncomplicated course and recover fully. Chronic fatigue syndrome is not caused by EBV infection.

Generally, the treatment is supportive in the absence of complications. If ampicillin is given to a patient with EBV to treat a possible strep throat infection, there is an approximately 95 percent incidence of rash due to transient production of EBV-induced antibodies against ampicillin. Acyclovir has in vitro effects on EBV replication, but in vivo clinical studies have failed to show any clinically significant effect. [29]

Complications of EBV infections are uncommon and usually do not result in long-term morbidity. The upper airway in approximately 3 percent of children may be obstructed by severe tonsillitis/pharyngitis. [30] Management includes ENT consultation for airway control, if required. Prednisone, 1 to 2 mg/kg/day, should be given to patients with airway compromise. Humidified oxygen and a nasopharyngeal airway are also helpful. Tonsillectomy is usually not necessary and should be reserved for patients who fail to respond to conservative measures. If endotracheal intubation is required, a prolonged period of intubation should be anticipated due to the extent of edema.

The spleen may rupture spontaneously or secondary to minor trauma. The incidence of splenic rupture is believed to be 0.1 to 0.5 percent of patients with EBV. It most commonly occurs during week 2 or 3 of illness. Presenting complaints may be abdominal pain, left scapular pain, or hypotension. Abdominal pain is unusual in infectious mononucleosis and should prompt consideration of splenic rupture. Patients with EBV should be instructed to avoid contact sports and strenuous activity for 4 weeks following the onset of clinical disease. Patients with splenic rupture should be admitted to a general surgical service.

Hematologic complications include autoimmune hemolytic anemia and thrombocytopenia. Corticosteroids will benefit some patients with hematologic complications and should be initiated in the emergency department for those admitted with severe anemia or severe thrombocytopenia. Refractory severe thrombocytopenia may be treated with splenectomy.

Neurologic complications of EBV are quite rare, but may include encephalitis, meningitis, cranial nerve palsies, and the Guillain-Barré syndrome. The CSF usually contains atypical lymphocytes. Recovery is usually complete.

In immunocompromised patients, EBV may be a cause of B-cell lymphomas and other lymphoproliferative syndromes. EBV has been implicated as a causal agent in African Burkitt lymphoma and in nasopharyngeal carcinomas. Death may be caused by overwhelming EBV infection in patients with Duncan disease (an X-linked recessive disorder), which is clinically silent until EBV infection. Patients with HIV may develop hairy leukoplakia that will respond to acyclovir therapy.

The diagnosis of EBV is based on clinical findings and on nonspecific laboratory tests. Confirmatory EBV-specific antibody testing is available, but same-day results are generally not available, so these tests have little value in the setting of the emergency department. The complete blood count is usually moderately elevated, with elevated percentages of lymphocytes and monocytes. Atypical lymphocytes are usually found and may be up to 30 percent of the white blood cells.

The heterophil antibodies are produced in 80 to 90 percent of patients older than age 4. More than 50 percent of children younger than age 4 will not have detectable heterophil antibodies. [31] Commercially available tests for heterophil antibodies (Monospot, Mono-plus, Mono-latex, and Mono-lex) have a sensitivity of 78 to 83 percent, with a specificity of 98 to 100 percent. [32] False negatives may occur more frequently during the first week of illness. Patients with classic symptoms of infectious mononucleosis, atypical lymphocytes, and a positive heterophil antibody test generally require no further testing to confirm the diagnosis. Patients with classic symptoms who have a negative heterophil antibody test should have repeat heterophil testing performed in a week, and if still negative, specific EBV antibody testing may be indicated. Viral capsid antigen (VCA) antibodies of the IgG and IgM classes are present in high titers during acute disease, with IgG persisting for life and IgM persisting for 4 to 8 weeks. The presence of IgM antibodies to VCA is a sensitive and specific indicator of acute EBV infection. Antibodies to Epstein-Barr nuclear antigen develop 4 to 6 weeks after the onset of clinical illness and persist for life, their presence is evidence against acute EBV infection. Other illnesses which may present with a similar clinical picture, but with negative EBV tests include CMV mononucleosis, acute toxoplasmosis, primary HIV infection and strep throat.

CYTOMEGALOVIRUS

Cytomegalovirus (CMV, or human herpesvirus 5) is another ubiquitous virus with worldwide distribution. It is, like the other members of the herpesvirus family, capable of causing a primary illness and then existing in a latent state in the human host indefinitely with the ability to reactivate at a later time. It is present in approximately 1

percent of newborns and in 40 to 100 percent of adults, depending on geographic location, socioeconomic status, attendance at day care, and sexual behavior. There are two peaks of seroconversion, the first in the perinatal period and the second during young adulthood, presumably related to sexually activity. CMV is not easily spread by casual contact, but requires repeated or prolonged intimate contact for transmission. It is found in milk, saliva, urine, semen, and cervical secretions. CMV is also transmitted via blood transfusions containing viable leukocytes or via solid organs or bone marrow during transplantation.

CMV is one of the TORCH agents [*t*oxoplasmosis, *o*ther (viruses), *r*ubella, *C*MV, and *h*erpes (simplex viruses)] and is capable of causing intrauterine infection. Fewer than 25 percent of neonates with intrauterine CMV will display symptoms. Those at highest risk are those whose mother acquires primary disease during the first half of the pregnancy. A seropositive mother's antibodies to CMV appear to provide the fetus some protection. Classic intrauterine CMV (congenital cytomegalic inclusion disease) involves multiple organs, including jaundice, hepatosplenomegaly, microcephaly, petechiae, and inner ear problems, as well as CNS defects. Children who are asymptomatic at birth may still have hearing loss that results in lower IQ scores and learning disabilities later in life.

In contrast to intrauterine infection, perinatal infection (presumably acquired from the cervix of the mother during birth or from breast milk) is usually asymptomatic and has no long-term consequences.

In healthy immunocompetent children and adults, CMV infection is also usually asymptomatic. When CMV does cause disease in this setting, it is typically an illness resembling EBV infectious mononucleosis. Typical presenting complaints include fever, chills, myalgia, and headache. Clinical features include a prolonged fever (1 to 5 weeks), an atypical lymphocytosis, lymphadenopathy, splenomegaly, and mild elevations of the liver transaminase levels. Pharyngitis and tonsillitis are not usually present. There are rarely complications or long-term health consequences. The diagnosis of CMV mononucleosis should be considered in individuals who have a mononucleosis-type illness but are heterophil-antibody negative. The complications of CMV in immunocompetent patients include the Guillain-Barré syndrome, viral pneumonitis, hepatitis, hemolytic anemia, and thrombocytopenia.

In patients with HIV, CMV can cause illness with significant morbidity. Symptomatic infections generally do not occur in patients who are simply HIV positive, but in those with more advanced disease, such as ARC (AIDS-related complex) or AIDS. The most common illness is CMV retinitis, which occurs in more than 10 percent of AIDS patients. Typical complaints are of floaters or of decreased vision. Careful funduscopic examination may reveal characteristic retinal hemorrhages and exudates. Progression to blindness will occur without chronic suppressive therapy with IV ganciclovir or foscarnet. CMV may cause gastrointestinal disease as either an esophagitis or as a colitis. Additionally, CMV can cause an adrenalitis resulting in adrenal insufficiency.

CMV causes significant morbidity and mortality in transplant patients. It can infect numerous different organs, causing colitis, hepatitis, pneumonia, and CNS disease. The most serious infection is CMV pneumonia, which is most common in recipients of bone marrow transplants. The CMV seen in transplant patients may represent primary infection after exposure from the transplanted tissue itself or in transfused blood products, or reactivation of latent infection. The primary infections tend to be more severe. CMV infections occur 4 to 8 weeks after transplant typically, and CMV should be included in the differential diagnosis for patients presenting with a febrile illness within the first 3 months after transplant. CMV may also contribute to rejection of the transplanted organ.

The diagnosis of CMV is difficult because most people are seropositive. The presence of IgM antibodies is helpful, but not very sensitive or specific because of false negatives during some acute infections and their persistence beyond the acute infection in others. To make a definitive diagnosis based on serologies, a conversion from seronegative to seropositive or an acute rise in antibody titer should be seen, and this will require samples from before the illness and during the illness. Another method of diagnosis is by viral culture, which, using the "shell" method, takes only 48 h. Children can shed virus in their urine and respiratory secretions for extended periods following infection, but, in healthy adults, virus is not usually shed in the urine or respiratory tract except during acute illness. Healthy adults may shed virus in semen and cervical secretions. In immunocompromised individuals, a biopsy of the organ suspected to be infected with CMV is the preferred method of diagnosis, because of the prevalence of false-positive cultures in immunocompromised patients. Biopsy specimens of infected organs will show characteristic CMV inclusion bodies. In the emergency department, definitive diagnosis is not available, and suspicion of CMV should be based on clinical grounds such as presentation and time from transplant. A review of transplant records may yield clues, such as the recipient's and donor's CMV status prior to transplantation. The disposition of the patient depends on the clinical setting, not on the diagnosis of CMV, and should be discussed with the patient's primary care provider.

CMV is treated with either ganciclovir or foscarnet. Ganciclovir is approved for therapy of CMV retinitis in AIDS patients and for prevention of CMV in transplant patients. It is also used for treating CMV infections in other organ systems. In AIDS-associated CMV retinitis, ganciclovir is given initially at higher doses for 2 to 3 weeks, followed by lifetime suppressive therapy. For other CMV infections, ganciclovir is given for a period of 2 to 3 weeks and then stopped. Foscarnet is used for resistant CMV infections or for patients unable to take ganciclovir. Neither medication cures patients of CMV, but instead they suppress the acute disease process.

151 GENERAL MANAGEMENT OF POISONED PATIENTS

Jason B. Hack
Robert S. Hoffman

The perception that most people have of a poisonous substance is consistent with common definitions. Mofenson and colleagues established guidelines that must be fulfilled for a substance, and its subsequent exposure, to be categorized as nontoxic (Table 151-1).[1,2] A *poisoning* is an event where a living organism is exposed to a chemical that adversely affects the functioning of that organism. The exposure to the toxin may be occupational, environmental, recreational, or medicinal. A poisoning may result from varied portals of entry, including inhalation, insufflation, ingestion, cutaneous and mucous membrane exposure, and injection. Toxic exposures commonly occur, for example, when substances are tasted or swallowed. Toxins may be in the form of gas or vapors or in a suspension such as dust. Caustics, vesicants, or irritants may affect the skin. A toxin may enter the body transdermally and affect internal structures. Parenteral exposure is also common through intravenous or subcutaneous injection of medications or drugs of abuse.

Only one substance is involved in the exposure.
The substance must be absolutely identified.
The substance's product label must not contain any consumer product safety
  commission signal words indicating a potential hazard of toxicity.
The exposure must have been unintentional.
The route of exposure must be known.
An approximate amount of the substance involved in the exposure must be
  known.
The exposed individual must be free of symptoms for the extent of the
  observation period.
Follow-up consultation must be easily available or a responsible parent or
  guardian must be present.

Note: All of the listed criteria must be fulfilled in order for an ingestion to be
classified as nontoxic.
Source: Adapted from Mofenson et al[1] and Mofenson and Greenber.[2]

TABLE 151-1   Nontoxic Ingestions

A poison may affect the body in many ways. It may inhibit or alter normal cellular function, change normal organ function, or may change the normal uptake or transport of substances into or within the organism. The toxin may also exclude essential substrates in the environment from being efficiently utilized by the organism. This chapter discusses the general management of poisoned patients. The following chapters discuss specific approaches to patients exposed to individual classes of drugs.

In 1996, there were 2,155,952 toxic exposures reported to poison centers in the United States: 1,137,295 (52.6 percent) involved children younger than 18 years of age. Some authors currently list poisoning as the third leading cause of death in the United States and, between 1985 and 1995, the incidence of toxin-related deaths is said to have increased approximately 300 percent. Although many of these exposures were referred to as "accidents," most were preventable or avoidable by modalities such as increased awareness and education, increased parental control over children, instituted checks and balances in hospitals and pharmacies, computer networking and recognition of potential drug interactions, better hospital protocols to ensure patient identification, detailed procedures to check proper dosing, better warning labels and packaging on products with potential toxicity, and better access to mental health care by the underinsured. The public must be made aware of the potential tragedy when nonfood (potentially harmful) items are stored in food areas behind insufficiently secured barricades accessible to children, as well as the potential health threat when toxins are stored in empty food containers.

Poison centers should be an integral part of the management of exposed patients. These centers are typically staffed with specialists who are trained in the management of poisoned patients, have extensive reference material at their disposal, and have rapid access to medical toxicologists if more extensive evaluation is required. Routine consultation in cases where toxic exposure is suspected can help focus diagnosis and treatment and reduce cost and unnecessary hospitalizations.

EMERGENCY DEPARTMENT MANAGEMENT OF POISONED PATIENTS

ABCs

The first priorities are always the ABCs. Once the airway and respiratory status is secured, abnormalities of blood pressure, pulse, rectal temperature, and oxygen saturation must be corrected. Although the proper use of antidotes is essential in the treatment of poisoned patients, only in very rare incidences (such as cyanide poisoning) would the administration of an antidote take precedence over completing the primary evaluation and normal attempts to stabilize the ABCs.

Medical History

As much detailed information as possible must be obtained about the medical history. Answers to questions pertaining to the number of exposed persons and the type, amount, and route of exposure are essential. In addition, the patient's intent must be extensively appraised. Clinicians must be aware of the inherent inaccuracies in these types of histories. The patient's motivation, potential for secondary gain, and perceived risk of arrest all may affect the history. Corroborating information should be obtained from the patient's private physician, witnesses, or emergency medical technicians who were on scene. Histories of where in the environment the patient was found, empty pill bottles or containers nearby, smells or unusual materials in the home, the occupation of the person, or the presence of a suicide note all may provide important clues to identifying the exposure.

Toxicologic Physical Examination

The comprehensive physical examination must be performed on a fully undressed patient. This affords the physician every opportunity to check the patient's clothing for substances still retained in the pockets or substances hidden on the patient's body (waistbands, groin, or between skinfolds). In addition, physicians must pay special attention to certain aspects of the physical examination. Care must be taken when searching belongings, particularly pockets, because health care providers have been stuck by uncapped needles.

The skin must be examined for cyanosis or flushing, excessive diaphoresis or dryness, signs of injury or injection, ulcers, or bullae. Bruising may be a clue as to duration of unconsciousness, as well as coagulopathy. Examine the eyes for pupil size, reactivity, nystagmus, dysconjugate gaze, or excessive lacrimation. Hypersalivation or excessive dryness should be noted in the oropharynx. The chest examination should include careful evaluation of the lungs to assess for bronchorrhea, or wheezing, and the heart must be assessed for its rhythm, rate, and regularity. Bowel sounds, urinary retention, and abdominal tenderness or rigidity must also be noted. The extremities must be evaluated for tremor or fasciculation. Cranial nerves, reflexes, resting muscle tone, coordination, cognition, and the ability to ambulate all must be assessed.

Toxidromes

The term *toxidrome* refers to the collection of signs and symptoms that are observed after an exposure to a substance (a toxic "fingerprint"). Toxidromes include grouped, physiologically based abnormalities of vital signs, general appearance, skin, eyes, mucous membranes, lungs, heart, abdomen, and neurologic examination that are known for many substances and typically helpful in establishing a diagnosis when the exposure is not well defined (Table 151-2). Similarly, certain clinical findings may narrow the etiologic possibilities (Table 151-3).

TABLE 151-2   Toxidrome

TABLE 151-3   Agents that May Alter Presenting Signs or Symptoms*

DECONTAMINATION

The general approach to most toxic exposures involves the removal of the patient from the substance or of the substance from the patient. Toxins outside the body must be washed away. Toxins inside the body must be either bound within the gut lumen to make it unavailable for absorption or have its elimination enhanced from the gut, the blood, or the tissues.

Gross Decontamination

Patients may still have the toxin on their skin or clothing. Decontamination is generally achieved by undressing patients completely and washing them thoroughly with copious amounts of water. Patients requiring assistance should be attended to by properly gowned staff in an isolated area. Patients should be scrubbed with soft brushes so as not to injure their skin (thereby allowing the toxin to enter through an injured barrier). The towels used to dry patients, and their clothing, shoes, socks, watches, and jewelry, should all be handled as potentially hazardous waste. This gross decontamination will decrease the likelihood of spreading illness among staff members and other patients.

Eyes

Following ocular exposures, the eyes must be immediately flushed with copious amounts of irrigation solution, after topical analgesia. This irrigation should continue until a copious amount (usually several liters) of irrigant is used and, if appropriate, the pH of the eyes returns to a physiologic range.

Gastrointestinal Decontamination

Each of the methods used to decontaminate the gastrointestinal (GI) tract have potential benefits and risks that must be considered prior to their use. The three general methods of decontamination involve removal of the toxin from the stomach, binding it inside the gut lumen, or mechanically flushing it through the GI tract. The choice of method(s) used is determined by the toxin ingested, the time course, the patient's clinical status, and the skills of the physician available. GI decontamination must never be initiated as a punitive action.

GASTRIC EMPTYING

Emesis

Emesis is achieved by administration of syrup of ipecac. Syrup of ipecac is a plant-derived compound composed of two alkaloidal substances—emetine and cephaeline—which work both peripherally on the stomach and centrally on the chemotactic trigger zone to induce vomiting. Dosing of syrup of ipecac is 15 mL for children 1 to 12 years of age, and 30 mL for adults, usually followed by sips of water. The dose may repeated once if vomiting does not occur after 30 min. Approximately 90 percent of patients vomit within 20 min after the first dose, and up to 97 percent vomit if a second dose is given. A typical patient vomits less than 3

to 5 times, and symptoms usually resolve within 2 h.

The ingested toxin should be suspected as the cause if protracted vomiting occurs. Contraindications to the administration of syrup of ipecac include ingestions with potential to alter mental status; active or prior vomiting; caustic ingestion; a toxin with more pulmonary than GI toxicity (e.g., hydrocarbons); and potential for seizures. Rare but potential complications of syrup of ipecac–induced emesis include aspiration, Boerhaave syndrome, Mallory-Weiss tear, and intractable vomiting.

The clinical situations where syrup of ipecac would be used in the hospital setting are limited. Most patients reach the hospital beyond the time frame when the use of syrup of ipecac would be beneficial, because the toxin has been absorbed or has passed through the pylorus. Also, even when syrup of ipecac is given with activated charcoal in less than 60 min after ingestion, it does not alter outcome when compared to treatment with activated charcoal and a cathartic. Ipecac's administration also prolongs the time to administration of oral antidotes by 1 to 6.5 h. [3]

Syrup of ipecac may still be indicated, especially when it can be given in the home immediately after an ingestion of a known toxin that is still expected to be in the stomach and that does not have the previously listed contraindications. Possible rare hospital indications for its use include very recent ingestions of substances not expected to compromise the airway or lead to altered mental status or hemodynamic derangement or seizure, a recent ingestion of a pill that is known not to be able to fit into the holes of the appropriately sized orogastric tube, or a substance known not to adsorb to activated charcoal (see the following sections).

Orogastric Lavage

The principal method of gastric emptying is orogastric lavage, which is performed with the patient lying in the left lateral decubitus position. A 36 to 40 French tube is used for adults (22 to 24 French tube for children), which is inserted after careful measurement of the depth (from the chin to the xiphoid process). Correct positioning must be assessed by insufflation of air to ensure accurate placement in the stomach. Lavage with room-temperature water is commonly continued until the effluent is clear. Before the tube is removed, activated charcoal should be instilled in a dose of 1 g/kg, if indicated. The contraindications to this procedure include pills that are known not to fit into the holes of the orogastric lavage hose, nontoxic ingestions, non-life-threatening ingestions, caustic ingestions, any patient whose airway integrity is not assured, or toxic ingestions that are more damaging to the lungs than to the GI tract. Complications of this procedure include insertion of the tube into the trachea, aspiration, esophageal or gastric perforation, decreased oxygenation during the procedure, [4] and inability to withdraw the tube once inserted (knot formation).

Although the perceived benefits of orogastric lavage are the immediate return of small pills or pill fragments, and a reduction in the amount of substance available for further intoxication, studies typically demonstrate drug removal ranging from only 35 to 56 percent. Of three large studies that evaluated the clinical efficacy of orogastric lavage, [3,5,6] only one showed any benefit from the procedure, and only if it was initiated in obtunded patients within 1 h of the ingestion. [3] Indications for this procedure are generally limited to ingestion of a life-threatening toxin that requires ventilatory support, depresses mental status, or may cause seizures.

ADSORPTION OF THE TOXIN IN THE GUT LUMEN

Activated Charcoal

The most appropriate agent to decontaminate the GI tract is activated charcoal, which is produced by pyrolysis of carbonaceous materials and activated by steam cleaning to increase its surface area. Activated charcoal is beneficial because it adsorbs the toxin within the gut lumen, making the toxin less available for absorption into the tissues, and because it enhances elimination. It establishes a free-drug concentration gradient favoring movement back into the GI lumen to enhance elimination ("GI dialysis"), [7] and it can also bind the drug in the bile, interrupting the enterohepatic circulation. The benefits of this technique include its capability to decontaminate the gut without requiring invasive procedures, its rapid administration, and its proven safety in both adults and children.

Activated charcoal is typically given in a slurry of water or juice by mouth or through a nasogastric tube, in an activated charcoal-drug dose of 10:1 (thought to be the smallest dose of activated charcoal that can be given with out reducing its efficacy [8]) or in 1 g/kg, whichever is larger. The first dose of activated charcoal is often given with a cathartic to reduce GI transit time. Sorbitol, and magnesium citrate solution, are the most commonly used cathartics (see the cathartic section).

Contraindications to activated charcoal include isolated ingestion of a substance known not to adsorb to activated charcoal (such as iron, lithium, or lead), or if the patient is to undergo endoscopic evaluation such as would be required following a caustic ingestion. The risks, which are exceedingly rare, include aspiration and intraluminal impaction in patients with abnormal gut motility. Clear indications for administration of activated charcoal are ingestion of any drug known to adsorb to it or after unknown ingestion by patients with protected airways.

Multiple-Dose Activated Charcoal

One dose of activated charcoal is usually sufficient to achieve a therapeutic effect. Multiple-dose activated charcoal, however, should be administered in specific instances, such as after ingestion of very large doses, substances that form bezoars in the GI tract, potentially injurious toxins that slow gut function, or toxins that are released slowly into the gut lumen. Multiple-dose activated charcoal is usually given as follows: the first dose is up to 1 g/kg body weight, which is then followed by subsequent doses of 0.25 to 0.50 g/kg. Repeated doses of activated charcoal should be given in an interval ranging from 1 to 4 h. To prevent excessive fluid loss and electrolyte imbalance, only the first dose of activated charcoal should be given with a cathartic.

Multiple-dose activated charcoal is contraindicated in patients who have decreased gut motility, because the risks of the procedure include aspiration from gastric distention, and impaction of charcoal within the gut. The benefits of multiple-dose activated charcoal include achievement of a 10:1 activated charcoal to drug ratio in patients with very large ingestions and the binding of drugs within the gut lumen after ingestion of substances that have a large enterohepatic or enteroenteric circulation. Patients having ingested life-threatening toxins who have decreased gut motility can receive multiple doses, but the stomach must be suctioned just prior to the administration of the next dose of activated charcoal to minimize distention.

Cathartics

Typically, activated charcoal is administered with an osmotic cathartic, such as a 70% sorbitol solution (1 g/kg), or a 10% solution of magnesium citrate (in a dose of 250 mL for adults and 4 mL/kg for children). Cathartics have been repeatedly shown to decrease the transit time for the passage of the activated charcoal (and presumably the adsorbed toxin) through the GI tract. [9,10] Although most studies fail to show a benefit of administering a cathartic alone, [11,12] several studies suggest that there is a decrease in peak serum plasma concentrations, and area under the curve when the cathartic is administered with activated charcoal. [13,14] No definitive clinical human data, however, suggest that the addition of a cathartic to a dose of activated charcoal either limits the toxin's bioavailability or changes the patient's clinical outcome.

Indications for use of cathartics generally mirror those for the administration of activated charcoal. When multiple-dose activated charcoal is used, only the first dose is accompanied by a cathartic, to limit complications. Complications of cathartic administration include nausea and abdominal pain, severe volume depletion, electrolyte imbalances and fluid shifts, and hypermagnesemia in patients with renal compromise.

Contraindications for cathartic use are, after an ingestion of a substance that will result in diarrhea, children younger than age 5, patients with renal failure (only magnesium-containing cathartics are contraindicated), intestinal obstruction, or an ingestion of any caustic material.

IRRIGATION OF THE BOWEL LUMEN

Whole Bowel Irrigation

Another technique for clearing the gut is whole bowel irrigation, which involves the installation of large volumes of polyethylene glycol in an electrolyte and osmotically balanced solution that neither causes fluid nor electrolyte shifts. This technique is accomplished in adults by the installation of 2 L/h polyethylene glycol solution either by mouth or through an nasogastric tube or, in children, by the installation of 50 to 250 mL/kg/h or as much of polyethylene glycol solution as tolerated. The end point is clear rectal effluent. When done properly, this technique produces a rapid catharsis by mechanically forcing ingested substances through the bowel at a rapid rate.

Contraindications include patients with preceding diarrhea, ingestions that are expected to result in significant diarrhea (except for heavy metals, as these substances do not adsorb well to activated charcoal) and patients with absent bowel sounds or with obstruction. The complications included bloating, cramping, and rectal irritation from frequent bowel movements. Close nursing care is needed to maintain patient cleanliness.

Controlled studies clearly demonstrating improvement in clinical outcome after this procedure are lacking, but many authors describe limited symptomatology following potentially toxic doses of substances known not to adsorb to activated charcoal. [15] Common indications for whole bowel irrigation include ingestion of sustained-release preparations, and ingestions that are known not to adsorb to activated charcoal; substances that form bezoars; in clinical situations where nonobstructive, nonsharp foreign bodies are present in the bowel (such as drug vials); and, in cases of illicit drug body packing.

ENHANCED ELIMINATION

Alkalinization

Urinary alkalinization is beneficial in the treatment of certain ingestions. The urinary pH is manipulated to exploit physiologic properties of specific toxins. Only nonionized substances are free to move passively across membranes. Ionized particles must remain in the fluid-filled compartments in which they were formed. Weak acids are mostly uncharged at physiologic pH, but become charged in alkaline environments. By significantly raising the urinary pH with intravenous sodium bicarbonate, toxins that are weak acids are converted from their nonionized form to their ionized form and are therefore held within the urinary collection system. This "ion trapping" keeps the toxin within the renal tubules, thereby enhancing its excretion. This creates an imbalance in the concentration gradient of the toxin between the blood and the urinary collection system, drawing more toxin into the renal lumen. The ideal toxin that can be eliminated by this technique is one with substantial urinary excretion and with a pK_a less than the serum pH (Table 151-4).

Drugs	Agents Where Urinary Alkalization Is Commonly Considered	Agents Where Hemodialysis Is Commonly Considered
2-4-D (herbicide)	✓	
Phenobarbital	✓	
Chlorpropamide	✓	
Salicylates	✓	✓
Methanol	✓	✓
Ethylene glycol		✓
Lithium		✓
Theophylline*		✓

*Indicates also removed by hemoperfusion.

TABLE 151-4 Agents That Other Modalities May Increase Their Excretion

Administer an intravenous bolus of 1 to 2 meq/kg sodium bicarbonate, followed by either intermittent boluses of sodium bicarbonate or a continuous intravenous infusion to achieve a urinary pH of 7.5 to 8.0. Serum pH should not be allowed to rise above 7.5 to 7.55. Pronounced hypokalemia may result from this technique and must be corrected aggressively. Hypokalemia induces the kidneys to reabsorb potassium preferentially. To remain electronegatively neutral, hydrogen ions are excreted, inhibiting the production of an alkaline urine. This may result in a paradoxically acidic urine.

The benefit of urinary alkalinization is a decrease in toxin serum half-life from increased urinary excretion. The risks include congestive heart failure, pulmonary edema, pH shifts, and profound hypokalemia. Therefore, contraindications to this procedure include patients who cannot tolerate the volume or sodium load, hypokalemia, renal insufficiency, and ingestion of a toxin that does not respond to alkalinization.

Hemodialysis

Hemodialysis is generally reserved for specific toxins that must be both potentially life threatening and amenable to removal by this method (see Table 151-4). A semipermiable membrane is used to create a concentration gradient to filter out toxins. The benefits include the ability to remove toxins that are already absorbed from the gut lumen, removal of substances that do not adhere to activated charcoal, and the ability to remove both the parent compound and the active toxic metabolites. Hemodialysis is much less effective where the toxin ingested has a large volume of distribution (>1 L/kg), has a large molecular weight (more than 500 Da), or is highly protein bound.

Hemodialysis is rarely absolutely contraindicated, but relative contraindications include hemodynamic instability, very small children, patients with poor vascular access or profound bleeding diatheses. Risks of hemodialysis are typically minimal in experienced centers, but they include large fluid shifts, electrolyte imbalances, infection and bleeding at the catheter site, and intracranial hemorrhage.

Hemoperfusion, which is also used for decontamination of a patient's systemic circulation, involves placing a filter filled with activated charcoal into the circuit of the hemodialysis machine. This filtration alleviates the constraints of protein binding and molecular size, both of which limit the utility of hemodialysis. Toxins that can be removed by this method must adsorb well to activated charcoal and have a small volume of distribution. In practice, it is only commonly recommended for theophylline overdoses.

INITIAL INTERVENTIONS

Patients may be unresponsive or have an altered mental status for many reasons. Four possible diagnoses (hypoxia, opioid intoxication, hypoglycemia, and Wernicke encephalopathy) may be easily overlooked, but are readily treated by the administration of specific antidotes. Within the first few minutes after the patient's arrival, the administration of empiric antidotes [supplemental oxygen, 1.0 to 2.0 mg intravenous naloxone in adults and 0.01 mg/kg in children, 50 mL 50% dextrose in water (50% D/W) for adults and 1 gm/kg glucose as 10% or 25% D/W for children, and 100 mg thiamine in adults] should be considered after taking into account the medical history, vital signs, and laboratory data immediately available. These treatments are simple, inexpensive, and generally without undue risk of an adverse reaction when used appropriately. Thiamine is generally not administered for unexplained unresponsiveness in children. However, 1 g/kg of glucose is often administered when serum glucose cannot be rapidly ascertained or hypoglycemia excluded. Naloxone (0.01 mg/kg titrated to effect), may be given, particularly in older children where accidental or intentional opioid exposure cannot be excluded. Intentional poisoning of children as a form of child abuse does occur.

The suggestion that the administration of thiamine should precede the administration of 50% D/W to prevent the precipitation of acute Wernicke encephalopathy is unfounded. [16] The most important management issue with both 50% D/W and thiamine is that both should be given in a timely manner in the emergency department so that these often occult diagnoses are added to the differential diagnosis and are treated promptly.

Although opioid intoxication often presents with the classic triad of central nervous system (CNS) depression, miosis, and respiratory depression, only respiratory status is useful as an indicator of a patient response to naloxone. [17] Many toxins, though, produce miosis or CNS depression, and some opioids classically leave pupil size unaltered, making these findings less useful in isolation.

Naloxone, which is a competitive opioid antagonist that can be administered intravenously or intramuscularly, is appropriate to use for a hypoventilating but nonintubated, opioid intoxicated patient. Extremity restraints for the patient should be considered before administering the drug. Naloxone may completely reverse the symptoms observed, restoring effective ventilations and mental status for 20 to 60 min, so patients should be observed for 2 to 3 h afterward. The risks include the precipitation of an acute withdrawal syndrome. Although acute withdrawal is never life threatening, vomiting from withdrawal can result in aspiration. Thus, the reflexive administration of large doses of naloxone should be discouraged. Patients who become resedated may require additional naloxone doses administered either in intermittent boluses or via a continuous infusion. The latter is achieved by the administration of two-thirds the dose of the naloxone that fully aroused the

patient in the initial bolus, but infused over an hour with the dose adjusted to the patient's ventilatory status.

152 TRICYCLIC ANTIDEPRESSANTS

Kirk C. Mills

EPIDEMIOLOGY

Tricyclic antidepressants (TCAs) are associated with more drug-related deaths than any other class of prescription medication. Their complex pharmacologic activity, low therapeutic index, and general availability predispose to the development of clinical toxicity. The 1997 Annual Report of the American Association of Poison Control Centers Toxic Exposure Surveillance System indicated that 1 of every 27 adult exposures to a pharmaceutical medication involved a TCA. [1] Over the past 5 years, there have been an average of 19,000 exposures and 120 associated deaths related to TCAs. However, these numbers undoubtedly underestimate the true magnitude of TCA-related drug toxicity. Most reported TCA exposures occur in young adults, with approximately 60 percent of all exposures believed to be intentional.

TCAs are used primarily for the treatment of major depression. In addition, they are prescribed frequently for other psychiatric and medical conditions such as obsessive-compulsive disorder, attention-deficit disorder, panic and phobia disorders, anxiety disorders, eating disorders, chronic pain syndromes, peripheral neuropathies, nocturnal enuresis, migraine headache prophylaxis, and selected drug withdrawal therapy. There are currently eight different TCAs available in the United States (Table 152-1), but many more varieties are available in other countries. The five most commonly reported TCAs involved in drug exposures include amitriptyline (40 percent), imipramine (17 percent), doxepin (14 percent), nortriptyline (12 percent), and desipramine (6 percent). Two related antidepressants, maprotiline and amoxapine, have minor structural differences when compared with traditional TCAs but have similar toxicity in overdose and thus will be included in this chapter. Cyclobenzaprine (Flexeril) is a muscle relaxant that is almost structurally identical to amitriptyline but lacks antidepressant activity. It tends to have less cardiotoxicity than amitriptyline but can still produce significant central nervous system (CNS) sedation and antimuscarinic toxicity in overdose. [2] The average therapeutic dose for TCAs is highly variable. Initially, lower doses are used, followed by gradual increases until the desired therapeutic response is achieved. In addition, this process allows most patients to become acclimated to the typical TCA-induced adverse effects such as CNS sedation and dry mucous membranes.

TABLE 152-1   Tricyclic Antidepressants

TCA-related drug toxicity is not just limited to cases of drug overdose. There are at least eight different possible mechanisms for developing TCA-related drug toxicity while taking therapeutic doses. First, mild to moderate toxicity commonly will develop if unacclimated individuals are started on higher therapeutic doses. Second, toxicity can result when TCAs are combined with other medications having similar pharmacologic actions (e.g., antihistamines, antipsychotics). Third, a subset of the population consists of slow metabolizers of TCAs, and as such, these people will develop higher plasma TCA levels for any given dose. Fourth, many drugs have the potential to inhibit the metabolism of TCAs, resulting in elevated TCA plasma levels. Fifth, some TCAs are available as mixed-drug formulations combined with either benzodiazepines or antipsychotic agents, having the potential for additional drug toxicity. Sixth, patients with certain medical conditions such as underlying heart problems or seizure disorders are more susceptible to TCA toxicity at therapeutic doses. Seventh, TCAs have the potential to produce serotonin syndrome, especially in combination with other serotonergic medications (see Chap. 153, "Newer Antidepressants and Serotonin Syndrome"). Finally, rare cases of neuroleptic malignant syndrome have been reported in association with therapeutic use of TCAs.

PATHOPHYSIOLOGY

TCAs have a distinct chemical structure comprised of three aromatic rings: a central seven-member ring, two outer benzene rings, and an aminopropyl side chain connected to the central ring. There are only minor structural differences among the TCAs, usually on the central aromatic ring or aminopropyl side chain. Amoxapine is unique in that it has an aromatic side chain. Maprotiline has an ethylene bridge across a six-member center ring, giving it a tetracyclic chemical structure. It is not surprising that other chemicals that share the same basic tricyclic chemical structure as the TCAs, such as carbamazepine and phenothizaines, would manifest similar toxicity in overdose.

TCAs are nonselective agents that exhibit a multitude of pharmacologic effects (Table 152-2) and have considerable variation in potency. There are subtle and potentially clinically significant pharmacologic differences among the TCAs at therapeutic plasma levels. However, these differences become less important at the higher plasma levels typically seen in overdose. Only a few of their pharmacologic actions are believed to have a direct therapeutic effect, such as inhibition of amine reuptake (norepinephrine, serotonin) and antagonism of postsynaptic serotonin receptors (5-HT2). Thus, the remaining pharmacologic actions are essentially without therapeutic benefit but significantly contribute to TCA-related adverse effects and overdose toxicity. Most clinical findings seen in TCA overdose can be explained by the following seven pharmacologic actions, listed in descending order of general potency.

TABLE 152-2 Pharmacologic Profile of Tricyclic Antidepressants

Antihistaminic Effects

TCAs are potent inhibitors of peripheral and central postsynaptic histamine receptors. Doxepin is a particularly potent antihistamine, but its nonspecific pharmacologic activity makes it impractical as a therapy for seasonal allergies or other allergic conditions. Antagonism of central histamine receptors primarily leads to CNS sedation and may contribute significantly to the development of coma frequently seen in TCA overdose.

Antimuscarinic Effects

TCAs frequently produce antimuscarinic symptoms. They are competitive inhibitors of acetylcholine at central and peripheral muscarinic receptors. This action is commonly referred to as being *anticholinergic,* but the term *antimuscarinic* is more precise because TCAs do not antagonize acetylcholine at nicotinic receptors. Central antimuscarinic symptoms vary from agitation to delirium, confusion, amnesia, hallucinations, slurred speech, ataxia, sedation, and coma. Peripheral antimuscarinic symptoms include dilated pupils, blurred vision, tachycardia, hyperthermia, hypertension, decreased oral and bronchial secretions, dry skin, ileus, urinary retention, increased muscle tone, and tremor. Antimuscarinic symptoms are especially common when TCAs are combined with other medications that also have antimuscarinic activity. Examples include antihistamines, antipsychotics, antiparkinsonian drugs, antispasmodics, and some muscle relaxants.

Physostigmine is an inhibitor of acetylcholinesterase activity and potentially can reverse antimuscarinic symptoms. Historically, it was used to reverse TCA-induced antimuscarinic symptoms, but its use is often associated with life-threatening complications. Although antimuscarinic symptoms are a common finding in TCA overdose, they are not directly responsible for TCA-related deaths. Therefore, antimuscarinic symptoms are an important clinical marker of TCA toxicity, but they do not require specific therapy other than supportive care alone. Physostigmine has no role in the current management of TCA overdose emergency department (ED) patients.

Inhibition of a-Adrenergic Receptors

Inhibition of postsynaptic central and peripheral a-adrenergic receptors is a characteristic action of most TCAs. They do not inhibit b-adrenergic receptors. TCAs have a much greater affinity for a_1- than a_2-adrenergic receptors. Inhibition of a_1 receptors produces CNS sedation, orthostatic hypotension, and pupillary constriction. This action frequently offsets antimuscarinic-induced pupillary dilation. Thus, patients with TCA toxicity can present with constricted, dilated, or midpoint-sized pupils. Orthostatic hypotension is often associated with reflex tachycardia. The antihypertensive effect of clonidine can be negated by TCAs because of their ability to block the binding of clonidine to a_2 receptors.

Inhibition of Amine Uptake

Inhibition of amine reuptake is believed to be the most important mechanism by which TCAs are efficacious in treating depression. TCAs are potent inhibitors of norepinephrine (NE) and serotonin (5-HT) reuptake but have little affinity for inhibition of dopamine (DA) reuptake. [3] Inhibition of neurotransmitter reuptake leads to increased synaptic levels and subsequent augmentation of the neurotransmitter response. Inhibition of NE reuptake is thought to produce the early sympathomimetic effects occasionally seen in some TCA overdoses and may contribute to the development of cardiac dysrhythmias. Serotonin syndrome results from increased 5-HT brainstem activity and has been produced by TCAs that are particularly potent 5-HT uptake inhibitors such as clomipramine and amitriptyline. In general, TCAs must be used in combination with other serotonergic agents to produce serotonin syndrome. Myoclonus and hyperreflexia often are attributed to increased serotonin activity.

Sodium Channel Blockade

TCA-induced cardiotoxicity is the single most important factor contributing to patient mortality. Life-threatening cardiotoxicity results from TCA-induced inhibition of sodium influx through voltage-dependent sodium channels. Inhibition of fast sodium channels in His-Purkinje cells leads to delayed depolarization and conduction abnormalities. [4] Impaired sodium entry into myocardial tissue leads to decreased contractility. Sodium channel blockade is often referred to synonymously as *membrane stabilizing, quinidine-like,* or *local anesthetic effect.* Sodium channel blockade results in a prolongation of phase 0 of the action potential, which becomes more pronounced with rapid heart rates, hyponatremia, and acidosis. This effect expresses itself on the electrocardiograph (ECG) as prolongation of PR and QRS intervals and right-axis deviation (RAD) of the terminal 40 ms. The RAD is most pronounced in the terminal 40 ms of limb leads, as demonstrated on ECG by a terminal R wave in lead aVR and an S wave in lead I. Rapid influx of sodium is necessary for the release of intracellular calcium stores and subsequent myocardial contractility. Some of the negative chronotropic effect of sodium channel blockade can be attenuated by the sinus tachycardia secondary to antimuscarinic activity. Bradycardia is particularly worrisome when accompanied by QRS complex widening because it indicates profound sodium channel blockade. Local changes in electrical conduction can predispose to ventricular dysrhythmias by establishing reentry loops. In summary, severe sodium channel blockade culminates in depressed myocardial contractility, various types of heart blocks, RAD, hypotension, wide QRS, and cardiac ectopy.

Sodium channel blockade can be overcome in part by serum alkalinization (pH 7.50–7.55) and increasing the serum sodium concentration. In humans, intravenous sodium bicarbonate (NaHCO3) is thought to be more effective than either hyperventilation (alkalinizes blood) or sodium chloride (increases Na $^+$) in treating TCA cardiotoxicity. One explanation for the greater effectiveness of NaHCO$_3$ is that it produces both blood alkalinization and increased serum sodium concentration. The mechanism by which blood alkalinization partially reverses sodium channel blockade remains unknown, but it does not appear to be related to enhancement of plasma TCA serum protein binding. It may decrease the overall inhibition to sodium ion influx. Recent animal data suggest that hypertonic saline (7.5% NaCl) may be more efficacious than sodium bicarbonate or hyperventilation in reversing TCA cardiotoxicity. [5] Whether this finding also will be applicable to humans is currently unknown. Hypertonic saline is believed to act primarily by increasing the extracellular sodium concentration gradient, thus favoring the inward movement of sodium ions.

Potassium Channel Antagonist

TCAs block myocardial potassium channels and inhibit the efflux of potassium ions during repolarization. This effect is seen on ECG as QT interval prolongation, which is more pronounced at slower heart rates. Many TCA overdose patients develop sinus tachycardia, which is partially protective against severe QTc interval prolongation. Torsades de pointes is a life-threatening complication of severe QT interval prolongation, but it is rarely seen in TCA overdoses. [6]

GABA-A Receptor Antagonist

Generalized seizures commonly occur in the setting of TCA overdoses. Possible mechanisms for these seizures include TCA-induced g-aminobutyric acid receptor A (GABA-A) antagonism, neuronal sodium channel blockade, central anticholinergic activity, and effects on biogenic amines. The exact etiology of these seizures remains speculative, but TCA-induced antagonism of the GABA-A may represent the most important mechanism. All drugs that inhibit GABA-A neurotransmission are associated with seizures. Benzodiazepines and barbiturates are potent GABA-A agonists and are considered the anticonvulsants of choice in treating TCA-induced

seizures. Propofol (Diprivan) is a short-acting intravenous anesthetic with anticonvulsant activity. It should be considered for patients with resistive seizures, especially in the setting of hypotension.

PHARMACOKINETICS

All TCAs share similar pharmacokinetic properties. They are highly lipophilic and readily cross the blood-brain barrier, and peak plasma levels occur between 2 and 6 h after ingestion at therapeutic doses. Gastrointestinal absorption can be prolonged because of their antimuscarinic effect on gut motility. Bioavailability is only 30 to 70 percent because of extensive "first pass" hepatic metabolism. They are highly protein bound to a $_1$ acid glycoproteins. Their apparent volume of distribution is extremely large and ranges from 10 to 50 L/kg. Tissue TCA levels are commonly 10 to 100 times greater than plasma levels. Only 1 to 2 percent of the total body burden of TCAs is found in the blood. These pharmacokinetic properties explain why attempts at removing TCAs by hemodialysis, hemoperfusion, peritoneal dialysis, or forced diuresis are generally unproductive.

TCAs are eliminated almost entirely by hepatic oxidation, which consists of N-demethylation of the amine side-chain groups and hydroxylation of ring structures. The removal of a methyl group from the tertiary amine side chain usually produces an active metabolite designated by the desmethyl prefix (see Table 152-1). These active metabolites often will have different pharmacologic activities when compared with the parent compounds. Amoxapine and maprotiline both have active metabolites. Although secondary amines such as desipramine, nortriptyline, and protriptyline are effective antidepressants, their metabolites are generally considered inactive. Clinical toxicity from tertiary TCAs usually lasts longer than that from secondary TCAs alone because of the production of active metabolites. Some TCAs undergo enterohepatic circulation prior to their eventual oxidation, conjugation, and renal elimination, but this does not significantly contribute to their toxicity.

The average elimination half-life of TCAs is approximately 24 h (range 6-36 h) at therapeutic doses, but this can increase to 72 h after overdose. Inhibition of TCA metabolism by other drugs that use the same hepatic enzymes can prolong the half-life of TCAs. This carries the risk of elevating TCA plasma levels and producing clinical TCA toxicity at therapeutic doses. Approximately 7 percent of the U.S. population are genetically slow metabolizers of TCAs. This predisposes them to develop higher plasma levels at any given daily TCA dose.

TOXICITY

Therapeutic doses for TCAs are highly variable and are determined by many factors but range from 1 to 5 mg/kg per day (see Table 152-1). Any dose greater than this has the potential to produce TCA toxicity. Life-threatening symptoms usually occur with ingestions of greater than 10 mg/kg in adults. Pediatric patients are particularly susceptible to the antimuscarinic activity of TCAs. Other patients at higher risk for TCA toxicity include patients who have coingested cardiotoxic or CNS-depressive medications, geriatric patients, and patients with heart disease. Desipramine is the most potent sodium channel blocker among the TCAs. [3] It has twice the fatality rate of other TCAs. Some TCAs, especially desipramine, are able to precipitate severe cardiotoxicity (e.g., wide QRS complex, hypotension) without producing significant antimuscarinic symptoms. TCA-related fatalities are commonly associated with ingestions of greater than 1 g. Most TCA overdose fatalities occur within the initial hours after ingestion, often before the patient reaches the hospital. Fatalities more than 24 h after ingestion are unusual with appropriate medical therapy.

Quantitative plasma TCA levels are very helpful in monitoring chronic drug therapy (e.g., compliance, metabolism) and are frequently used by psychiatrists for this purpose. However, quantitative plasma TCA levels have limited application to ED patients. The results of quantitative levels are rarely available to emergency physicians during the time of patient evaluation and therefore have negligible impact on patient care. Some studies have shown that patients with a combined plasma level of parent TCA and metabolite of greater than 1000 ng/mL are at greater risk for developing seizures and cardiotoxicity. However, the severity of clinical toxicity does not always correlate with the extent of plasma TCA elevation. Patients can develop severe toxicity at plasma levels less than 1000 ng/mL. [8,9] Conversely, patients with plasma TCA levels much greater than 1000 ng/mL may not develop seizures or ventricular dysrhythmias. Serious toxicity rarely develops at therapeutic levels alone (<300 ng/mL). When this occurs, other causes should be entertained to explain the patient's condition. As always, the most important thing is to treat the patient and not the drug level.

An interesting but confounding characteristic of TCAs is their ability to undergo significant postmortem drug redistribution. [10] Plasma levels can increase by as much as 10- to 50-fold after death as tissue binding sites release TCAs back to the blood. This is a time-dependent process. The diagnostic accuracy of postmortem TCA levels is inversely proportional to the time they were obtained after death. The relevance of TCA postmortem drug redistribution to emergency physicians relates to ED deaths of patients taking TCAs therapeutically. The medical examiner may inappropriately assign the cause of death to unrecognized TCA overdose if elevated levels are detected and no other cause of death is uncovered. This, in turn, may raise false concerns about the care provided to the patient during his or her ED resuscitation.

CLINICAL FEATURES

The clinical presentation of TCA toxicity varies tremendously from mild antimuscarinic symptoms to severe cardiotoxicity secondary to sodium channel blockade. In up to 70 percent of TCA poisonings, coingested drugs also are involved, and the additional toxicity from these coingestants should be considered when evaluating these patients. Antimuscarinic symptoms commonly serve as markers for TCA toxicity (e.g., dry mouth and axillae, sinus tachycardia), but they alone are rarely responsible for patient fatalities. Moreover, antimuscarinic symptoms are not uniformly present in TCA toxicity. As an example, sinus tachycardia is the most frequent dysrhythmia noted in TCA toxicity, but it is only present in approximately 70 percent of symptomatic patients. Altered mental status is the most common symptom reported following TCA exposure.

Mild to moderate TCA toxicity may present as drowsiness, confusion, slurred speech, ataxia, dry mucous membranes and axilla, sinus tachycardia, urinary retention, myoclonus, and hyperreflexia. Antimuscarinic syndrome is classically associated with decreased bowel tones and ileus. However, bowel function is fairly resistant to inhibition and active bowel sounds can be present even in seriously ill patients. Therefore, the presence of active bowel tones does not rule out the possibility of antimuscarinic syndrome. Mild hypertension is observed occasionally and rarely requires treatment. Nontolerant individuals occasionally develop coma and respiratory depression after relatively small overdoses without obvious peripheral antimuscarinic effects and without QRS widening. Overflow urinary incontinence may be mistaken for normal micturition in pediatric (diaper-dependent) patients.

Serious toxicity is almost always seen within 6 h of major TCA ingestion and consists of the following symptoms: coma, cardiac conduction delays, supraventricular tachycardia, hypotension, respiratory depression, premature ventricular beats, ventricular tachycardia, and seizures. [8] Secondary complications from serious toxicity include aspiration pneumonia, anoxic encephalopathy, hyperthermia, and rhabdomyolysis. Pulmonary edema is a well-recognized complication of TCA overdose. Seizures are usually generalized and brief in duration. The exception to this rule is seen in amoxapine and maprotiline overdoses. These agents can cause status epilepticus. Amoxapine seizures commonly occur without corresponding QRS widening.

DIAGNOSIS

TCA toxicity should be suspected in all patients with a positive serum TCA drug screen in conjunction with corresponding clinical toxicity and/or characteristic ECG abnormalities. Most cases of TCA toxicity will be associated with elevated quantitative TCA plasma levels. However, these are routinely not available to the emergency physicians, nor do they have an impact on ED care. Conversely, qualitative TCA drug tests are available in most hospitals and have a rapid turnaround time. They can be used to confirm the presence of TCAs but cannot differentiate between therapeutic and toxic levels. False-positive qualitative serum TCA drug screen results can occur with diphenhydramine, carbamazepine, cyclobenzaprine, cyproheptadine, and phenothiazines. Some of these medications also can produce typical TCA electrocardiographic abnormalities and similar clinical toxicity. False-negative serum TCA drug tests are extremely unusual. They should be repeated with a new specimen if there is a high clinical suspicion for TCA exposure. Urine drug testing may be helpful in identifying other toxicologic causes for the patient's condition. The differential diagnosis of TCA toxicity encompasses those drugs which can mimic any one of the three criteria used in making the diagnosis (Table 152-3). However, the quintessential point for emergency physicians is that the initial treatment for all these medications is identical and should not be delayed until definitive drug test results become available.

TABLE 152-3   Differential Diagnosis of Tricyclic Antidepressant Toxicity

ECG abnormalities are seen commonly with TCA toxicity and generally are useful in identifying patients at increased risk for seizures and ventricular dysrhythmias. The "classic" TCA electrocardiogram is shown in Fig. 152-1, consisting of sinus tachycardia, right-axis deviation (RAD), and prolongation of the PR, QRS, and QT intervals. This "classic" ECG pattern is seen frequently in moderate to severe TCA toxicity, but its absence does not eliminate the possibility of TCA toxicity during the first 6 h after ingestion. Figure 152-2 is an ECG 4 days later with near-complete resolution of all abnormalities. Moderate prolongation of the QT interval is noted frequently, even at therapeutic TCA doses. Nonspecific ST-segment and T-wave abnormalities are commonly observed in TCA overdose. Less common ECG abnormalities include right bundle branch block and high-degree atrioventricular blocks.
FIG. 152-1. "Classic" TCA electrocardiographic abnormalities. Sinus tachycardia and prolonged PR, QRS, and QT intervals. Also, right axis deviation (RAD) of terminal 40 ms.
FIG. 152-2. Repeat ECG 4 days later in the same patient as in Fig. 152-1. Only mild QTc prolongation persists.

Life-threatening complications can occur in the absence of significant ECG abnormalities.[9] However, these complications are more likely in the presence of a widened QRS greater than 100 ms and/or RAD of the terminal 40 ms of greater than 120°. The risk of seizures increases as the QRS complex exceeds 100 ms, and ventricular dysrhythmias are more likely if QRS prolongation exceeds 160 ms. RAD is commonly demonstrated as a positive terminal R wave in lead aVR and a negative S wave in lead I (Fig. 152-3). Both abnormalities are equally helpful in identifying patients at risk for serious toxicity.[11] They usually occur together but can occur in exclusion of each other. The development of RAD of the terminal 40 ms and/or QRS widening appears to be less predictable of TCA-induced cardiotoxicity in young children.[12] Pediatric ECGs tend to have a wider range of acceptable variant features, and this complicates the ECG identification of TCA toxicity.
FIG. 152-3. A. An example of terminal 40 ms RAD during TCA toxicity. Note the large R wave in aVR and S wave in lead I. **B.** The same patient after complete resolution of TCA toxicity. Note the decrease in the R wave height in aVR and S wave in lead I.

ECG abnormalities universally develop within 6 h of ingestion and usually resolve over 36 to 48 h.[13] The identification of either QRS widening greater than 100 ms or terminal RAD greater than 120° warrants sodium bicarbonate therapy and admission to a monitored hospital bed. Unfortunately, up to 10 percent of the population will have a prolonged QRS of more than 100 ms or terminal RAD without exposure to sodium channel blocking drugs. Therefore, these ECG abnormalities in isolation are not 100 percent specific for TCA toxicity. Most patients on TCA therapy do not have prior ECGs available for comparison. Thus, any observed ECG abnormalities must be assumed attributable to TCA exposure until proven otherwise.

TREATMENT

All patients should be evaluated immediately for alterations of consciousness, hemodynamic instability, and respiratory impairment. Every patient requires an

intravenous line, continuous ED cardiac monitoring, and an ECG. Serial ECGs will be required in most patients. Suggested laboratory studies include determinations of serum electrolyte, creatinine, and glucose levels. A quantitative serum acetaminophen level is recommended in all overdose patients. Most symptomatic patients will require arterial blood gas measurement. Patients with antimuscarinic symptoms may require a urinary catheter to prevent urinary retention and a nasogastric tube if bowel sounds are absent. Patients who are initially asymptomatic may deteriorate rapidly and therefore should be monitored closely for several hours. Emergency physicians should report all TCA exposures to a regional poison control center.

Gastrointestinal Decontamination

Although the best method of gastrointestinal decontamination in TCA ingestions remains undefined, a few generalizations are still possible. [14] The risks associated with using syrup of ipecac outweigh any beneficial effects, and its use cannot be recommended. Activated charcoal (AC) has been shown to effectively bind TCAs and decrease their absorption. Therefore, all patients should receive 1 g/kg of AC. Whether gastric lavage and AC is better than AC alone remains unproven. Studies have shown that the gastric lavage is most effective when it is performed within the first few hours after ingestion. Most emergency physicians opt to perform gastric lavage and give AC to patients who present relatively early after TCA ingestion. The proper method of performing gastric lavage in alert patients is to place the patient in the left lateral decubitus position to prevent pulmonary aspiration. Obtunded patients require endotracheal intubation prior to performing gastric lavage. Asymptomatic patients with reliable histories of minimal TCA ingestions can be treated with AC alone and observed for toxicity. Some authors have recommended giving repeat doses of AC to enhance TCA elimination, but these recommendations should be viewed cautiously in the setting of decreased intestinal motility.

Sodium Bicarbonate Therapy

Indications for sodium bicarbonate therapy include QRS complex widening greater than 100 ms, hypotension refractory to fluid hydration, and ventricular dysrhythmias. Sodium bicarbonate has been shown to improve conduction, increase contractility, and suppress ventricular ectopy. It is given as an initial bolus of 1 to 2 meq/kg, which can be repeated until patient improvement is noted or until blood pH equals 7.50 to 7.55 (Fig. 152-4). Alkalinization beyond this point can be deleterious and therefore is discouraged. Continuous infusions of sodium bicarbonate are usually administered as 3 ampules (50 meq/50 mL) placed in 1 L of 5% D/W or 2 ampules added to 5% D/0.45 NS (slightly hypertonic with $NaHCO_3$ added) solution and run at a rate of 2 to 3 cc/kg/h. Adjustments in the intravenous rate are made based on blood pH measurements, serum sodium level, and clinical response to therapy. Hypokalemia is an expected complication of $NaHCO_3$ therapy. Intravenous potassium supplementation is usually required, and serum potassium levels should be measured frequently.
FIG. 152-4. A. Cardiac rhythm strip of a patient with a wide QRS, recorded 3 h after ingesting amitriptyline. **B.** Narrowing of the QRS complex in same patient after receiving an intravenous bolus of sodium bicarbonate.

Altered Level of Consciousness

Patients with altered level of consciousness require a trial of intravenous dextrose, thiamine, naloxone, and oxygen to rule out reversible causes of CNS depression. Antagonism of postsynaptic muscarinic, histamine, and a-adrenergic receptors contributes to the development of altered mentation in TCA overdoses. Coma from TCA toxicity is typically rapid in onset. Unresponsive patients may have unrecognized head or neck trauma. Flumazenil should not be given to patients suspected of having mixed-drug overdoses involving TCAs and benzodiazepines because this may precipitate generalized seizures. There is a very high incidence of pulmonary aspiration among TCA overdose patients who present comatose to the ED. Agitation is commonly observed prior to the onset of coma, as well as in previously comatose patients as they awaken. Agitation is best controlled with reassurance, decreased environmental stimulation, and benzodiazepines. As mentioned previously, physostigmine should not be administered to patients taking TCAs.

Seizures

Most seizures occur within the first 3 h following ingestion. Typically, these seizures are generalized and brief in duration. Multiple seizures are reported in approximately 10 to 30 percent of TCA overdoses. Focal seizures are atypical and require further neurologic evaluation. Seizures are especially common with maprotiline and amoxapine ingestions and require aggressive management because status epilepticus is frequently associated with these two particular antidepressants. Benzodiazepines (e.g., diazepam, lorazepam) are the anticonvulsants of choice to stop existing seizure activity. Barbiturates (e.g., phenobarbital) are indicated to treat seizures resistant to benzodiazepines. The initial intravenous dose of phenobarbital is 15 mg/kg, but this can be increased in patients with continued seizure activity and adequate blood pressure. Hypotension is a major side effect. Endotracheal intubation and respiratory support will be required when benzodiazepines are combined with barbiturates or propofol. Phenytoin is an ineffective anticonvulsant for stopping TCA-induced seizures. Physostigmine and $NaHCO_3$ do not stop TCA-induced seizures. If seizures continue despite adequate dosing with benzodiazepines and phenobarbital, consideration should be given to paralyzing the patient with a neuromuscular blocking agent. This will stop the physical manifestations of the seizure and its secondary effects, which include metabolic acidosis, hyperthermia, rhabdomyolysis, and renal failure. It does not stop brain seizure activity. Therefore, following the induction of muscle paralysis, these patients require electroencephalographic (EEG) monitoring and continued anticonvulsant therapy.

Hypotension

Hypotension should be treated initially with isotonic crystalloid fluids in increments of 10 mL/kg. In the setting of impaired cardiac contractility, pulmonary edema can develop if excessive fluids are administered. Hypotension that does improve with appropriate fluid challenges should be treated with $NaHCO_3$ (regardless of QRS width). Vasopressors should be used when hypotension is unresponsive to fluids and sodium bicarbonate therapy. The most effective vasopressor is norepinephrine, because it directly competes with TCAs at a-adrenergic receptors. Dopamine is less effective than norepinephrine in reversing TCA-induced hypotension. [15] In many cases, dopamine administration actually will cause a lowering in systolic blood pressure due to its b-adrenergic and dopaminergic actions that promote vasodilation. If used, it should be adjusted at the upper range of the dose (12 to 20 µg/kg/min). A pulmonary artery catheter should be placed in patients whose hypotension is refractory to fluid, $NaHCO_3$, and vasopressor therapy. Mechanical irritation of the heart during pulmonary artery catheter placement may precipitate life-threatening conduction abnormalities and ventricular dysrhythmias. Hypotension induced by TCAs represents a potentially reversible cause of cardiovascular collapse. Mechanical support of the circulation with cardiopulmonary bypass, overdrive pacing, or aortic balloon pump assistance may be warranted in patients with refractory hypotension, although no studies document their effectiveness.

Dysrhythmias

TCAs frequently alter cardiac rate, conduction, and contractility. Asymptomatic patients with sinus tachycardia, isolated PR and QT prolongation, or first-degree atrioventricular (AV) block do not require specific pharmacologic therapy. Conduction blocks greater than first-degree AV block are worrisome because they can rapidly progress to complete heart block secondary to impaired infranodal conduction. Most patients with QRS prolongation greater than 100 ms should be treated with $NaHCO_3$ therapy, although this is somewhat controversial. This recommendation is made despite the absence of randomized, controlled human trials demonstrating $NaHCO_3$ therapy benefits in otherwise asymptomatic patients with QRS prolongation. [16] Nonetheless, the early use of sodium bicarbonate in the setting of sodium channel blockade has become a common practice for treating QRS widening. Hyperventilation represents a reasonable alternative to sodium bicarbonate

therapy in the setting of renal failure, pulmonary edema, or cerebral edema.

Ventricular dysrhythmias should be treated immediately with sodium bicarbonate administration. Lidocaine is the second agent of choice in treating ventricular dysrhythmias. Excessive lidocaine administration is capable of producing seizures. Bretylium is generally considered a third-line drug for ventricular dysrhythmias. Synchronized cardioversion is appropriate in patients with unstable dysrhythmias. Torsade de pointes should be treated initially with 2 g of intravenous magnesium sulfate. Efforts should be made to rule out other causes of torsades de pointes. Overdrive pacing is frequently required to prevent a recurrence of this dysrhythmia. Intravenous isoproterenol may be of some benefit in treating recurrent torsade de pointes when overdrive pacing is not available. The following medications are contraindicated in the treatment of TCA-induced dysrhythmias: all class IA and IC antiarrhythmic agents, beta blockers, calcium channel blockers, and all class III antiarrhythmic agents.

DISPOSITION

Patients who remain asymptomatic 6 h after ingestion do not require hospital admission for toxicologic reasons. They may still require hospital admission because of other coexisting medical or psychiatric conditions. Psychiatric evaluation is warranted for intentional drug ingestions. All symptomatic patients require hospital admission to a monitored bed. Patients demonstrating signs of moderate to severe toxicity should be admitted to an intensive care unit. Hospitalized patients can be cleared medically after 12 h of being asymptomatic: including a normal or baseline ECG, normal mental status, and resolution of all antimuscarinic symptoms.

153 NEWER ANTIDEPRESSANTS AND SEROTONIN SYNDROME

Kirk C. Mills

The newer antidepressants are commonly referred to as atypical, heterocyclic, or second-generation antidepressants to distinguish them from monoamine oxidase inhibitors (MAOIs) and tricyclic antidepressants (TCAs). This distinction is important because newer antidepressants are more selective in their pharmacologic activity and have drastically different toxicologic behavior than MAOIs and TCAs. As a group, the newer antidepressants are the most popular form of psychopharmacologic therapy for the treatment of major depression. In addition, they are also commonly prescribed in the treatment of many other psychiatric disorders such obsessive-compulsive disorder, panic disorders, and eating disorders. Although none of the newer antidepressants have been labeled by the Food and Drug Administration for use in children, their use in adolescents and older children is not uncommon.

Emergency physicians are increasingly challenged to evaluate patients who have taken these newer antidepressants. Questions commonly arise as to the extent of management needed to treat these patients appropriately. Therefore, the newer antidepressants are discussed individually in this chapter, highlighting specific treatment recommendations. Importantly, all antidepressants, especially the MAOIs and selective serotonin reuptake inhibitors (SSRIs), have the potential to produce the serotonin syndrome, a recently recognized drug-induced disorder, which is discussed at the end of this chapter. The newer antidepressants that are discussed in this chapter include trazodone (Desyrel), nefazodone (Serzone), bupropion (Wellbutrin), mirtazapine (Remeron), venlafaxine (Effexor), and the SSRIs: fluoxetine (Prozac), sertraline (Zoloft), paroxetine (Paxil), fluvoxamine (Luvox), and citalopram (Celexa).

GENERAL PRINCIPLES OF NEWER ANTIDEPRESSANTS

The newer antidepressants are a heterogeneous group of drugs that differ significantly in chemical structure, mechanism of action, pharmacokinetic characteristics, and adverse effect profile. Nonetheless, they also share many important similarities that are summarized in the following seven points. For brevity within this chapter, most of these points are not repeated for each individual drug:

1. These agents do not significantly inhibit cardiac sodium, calcium, or potassium ion channels. Therefore, they do not demonstrate the same cardiotoxicity or electrocardiographic conduction abnormalities typically seen with TCAs.

2. These agents do not inhibit monoamine oxidase activity and are not associated with tyramine-like reactions. The use of indirect sympathomimetics is not contraindicated.

3. They have negligible affinity for acetylcholine, dopamine, g-aminobutyric acid (GABA), glutamate, or b-adrenergic receptors. Although their exact mechanism of action remains poorly understood, it is traditionally attributed to inhibition of neurotransmitter reuptake (except mirtazapine).

4. Newer antidepressants (except bupropion) appear to have a much higher safety margin than the MAOIs and TCAs. Nonetheless, they can still cause fatalities, especially at very high doses or when combined with other drugs. Importantly, there is extremely limited human data on the "typical" presentation or optimal management of patients having overdosed on newer antidepressants. Therefore, current management recommendations may require modification as more information becomes available. Emergency physicians should routinely contact a regional poison control center (PCC) to report exposures to newer antidepressants. Also, consultation with a medical toxicologist is available through most regional PCCs.

5. Attempts at enhancing the elimination of newer antidepressants via hemodialysis, hemoperfusion, forced diuresis, or multiple-dose activated charcoal are unlikely to be successful and therefore not recommended. Whole bowel irrigation does not offer any advantage over single-dose activated charcoal in providing gastrointestinal decontamination to patients exposed to newer antidepressants.

6. The newer antidepressants are not detected by routine hospital serum and urine drug screens. Certain specialty laboratories do have the capability to measure parent drug and metabolite plasma levels, but this information is only useful for the confirmation of suspected drug overdose. Specific levels are not immediately available to emergency physicians nor do they affect the management of these patients. Postmortem drug redistribution is likely to occur with the newer antidepressants and, thus, postmortem drug level interpretation must take this factor into consideration.

7. Since all of the newer antidepressants are metabolized primarily by the liver, hepatic dysfunction can lead to elevated drug levels and subsequent drug toxicity. Also, drug interactions are possible when the newer antidepressants are combined with other drugs dependent on hepatic metabolism.

TRAZODONE

Trazodone hydrochloride (Desyrel) was released in the United States in 1982 for the treatment of endogenous depression. In 1997, the American Association of Poison Control Centers Toxic Exposure Surveillance System (AAPCC-TESS) recorded 10,460 exposures to trazodone.[1] During the past 5 years, the frequency of reported trazodone exposures has increased by almost 300 percent. Thus, trazodone exposures represent an increasingly common poisoning concern for emergency physicians. Trazodone is relatively safe in overdose when compared with MAOIs and TCAs. The calculated fatality rate for trazodone is 1 in 1200 exposures. This is approximately seven to ten times less than the fatality rate for MAOI or TCA exposures. The average daily therapeutic dose for trazodone is between 150 to 400 mg, with a maximum dose of up to 600 mg restricted to psychiatric inpatients. Trazodone is available as 50-mg, 100-mg, 150-mg, and 300-mg tablets. There is a low potential for trazodone abuse, and a distinct withdrawal syndrome has not been observed with its abrupt discontinuation. Trazodone is a category C risk in pregnancy.

Trazodone is a triazolopyridine derivative that is structurally unrelated to other antidepressants. Its antidepressant action is believed to be due to a combination of serotonin (5-hydroxytryptamine or 5-HT) reuptake inhibition and antagonism of postsynaptic 5-HT $_2$ receptors.[2] Trazodone is a moderately potent nonselective a-adrenergic receptor blocker with at least five times greater affinity for a $_1$- than a$_2$-adrenergic receptors. Consequently, trazodone is frequently associated with orthostatic hypotension, which is maximal within the first 6 h of use and can be minimized by taking the medication at bedtime. Sedation, which is a common side effect of trazodone therapy, is believed to be secondary to inhibition of central a-adrenergic and histamine receptors.

Trazodone is rapidly and completely absorbed, with peak plasma levels occurring between 1 and 2 h following oral administration. It is highly protein bound and has a moderate volume of distribution (1.2 L/kg). The majority of trazodone undergoes hepatic oxidation by the cytochrome P-450 isoenzyme system. It has one active

metabolite, *m*-chlorophenylpiperazine (*m*-CPP), which has a complex pharmacologic profile, such as inhibition of 5-HT uptake, stimulation and inhibition of multiple postsynaptic serotonin receptors, and interactions with other neurotransmitter systems. The overall contribution of *m*-CPP to the therapeutic and toxic effects of trazodone is currently under investigation. The half-life of trazodone ranges from 5 to 9 h at therapeutic doses but can increase up to 13 h in overdose.

The adverse effect profile for trazodone is very favorable when compared with other antidepressants except for its association with priapism. Trazodone is the most common cause of drug-induced priapism. The estimated incidence of priapism while on therapeutic doses ranges from 1 in 1000 to 1 in 10,000 patients. Any patient with a history of increased frequency, duration, or inappropriate penile or clitoral engorgement should immediately discontinue trazodone therapy. Human volunteer and laboratory animal studies have proven that trazodone is far less cardiotoxic than TCAs. Therapeutic use of trazodone has been occasionally reported to be arrhythmogenic, especially in patients with underlying cardiac risk factors such as conduction abnormalities or ischemic heart disease. Examples of cardiac rhythm abnormalities reported in association with trazodone therapy include sinus arrest, sinus bradycardia, various atrioventricular blocks, complete heart block, atrial fibrillation, and ventricular dysrhythmias (premature ventricular beats or torsade de pointes). The most frequently reported dose-related adverse effects are drowsiness, dizziness, dry mouth, nausea and vomiting, and orthostatic hypotension. There have been rare case reports of patients experiencing reversible liver enzyme elevation, jaundice, and abnormal liver histology in association with trazodone therapy.

Pharmacokinetic drug interactions are relatively uncommon with trazodone. Trazodone levels may be increased by concurrent fluoxetine administration. Increased serum digoxin and phenytoin levels have been reported in patients receiving trazodone. Elderly patients have a predisposition for developing elevated plasma trazodone levels at any given therapeutic dose. Pharmacodynamic interactions are most common with coingestants such as ethanol, central nervous system (CNS) depressants, or a-adrenergic blockers.

Acute Overdose Toxicity

There is no established toxic dose for trazodone. As a general guideline, serious toxicity in an average adult is unexpected with ingestions of less than 2 g. This safety margin is significantly reduced when other medications are coingested with trazodone. The most common symptom of acute trazodone poisoning is CNS depression. Other CNS-related symptoms include ataxia, dizziness, coma, and seizures. Trazodone rarely produces coma or seizures when it is the only drug ingested. Pupils are usually normal size and remain reactive to light. Infrequently, patients may complain of muscle weakness. Trazodone-induced CNS symptoms show marked improvement within 6 to 12 h after ingestion and are almost always resolved by 24 h. Orthostatic hypotension is the most frequently reported cardiovascular abnormality noted in trazodone overdose and usually responds to fluid administration. Mild abnormalities of sinus rhythm, such as sinus bradycardia and tachycardia, are frequently encountered. The most common electrocardiographic abnormality is moderate prolongation of the QTc interval. Polymorphic ventricular tachycardia (torsade de pointes) has been reported in rare cases. Commonly reported gastrointestinal complaints include nausea, vomiting, and nonspecific abdominal pain. Respiratory depression is infrequently observed with pure trazodone overdoses. Priapism has been reported following an acute overdose of 3.5 g.

Treatment

An intravenous line should be started and cardiac monitoring initiated on all patients. In pure trazodone ingestions, significant neurologic and cardiac toxicity is not expected and supportive care is usually the only treatment required. Specific antidotal therapy is not available. Gastrointestinal decontamination can be applied selectively in cases where the dose ingested can be accurately calculated. Ingestion of 1500 mg or less of trazodone in an adult carries a low risk of toxicity, as long as trazodone is ingested as a single agent and the patient does not have any underlying cardiac or neurologic risk factors. These patients should receive 1 g/kg of activated charcoal, and gastric lavage is probably unnecessary. Ingestions of more than 2000 mg of trazodone poses the greatest risk for associated toxicity and complications. Also, patients having coingested other drugs and/or ethanol have a higher incidence of coma, seizures, and respiratory arrest. Gastric decontamination in these patients is best achieved by early gastric lavage followed by administration of activated charcoal. Hypotension should be initially treated with isotonic intravenous fluid administration. If the use of a vasopressor becomes necessary, direct-acting vasopressors (e.g., norepinephrine) are recommended. Drugs with b-adrenergic receptor activity (e.g., dopamine) can theoretically potentiate the hypotension in the presence of trazodone-induced a-adrenergic receptor antagonism. Patients who have remained asymptomatic for at least 6 h can be safely discharged from the emergency department. This assumes that any necessary psychiatric evaluation has been completed or arranged. All intentional trazodone ingestions should be properly evaluated for the presence of other drugs (e.g., acetaminophen). Patients with neurologic and/or cardiac symptoms persisting longer than 6 h after ingestion will require hospital admission to a monitored bed. In addition, patients with coingestants associated with delayed toxicity will require prolonged observation or formal hospital admission.

NEFAZODONE

Nefazodone (Serzone), was approved in 1995 for the treatment of depression. It is both structurally and functionally related to trazodone. Nefazodone inhibits serotonin reuptake and also antagonizes postsynaptic 5-HT$_2$ receptors.[3] It has little affinity for other receptors except slight antagonism of postsynaptic a$_1$ receptors. Nefazodone is available in 100-mg, 150-mg, 200-mg, and 250-mg tablets. The recommended effective dose for nefazodone is between 300 and 600 mg/day. Although nefazodone is rapidly absorbed, it has a bioavailability of only 20 percent due to extensive first-pass hepatic metabolism. Peak levels occur within 1 h, and its elimination half-life ranges from 2 to 6 h. It is 99 percent protein bound, with a relatively small volume of distribution. It has three active metabolites: hydroxynefazodone, desethylhydroxynefazodone, and *m*-CPP. The hydroxynefazodone metabolite is pharmacologically equivalent to the parent compound. The *m*-CPP metabolite is noteworthy only because it is also produced by trazodone. Nefazodone can inhibit the metabolism of terfenadine, astemizole, and cisapride, which in turn can lead to life-threatening prolongation of the QT interval (torsade de pointes). Certain benzodiazepines such as alprazolam and triazolam have marked increased CNS effects in the presence of nefazodone. Overall, nefazodone has a favorable adverse effect profile. Compared with placebo, however, nefazodone has a higher incidence of headache, dizziness, drowsiness, asthenia, tremor, dry mouth, nausea, constipation, and blurred vision. It also predisposes patients to postural hypotension and priapism but not to the same degree as trazodone. Nefazodone has a category C rating in pregnancy.

Treatment

Experience with nefazodone in overdose is extremely limited. Unpublished premarketing data suggest that nefazodone is relatively safe in overdose. The most common symptoms reported include nausea, vomiting, and somnolence. There were no fatalities with pure nefazodone ingestions ranging from 1000 to 11,200 mg. Based on its pharmacokinetic profile, the onset of nefazodone toxicity would be expected to occur within the first 6 h following an overdose. At present, management of nefazodone overdoses should follow the aforementioned guidelines for trazodone.

BUPROPION

Bupropion (Wellbutrin) has been available in the United States since 1989 for the treatment of major depression. The actual incidence and severity of bupropion exposures are unknown because the AAPCC-TESS data do not include a separate category for bupropion exposures. However, since bupropion has recently been approved for the treatment of smoking cessation (Zyban), the potential for bupropion poisoning is considerable. Both Wellbutrin and Zyban tablets are manufactured by the same company and are available in similar 150-mg sustained-release formulations. For smoking cessation, Zyban (150 mg) is administered either once or twice daily for no more than 12 consecutive weeks. Wellbutrin comes in a variety of shapes and formulations, including sustained-release tablets (100 and 150 mg) and regular-release tablets (100 and 75 mg). The recommended starting dose of Wellbutrin is 100 mg given twice daily, gradually increasing up to 300 mg/day. The incidence of seizures drastically increases at doses greater than 450 mg/day, and higher doses are therefore prohibited. The combination of the two bupropion preparations, Wellbutrin and Zyban, is contraindicated due to obvious concern for bupropion toxicity. Other contraindications include patients with bulimia, anorexia nervosa, epilepsy, or taking MAOIs. Bupropion is a category B drug in pregnancy. The information in this section is derived from studies utilizing only the Wellbutrin form of bupropion. It is assumed that this information is equally applicable to Zyban exposures, and therefore no further distinction in this chapter is made between these two bupropion products.

Bupropion has a monocyclic phenylaminoketone chemical structure that resembles those of the phenylethylamines (e.g., amphetamine).[4] However, bupropion does not produce stimulant effects or drug-addictive behavior at therapeutic doses. The therapeutic mechanism of action for bupropion is poorly understood but currently believed to be related to its ability to inhibit dopamine neuronal reuptake. It does not directly stimulate postsynaptic dopamine receptors. In vitro studies show bupropion to be a weak inhibitor of norepinephrine and serotonin neuronal reuptake. Bupropion is rapidly absorbed after oral administration and undergoes extensive first-pass hepatic metabolism. It is highly protein bound, has an extremely large volume of distribution, and readily crosses the blood-brain barrier. Peak plasma levels occur within 2 h for regular-release tablets and 3 h for sustained-release preparations. Its elimination half-life ranges between 14 to 20 h. Bupropion has one important metabolite—hydroxybupropion—which is less potent than bupropion, preferentially inhibits norepinephrine reuptake, and may contribute to seizure

development.

Bupropion antidepressant therapy is well tolerated. It does not produce CNS depression, orthostatic hypotension, or cardiovascular changes, or impair sexual function at therapeutic doses. The most commonly reported adverse effects are of mild severity and include dry mouth, dizziness, agitation, nausea, headache, constipation, tremor, anxiety, confusion, blurred vision, and increased motor activity. Bupropion has been reported to infrequently produce catatonia, hallucinations, psychosis, and paranoia that are probably related to its dopaminergic activity.

Abrupt discontinuation of bupropion has not been associated with any withdrawal symptoms but may pose a slight theoretic risk of precipitating neuroleptic malignant syndrome, since bupropion is considered a dopamine agonist. Bupropion is relatively free of significant drug interactions. In general, bupropion should not be combined with selective serotonin reuptake inhibitors, lithium, MAOIs, TCAs, dopaminergic drugs (e.g., levodopa), or drugs that are known to lower patient seizure threshold (e.g., phenothiazines).

Acute Overdose Toxicity

Bupropion differs from other new antidepressants in that it has a low toxic to therapeutic ratio. Toxicity can occur at doses equal to or just slightly greater than the maximum therapeutic dose of 450 mg/day. As a general rule, significant toxicity is not expected in pure bupropion overdose with adult ingestions of less than 450 mg. The largest case series of bupropion overdoses reported that symptomatic patients ingested a mean of 2310 mg and the lowest symptomatic dose was 200 mg. [5] Patients who remained asymptomatic ingested a mean of 1325 mg and the largest asymptomatic dose was 4000 mg. The most commonly reported symptoms in pure bupropion overdose include sinus tachycardia (43 percent), lethargy (41 percent), tremor (24 percent), generalized seizures (21 percent), confusion (14 percent), and vomiting (14 percent). Mild hyperthermia is occasionally reported. Sinus tachycardia is the most common electrocardiographic abnormality. An isolated case of moderate QT interval prolongation has been reported in conjunction with a massive bupropion overdose. Otherwise, bupropion does not produce myocardial conduction abnormalities. Hypotension is unexpected in pure bupropion overdoses but has been reported in mixed-drug overdoses. Hypertension is usually of only mild to moderate severity. Coma and cardiac arrest have been reported in severe bupropion overdoses. The hallmark of bupropion toxicity is generalized seizures. The actual incidence of seizures is unknown but is probably greater than the estimated 21 percent obtained by retrospective studies. There is no correlation between the development of seizures and the presence of other symptoms such as sinus tachycardia. Therefore, seizures can develop in otherwise asymptomatic patients. Seizures usually occur within the first 1 to 4 h after ingestion of regular-release bupropion. The average time of seizure onset is 3.7 h, but they may be delayed for up to 8 h. Recent case reports suggest that sustained-release preparations may predispose patients to seizures up to 14 h after exposure. Laboratory study findings are usually normal except for rare cases of mild hypokalemia.

Treatment

Emergency physicians should anticipate the possible early onset of generalized seizures in all cases of bupropion ingestion. A peripheral intravenous line should be established and cardiac monitoring initiated in all patients. Rapid gastrointestinal decontamination is recommended using gastric lavage and administering 1 g/kg of activated charcoal. Syrup of ipecac is contraindicated due to risk of seizures. Significant cardiotoxicity is not expected except in mixed-drug overdoses. Sinus tachycardia is rarely of hemodynamic significance. Seizures that last longer than 5 min, are focal in nature, or repetitive should be aggressively treated with benzodiazepines. Diphenylhydantoin (phenytoin) is generally less effective than benzodiazepines or phenobarbital in stopping drug-induced seizures but was reportedly effective in stopping seizure activity in one case of bupropion-induced status epilepticus. Hospital admission is recommended for all patients with seizures, sinus tachycardia, or lethargy. Asymptomatic patients having ingested only regular-release bupropion can be medically cleared after 8 h of observation. In many cases, a psychiatric evaluation may also be necessary. Similar guidelines for sustained-release bupropion preparations have not been established. Therefore, patients ingesting more than 450 mg of sustained-release bupropion probably require longer periods of monitoring before medical clearance.

MIRTAZAPINE

Mirtazapine (Remeron), a tetracyclic compound structurally unrelated to other currently available antidepressants, has been available in the United States since 1996.[6] In contrast to all other atypical antidepressants, mirtazapine does not inhibit neuronal amine uptake. Instead, it blocks central presynaptic a $_2$-adrenergic receptors and postsynaptic serotonin receptors, subtypes 5-HT$_2$ and 5-HT$_3$. This has the net therapeutic effect of increasing central norepinephrine and serotonin (5-HT$_1$) neurotransmission. Mirtazapine has a high affinity to block histamine (H $_1$) receptors and a low affinity for all other postsynaptic receptors. Mirtazapine is commonly associated with somnolence (antihistamine effect) and less often associated with weight gain and increased appetite. It is supplied as 15-mg and 30-mg tablets, with an average daily dose range of between 15 to 45 mg. It is has a category C rating in pregnancy. Because it might cause serotonin syndrome, its use is discouraged in combination with MAOIs. Although not specifically contraindicated, the use of other serotonergic agents (e.g., meperidine, dextromethorphan, and tramadol) should also be avoided in patients taking mirtazapine.

Mirtazapine has a similar pharmacokinetic profile as other atypical antidepressants. It is rapidly and completely absorbed following oral administration. Bioavailability is approximately 50 percent due to significant first-pass hepatic metabolism. Peak levels occur within 2 h after ingestion. Mirtazapine is metabolized by the hepatic oxidase enzyme system (P-450), with only minor active metabolites. Theoretically, since mirtazapine is metabolized by the P-450 enzyme system, drug interactions with other P-450-dependent medications is possible. Presently, no such interactions have been reported, although experience with mirtazapine is very limited. The elimination half-life for mirtazapine averages 26 h for males and 37 h for females. The difference in mirtazapine half-life between men and women is attributed to decreased P-450 metabolism in females. Mirtazapine is highly protein bound (85 percent) and has a large volume of distribution (5 L/kg). Plasma levels are unlikely to be affected by attempts at extracorporeal removal.

Acute Overdose Toxicity

Mirtazapine appears to be associated with limited toxicity in overdose. Presently, only 11 cases of mirtazapine overdose have been reported in the medical literature. The most common presentation includes sedation, confusion, sinus tachycardia, and mild hypertension. [7] Doses up to 1350 mg have been tolerated without significant sequelae. The risk of coma and respiratory depression is greatest at larger doses or when combined with other CNS-depressant drugs. Vital sign abnormalities are rarely of clinical significance and have not required specific treatment.

Treatment

Treatment guidelines have not been established for mirtazapine overdoses. Based on the currently available data, the following recommendations seem logical but may require modification as experience with mirtazapine increases. For this reason, PCC consultation is strongly encouraged for most cases involving the use of mirtazapine. Fortunately, mirtazapine toxicity usually resolves over 24 h with supportive care alone. Single-dose activated charcoal is the gastrointestinal decontamination method of choice. Gastric lavage may be warranted in selected patients presenting early after large overdoses or with significant coingestants. Syrup of ipecac is contraindicated, and whole bowel lavage is unnecessary. Symptomatic patients should be admitted to a monitored bed, but significant cardiac toxicity is unlikely. Electrocardiographic abnormalities other than sinus tachycardia have not been reported. Asymptomatic patients can be medically cleared after 8 h of observation.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

SSRIs represent a structurally heterogeneous group of drugs that share a selective affinity to inhibit presynaptic serotonin reuptake without significantly affecting norepinephrine or dopamine reuptake. The increase in synaptic serotonin levels may not entirely explain their therapeutic effects. [8] As with most antidepressant agents, acute alterations in biogenic amine levels do not correlate with immediate clinical response to drug therapy. Secondary receptor and cellular compensatory mechanisms are currently believed to play an important role in their mechanism of action. SSRIs are essentially devoid of direct presynaptic or postsynaptic receptor interactions. Thus, they are associated with very few unwanted pharmacologic actions, in contrast to TCAs.

SSRIs represent the most common form of pharmacotherapy for depression in the United States. In 1997, the AAPCC-TESS recorded 27,941 exposures to SSRIs, with 21 associated deaths. This was the first year that the AAPCC-TESS specifically tracked SSRI exposures. It is expected that exposures to SSRI will continue to be a common problem faced by emergency physicians. There are currently five SSRIs available in the United States: fluoxetine (Prozac, released in 1988), sertraline (Zoloft, released in 1991), paroxetine (Paxil, released in 1993), fluvoxamine (Luvox, released in 1994), and citalopram (Celexa, released in 1998). There are slight potency differences between SSRIs, but their clinical efficacy appears to be comparable. The daily equivalent doses of the SSRIs are as follows: fluoxetine, 20 mg;

paroxetine, 20 mg; citalopram, 40 mg; sertraline, 50 mg; and fluvoxamine, 150 mg. In pregnancy, some SSRIs (fluoxetine and sertraline) have a category B rating, whereas others (paroxetine and fluvoxamine) have a category C rating.

The SSRIs have similar pharmacokinetic profiles, including rapid and complete oral absorption, peak plasma levels occurring 4 to 8 h after ingestion (citalopram, 2 to 4 h), significant first-pass hepatic metabolism, high degree of protein binding (except citalopram), and large volume of distribution. Fluoxetine is the only SSRI with a clinically significant active metabolite, norfluoxetine, which is equally as potent as fluoxetine. The half-lives of fluoxetine and norfluoxetine are 2 to 4 days and 7 to 14 days, respectively. The effects of fluoxetine may last for up to 5 weeks because of the prolonged period necessary to allow for norfluoxetine metabolism. Sertraline and paroxetine have similar half-lives of approximately 24 h. The half-life of citalopram is estimated at 33 h, whereas fluvoxamine has the shortest half-life at 15 h. The SSRIs are metabolized almost entirely by the hepatic cytochrome P-450 isoenzyme system. It is becoming increasingly recognized that the SSRIs can inhibit the metabolism of other drugs dependent on the cytochrome P-450 isoenzyme system.[9] Clinically significant drug interactions are most likely to occur with drugs that have a low therapeutic index, for example, TCAs, antipsychotics, anticonvulsants, benzodiazepines, opiates, theophylline, warfarin, terfenadine, astemizole, and cisapride. SSRIs are contraindicated in combination with MAOIs. This includes a 2-week abstinence ("washout") period for most SSRIs and a 5-week abstinence period for fluoxetine. The administration of other serotonergic agents in combination with SSRIs should also be avoided whenever possible.

The most serious drug-related adverse effect of SSRI psychopharmacotherapy is the potential to produce serotonin syndrome (see discussion below). Other CNS-related adverse effects include headache, sedation, insomnia, dizziness, weakness or fatigue, tremor, and nervousness. Seizures are very uncommon but have been reported with all SSRIs. Serotonin has varying effects on the dopaminergic system. In many cases, extrapyramidal related symptoms such as dystonic reactions, akathisia, dyskinesia, hypokinesia, and parkinsonian symptoms have been reported in association with SSRI therapy. [10] Consequently, SSRIs should be used cautiously with antipsychotic agents because SSRIs can potentiate antidopaminergic activity. Gastrointestinal complaints such as nausea, diarrhea, constipation, vomiting, and anorexia are commonly reported by patients taking SSRIs. Other adverse effects less commonly reported include dry mouth, increased sweating, blurred vision, hyponatremia, and hypoglycemia. Hyponatremia is believed to be secondary to inappropriate secretion of antidiuretic hormone (syndrome of inappropriate antidiuretic hormone or SIADH). Sexual dysfunction (e.g., anorgasmia) is a relatively common SSRI-related adverse effect and is reversible with drug discontinuation. Priapism has been reported but is extremely rare. A withdrawal syndrome consisting of nonspecific neurologic, psychiatric, and gastrointestinal symptoms has been described in conjuncture with abrupt SSRI discontinuation. It is less likely to occur with fluoxetine, since it has a long-acting metabolite.

Acute Overdose Toxicity

Despite the tremendous popularity of SSRIs, there is limited information on their toxicity in overdose. The greatest amount of human overdose experience has been with fluoxetine.[11] The information from case series involving the other SSRIs is consistent with the information accumulated on fluoxetine. [12,13,14] and [15] However, important differences may exist between the different SSRIs that will become evident only with greater exposure of patients to individual SSRIs. Fortunately, all of the SSRIs are characterized by a high toxic to therapeutic ratio, and fatalities are uncommon with pure SSRI overdoses. Approximately one-half of all adult patients and 75 percent of pediatric patients remain asymptomatic following SSRI overdose. The most common symptoms seen in SSRI overdose include nausea, vomiting, sedation, tremor, and sinus tachycardia. These symptoms are almost identical to the adverse effect profile of SSRIs except for sinus tachycardia, which is more common in overdose and rarely reported as an adverse effect. Less frequently observed symptoms include mydriasis, seizures, diarrhea, agitation, hallucinations, hypertension, and hypotension. Sertraline may produce mild CNS stimulation in pediatric patients. [13] Sinus bradycardia was observed more frequently in fluvoxamine overdoses than with other SSRIs. Citalopram produced QRS widening in approximately one-third of cases when more than 600 mg was ingested.[15] In another case series, prolongation of the QT interval has been reported in association with significant citalopram ingestions. Other SSRIs have rarely been reported to produce similar electrocardiographic abnormalities. It most cases, the electrocardiographic abnormalities gradually resolve over 24 h. Tachycardia, mild hypotension, and lethargy are more commonly seen when SSRIs are combined with ethanol. Mixed-drug ingestions can produce a wide variety of additional symptoms, depending on the coingestant toxicity. Serotonin syndrome can occur as a consequence of acute SSRI overdose. The results of laboratory tests are usually normal in SSRI overdoses. As previously mentioned, SSRI therapy has been associated with drug-induced SIADH secretion, which may result in symptomatic hyponatremia.

Treatment

Patients who intentionally overdose with SSRI require immediate attention, establishment of a peripheral intravenous line, and cardiac monitoring. Overall, pure SSRI overdoses are associated with limited toxicity except for the infrequent development of life-threatening complications such as generalized seizures and serotonin syndrome. The optimal method of gastrointestinal decontamination in SSRI poisoning remains undetermined. Based on the high therapeutic index and unlikelihood of serious toxicity, single-dose activated charcoal (1 g/kg) is logical for most ingestions, and gastric lavage is probably unnecessary in the majority of SSRI overdoses. However, gastric lavage may have greater utility in the setting of mixed-drug overdoses or if extremely large doses of SSRIs have been recently ingested. Due to the potential for seizures and CNS sedation, syrup of ipecac is contraindicated in adult intentional ingestions.

All patients should be observed for at least 6 h, during which supportive care is generally all that is required. Psychiatric evaluation is warranted for intentional ingestions. Hospital admission is recommended for all patients who remain tachycardic or lethargic 6 h after ingestion. Patients at higher risk for complications include those with underlying seizure disorders, symptoms of serotonin syndrome, or mixed-drug overdoses that have the potential for additional or delayed toxicity. Sodium bicarbonate therapy is indicated in cases of SSRI-induced QRS prolongation, primarily seen after citalopram ingestions of greater than 600 mg, and is administered in an identical manner as described in Chapter 152. Other SSRIs have only rarely been associated with QRS widening. Benzodiazepines are recommended as initial anticonvulsant therapy. Barbiturates are probably equally as effective as benzodiazepines but are more sedating. Rare reports of delayed seizures, up to 16 h after ingestion, have been reported. Delayed onset of serotonin syndrome or extrapyramidal reactions are theoretic possibilities that should be considered in all patients.

VENLAFAXINE

Venlafaxine (Effexor), a bicyclic compound that is structurally different from other antidepressants, was released in 1994 for the treatment of depression. In contrast to the SSRIs, venlafaxine is a nonselective inhibitor of serotonin, norepinephrine, and dopamine reuptake. [16] Whether this nonselectivity offers any advantage over SSRIs, bupropion, trazodone, nefazodone, or mirtazapine is currently unknown. Venlafaxine has no significant direct effect on presynaptic or postsynaptic neurotransmitter receptors and does not inhibit MAO activity. It is available in 25-mg, 37.5-mg, 50-mg, 75-mg, and 100-mg tablets. The recommended starting dose is 75 mg/day, which can be gradually increased up to a maximum daily dose of 375 mg. It has a category C rating in pregnancy.

Peak levels occur 2 h after ingestion. It is poorly protein bound (27 percent), and it has volume of distribution of 6 to 7 L/kg and a half-life of approximately 5 h. The majority of venlafaxine undergoes hepatic P-450 oxidation, but it is a weak inhibitor of P-450 enzyme activity. To date, no significant pharmacokinetic drug interactions have been reported. It has one active metabolite, *O*-desmethylvenlafaxine, which is pharmacologically similar to its parent drug, except for a longer half-life of 11 h. The adverse effect profile for venlafaxine is similar to the aforementioned one for SSRIs. The only notable exception is the occurrence of mild to moderate hypertension when doses exceed 225 mg/day, which is probably secondary to inhibition of norepinephrine reuptake. Venlafaxine has the same potential as other serotonin agonists to produce serotonin syndrome. Therefore, it should not be combined with MAOIs or other serotonin agonists. Because of its shorter half-life, venlafaxine requires only a 1-week abstinence period before initiating MAOI therapy. However, a 2-week abstinence period is still required after MAOI discontinuation before starting venlafaxine therapy.

Acute Overdose Toxicity

Information regarding venlafaxine toxicity in overdose is limited to isolated case reports. Unfortunately, most of these cases also include significant coingestants, confounding the interpretation of "pure" venlafaxine toxicity. Sympathetic nervous system stimulation, via inhibition of norepinephrine reuptake, predisposes patients to tachycardia, hypertension, diaphoresis, tremor, and mydriasis. These symptoms are frequently seen in venlafaxine overdoses. Severe hypotension, requiring vasopressors, was reported one case. Otherwise, most vital sign abnormalities are of moderate severity and do not require specific pharmacologic therapy. CNS sedation is also commonly reported and occasionally progresses to coma requiring endotracheal intubation and ventilatory support. Generalized seizures are frequently reported and tend to occur early after ingestion. Electrocardiographic abnormalities include sinus tachycardia, QRS widening, and QTc interval prolongation. In most cases, symptoms completely resolve gradually over 36 h with supportive care alone.

Treatment

There are no established guidelines for treating venlafaxine overdoses. All patients require at least 6 h of observation. Venlafaxine toxicity is often precipitous and should be anticipated in all intentional overdoses. These patients require immediate emergency physician evaluation, establishment of a peripheral intravenous line, and cardiac monitoring. Venlafaxine appears to have greater toxicity in overdose than SSRIs and probably deserves more aggressive gastric decontamination.

Gastric lavage should be strongly considered for most intentional ingestions with early presentation. Accidental ingestions can be treated with single-dose activated charcoal alone. Benzodiazepines are the anticonvulsants of choice. Hypertension and sinus tachycardia rarely require specific pharmacologic therapy. b Blockers have the theoretical disadvantage of allowing unopposed a-adrenergic receptor stimulation. Sodium bicarbonate therapy should be considered in venlafaxine overdoses associated with QRS widening greater than 100 ms. All symptomatic patients should be admitted to a monitored bed.

SEROTONIN SYNDROME

Serotonin syndrome is a rare but important idiosyncratic drug-induced complication of antidepressant therapy. [17] It can be produced by any drug or, more commonly, by a combination of drugs that increase central serotonin neurotransmission (Table 153-1). The stimulation of specific postsynaptic serotonin receptors (5-HT_{1A} and 5-HT_2) is required for full expression of this syndrome. Drugs (like ondansetron) that block serotonin postsynaptic receptors are incapable of inducing this syndrome. The majority of cases occur at therapeutic levels, with fewer than 13 percent of cases being associated with drug overdose. Serotonin syndrome is characterized by alterations in cognition and behavior, autonomic nervous system function, and neuromuscular activity. The degree of abnormality in any one area is highly variable. Serotonin syndrome usually occurs either relatively soon after the dose of a potent serotonin agonist (MAOI or SSRI) has been increased or shortly after a second serotonergic agent (e.g., dextromethorphan) has been added. The importance of serotonin syndrome in emergency practice is twofold. First, the diagnosis of serotonin syndrome is very challenging due to its nonspecific symptomatology. Mild cases of serotonin syndrome are frequently attributed to other psychiatric and medical disorders. Severe cases are often misdiagnosed as neuroleptic malignant syndrome. Second, without proper recognition of patients at risk for serotonin syndrome, emergency physicians may inadvertently precipitate serotonin syndrome by administering serotonergic agents (e.g., meperidine). Therefore, emergency physicians should exercise the same drug-interaction precautions in treating patients taking newer antidepressants as those listed in Chapter 154, "Monoamine Oxidase Inhibitors."

TABLE 153-1   Serotonergic Potential of Various Drugs

The true incidence and severity of serotonin syndrome are unknown. Prospective studies on serotonin syndrome tend to overestimate its incidence and underestimate its severity. Conversely, case reports are often associated with incomplete documentation and tend to overestimate the severity and underestimate the incidence of serotonin syndrome. The most commonly reported signs and symptoms associated with serotonin syndrome are listed in Table 153-2. Interestingly, muscle rigidity, when present, is especially prominent in the lower extremities. This finding can serve as a valuable clinical marker for serotonin syndrome. Patients with ataxia should be carefully examined for lower extremity hypertonia. Unilateral muscle rigidity or focal neurologic findings have not been reported. Seizures are always generalized and usually short-lived. Hyperthermia is usually of moderate severity, but temperatures greater than 106°F (41°C) are not rare. Hypertension is twice as common as hypotension and is associated with a more favorable prognosis.

TABLE 153-2   Clinical Presentation of Serotonin Syndrome*

There are no confirmatory laboratory tests for serotonin syndrome. Therefore, the diagnosis of serotonin syndrome is based entirely on clinical suspicion and exclusion of other psychiatric and medical conditions. Serum chemistry tests, drug levels, cerebral spinal fluid analysis, and brain computed tomographic scan results are usually within normal limits. The differential diagnosis for serotonin syndrome is identical to those conditions listed in Chap. 154, "Monoamine Oxidase Inhibitors," Table 154-3.

The initial treatment of serotonin syndrome includes discontinuing all serotonergic drugs and providing appropriate supportive care. All patients with serotonin syndrome should be admitted to the hospital until their symptoms have completely resolved. The more severely ill patients require admission to an intensive care unit. Approximately 25 percent of patients require endotracheal intubation and ventilatory support. Most patients will show dramatic improvement within 24 h after symptom onset. However, fatalities have been reported. There is an estimated 11 percent mortality rate associated with serotonin syndrome.

At present, there are no accepted guidelines for the use of serotonin antagonists in the treatment of serotonin syndrome. Isolated human case reports suggest that cyproheptadine, methysergide, and propranolol have the potential to be effective antiserotonergic agents. Benzodiazepines are nonspecific serotonin antagonists and can be used to decrease patient discomfort and promote muscle relaxation. Cyproheptadine (Periactin) appears to be the most effective antiserotonergic agent in humans.[17,18] It should be on most hospital formularies. The initial dose is 4 to 8 mg PO. This dose can be repeated in 2 h if no response is noted to the initial dose. Cyproheptadine therapy should be discontinued if no response is noted after 16 mg has been administered. Patients who respond to cyproheptadine are usually given 4 mg every 6 h for 48 h to prevent recurrences. The use of dopamine agonists (e.g., bromocriptine) have no accepted role in managing patients with serotonin syndrome. Dantrolene (0.5 to 2.5 mg/kg IV q6h, maximum 10 mg/kg/24 h or 50 to 100 mg bid PO) is a nonspecific muscle relaxant that is occasionally used in serotonin syndrome, but it should be primarily restricted for the treatment of malignant hyperthermia. Patients with muscle rigidity, seizures, or hyperthermia should be closely monitored for rhabdomyolysis and/or metabolic acidosis. Once a patient recovers from serotonin syndrome, it is best to avoid future exposure to serotonergic drugs (Table 153-1), although the risk of recurrence is unknown.

154 MONOAMINE OXIDASE INHIBITORS

Kirk C. Mills

EPIDEMIOLOGY

Monoamine oxidase inhibitors (MAOIs) have been in clinical use for over 40 years; they were the first effective agents in the treatment of major depression. However, because of their inherent toxicity and the development of safer antidepressants, MAOIs are now generally reserved for atypical or refractory cases. Despite their decreasing popularity, MAOIs still pose one of the most complex pharmacologic and toxicologic challenges faced by emergency medicine physicians. They are associated with a narrow therapeutic index, potential for fatal food (e.g., tyramine reaction) and drug (e.g., serotonin syndrome) interactions as well as severe toxicity in overdose. Currently, three MAOIs are used as antidepressants in the United States: phenelzine (Nardil), tranylcypromine (Parnate), and isocarboxazid (Marplan). Approximately 14 million tablets of tranylcypromine were sold during 1997 and 40,000 prescriptions for phenelzine were filled during the first quarter of 1998 (personal communication: Parke-Davis and SmithKline Beecham Pharmaceuticals). The American Association of Poison Control Centers Toxic Exposure Surveillance System recorded 2325 exposures to MAOIs between 1997 and 1993.[1] Of these exposures, 75 percent occurred in adults, 40 percent were intentional ingestions, and 80 percent of patients developed symptoms. There were also 21 reported MAOI-related deaths during the same 5-year period, averaging 1 death for every 100 exposures. Mortality rates of up to 33 percent have been reported.[2] In contrast, trazodone (an atypical antidepressant) averaged 1 death for every 1200 exposures.[1] This comparison underscores the greater toxicity of MAOIs as compared with newer antidepressant agents.

The only federally approved indication for MAOI antidepressant therapy is for the treatment of nonendogenous depression (i.e., atypical depression or depression refractory to other antidepressants). Other conditions that have shown positive responses to MAOI antidepressant therapy include social phobia disorders, panic disorders, posttraumatic stress syndrome, obsessive-compulsive disorder, bulimia, and narcolepsy. MAOIs inhibitors are not approved for use in children below 16 years of age. Several newer MAOI antidepressants with improved safety and tolerability have been developed, but they are available only outside the United States. Conceivably, some of these newer MAOI antidepressants may gain future approval for domestic release and marketing.

St. John's wort (*Hypericum perforatum*) is a popular over-the-counter herbal treatment for depression and has been reported to demonstrate slight MAOI activity.[3] A specific history of herb use should be sought, since most patients do not consider St. John's wort a "drug." Although generally safe, St. John's wort should still be viewed with caution, since even mild MAOI activity may become more clinically significant in overdose or with certain drug interactions.

Selegiline (Eldepryl) is a MAOI that is devoid of antidepressant activity but is used as an adjunct to the treatment of Parkinson disease.[4] However, at increasing doses, it has activity similar to that of traditional MAOI antidepressants (see below). Some drugs have MAOI activity as an unrelated action, which may predispose patients using them to experience drug interactions. Examples include procarbazine (Matulane), a chemotherapeutic agent for severe Hodgkin lymphoma, and furazolidone (Furoxone), a synthetic nitrofuran with antimicrobial and antiprotozoan activity. Pargyline (Eutonyl) has been discontinued for over a decade but was an antihypertensive agent whose primary mechanism of action was MAO inhibition. Although the information in this chapter has relevance to all drugs with MAOI activity, it focuses primarily on phenelzine, tranylcypromine, isocarboxazid, and selegiline toxicity.

PATHOPHYSIOLOGY

Monoamine oxidase (MAO) is an intracellular enzyme bound to the outer mitochondrial membrane.[5] It has been identified in most human cells. A notable exception is erythrocytes, which do not contain mitochondria. MAO removes amine groups from both endogenous and exogenous biogenic amines. This oxidation deamination process is the primary mechanism by which endogenous biogenic amines such as norepinephrine (NE), dopamine (DA), and 5-hydroxytryptamine (serotonin or 5-HT) become inactivated. A second important function of MAO is to decrease the systemic availability of absorbed dietary biogenic amines (e.g., tyramine) via hepatic and intestinal metabolism. Therefore, inhibition of MAO leads to the accumulation of neurotransmitters in presynaptic nerve terminals (both centrally and peripherally) and allows for increased systemic availability of dietary amines. Monoamine oxidase has a negligible role in metabolizing circulating catecholamines, which are either secreted endogenously (e.g., by the adrenal gland) or administered intravenously (e.g., epinephrine). This function is accomplished by a different enzyme, catechol-O-methyl transferase (COMT), which is located extraneuronally and is not affected by MAOIs.

MAO is actually two separate isoenzymes, designated MAO-A and MAO-B. Each isoenzyme has its own relative preference for different neurotransmitters, dietary amines, and MAOIs. These substrate preferences are entirely dose-dependent and can be overcome at higher substrate concentrations or MAOI doses (e.g., selegiline). For example, MAO-A has a 1000 times greater affinity for serotonin than MAO-B, but the ability of MAO-B to metabolize serotonin increases at higher serotonin concentrations. Norepinephrine is primarily metabolized by MAO-A, whereas MAO-A and MAO-B have equal ability to metabolize dopamine and tyramine. Overall, the human brain contains more MAO-B than MAO-A, with MAO-B predominance increasing with advancing age. Dopamine neurons appear to lack MAO-B activity and have limited MAO-A activity.[6] Significant MAO-B activity has been detected in surrounding astrocytes and glial cells. Thus, dopamine inactivation may be dependent on astrocyte and glial-cell metabolism. Interestingly, MAO-B is the exclusive isoenzyme found in serotonergic neurons. This paradox may be explained by simple conservation of energy, where the MAO-B isoenzyme has a lower affinity for 5-HT and allows for more 5-HT to become recycled. It also allows for increased metabolism of nonserotonin bioamines, thus keeping the neuron free of false neurotransmitters. Intestinal MAO activity is mostly secondary to MAO-A, whereas approximately equal proportions of both isoenzymes are found in the liver. The dual representation of both isoenzymes in the intestines and liver affords greater protection against the tyramine reaction if only one isoenzyme is inhibited (i.e., selective inhibitors).

MAOIs share structural similarities with endogenous amines (e.g., NE, 5-HT, DA), and this allows them to act as potential substrates for MAO. The antidepressant activity of phenelzine, tranylcypromine, and isocarboxazid has generally been attributed to their ability to increase NE and 5-HT neurotransmission by increasing presynaptic concentrations of serotonin and norepinephrine. The actual mechanism by which they exert their therapeutic effects remains unproved but is probably related to delayed postsynaptic receptor modifications (e.g., downregulation). Other potential mechanisms of action include indirect release of neurotransmitters and inhibition of neurotransmitter reuptake. MAOIs also inhibit other enzyme systems (e.g., pyridoxal phosphokinase, diamine oxidase, etc.), but this finding is of uncertain clinical significance. Selegiline has limited effects on NE and 5-HT metabolism at therapeutic doses (10 mg/day). The therapeutic benefit of selegiline in Parkinson disease is thought to be related to increased striatal dopamine neurotransmission and protecting against neuronal damage from oxidative stress.[4,6] However, at doses greater than 30 mg/day, selegiline is capable of increasing presynaptic NE and 5-HT concentrations and thus has the potential to produce drug-related toxicity similar to that of phenelzine and tranylcypromine.

All of the currently available MAOI antidepressants are irreversible and nonselective (MAO-A, MAO-B) in their enzyme inhibition. MAOIs form irreversible covalent bonds with the MAO enzymes, and this renders the enzyme permanently inactive. Once an irreversible MAOI has been discontinued, it takes approximately 2 weeks before new enzyme synthesis has returned MAO activity to 50 percent of normal. MAOIs do not affect enzyme production. At therapeutic doses, selegiline primarily inhibits MAO-B, but this selectivity is lost at higher doses. Reversible MAOIs do not form irreversible covalent bonds with MAO. Thus, new enzyme synthesis is not necessary to restore MAO activity and MAO activity will gradually return to normal over a period of hours as the drug-enzyme complex spontaneously dissociates. As previously mentioned, reversible MAOIs are currently not available in the United States but are commonly utilized in other countries. Examples of reversible MAOIs include moclobemide, toloxatone, brofaromine, and cimoxatone.

All MAOIs are rapidly and completely absorbed from the gastrointestinal tract.[8] They have relatively low bioavailability because of a large first-pass effect of hepatic metabolism. Their dependence on hepatic metabolism predisposes them to potential drug interactions with other drugs requiring hepatic oxidation. Peak drug levels

usually occur 1 to 3 h after ingestion. They have relatively large volumes of distribution (1 to 5 L/kg) and are highly protein-bound. Elimination half-life averages between 2 and 3 h. It is important to recognize that clinical toxicity is usually delayed well after most of the MAOI has already been metabolized. Thus, blood MAOI levels do not correlate with clinical toxicity. Selegiline has many active metabolites, such as desmethylselegiline, amphetamine, and methamphetamine. Tranylcypromine has long been suspected of having amphetamine as a metabolite, but this has rarely been detected. Phenelzine metabolism results in multiple active metabolites such as B-phenylethylamine, which also serves as a substrate for MAO-B. [7] The pharmacokinetic profile of most MAOIs suggests that attempts at extracorporeal removal (e.g., hemodialysis) or administering repeat doses of activated charcoal would be unsuccessful in significantly reducing MAOI plasma levels.

TYRAMINE REACTION

Tyramine is an exogenous dietary amine that is normally metabolized by intestinal and hepatic MAO enzymes. [8] In patients taking a nonselective MAOI, a greater amount of tyramine is able to reach the systemic circulation. Tranylcypromine is more frequently associated with tyramine reactions than phenelzine or isocarboxazid. Selegiline (MAO-B selective) is unlikely to produce a tyramine reaction if taken at therapeutic doses. Tyramine is classified as an indirect sympathomimetic and is structurally similar to amphetamine. Like most indirect sympathomimetics, tyramine enters the presynaptic neuron through amine uptake pumps. Once inside the neuron, indirect sympathomimetics are capable of releasing presynaptic stores of norepinephrine and to a lesser degree serotonin and dopamine. Tyramine can also displace epinephrine from the adrenal gland. This action produces the "cheese" reaction since aged cheese contains a large amount of tyramine. In similar fashion, broad (fava) beans contains large quantities of dopamine.

Tyramine is found in over 70 foods and beverages, and any one of these sources may trigger such a reaction. [9] It has been reported that less than 30 percent of patients comply with a MAOI-restrictive diet. In addition, approximately 4 to 8 percent of compliant patients will experience a tyramine reaction during their course of therapy. Nonetheless, newer guidelines call for avoiding only a few high-risk food groups such as meat or fish that is not fresh, sauerkraut, aged meats and cheeses, alcohol (Chianti wine and vermouth), pickled fish (herring), concentrated yeast extracts, and broad beans.

The tyramine reaction is typically of rapid onset, occurring within 15 to 90 min after the dietary amine is ingested. The severity of this reaction is highly variable and partially related to the total amount of tyramine ingested. The hallmark symptom of the tyramine reaction is a severe occipital or temporal headache. Other associated symptoms include hypertension, diaphoresis, mydriasis, neck stiffness, pallor, neuromuscular excitation, palpitations, and/or chest pain. Most symptoms gradually resolve over 6 h without specific therapy but fatalities have been rarely reported, usually due to intracranial hemorrhage or myocardial infarction. Therefore, an electrocardiogram should be obtained on all patients with tyramine-associated chest pain. Focal neurologic findings or a persistent severe headache warrants investigation with a computed tomography (CT) scan of the head.

In cases of severe hypertension the drug of choice remains phentolamine (Regitine), which is given intravenously in 2.5- to 5-mg doses every 5 to 15 min until the blood pressure is controlled. The half-life of phentolamine is approximately 20 min, and its duration of action less than 1 h. Nitroprusside (Nipride) is another rapidly acting direct vasodilator, which is always administered as a continuous infusion (1 to 4 µg/kg per minute). In cases of moderate hypertension, nifedipine (Procardia) and prazosin (Minipress) have been reported to be effective. Newer recommendations for the treatment of accelerated chronic hypertension discourage the use of nifedipine due to concerns of excessive blood pressure reduction. These concerns may not apply to the acute hypertension seen in tyramine reactions. Beta-adrenergic blockers should be considered contraindicated due to unopposed alpha-receptor stimulation. Hospital admission should be strongly considered for patients whose symptoms do not completely resolve within 6 h after onset.

DRUG INTERACTIONS

Chronic MAOI drug therapy predisposes to many potentially significant drug interactions (Table 154-1). However, documentation of human MAOI drug interactions is often limited to single case reports or case series. [10] Controlled human studies are impractical due to the life-threatening nature of these reactions. Animal studies often have limited applicability to human toxicity. Most importantly, emergency physicians should never administer medications to patients taking MAOIs unless absolutely necessary. Drug compatibility with monoamine oxidase inhibitors should always be confirmed prior to drug administration.

TABLE 154-1   Drugs Contraindicated with MAOIs*

Drug interactions involving MAOIs can be grouped into three categories: pharmacodynamic, pharmacokinetic, and idiosyncratic. The most common pharmacodynamic reaction involves indirect-acting sympathomimetics. They have the potential to produce a hyperadrenergic condition similar to the tyramine reaction (see above) and can be found in over-the-counter preparations, drugs of abuse, and some prescription products. Pharmacokinetic drug interactions have been noted with MAOIs because they are metabolized through the cytochrome oxidase enzyme system and thus can inhibit the metabolism of other drugs. The potentiation of opiate and sedative-hypnotic drugs is an example of this type of enzyme inhibition. Tranylcypromine and phenelzine have been shown to increase insulin release and predispose to hypoglycemia, especially in patients taking oral sulfonylureas agents. Insulin dosage may also warrant reduction. Serotonin syndrome is a rare, potentially life-threatening idiosyncratic reaction. It most commonly occurs when MAOIs are combined with other serotonergic agents. A complete description of serotonin syndrome as well as a listing of serotonergic medications can be found in Chap. 153, on newer antidepressants. However, specific emphasis pertaining to emergency physicians is placed on the avoidance of using meperidine (Demerol), [11] dextromethorphan, or tramadol (Ultram) in combination with MAOIs. Even after a patient discontinues MAOI therapy, it still takes 2 weeks before 50 percent of MAO enzyme activity returns. Consequently, there should always be at least a 2-week abstinence period between the time of MAOI discontinuation and the time that any contraindicated drug is administered. This recommendation is particularly important to prevent the development of serotonin syndrome.

It is also important to note which medications are generally considered safe in patients on MAOIs (Table 154-2). Aspirin, acetaminophen, ibuprofen, and morphine have been used in combination with MAOIs without complications. Morphine should be given in decreased doses due to impaired morphine metabolism and enhanced opiate effects. Direct-acting sympathomimetic agents (e.g., norepinephrine) can be used with caution, utilizing the lowest possible effective dose. Direct sympathomimetics do not rely on the release of neurotransmitters for their activity and they are inactivated by the enzyme COMT, which is unaffected by MAOIs.

TABLE 154-2   Drugs Considered Safe with MAOIs*

CLINICAL FEATURES (ACUTE OVERDOSE)

MAOIs have a dangerously low toxic-to-therapeutic ratio. Ingestions of greater than 2 to 3 mg/kg of body weight can be life-threatening, and doses that are less than 2 mg/kg may still produce mild to moderate toxicity. The lethal dose of irreversible MAOI toxicity is reported to be between 4 and 6 mg/kg. [12] Deaths have been reported in adults with as little as 170 mg of tranylcypromine and 375 mg of phenelzine. Selegiline overdoses have not been reported but should be assumed to produce toxicity similar to that of the traditional MAOI antidepressants until determined otherwise. The average therapeutic dose of tranylcypromine ranges from 20 to 40 mg/day, with a maximum daily dose of 60 mg/day. It is available as a small, round, red 10-mg tablet. Therapeutic doses of phenelzine range between 45 and 75 mg/day, with a maximum of 90 mg/day. The drug comes as a small, round, orange 15-mg tablet. Isocarboxazid is manufactured as a 10-mg peach-colored tablet with therapeutic doses ranging between 10 and 30 mg/day. Selegiline has a standard dose of 10 mg/day and comes as an aqua 5-mg capsule.

An important clinical aspect of MAOI overdoses is that symptoms are characteristically delayed between 6 to 12 h postingestion but can be delayed as long as 24 h. The delayed onset of toxicity is believed to be secondary to the gradual accumulation of NE and 5-HT levels in the brain and in peripheral sympathetic neurons. Symptoms of MAOI overdose are most consistent with a hyperadrenergic state secondary to excessive stimulation of alpha- and beta-adrenergic receptors, but symptoms related to excessive serotonin receptor activity are also seen. Patients on chronic MAOI therapy may show earlier signs of toxicity due to preexisting enzyme inhibition. In severe cases, the hyperadrenergic state can be rapidly followed by hypotension and central nervous system depression resembling a sympatholytic condition. Toxicity usually persists for 1 to 4 days after ingestion.

The signs and symptoms of MAOI toxicity are often nonspecific. Even in its most severe form, it can resemble numerous other conditions (see below). Most clinical overdose information has come from single case reports or case series, with tremendous variation in presentation. Hence, there is no "typical" presentation to MAOI toxicity nor is there an orderly progression of symptoms. The clinician should anticipate the rapid development of life-threatening symptoms in all MAOI overdose patients. The initial symptoms of MAOI overdose are reported to include headache, agitation, irritability, nausea, palpitations, and tremor. The earliest signs of MAOI toxicity include sinus tachycardia, hyperreflexia, hyperactivity, fasciculations, mydriasis, hyperventilation, nystagmus, and generalized flushing. In cases of moderate toxicity, opisthotonus, muscle rigidity, diaphoresis, chest pain, hypertension, diarrhea, hallucinations, combativeness, confusion, marked hyperthermia, and trismus may become evident. A peculiar ocular finding has been observed with some cases of MAOI toxicity and is described as a "ping-pong" gaze because of the bilateral, wandering horizontal eye movements. The mechanism of this gaze disorder is unknown. In all cases, it gradually resolves as the patient improves. Severe toxicity is accomplished by bradycardia, cardiac arrest, hypoxia, papilledema, hypotension, seizures, coma, and worsening hyperthermia. Hypotension is an ominous finding that commonly remains resistant to therapeutic attempts at correction. Fetal demise, cerebral edema, pulmonary edema, and intracranial hemorrhage have all been reported in association with MAOI overdoses. The most common electrocardiographic abnormality seen in MAOI toxicity is sinus tachycardia, but T-wave abnormalities are not uncommon. Deaths are usually secondary to multiple organ failure.

DIAGNOSIS

MAOI poisoning is not associated with any confirmatory laboratory tests. It remains a clinical diagnosis based solely on the history of excessive MAOI ingestion. Plasma MAOI levels and drug screens cannot be relied upon to assist in making the diagnosis of MAOI toxicity for two reasons. First, all commonly used drug screens are qualitatively unable to detect MAOIs. Second, specific quantitative plasma MAOI levels are not routinely available in most hospitals, nor do they correlate with observed clinical toxicity. Selegiline is likely to produce amphetamine metabolites, which can be detected on most urine drug screens. Tranylcypromine has the potential to produce amphetamine metabolites, but these have rarely been detected. The best use of laboratory tests is to assist in the differential diagnosis of MAOI toxicity and to identify possible complications of MAOI overdose, which include hypoxia, rhabdomyolysis, renal failure, hyperkalemia, metabolic acidosis, hemolysis, and disseminated intravascular coagulation. Leukocytosis and thrombocytopenia are commonly seen with MAOI toxicity.

The differential diagnosis of a MAOI overdose includes all drugs and medical conditions capable of producing a hyperadrenergic state, altered mental status, and/or muscle rigidity. As evidenced by the extensive number of conditions listed in Table 154-3, the differential diagnosis of the unknown MAOI ingestion is extremely challenging. In addition, MAOI toxicity can also be associated with a sympatholytic presentation, thus broadening the differential possibilities even further. In reality, without a history of exposure to MAOIs, it is highly unlikely that the correct diagnosis will be made in the emergency department (ED), since no confirmatory tests are available.

TABLE 154-3   Differential Diagnosis of Monoamine Oxidase Inhibitor Overdose

An interesting diagnostic dilemma exists when a patient on chronic MAOI therapy presents with elevated blood pressure. At therapeutic doses, hypertension can result from tyramine reactions, spontaneous hypertensive crisis, and serotonin syndrome. Tyramine reactions are likely to occur in close relation to food or drug ingestions containing indirect sympathomimetics. Spontaneous hypertensive crisis is a rare condition usually occurring in relation to recent MAOI dosing. [13] Serotonin syndrome most commonly occurs shortly after exposure to other serotonergic agents and is usually associated with significant cognitive-behavioral and neuromuscular abnormalities.

MANAGEMENT

General Emergency Department Care

All MAOI overdose patients require immediate emergency physician evaluation, establishment of at least one preferably large-base peripheral intravenous line, cardiac monitoring, supplemental oxygen, and gastric decontamination. General laboratory tests should be ordered on all patients, with particular emphasis on identifying early hyperkalemia, metabolic acidosis, and rhabdomyolysis. There are no known antidotes for MAOI toxicity. ED management is therefore directed toward supportive care and early treatment of complications. Onset of toxicity is usually gradual and delayed, sometimes up to 24 h postingestion. However, the abrupt development of seizures, coma, respiratory insufficiency, hyperadrenergic storm, and cardiovascular collapse is entirely possible. Greater toxicity for any given dose of MAOI is predicted in the setting of significant underlying medical problems, pediatric patients, geriatric patients, or coingested drugs.

The best method of gastric decontamination in the setting of MAOI overdose has never been studied. Therefore, the following recommendations are general guidelines based on the pharmacokinetic profile of MAOIs as well as results of human case reports. Syrup of ipecac is contraindicated in the setting of MAOI overdose because of the significant potential for cardiovascular collapse and loss of consciousness. Activated charcoal should be administered as a single dose of 1 g/kg as soon as possible. Multiple-dose administration of activated charcoal is not expected to be advantageous. Gastric lavage is recommended in all significant ingestions and should be performed within the first 2 h after ingestion to maximize drug removal. Since MAOIs are rapidly absorbed, delayed gastric lavage or

whole-bowel irrigation is unlikely to be of any clinical benefit. Hemodialysis, hemoperfusion, and peritoneal dialysis have no established role in the treatment of MAOI poisoning. Urinary acidification is not recommended because it is ineffective at enhancing MAOI elimination and predisposes to acute renal failure secondary to myoglobin precipitation within renal tubules.

Management of Specific Conditions

HYPERTENSION   The acutely hypertensive patient should be treated only with short-acting intravenous antihypertensive agents because of the potential to develop precipitous hypotension. In most cases, an intraarterial catheter is required for accurate blood pressure monitoring. The traditional antihypertensive agents of choice are phentolamine (Regitine) and nitroprusside (Nipride). Phentolamine is a nonspecific alpha-adrenergic receptor blocker usually administered in 2.5- to 5.0-mg boluses every 10 to 15 min until blood pressure elevation is controlled. It can also be given as a continuous infusion (0.2 to 0.5 mg/min) for maintenance therapy. Phentolamine use is commonly associated with reflex tachycardia. Nitroprusside is as effective as phentolamine. It is given as a continuous infusion with an initial rate of 1 µg/kg per minute and then titrated according to blood pressure response. Prolonged high doses of nitroprusside can predispose to cyanide toxicity, but this potential complication is rarely noted in the ED. The addition of thiosulfate to nitroprusside infusions eliminates the possibility of cyanide toxicity. Nitroglycerin is indicated for the relief of anginal chest pain and in patients with signs of myocardial ischemia. Fenoldopam (Corlopam) is a recently approved short-acting parenteral antihypertensive agent.[14] Its mechanism of action is secondary to peripheral dopamine (D_1) receptor stimulation. It reportedly does not cross the blood-brain barrier. There are no known contraindications to its use in MAOI-induced hypertension. Fenoldopam is administered as a titratable infusion with a suggested starting dose of 0.05 to 0.1 µg/kg per minute. Intravenous diltiazem (Cardizem) is expected to be an effective antihypertensive agent, but its long duration of action makes it less desirable than the previously mentioned shorter-acting agents. Beta blockers pose a theoretical risk of increasing the blood pressure through unopposed vasoconstriction and would appear to be contraindicated. Despite this concern, beta blockers have occasionally been used to treat hyperadrenergic symptoms in MAOI overdose without serious complications. At best, beta blockers should be used with great caution in the setting of MAOI toxicity. Labetalol is a beta blocker with slight alpha-receptor blocking ability. The theoretical benefit of its alpha-blocking capacity must be balanced against its beta-blocking activity, which is seven times greater.

HYPOTENSION   Hypotension carries a poor prognosis in MAOI overdose. Isotonic intravenous fluid boluses of 10 to 20 mL/kg are the initial treatment of hypotension. When vasopressors are required, it is important to avoid all indirect-acting agents (see Table 154-1). Norepinephrine is the vasopressor of choice, with epinephrine as the second choice. MAOI patients usually demonstrate an increased sensitivity to vasopressors, and lower initial doses are recommended.

DYSRHYTHMIAS   Sinus tachycardia rarely calls for specific drug therapy unless it is producing cardiac ischemia. Lidocaine and procainamide are the most effective antiarrhythmics in treating MAOI-induced ventricular dysrhythmias. Bradycardia may quickly degrade into asystole in the later stages of the overdose and require pacemaker placement. Pharmacologic treatment of bradycardia includes atropine, isoproterenol, and dobutamine. Bretylium should be avoided due to its indirect sympathomimetic activity (see Chap. 18).

SEIZURES   Benzodiazepines are the anticonvulsants of choice in treating MAOI-induced seizures. Barbiturates are as effective as benzodiazepines but may cause hypotension, especially at higher doses. Phenytoin is generally ineffective in stopping drug-induced seizures. General anesthesia and/or muscle paralysis may be necessary in cases of status epilepticus to prevent the metabolic acidosis, hyperthermia, and rhabdomyolysis that commonly accompany persistent seizure activity. Muscle paralysis is best accomplished using nondepolarizing neuromuscular blocking agents. The action of succinylcholine may be enhanced by MAOIs. Pancuronium is probably less desirable than other nondepolarizing agents because of its propensity to produce elevations in heart rate and blood pressure. Vecuronium in doses of 0.25 mg/kg may produce paralysis in 90 s although its use with succinylcholine is relatively contraindicated in this setting. Tachycardia and histamine release do not occur. Electroencephalographic monitoring is required when muscle paralysis is used to control the peripheral manifestations of seizure activity. See Chap. 224 for details of treating seizures.

HYPERTHERMIA   Antipyretics are generally ineffective at lowering drug-induced fever. Benzodiazepines are useful first-line agents by reducing muscle hyperactivity and thus decreasing secondary heat production. Increasing evaporative and conductive heat loss is essential for the successful treatment of hyperthermia. This is best accomplished by using cool mist spray, evaporative fans, and ice baths. Hyperthermia is often resilient in the setting of persistent muscle rigidity. Muscle paralysis (nondepolarizing agents) should be considered when diffuse rigidity is refractory to benzodiazepine therapy. Dantrolene has been successfully used as a muscle relaxant in resistant cases of muscle rigidity. The intravenous dose of dantrolene ranges from 0.5 to 2.5 mg/kg every 6 h. Dantrolene is associated with hepatotoxicity and should be used only when other measures have failed. Older reports of MAOI-induced hyperthermia cited successful treatment with phenothiazines (chlorpromazine). However, these agents are not currently recommended owing to their potential to lower the seizure threshold, worsen hypotension, and produce extrapyramidal reactions.

ADMISSION CRITERIA

All intentional MAOI overdoses and accidental exposures of greater than 1.0 mg/kg require admission to an intensive care unit. Accidental exposures of less than 1.0 mg/kg will require hospital admission but are unlikely to develop life-threatening complications. Therefore, these patients can be admitted to a less acutely monitored bed. It is important to remember that even a single MAOI pill may produce life-threatening drug interactions, such as serotonin syndrome, under the right circumstances. Therefore, emergency physicians should have a very low threshold to admit all MAOI exposures. Asymptomatic patients should be monitored for at least 24 h before medical clearance. Vital sign abnormalities should be recognized early and treated appropriately. Dietary and medication restrictions should be meticulously followed during the hospitalization. All patients should be instructed to avoid contraindicated foods and medications for a minimum of 2 weeks. Consultation with a medical toxicologist through the nearest regional poison control center is strongly recommended. Patients who require transfer to hospitals with intensive care units should be transferred as soon as possible to avoid the problems anticipated with delayed onset of toxicity. All patients being transferred should be accompanied by medical personnel capable of performing advanced cardiac life support and endotracheal intubation.

155 ANTIPSYCHOTICS

Richard A. Harrigan
William J. Brady

A group of antipsychotic drugs, classically termed *neuroleptics,* have been in use since the 1950s for the treatment of schizophrenia and other related psychoses (Table 155-1). Although they have revolutionized the treatment of these disorders, these agents are known to cause myriad adverse effects, both in therapeutic and toxicologic situations. A propensity to affect neurologic function led to the term *neuroleptic,* which is less appropriate today in light of the development of newer agents for the treatment of schizophrenia that are less likely to cause these effects; thus, these agents are now usually classified as *antipsychotic* agents (see Table 155-1). In addition to the treatment of various psychoses, however, these drugs also are used for nonpsychiatric conditions, such as chemical restraint of agitated or violent patients; control of nausea and emesis; pain and nausea relief in various headache syndromes; suppression of hiccups; and control of various involuntary motor disorders, including Tourette's syndrome, Huntington's chorea, and various disorders of the basal ganglia.

TABLE 155-1   Pharmacologic Classification of Typical and Atypical Antipsychotic Agents

Conventional, or *typical,* antipsychotics are a diverse group of older agents that gained widespread acceptance for the control of the positive symptoms (e.g., hallucinations, delusions, and disordered thought) of schizophrenia and related psychoses. These agents cause numerous adverse effects, however, and do little if anything to ameliorate the cognitive dysfunction and negative symptoms (e.g., withdrawal, flat affect, and loss of drive) that are also characteristic of the disease. Thus, a newer class of *atypical* antipsychotic drugs has emerged, featuring improved clinical efficacy and a different side-effect and toxicologic profile. [1]

PHARMACOLOGY

The typical antipsychotics share a similarity in pharmacotherapeutic and adverse-effect profiles. They are all dopamine receptor antagonists; this blockade in the limbic system is thought to be primarily responsible for the antipsychotic activity of these agents. Dopaminergic antagonism in the basal ganglia also occurs, causing disinhibition of cholinergic neurons; this in turn may lead to various involuntary movement disorders, termed *extrapyramidal side effects,* as discussed below.[1] In addition to blocking dopaminergic receptors, these typical antipsychotics also block, to varying degrees, a-adrenergic (principally a $_1$), muscarinic, and histaminic receptors. a$_1$-Adrenergic antagonism leads to orthostatic hypotension and reflex tachycardia due to peripheral vasodilatation. Anticholinergic activity at muscarinic sites leads to hyperthermia, tachycardia, pupillary dilatation, dry mouth, urinary retention, and constipation. Histamine blockade results in central nervous system sedation.[1,2] Generally speaking, drugs of higher potency (i.e., low milligram-per-day dosage) tend to cause significant dopaminergic antagonism and thus are more likely to cause extrapyramidal effects; examples include haloperidol, fluphenazine, and thiothixene. Drugs of lower potency (i.e., high milligram-per-day dosage) are less likely to cause extrapyramidal effects, but are more likely to cause sedation and orthostatic hypotension, due to strong antihistaminic and anticholinergic/muscarinic effects; examples include chlorpromazine and thioridazine. [2,3] It should be emphasized, however, that all typical antipsychotics could cause some degree of extrapyramidal symptoms, sedation, orthostatic hypotension, and various anticholinergic effects.

The newer, *atypical* antipsychotic agents, in addition to featuring varying degrees of antagonistic activity at dopaminergic, a-adrenergic, histaminic, and cholinergic/muscarinic receptor sites, block serotonergic sites with varying affinity. [1,4] These drugs exhibit greater clinical efficacy in that they also improve negative symptomatology and cognitive dysfunction, and they are less likely to cause extrapyramidal effects and thus are more attractive than the typical antipsychotics. There is evidence that these newer agents also are effective in neuroleptic treatment-resistant patients who are so labeled due to treatment failures with the typical antipsychotic agents.[1]

Pharmacokinetically, all antipsychotic agents are similar, given well-controlled, therapeutic situations. Bioavailability is erratic and peak plasma levels occur 2 to 6 h after oral administration, although clinical effects are seen within the first 30 to 60 min. [3,4] Those agents available for parenteral administration achieve higher plasma levels, resulting in a more rapid onset of action, than do the oral preparations; [2] none of the new atypical antipsychotics are available in injectable form. Protein binding, lipophilicity, and volume of distribution are uniformly high for all antipsychotics, rendering dialysis an ineffective means of treating toxicity. Elimination is via hepatic metabolism—both hepatic microsomal enzyme oxidation and enterohepatic circulation—followed by renal excretion, to varying degrees. [2,4] The newer atypical antipsychotics all carry warnings regarding use in patients with concomitant hepatic disease, and only quetiapine does not carry such precautions in renal disease, due to trivial excretion of unchanged drug by the kidney. Plasma-level monitoring can establish compliance, but is not generally recommended with the antipsychotics, in either therapeutic or toxicologic assessment situations. [2,4]

ADVERSE EFFECTS

Extrapyramidal Disorders

With their diverse neurotransmitter blockade capabilities, the antipsychotics may exhibit a wide variety of adverse effects, including those commonly seen with other drugs featuring antihistiminic, anticholinergic, and antiadrenergic properties. The focus here is on those adverse effects resulting from blockade of dopaminergic sites. These acute extrapyramidal disorders occur in some form in the majority of patients being treated with typical antipsychotic agents. [1] Dopaminergic receptor-mediated side effects can be seen with any antipsychotic agent, but are most frequently seen with the typical agents, especially those of higher potency. [2] However, any of the following conditions can occur with all antipsychotic drugs, as well as with other structurally similar agents that are not classified as antipsychotics, such as droperidol (Inapsine), promethazine (Phenergan), and prochlorperazine (Compazine). [3]

Dystonic reactions are involuntary muscle contractions that may affect the muscles of the neck (torticollis), jaw (trismus), trunk (opisthotonos), tongue, or those surrounding the eye (oculogyric crisis). Laryngospasm, although rare, may also occur, and threaten the airway. Dystonia may involve an isolated muscle group or, more frequently, a combination of the above. Affected patients commonly exhibit evidence of adrenergic hyperactivity, including diaphoresis, tachycardia, tachypnea, and hypertension, and are often in obvious pain and quite anxious. [5] A history of therapeutic (including long-acting depot preparations of some antipsychotics such as fluphenazine and haloperidol) and illicit drug use is key; dystonic reactions have been reported with a variety of agents, including tricyclics, "street Valium" (haloperidol), and cocaine.[5] Acute treatment includes administration of diphenhydramine (Benadryl), 25 to 50 mg intramuscularly or intravenously; the latter route provides the most rapid relief, usually within 10 min. If symptoms are not relieved, the dose may be repeated in 15 to 30 min, or an alternative agent can be used, such as benztropine (Cogentin), 1 to 2 mg, via either parenteral route. Benzodiazepines may serve as adjunctive therapy and are especially useful when cocaine is the offending agent. Due to the prolonged effects of the dystonia-inducing agent, oral therapy with either diphenhydramine or benztropine should be continued for 2 to 5 days.[5]

Akathisia is a condition wherein patients demonstrate motor restlessness with corresponding anxiety; it can be mistaken for a worsening of the underlying psychiatric disorder. This assumption may lead to increasing the dose of the offending agent, thus making the symptoms worse. Administration of diphenhydramine or related agents may be diagnostic and therapeutic; a reduction in dose of the antipsychotic, or a switch to a less potent agent, is a possible long-term solution. [2,3] *Bradykinesia*, or drug-induced parkinsonism, is another extrapyramidal side effect of this drug class and should be treated in a similar fashion. [1,2]

Tardive Dyskinesia

This involuntary movement disorder is idiosyncratically associated with chronic therapy with the typical antipsychotic agents. Symptoms classically include involuntary, repetitive, choreoathetoid movements of the face, mouth, and tongue, and may be mild or severe and debilitating; uncommonly, the limbs and trunk are also affected. Elderly patients, especially those with diabetes mellitus and organic brain damage, seem to be at increased risk. The overall incidence is approximately 5 percent per year of exposure to the offending agent. The pathophysiology of tardive dyskinesia is unclear. Traditionally, it has been attributed to an emerging supersensitivity of dopaminergic receptors in the striatum under chronic blockade by the antipsychotic agent. Alternate theories also implicate other neurotransmitters, whereas others invoke the possibility of direct neurotoxicity resulting in free radical production. The new atypical antipsychotics are believed to be much less likely to cause this syndrome, although this is not yet clear. A number of drugs and treatment modification strategies have been advanced as therapeutic options for tardive dyskinesia; there are no emergency management issues other than recognizing the syndrome.[1,6]

Neuroleptic Malignant Syndrome

This syndrome is an idiosyncratic, rare, and potentially fatal reaction most commonly associated with the use of antipsychotic drugs, although other drug classes also have been implicated. Clinical features include hyperthermia, muscle rigidity, autonomic instability, and alteration in mental status. Neuroleptic malignant syndrome (NMS) may occur at any time during therapy with the causative agent or may present when dopamine agonist therapy is discontinued. Risk factors include age (young or middle-aged adults are most commonly affected); a concomitant condition of exhaustion, dehydration, or a general debilitated state; and a history of NMS. [7] Typically, patients present with high fever, from 39°C to 42°C, but onset of hyperthermia may be delayed. [7,8] Manifestations of autonomic dysfunction include tachycardia, labile hypertension, pallor, vasoconstriction, and diaphoresis. [9] A "lead-pipe" rigidity of the musculature is almost universal, while other manifestations of motor dysfunction also may occur, including tremors, myoclonus, dystonia, dyskinesia, dysphagia, dysarthria, and opisthotonus. Alteration in mental status ranges from confusion and agitation to stupor or coma.[8] Characteristic laboratory findings include leukocytosis, myoglobinuria, and elevation of creatine phosphokinase; metabolic acidosis, renal insufficiency, electrolyte abnormalities, and elevated hepatic transaminases may also occur. The differential diagnosis includes meningoencephalitis, tetanus, collagen vascular disease, malignant hyperthermia, lethal catatonia, heatstroke, thyroid storm, pheochromocytoma, strychnine poisoning, and toxicity from a variety of drugs, including anticholinergic poisoning and the serotonin syndrome. [7,8] and [9] Perhaps the two syndromes most difficult to distinguish from NMS are malignant hyperthermia and lethal catatonia, as all three feature fever and muscle rigidity. Malignant hyperthermia is associated with causative exposure to certain anesthetic agents, whereas lethal catatonia, a type of heat exhaustion, follows a period of manic hyperactivity and does not feature autonomic instability.

The cornerstone of treatment of NMS is supportive care, with rapid cooling, fluid and electrolyte repletion, and critical care monitoring all being paramount (Table 155-2). Intubation should be considered, and aggressive muscle relaxation should be pursued with intravenous benzodiazepines. The offending pharmacologic agent should be discontinued, or the previously withdrawn dopamine agonist should be restarted. [8,9] Dantrolene, a nonspecific skeletal muscle relaxer that is employed in the treatment of malignant hyperthermia, also has been used with good results, especially in cases wherein muscle rigidity is a predominant feature. [9,10] Specific therapy for NMS has been advocated, some of which is based on the presumed pathophysiology of the syndrome, which is central dopamine depletion. [8,9] Bromocriptine, carbidopa/levodopa, and amantadine have been used with equivalent success, both alone and in combination. [9,10] Centrally acting dopamine agonists may be most important in the treatment of significant hyperthermia and mental status alteration, and vasodilators such as minoxidil and nitroprusside should be considered when vasoconstriction is a problem.[9] Aggressive therapy has led to a reduction in mortality from NMS. [7]

Airway, breathing, IV access, and cardiac monitor.

Immediate skeletal muscle relaxation with repeated doses of IV benzodi-
    azepines and, if necessary, rapid-sequence intubation.

Reverse hyperthermia using mist and fan technique or packing in ice.

Rehydrate with IV crystalloid.

Obtain blood samples for ABG, WBC, Hgb, Hct, glucose, electrolytes,
    BUN, creatinine, CPK, hepatic enzymes, PT, PTT. Send urine for myo-
    globin.

TABLE 155-2   Initial Care of Neuroleptic Malignant Syndrome

Miscellaneous Adverse Effects

In addition to the various dopamine-related side effects just described (extrapyramidal disorders, tardive dyskinesia, and NMS), the antipsychotics may cause a variety of other untoward effects, some of which are highlighted here. All antipsychotics may cause sedation and impair mental capacity to some degree; [2,4] patients should be cautioned regarding activities requiring mental alertness, such as driving and operating heavy machinery. Photosensitivity may occur with the typical antipsychotics, especially the phenothiazines; it is not a characteristic of the atypical agents, with the exception of risperidone. To varying degrees, all may lower the seizure threshold. [2,4] Both typical and atypical agents are pregnancy category C with the exception of clozapine, which is category B; none of these agents are recommended in breast-feeding women.[2,4] Clozapine therapy carries the risk of agranulocytosis and is reserved for use in severely ill schizophrenics who have failed conventional treatment regimens; weekly monitoring of the leukocyte count is indicated. [1,2,4,11]

ACUTE OVERDOSE

Clinical Features

Despite the numerous adverse effects seen with antipsychotic agents, their therapeutic index is high, and lethal ingestion is rare. The most recent Toxic Exposure Surveillance System summary of fatal exposures from the American Association of Poison Control Centers lists only 21 deaths associated with antipsychotic agents and, in all but three of those cases, other agents were involved. [12]

In general, overdose with these drugs features an exaggerated version of the response that is expected, based on knowledge of the aforementioned adverse effects. Central nervous system depression, ranging from mild sedation to deep coma, frequently occurs and is attributable to anticholinergic and antihistaminic effects. Some degree of sedation is generally seen with overdose of any antipsychotic drug, but has been found to occur more frequently with chlorpromazine. [13] Seizures may be seen, as well as dysfunction in temperature regulation. [2,13,14] Anticholinergic and extrapyramidal effects may occur as with nontoxic ingestion and tend to vary with the potency of the drug: low-potency compounds tend to cause anticholinergic effects, and high-potency agents tend to cause extrapyramidal disorders. [2,3]

Cardiovascular effects may be seen as alterations in heart rate, blood pressure, and cardiac conduction. Tachycardia can be attributed both to anticholinergic effects and to a reflex response to vasodilatation; it is seen more often with the low-potency agents. [13] Hypotension is due to both a_1-adrenergic blockade and a direct depressant effect on the myocardium.[15,16] A variety of cardiac conduction disturbances may occur, from asymptomatic prolongation of the QT interval to fatal ventricular dysrhythmia. The piperidine phenothiazines (e.g., thioridazine) are the antipsychotic drugs with the highest potential for serious dysrhythmia: they may behave like type Ia antidysrhythmics in overdose, resulting in wide-complex tachycardia and possibly torsade de pointes. [13,14,15] and [16] Atrioventricular and intraventricular conduction disturbances may also occur. [13,14,15] and [16] Interestingly, intravenous haloperidol has been rarely associated with torsade de pointes during treatment of agitated patients; although the preponderance of experience suggests it may be safely administered via this route, some feel it may be more prudent to administer it intramuscularly. [3,17]

Clinical experience with overdose of the newer atypical agents is limited. Clozapine, with its profound anticholinergic effects, has been found to cause central nervous system depression and seizures, but appears to be unlikely to cause cardiac conduction disturbances or agranulocytosis. [11] Reports thus far with risperidone, olanzapine, and quetiapine suggest that patients should be monitored for obtundation, respiratory depression, and cardiac conduction abnormalities. [18,19] nad [20]

Treatment

Supportive care and decontamination of the gastrointestinal tract are the key principles of treatment in overdose with the antipsychotic agents (Table 155-3). Patency of the airway and assurance of adequate ventilation are paramount, especially in light of the fact that these agents may cause profound alterations in level of consciousness. Oxygen and naloxone should be administered to all patients with altered mental status, and blood glucose should be rapidly assessed at the bedside.[21] Crystalloid intravenous fluids should be given for hypotension. If further therapy is needed, pressors with b-adrenergic activity should be avoided (e.g., dopamine, epinephrine, and isoproterenol), because the a-adrenergic blockade seen with the antipsychotic agents results in unopposed b-adrenergic agonism, causing vasodilatation and worsening hypotension. [3,15,16]

Airway, breathing, IV access, and cardiac monitor.
Altered mental status
  Naloxone
  Empiric dextrose (or rapid glucose determination)
Hypotension
  Crystalloid infusion
  Norepinephrine or phenylephrine
Ventricular dysrhythmias
  Bicarbonate, 1-2 meq/kg IV bolus
  Lidocaine or phenytoin
Torsade de pointes
  Magnesium
  Isoproterenol
  Overdrive pacing
Gastrointestinal decontamination
  Activated charcoal 1 g/kg PO
  If patient is intubated, orogastric lavage using >34 Fr tube, followed by activated charcoal
Warming or cooling techniques for hyperthermia or hypothermia
Seizures
  Benzodiazepines
  Phenobarbital
  Phenytoin

TABLE 155-3   Care of Acute Ingestion

Continuous cardiac monitoring and a 12-lead electrocardiogram are cardinal management features. Ventricular dysrhythmias should be managed with type Ib antidysrhythmic agents (e.g., lidocaine), avoiding class Ia agents (e.g., quinidine, disopyramide, and procainamide), which may worsen cardiac toxicity. Wide-complex tachycardias should be treated with intravenous sodium bicarbonate due to the potential quinidine-like effect of certain agents, especially thioridazine. [13,14,15] and [16],[18] Torsade de pointes, if it occurs, should be managed with cardiac pacing, isoproterenol, or magnesium infusion. [13,17,22]

Gastrointestinal decontamination should be instituted as soon as the patient is stabilized; in most cases, orally administered activated charcoal (1 g/kg) will suffice. Gastric lavage should be considered in patients who present to the emergency department very soon after a life-threatening ingestion. [21] Multidose activated charcoal is theoretically indicated due to partial metabolism by enterohepatic circulation. High protein binding and a large volume of distribution, general characteristics of this drug class, render hemodialysis and forced diuresis ineffective management techniques. [3,4,11,15]

In addition to stabilization of the airway and cardiovascular status, and attention to gastrointestinal decontamination, other therapy may be given as needed. Intravenous benzodiazepines, phenobarbital, and phenytoin should be considered for control of seizures. [11,14] Electrolyte disturbances have been reported sporadically; serum chemistries should be obtained in serious ingestions, especially to exclude other causes of altered mental status and dysrhythmia, which may occur. Specific drug levels are not readily available and are not helpful in the acute management of these patients. [2,4] Acute extrapyramidal disorders should be treated as described above.

Disposition

Patients with alteration in mental status, which usually includes a depressed level of consciousness, and patients with evidence of cardiotoxicity are best managed in the intensive care unit. Thioridazine has been shown to cause serious dysrhythmias both early in the clinical course and after a significant delay; patients ingesting this agent warrant electrocardiographic monitoring for at least 24 h, even if asymptomatic. [13,14] Patients should receive appropriate psychiatric evaluation after emergency department assessment and treatment, if they are asymptomatic, have a physical examination and electrocardiogram without evidence of lingering toxicity, and are not believed to have ingested a piperidine phenothiazine. If psychiatric evaluation is unwarranted, they may be discharged from the emergency department.

Some basic caveats are listed in Table 155-4.

• High-potency antipsychotic drugs are more likely to cause extrapyramidal effects.
• Low-potency antipsychotic drugs are more likely to cause sedating and hypotensive effects.
• When evaluating patients with an apparent dystonic reaction, remember these atypical causes: depot preparations of antipsychotics, antiemetics, tricyclics, and illicit substances.
• Consider akathisia in the differential diagnosis of psychotic patients who appear more restless and agitated despite being on antipsychotic pharmacotherapy.
• Neuroleptic malignant syndrome may present initially without a fever.
• Thioridazine is the most cardiotoxic antipsychotic agent and may behave like a type Ia antidysrhythmic agent in overdose situations.
• Use pressors with predominantly α-adrenergic agonism when treating refractory hypotension after overdose with the antipsychotics.
• Hemodialysis is not helpful in the treatment of antipsychotic toxicity.

156 LITHIUM

Sandra M. Schneider
Daniel J. Cobaugh

EPIDEMIOLOGY

Besides treatment of bipolar disorder, many other medical and psychiatric uses for lithium have been suggested, including impulsive/aggressive behavior, neutropenia, alcohol dependence, and cluster and migraine headaches. Lithium toxicity may result from accidental or intentional overdose or from an alteration in lithium clearance. The true incidence of lithium toxicity and subsequent medical outcomes are not known, since there is not a mandatory reporting requirement for toxic exposures in the United States.

It has been estimated that up to 75 to 90 percent of patients who are chronically treated with lithium will develop toxicity some time in their therapy. [1] Over the past 5 years, the American Association of Poison Control Centers has reported over 25,000 cases of lithium toxicity. Of these 44 resulted in death. [2]

PATHOPHYSIOLOGY

Lithium is thought to cause toxicity through several mechanisms. It has the ability to compete with other similar molecular weight ions, including sodium, potassium, magnesium, and calcium, displacing them from both intracellular and bone sites. Competition with and displacement of other ions can result in lithium retention and subsequent toxicity. Therefore, activities, medical conditions, and medications that affect water and electrolyte balance can contribute to lithium toxicity. Loss of salt, water, or both leads to an increase in proximal reabsorption of lithium and a rise in lithium level. Inhibition of arginine vasopressin and the resultant hydroosmotic effects have also been attributed to lithium.

It is also thought that lithium, through adenylate cyclase inhibition, causes decreases in intracellular cyclic adenosine monophosphate. Decreases in cyclic guanosine monophosphate may also occur. Inositol may play a role in lithium's therapeutic and adverse effects. Inositol, in the form of phosphatidylinositol, is found in the phospholipids of cell membranes and plasma lipoproteins. It may be released from phospholipids in response to a variety of hormones and neurotransmitters. Activated inositol may interact with G proteins to form intracellular messengers that enhance intracellular calcium release and activate protein kinase C. [3] It has been suggested that lithium may increase inositol monophosphate and reduce free inositol through inhibition of inositol monophosphatase. Lithium is also thought to interfere with the release and re-uptake of the neurotransmitter norepinephrine at the nerve terminal site. [4] Lithium may enhance serotonin release from the hippocampus.[5] Finally, risk of lithium toxicity exists when it is combined with a variety of medications. The mechanism for toxicity differs based on the drug-drug interactions. A number of these potential drug interactions are listed in Table 156-1. In addition, the use of succinylcholine and vecuronium in patients taking lithium may result in a prolonged neuromuscular blockade.

TABLE 156-1 Drug Interactions with Lithium

The pharmacokinetics of lithium also play a vital role in toxicity. The absorption of lithium is rapid and complete following oral administration. Delayed absorption may occur with sustained-release products and following ingestion of a large number of pills. Toxic effects appear later and last longer. Lithium has a volume of distribution of 0.79 L/kg, which is similar to that of body water. Lithium distribution to and from the central nervous system (CNS) is slower, resulting in CNS symptoms that do not correlate with serum levels. Sustained toxic effects, even after hemodialysis, can be due to the slow distribution in the CNS. Lithium is not bound to plasma proteins. The half-life of lithium is reported to be approximately 29 h. There is no appreciable hepatic metabolism, and it is primarily excreted unchanged in the urine. The presence or development of renal insufficiency is an important factor in the development of lithium toxicity.

CLINICAL EFFECTS

The most common side effects (Table 156-2) are hand tremor, polyuria due to loss of urinary concentration ability, and rash. Hand tremor occurs in up to 65 percent of patients at some time,[6] and worsening of a baseline tremor is an important signal of developing toxicity. A decrease in urinary-concentrating ability occurs in most patients but is largely asymptomatic. Up to 12 percent of patients will develop nephrogenic diabetes insipidus. [7] In some patients, incomplete distal renal tubular acidosis develops (defect in urine acidification without acidemia). Neurologic side effects include memory loss, decreased mental concentration, and fatigue. Ataxia and dysarthria can develop and will often improve with cessation of therapy. Long-term lithium treatment can lead to electroencephalographic changes, including diffuse slowing, an increase in theta and delta waves, and a decrease in alpha activity.

TABLE 156-2 Side Effects with Chronic Lithium Therapy

Gastrointestinal (GI) side effects are common at initiation of treatment and are generally transient. GI symptoms that develop during the course of treatment may signal toxicity. Cardiovascular changes develop in part because lithium interferes with the sodium-potassium pump, leading to intracellular hypokalemia. This results in electrocardiographic findings of U waves, flattened or inverted T waves, and ST depression. Conduction abnormalities are less common.

Lithium toxicity may result from acute intentional overdose, from chronic overdose, or as a result of a change in lithium excretion (medications, dehydration, or salt depletion). Toxicity developing in patients taking chronic lithium therapy may be due to a change in the daily dose of medication or physiologic changes impairing the elimination of the drug. Renal failure or intravascular volume depletion is a precipitating cause in nearly all cases of chronic toxicity. [7] Other factors known to precipitate lithium toxicity are listed in Table 156-3.

Renal failure

Volume depletion

Hyperthermia/neuroleptic malignant syndrome

Infection

Congestive heart failure

Diabetes mellitus

Preexisting cerebral pathology (white matter infarct, frontal meningioma, HIV)

Gastroenteritis

Surgery

Cirrhosis

Decreased sodium intake

TABLE 156-3   Factors Precipitating the Development of Lithium Toxicity (Excluding Drug Interactions)

Patients with acute overdose can tolerate higher levels without toxicity. Acute ingestions classically cause more GI toxicity and less CNS toxicity. After ingestion, there is delay in transport of lithium into the intracellular compartment and across the blood-brain barrier. With time, equilibration occurs and toxicity develops. Neurologic symptoms often develop as GI symptoms are abating. Levels in patients with an acute ingestion do not correlate well with either symptoms or prognosis.

Patients with chronic overdose have lower serum levels, higher cellular levels, and classically display earlier and greater neurologic changes. Levels in such patients correlate better with prognosis and toxicity. Acute-on-chronic ingestions have aspects of both profiles of ingestion. As in most toxicities, the best guideline for therapy is the patient's condition, not the drug level.

Recognizing lithium toxicity is not always easy, particularly in patients with chronic overdose. CNS symptoms are the hallmark of chronic lithium toxicity. Table 156-4 lists a common grading system for toxicity. Patients commonly present with muscle fasciculations, ataxia, agitation or lethargy, and muscle weakness. At times, it may be difficult to distinguish between lithium toxicity and organic delirium. Although most patients present with slowing of their cognitive function, cases of lithium overdose presenting as mania have been reported. As toxicity worsens, confusion, lethargy, stupor, and, finally, coma develop. Rarely, extrapyramidal signs develop. Proximal muscle weakness, extensor plantar response, and auditory, visual, and tactile hallucinations have been reported. The electroencephalogram shows diffuse slowing and disorganization, with frontal intermittent rhythmic delta activity in severe cases.

Grade 1 level	1.5–2.5 meq/L: nausea, vomiting, tremor, hyperreflexia, ataxia, agitation, muscular weakness
Grade 2 level	2.5–3.5 meq/L: stupor, rigidity, hypertonia, hypotension
Grade 3 level	>3.5 meq/L: coma, seizures, myoclonus, collapse

Note: Levels are valid in chronic ingestions only.

TABLE 156-4   Grading of Lithium Toxicity

In addition to neurologic changes, renal dysfunction is common. Due to diabetes insipidus, patients complain of polyuria and polydipsia. Fluid losses may exacerbate toxicity. Acute renal failure may develop, particularly in patients with preexisting renal impairment, advanced age, diabetes, hypertension, or dehydration.

GI symptoms are common in both acute and chronic toxicity. Patients present with gastroenteritis, nausea, vomiting, diarrhea, bloating, or generalized abdominal pain. Leukocytosis can occur. Cardiac abnormalities are more common in acute toxicity, with hypotension, conduction abnormalities, and ventricular dysrhythmias. Electrocardiographic changes with transient ST depression and T-wave inversion are seen in some patients. Less common effects include hyperthermia, hypothermia, peripheral neuropathy, and severe leukopenia.

Up to 10 percent of patients die, generally of respiratory failure or cardiovascular collapse. [8] Most patients who recover will have no long-term sequelae. Chronic renal failure occasionally develops. Permanent cerebellar damage may develop and progress over several weeks following the toxic episode. [9,10] Patients have truncal ataxia, ataxic gait, scanning speech, and diffuse incoordination. Short-term memory loss, dementia, and a tremor of the hands and head accompany the cerebellar signs. Most patients improve over several months, but symptoms are permanent in some cases. Permanent seizure disorder has been reported.

TREATMENT

As in all toxicities, initial stabilization of patients must include protection of the airway, ventilatory support, and hemodynamic support. Intravenous access, cardiac monitoring (including 12-lead electrocardiogram), and laboratory analysis of blood and urine, including renal function, fluid/electrolytes, calcium, magnesium, complete blood count, urine specific gravity, and drug levels for lithium, acetaminophen, and other possible ingestants should be obtained. A complete medical history, including an assessment of baseline neurologic function, must be documented. Search for precipitating factors such as volume depletion or electrolyte imbalance. A complete listing of medications (prescription, over-the-counter, and herbal agents) taken in the previous week should be obtained. A thorough physical and neurologic examination is necessary.

Seizures should be treated with intravenous benzodiazepines. Refractory seizures may require phenobarbital or general anesthesia. Phenytoin decreases renal excretion of lithium and is often ineffective in drug-induced seizures.

GI decontamination is difficult in lithium toxicity. Activated charcoal is ineffective at adsorbing lithium at gastric pH. [11] Its use is not contraindicated, however, because it may be effective in cases of polydrug toxicity. Gastric emptying is as effective in lithium overdose as in other drug overdoses, and if it is done early after ingestion, some drug can be removed. Since lithium tablets are often quite large, small-bore tubing may be ineffective in removing the drug. Whole bowel irrigation (polyethylene glycol, 2 L/h in adults and 500 mL/h in children) is helpful, especially in cases where sustained-release medications have been ingested. Whole bowel irrigation initiated in the first hour can remove 60 percent of the drug. [12]

Aggressive hydration with normal saline is important. Nearly all patients with significant toxicity have some sodium and volume deficit. Sodium and water depletion impairs lithium elimination, and this increases and prolongs toxicity. In fact, in volume-depletion states, lithium may be preferentially resorbed by the kidney in an attempt to counter sodium loss. Volume repletion reestablishes normal elimination kinetics. Forced diuresis does not enhance lithium elimination once fluid losses have been replaced. In fact, loop and thiazide diuretics can be dangerous, because they further sodium and water loss. [13]

Although nearly all toxicologists agree that hemodialysis should be used for severely toxic patients, the threshold for initiating this treatment is still debated. Patients with levels greater than 3.5 meq/L (4.0 meq/L in acute ingestion), patients with little change in their lithium level of 1.5 to 3.5 meq/L after 6 h of hydration, or patients with sustained levels more than 1.0 meq/L after 36 h will benefit from hemodialysis. [14] In addition, patients with renal failure, those with rapidly increasing levels, or those who have ingested sustained-release preparations should be considered for treatment. Bicarbonate dialysate leads to greater intracellular extraction of lithium.[15]

The goal of hemodialysis is to reduce the serum lithium level to less than 1 meq/L. Because of the cellular concentration of lithium, an increase in serum levels following termination of dialysis is common.[16] Drug levels must be monitored for up to 8 h following dialysis. If levels rise to greater than 1 meq/L, hemodialysis should be reinstituted. Because of the intracellular concentration of lithium in the CNS, neurologic symptoms may persist and even worsen during treatment.

Peritoneal dialysis and charcoal hemoperfusion have been used but are less effective than hemodialysis (Table 156-5).

Therapy	Serum Half-life, h	Clearance, mL/min
No treatment	14–54	15
Saline		15
Peritoneal dialysis		10–15
Hemodialysis	4–6	50
Sodium polystyrene sulfonate	12	
Charcoal hemoperfusion		20

TABLE 156-5   Comparison of Half-Life of Lithium with Treatment

In less severe toxicity, sodium polystyrene sulfonate (SPS, or Kayexalate; 15 g qid PO or 30 g rectal) is useful in decreasing serum half-life of lithium. [17,18] Approximately 75 percent of lithium is bound to SPS in vitro compared with less than 25 percent when activated charcoal is used. Although experience with SPS is limited, it may be useful for mild to moderate toxicity. Because SPS is an exchange resin, large electrolyte shifts may occur during its use, and electrolyte level must be monitored and derangements treated aggressively.

Treatments mentioned in anecdotal case reports, such as sodium bicarbonate and acetazolamide (both in urinary alkalinization) and aminophylline, cannot be recommended at this time. Among treatments found to be ineffective or harmful are water loading, diuretics (furosemide, thiazide, ethacrynic acid, or spironolactone), and ammonium chloride.

DISPOSITION

Admission decisions must be weighted by the presence and persistence of factors predisposing the patient to toxicity, the acuity of the toxicity, and the circumstances that led to the toxicity. Acute ingestions must be treated as already described, and patients should be monitored for 4 to 6 h, even if asymptomatic, and receive psychiatric consultation. Remember that drug levels are less likely to correlate with symptoms in acute ingestion. Any patient with acute ingestion of a sustained-release preparation should be admitted. Patients with levels of greater than 1.5 meq need admission.

Patients with grade 1 chronic toxicity without additional risk factors may be managed with hydration for 4 to 6 h. Once levels return to the normal range (less than 1.5 meq), there is clinical improvement and usually, after psychiatric evaluation, the patient may be discharged. Repeat values obtained within 24 h by home health services can be considered.

Patients with grade 2 or 3 chronic toxicity require admission.

157 BARBITURATES

Raquel M. Schears

Barbiturates have been in common clinical use since 1903. These agents possess sedative properties used to reduce anxiety and hypnotic properties used to induce sleep—hence their classification as sedative-hypnotics. The therapeutic efficacy of these agents is best illustrated in their use as anticonvulsants in the treatment of seizure disorders, as induction agents in rapid-sequence intubation, and as antihypertensives in the management of increased intracranial pressure. [1]

Barbiturates abuse, both prescription and illicit, peaked in the 1970s. The availability, as measured by sales and by the accidental death rate, was significantly correlated with their use for suicide. [2] In the last two decades, the number of toxic exposures involving barbiturates and the incidence of overall barbiturate-related deaths have declined dramatically. This has been attributed to the advent and popularity of safer sedative-hypnotics such as the benzodiazepines and other major tranquilizers, rescheduling of barbiturates to class II, III, and IV drugs, and improvements in supportive care in overdose settings. [3] Nonetheless, illicit barbiturate use has again increased steadily in the United States since 1990, especially in adolescent populations. Reasons for this include youth perceptions that barbiturates are not very harmful and may be useful when taken in tandem with cocaine and methamphetamine to mitigate the unpleasant extremes of the stimulant effects. [4,5] Also worrisome is the featured prominence of barbiturates used in recent mass suicide rituals and recommended in prescriptions for suicide published in the popular press and on the Internet. [6] According to the 1997 Annual Report of the American Association of Poison Control Centers, barbiturates were involved in 5628 reported poisonings, with one-half of these captured as intentional overdoses that resulted in 54 deaths. [7] Clearly, barbiturates continue to rank among the most toxic classes of sedative-hypnotic agents that can pose life-threatening management problems for clinicians.

PHARMACOLOGY

The parent compound, barbituric acid (2,4,6-trioxohexahydropyrimidine), itself has no central depressant activity. R-group substitutions primarily at position 5 give these compounds their sedative-hypnotic properties. Substituting a sulfur for the oxygen at position 2 creates a thiobarbiturate, which is more lipid soluble than an oxybarbiturate (Fig. 157-1). High lipid solubility allows an agent to rapidly transit the blood-brain barrier and confers a shorter duration of action and greater degree of hypnotic activity. [5] Traditionally, barbiturates have been classified according to their duration of action (Table 157-1).
FIG. 157-1. Chemical structure of barbituric acid.

TABLE 157-1   Selected Properties and Classification of Commonly Used Barbiturates

Long-acting barbiturates tend to be weaker acids (lower p K_a values), less lipid soluble, and less protein bound than shorter-acting barbiturates. This translates to a delayed onset of action, decreased volume of distribution, and longer duration of action when compared with short-, ultrashort-, and intermediate-acting compounds. Furthermore, tissue permeability of long-acting barbiturates is uniquely affected by body fluid pH changes. Only nonionized drug is membrane permeable. Phenobarbital has a p K_a of 7.24 and is 95 percent ionized at pH 7.4. Ionization will increase in a basic medium, and permeability will decrease. Conversely, an acidic medium will facilitate phenobarbital permeability by maintaining more drug in a nonionized state. This principle underpins the therapeutic usefulness of alkaline diuresis in long-acting barbiturates overdose.

Short-, ultrashort-, and intermediate-acting barbiturates are not affected by body pH changes. Secobarbital, for example, has a p K_a of 7.9 and is 98 percent nonionized at pH 7.4. Rate of barbiturate delivery to the membrane determines tissue permeability with these classes. These compounds are stronger acids (higher pK_a values), more lipid soluble, and more protein bound, enabling a more rapid onset of action, greater volume of distribution, and shorter duration of action compared with the long-acting barbiturates. [5]

Bulk absorption of barbiturates occurs in the stomach and small intestine, where most of the drug exists in a nonionized state. Overall, barbiturates readily diffuse into the body tissues and cross the blood-brain barrier, with highest concentrations occurring in the brain, liver, kidney, and adipose tissue. Barbiturates are excreted in breast milk and easily cross the placenta. Fetal blood barbiturate concentrations closely reflect maternal plasma levels. [4] Interestingly, in utero exposure to phenobarbital has been significantly linked to verbal intelligence deficits in adult men. [8] Tolerance develops with chronic barbiturate use, and higher doses are

required to produce the same effects. Most barbiturates are metabolized by the liver to inactive by-products. Hepatic biotransformation occurs primarily through routes involving the cytochrome P-450 microsomal enzyme system. All barbiturates are capable of inducing the activity of this enzyme system. Increased rates of metabolism for many drugs, including oral contraceptives, anticoagulants, and corticosteroids, have been observed in patients with chronic barbiturate use. Depending on the degree of hepatic biotransformation, variable amounts of barbiturates are excreted unchanged in the urine. Barbital and phenobarbital are less protein bound and thus most dependent on the renal excretion pathway.[9] Elimination half-life of barbiturates can be greatly accelerated in infants and children and very prolonged in the elderly and in patients with liver or renal disease. [4,5]

The main action of barbiturates is to depress activity in nerve and muscle tissues. In the central nervous system (CNS) this is accomplished by enhancing the action of the primary inhibitory neurotransmitter g-aminobutyric acid (GABA) at the postsynaptic membrane. Additionally, barbiturates may act by inhibiting calcium-mediated excitatory neurotransmitter release at the presynaptic junction. [1,4,5]

CLINICAL FEATURES

Mild to moderate barbiturate intoxication closely resembles the drug "high" produced by alcohol. Drowsiness, disinhibition, ataxia, slurred speech, and mental confusion are common features that escalate with increasing dose. The progressive CNS depression seen with severe barbiturate intoxication predictably manifests as a range from stupor to coma to complete neurologic unresponsiveness. Scales gauging the depth of coma are useful in describing patient presentation and monitoring interval changes in the level of consciousness during treatment in overdose settings. [10] The most common vital sign abnormalities seen in overdose are hypothermia, respiratory depression, and hypotension. The abnormal temperature control and respiratory depression are centrally mediated phenomena, whereas hypotension is due primarily to increased vascular capacitance and venous pooling. The end product of these derangements can be a patient who is cold, apneic, and in shock. Pulse rate is not diagnostic; pupil size, light reactivity, nystagmus, and deep tendon reflexes are variable. Gastrointestinal tract motility is slowed, resulting in delayed gastric emptying and ileus. Skin bullae, referred to as barbiturate blisters, are uncommon and may indicate nothing more than the effects of local skin pressure.[5,10] Even when it is known that a barbiturate was ingested, it is prudent to consider coingestions and alternate explanations for the observed symptom complex.

Early deaths in barbiturate overdose result from cardiovascular collapse and respiratory arrest. Most common complications are hypoglycemia, followed by the delayed pulmonary problems of aspiration pneumonia, noncardiogenic pulmonary edema, and adult respiratory distress syndrome. Current mortality rates range between 1 and 3 percent and are more often the result of multiple organ system failure. Lethal dose is uncertain, but severe poisoning can be assumed if more than 10 times the hypnotic dose has been ingested in a single exposure. [10]

Laboratory evaluation in barbiturate overdose should include determination of glucose levels, blood chemistries, complete blood count, arterial blood gas measurement, toxicology screen, chest radiograph, and an electrocardiogram. Barbiturate serum levels are useful in establishing the diagnosis of a comatose patient and should be obtained and used to distinguish long- from short-acting agents because treatment approaches differ. As a rule of thumb, patients presenting with a serum concentration of more than 10 mg/dL for a long-acting barbiturate, more than 7 mg/dL for an intermediate-acting barbiturate, and more than 3 mg/dL for a short-acting barbiturate, left untreated, have a greater risk of death from the exposure. These measurements are not reliable in predicting clinical course in overdose because they do not reflect brain barbiturate concentrations and may underestimate the clinical condition of a patient in the setting of polydrug exposure. Such levels are also invalid in chronic barbiturate abusers who have developed physiologic tolerance and in patients with renal or hepatic disease who have decreased clearance.[4,5,10]

TREATMENT

In barbiturate overdose, reaching a treatment center predicts favorable outcome largely because supportive management alone is effective over a broad range of serum concentrations.

Airway Assessment and Stabilization

Airway assessment and stabilization are the first management priorities. Intubation in severe sedative-hypnotic overdose is often required and should precede any attempt at gastrointestinal evacuation. Standard monitoring of vital signs, cardiac electrical activity, and pulse oxymetry should be instituted, as should IV access and supplemental O_2.

Volume Expansion

Volume expansion is the mainstay of circulatory support in barbiturate-induced shock. In the absence of cardiac failure, rapid infusion of 1 to 2 L of isotonic intravenous fluid is indicated; administration of bolus therapy, e.g., 200-cc aliquots, is prudent in the elderly, those with cardiac decompensation, or in the face of renal impairment. If fluid resuscitation fails to correct hypotension, vasopressors such as dopamine and norepinephrine should be initiated. [11]

Gastric Emptying

Gastric lavage accomplished within 4 to 6 h of ingestion effectively decreases absorption of barbiturates. However, there are no data that gastric lavage is superior to activated charcoal alone. Given the CNS depression associated with this overdose, ipecac should not be used, and induction of emesis should be avoided.

Oral activated charcoal augments drug extraction by adsorbing drugs from the gastrointestinal tract. Multiple-dose activated charcoal (MDAC) is beneficial in reducing serum phenobarbital concentrations; however, no significant difference in clinical outcome has yet been demonstrated. [12,13] Still, most studies suggest that activated charcoal is at least as effective as lavage and may be better, given its immediate functional effectiveness. Loading dose of activated charcoal is 50 to 100 g, and this may be followed by a single dose of cathartic agent; standard MDAC is 20 to 50 g every 4 h. [14]

Forced Diuresis

Forced diuresis with fluid loading and diuretic therapy is most effective for phenobarbital. Intravenous furosemide should be titrated to effect a urinary flow of 4 to 6 mL/kg/h. Diuresis is contraindicated in the setting of hypotension or shock. Iatrogenic congestive heart failure and fluid overload preclude the usefulness of this therapy for other barbiturates that have limited renal excretion. [5,10]

Urinary Alkalinization

Urinary alkalinization will promote the excretion of long-acting barbiturates only, as explained earlier. The reasons for this singular application are pharmacologically based. Long-acting barbiturates tend to be weaker acids (lower pK_a values), less lipid soluble, less protein bound, and are appreciably excreted in the urine compared with shorter-acting barbiturates. In basic solutions, long-acting barbiturates (weak acids) are relatively more ionized. Since only nonionized drug forms can cross cell membranes, these barbiturates will be trapped in the tubular fluid and excreted if the urinary pH favors the ionized form. Alkalinizing the urine is not effective for shorter-acting barbiturates because these drugs have higher pK_a values (stronger acids), are more protein bound, and are metabolized primarily by the liver. The 5- to 10-fold increase in basal excretion rate is best accomplished by giving a 1 to 2 meq/kg sodium bicarbonate intravenous bolus, followed by 50 to 100 meq in 500 mL of 5% D/W. Drip rate is sufficient if it maintains an arterial pH of 7.45 to 7.50, urinary pH of 8.0, and urinary output of 2 mL/kg/h. Serum potassium must remain at least 4 meq/L to achieve continuous urinary alkalinization. Adequacy of therapy should be monitored every 2 to 4 h. [3,5]

Hemodialysis and Hemoperfusion

Hemodialysis and hemoperfusion are techniques used to maximize barbiturate elimination that are reserved for patients who are deteriorating despite institution of aggressive supportive care. Effectiveness of these modalities is limited by drug characteristics and potential complications.

DISPOSITION

Mild to moderate barbiturate intoxication responds well to general supportive care and MDAC. Frequent reassessment of neurologic status and vital sign parameters indicating improvement over 6 to 8 h allow eventual patient transfer to psychiatric services. Severe overdose with previously described historical and clinical features will require admission, ongoing medical stabilization, and psychiatric intervention. Early poison center contact and specialty service consultation is recommended.

BARBITURATE ABSTINENCE SYNDROME

Abrupt discontinuation of barbiturates in a chronically dependent user will produce minor withdrawal symptoms within 24 h and major life-threatening symptoms within 2 to 8 days. The severity of the withdrawal reflects the degree of physical dependence and drug half-life. Cessation of short-acting barbiturates results in more severe abstinence symptoms than stopping long-acting barbiturates. This is consistent with the clinical observation that the brain has more time to adapt to declining drug concentrations that are gradual. Clinical manifestations of abstinence mimic those described for alcohol withdrawal. Minor symptoms include anxiety, restlessness, depression, insomnia, anorexia, nausea, vomiting, muscle twitching, abdominal cramping, and sweating. Major symptoms include psychosis, hallucinations, delirium, generalized seizures, hyperthermia, and cardiovascular collapse. [3,4,15]

Priorities in the treatment of major abstinence symptoms are cardiovascular stabilization and seizure control. Intravenous benzodiazepines usually are effective in treating seizures, although intravenous barbiturates may be required. Due to the mortality associated with sedative-hypnotic abstinence, gradual in-hospital withdrawal of the addicting agent is recommended.[4,15]

158 BENZODIAZEPINES

George M. Bosse

Benzodiazepines are pharmacologic agents commonly used for the treatment of anxiety, insomnia, seizures, and alcohol withdrawal. They also are used in conscious sedation as well as general anesthesia. Fourteen generic benzodiazepines are currently approved for use in the United States (Table 158-1).

TABLE 158-1   Benzodiazepines Approved for Use in the United States

Benzodiazepines are frequently agents of accidental and intentional overdose. In the 1996 Annual Report of the American Association of Poison Control Centers Toxic Exposure Surveillance System, benzodiazepines accounted for 39,029 exposures, both as single agents and in combination with other drugs. [1] Although the ingestion of benzodiazepines alone appears to result in relatively few deaths, increased rates of morbidity and mortality do result from mixed overdose. Parenteral administration of benzodiazepines may also result in significant complications, particularly respiratory depression and hypotension.

PHARMACOLOGY

A specific benzodiazepine receptor has been identified in the central nervous system (CNS). [2] Specific peripheral receptor sites also have been identified, but the predominant clinical effects of benzodiazepines are mediated through the CNS receptors. Although the receptor has not been fully characterized, research supports the existence of a neuronal cell-surface protein complex containing a benzodiazepine receptor, a gamma-aminobutyric acid (GABA) receptor, and a chloride channel. GABA is an inhibitory neurotransmitter. Effects of stimulation of GABA pathways include sedation, anxiolysis, and striated muscle relaxation. Stimulation of the benzodiazepine receptor appears to increase the sensitivity of the GABA receptor complex to stimulation by GABA. The enhancement of GABA transmission by the administration of benzodiazepines is thought to occur by either increasing the affinity of the GABA receptor for its ligand or improving coupling between the GABA receptor and its associated chloride channel. Increased GABA output leads to inhibitory effects throughout the neuroaxis and the resultant typical clinical effects of benzodiazepines. The presence of an endogenous ligand for the benzodiazepine receptor has been proposed, but such a ligand has not been conclusively identified.

In general, benzodiazepines are well absorbed from the gastrointestinal tract. The onset of action after oral ingestion is limited more by the rate of absorption from the gastrointestinal tract than by the relatively rapid passage from the bloodstream into the brain. With the exception of lorazepam and midazolam, intramuscular injection of benzodiazepines results in unpredictable absorption.

Benzodiazepines are all relatively lipid soluble, with some variation among the agents. Increased lipid solubility is associated with more rapid diffusion across the blood-brain barrier. After single doses, the more highly lipophilic benzodiazepines have a shorter onset of action but also a shorter duration of activity. This short duration of activity occurs because of rapid egress of the drug from the brain and bloodstream into inactive tissue storage sites. For this reason, the half-life may not be a good indicator of the duration of action in an acute ingestion. For example, diazepam is a derivative with a long elimination half-life but a relatively short duration of action.

Benzodiazepine derivatives undergo metabolism by hepatic biotransformation through either oxidation or conjugation. Several derivatives are metabolized by both oxidative and conjugative processes. Oxidation often produces active metabolites, which prolong the biologic half-life of the parent compounds. Conjugation is a rapid process that produces inactive metabolites. Oxidation is more susceptible to impairment by such factors as disease states (e.g., chronic liver disease), demographic characteristics (e.g., old age), and concurrent treatment with drugs that impair oxidizing capacity (e.g., cimetidine, estrogen, isoniazid, ethanol, and phenytoin). Examples of agents that undergo conjugation primarily include oxazepam, lorazepam, and temazepam. Administration of benzodiazepines that undergo conjugation may be safer in susceptible groups.

Selection of a benzodiazepine for use by a physician depends on the clinical properties of the particular derivative. Although individual drugs are marketed for specific conditions, there is considerable overlap of activity. For this reason, some hospital formulary commitees have limited the number of available agents.

CLINICAL FEATURES

Isolated benzodiazepine overdose is notable for the relative lack of significant rates of morbidity and mortality. [3] Most reported cases of serious toxicity have occurred in the setting of coingestion of other agents or with parenteral administration. However, deaths in isolated overdose have been reported and appear to be more likely with short-acting derivatives, such as triazolam, alprazolam, and temazepam.

The clinical presentation of benzodiazepine intoxication is nonspecific. Clinical assessment also may be difficult because of the frequent coingestion of other agents. Except for additive effects, drug interactions of benzodiazepines with other sedative-hypnotics are unusual.

The nonspecific presentation of benzodiazepine toxicity is similar to that of other sedative-hypnotics. However, other agents can have at least a few distinguishing features. Chloral hydrate is known to precipitate cardiac dysrhythmias. Ethchlorvynol can produce prolonged coma and may be suspected by the presence of a vinyl-like odor. Glutethimide may give rise to fluctuating levels of CNS impairment and anticholinergic signs. Barbiturates are more likely than benzodiazepines to produce coma and depressant myocardial effects.

The predominant manifestations of benzodiazepines are neurologic. CNS effects include drowsiness, dizziness, slurred speech, confusion, ataxia, and impairment of intellectual function. Coma, particularly if prolonged, is atypical and should prompt suspicion of intoxication with other agents or a nontoxin-related medical condition. The elderly are more prone to manifest the CNS effects of benzodiazepines.

Paradoxical reactions, including excitement, anxiety, aggression, hostile behavior, rage, and delirium, have been reported but are uncommon. Although unclear, the etiology of such effects is probably not idiosyncratic. Benzodiazepines may have a disinhibiting effect, which, in the presence of various extrinsic factors, can lead to such actions as aggressive or hostile behavior. Other effects that have been reported and that have unclear etiologies include headache, nausea, vomiting, chest

pain, joint pain, diarrhea, and incontinence.

Uncommonly, respiratory depression and hypotension may occur, generally with either parenteral administration or in the presence of coingestants. Intravenous administration is more likely to cause serious cardiorespiratory effects with rapid administration of large doses. In addition, the elderly and those with underlying cardiorespiratory disease are more susceptible to adverse effects of intravenous administration. The use of propylene glycol as a diluent in parenteral preparations of diazepam has also been implicated as a factor in cardiorespiratory arrest.

Extrapyramidal reactions have been associated with the use of benzodiazepines. Various allergic, hepatotoxic, and hematologic reactions also have been reported, but they are infrequent. In general, benzodiazepines have no long-term organ-system toxicity other than that which can be ascribed to indirect effects from CNS or cardiorespiratory depression.

Laboratory data in benzodiazepine ingestion are of limited value. Determination of serum benzodiazepine levels is not indicated routinely because they do not correlate well with the clinical state. Qualitative testing may be helpful, but the laboratory may not test routinely for all available derivatives. Familiarity with laboratory capabilities at a given institution is essential.

TREATMENT

Benzodiazepines often are ingested with other agents, and the history frequently is inaccurate. Therefore, administration of concentrated dextrose, thiamine, and naloxone should be considered in such patients when depressed or altered mental status is present. Induction of emesis should be avoided in benzodiazepine overdose because CNS depression may ensue. Gastric lavage is safer and is recommended if the amount ingested is large or in coingestions with toxic agents. Activated charcoal binds benzodiazepines effectively and should be administered in most situations. Elimination enhancement by forced diuresis, hemodialysis, or hemoperfusion is not effective, and most patients do not manifest toxicity serious enough to warrant consideration of such measures. The patient should be monitored closely for CNS and respiratory depression. Indications for hospital admission include significant alterations in mental status, respiratory depression, and hypotension. If CNS depression persists or is profound, other agents or conditions must be considered.

Flumazenil is a unique selective antagonist of the central effects of benzodiazepines. [4] Clinical applications include the management of benzodiazepine overdose and reversal of benzodiazepine-induced conscious sedation. Its use in benzodiazepine toxicity may obviate the need for tracheal intubation and respiratory support. As a diagnostic aid in obscure alterations of mental status, flumazenil may reduce the need for expensive and invasive procedures, such as computed tomography or lumbar puncture.

In the emergency department, flumazenil is useful mainly in reversing the effects of benzodiazepines administered for diagnostic and therapeutic procedures. The plasma elimination half-life of flumazenil is approximately 1 h. Its duration of action is variable and depends on the dose of flumazenil and the benzodiazepine administered. Recurrent benzodiazepine toxicity may result once the effects of flumazenil have worn off. This is less likely for an agent with a short duration of action, such as midazolam. The dose of flumazenil is 0.2 mg intravenously every minute to response or to a total of 3 mg.

Several considerations should limit the empirical administration of flumazenil to a poisoned patient. Generalized seizures have occurred in patients given flumazenil after coingestions of benzodiazepines and seizure-inducing agents, particularly cyclic antidepressants. [5,6] Seizure activity after flumazenil administration has also occurred in patients physically dependent on benzodiazepines and in patients receiving benzodiazepines for control of a seizure disorder. The putative explanation for this convulsive activity is either the reversal of the cerebroprotective and anticonvulsive effects of benzodiazepines or the precipitation of a benzodiazepine withdrawal syndrome. Another reason to avoid empirical administration of flumazenil in overdose patients is that the history is often unreliable or unavailable. Flumazenil is also contraindicated in patients with a suspected elevation of intracranial pressure, such as in severe head injury. This contraindication is due to its effects on cerebral hemodynamics. In all cases of benzodiazepine toxicity, supportive care is the cornerstone of treatment.

BENZODIAZEPINE ABUSE AND DEPENDENCE

Genuine physiologic addiction to benzodiazepines may occur, particularly with prolonged and high doses. [3,7] However, the abuse potential of benzodiazepines appears to be low in comparison with that of agents such as alcohol, cocaine, opiates, and barbiturates. [8,9] Benzodiazepine abuse usually occurs in individuals with a history of abuse of other psychoactive drugs. Primary drug abuse with benzodiazepines is not common.

Benzodiazepine withdrawal may occur on abrupt discontinuation and is more likely in patients with prolonged use and high doses. Because of the long biologic half-life of several derivatives, withdrawal manifestations may not occur for several days to over 1 week after the benzodiazepine has been discontinued. Unfortunately, it is often difficult to distinguish between withdrawal and underlying symptoms for which the drugs were prescribed initially.

Reported withdrawal manifestations include anxiety, irritability, insomnia, nausea, vomiting, tremor, sweating, and anorexia. Serious manifestations, including confusion, disorientation, psychosis, and seizures, also have been reported. For patients with an acute organic brain syndrome, a history of possible benzodiazepine withdrawal should always be pursued. Withdrawal reactions may be avoided by dose tapering. Treatment of withdrawal reactions may be accomplished by drug substitution or by reintroduction of a benzodiazepine and subsequent tapering.

159 NONBENZODIAZEPINE SEDATIVE-HYPNOTICS

Raquel M. Schears

The term *nonbenzodiazepine sedative-hypnotic* is currently used to refer to a diverse group of agents that share the ability to allay anxiety and promote sleep, categorically exclusive of the benzodiazepines. Several of these chemical entities, such as ethchlorvynol, meprobamate, glutethimide, and methaqualone, are rarely encountered in clinical use, yet toxic exposures continued to be reported. Newer agents such as buspirone and zolpidem are used commonly, making toxicity and overdose characteristics important to recognize and treat in the emergency department (Table 159-1 and Table 159-2).

TABLE 159-1   Selected Properties and Characteristic Overdose Features of Nonbenzodiazepine Sedative-Hypnotic Drugs

Substance	No. of Exposures	Deaths
Chloral hydrate	510	1
Ethchlorvynol	124	1
Glutethimide	15	0
Meprobamate	254	1
Methaqualone	45	0
Buspirone	Unknown	0
Zolpidem	Unknown	0
Gamma-hydroxybutyrate	2	0

Source: From Litovitz et al.[11]

TABLE 159-2   Reported Toxic Exposures to Nonbenzodiazepine Sedative-Hypnotic Agents in 1996

Some chemical compounds possess sedative-hypnotic properties but were marketed as health food products and until recently escaped Food and Drug Administration (FDA) regulation. Among these drugs, gamma-hydroxybutyrate (GHB) is gaining notoriety as a product to illicitly inflict the harm of involuntary intoxication or chemical submission, commonly referred to as "date rape." GHB has no legitimate clinical purpose in the United States and is being cited increasingly as a toxic and dangerous agent. Despite this irony, it remains readily available via recipes on the Internet and stovetop component mixes by mail order. Certainly, patients presenting with complaints of drug-induced physical and sexual assault will pose novel diagnostic, medical, and legal problems to challenge emergency physicians.[1]

Agents in this chapter share certain pharmacologic and clinical similarities. These drugs tend to be highly lipophilic and concentrate in the central nervous system (CNS), causing varying degrees of CNS depression with gradual redistribution and eventual hepatic degradation. Clinically, mild intoxication manifests as sedation and incoordination that progresses to lethargy, worsening ataxia, and deepening coma in overdose.

It is recognized that reaching a treatment center predicts a favorable outcome in all types of nonbenzodiazepine sedative-hypnotic overdoses. Improvements in general supportive care underpin declining trends seen in mortality associated with these agents over broad dose ranges. Therefore, general treatment guidelines take precedence in management of all these agents in overdose.

This chapter reviews current drugs implicated and reported as toxic exposures of the nonbenzodiazepine sedative-hypnotic variety. Departures from general clinical presentation, complications, and management of overdose unique to a specific agent correspondingly will be highlighted in the discussion of that agent.

GAMMA-HYDROXYBUTYRATE (GHB)

GHB is an endogenous metabolite of gamma-aminobutyric acid (GABA), the major inhibitory neurotransmitter in the CNS. GHB is a putative neurotransmitter capable of inducing profound CNS depression. Abroad, it is used primarily as an anesthetic and in the treatment of narcolepsy and substance withdrawal. In the United States, it is only used for investigational research and is not approved for any clinical use. In the 1980s it was sold to bodybuilders as a health food product. GHB was touted as an effortless means to diet and build muscles during sleep by enhancing fat metabolism and the release of growth hormone. Within the last few years, it has become more prevalent as a drug of abuse for its reported euphoric and aphrodisiac effects in "rave" clubs and on college campuses. Despite a 1990 ban by the FDA on manufacture and sales, possession of GHB remains legal under federal law. [1]

The substance is considered an alternative to "ecstasy" or methamphetamine and is often coingested with alcohol. At least five fatalities related to GHB overdose have been reported. Data from the Drug Abuse Warning Network (DAWN) strongly suggest that there has been an increase in the abuse of GHB. The data indicate that GHB-related hospital emergency department (ED) visits increased from 20 in 1992 to 629 in 1996. Two-thirds of the episodes occurred among those aged 18 to 25 years, and 79 percent of patients were Caucasian males. Nearly 60 percent of episodes involved multiple drugs. Among episodes involving GHB for which a motive was reported, 91 percent reported "recreational use" as the reason for drug use. In those episodes in which a reason for the ED visit was documented, "overdose" was listed in 65 percent of the episodes and "unexpected reaction" in 33 percent. [2]

More recently, GHB has been cited as an agent of choice for substance-induced rape along with flunitrazepam (Rohypnol). These drugs are favored because of their abrupt coma-inducing effects, ready accessibility, and ease of administration. GHB is available as an odorless, colorless, and nearly tasteless liquid, powder, or capsule. Concerns regarding such illicit use, compounded by the growing popularity of GHB, prompted passage of a 1996 federal law, the Drug-Induced Rape Prevention and Punishment Act, which sets prison terms of up to 20 years for anyone convicted of using any controlled substance with the intent to commit a violent

crime, including sexual assault. GHB case reports continue to demonstrate it to be a potentially life-threatening substance, especially when combined with other drugs of abuse. Furthermore, the unique difficulties posed by alleged substance-induced rape and assault require special consideration.

GHB is rapidly absorbed from the gastrointestinal (GI) tract, with peak plasma concentrations occurring 20 to 60 min after ingestion. The drug freely diffuses across the blood-brain barrier and concentrates in the CNS, kidney, heart, and muscle tissue. GHB is a CNS depressant capable of increasing dopamine levels and altering endogenous opioid systems, and it may have effects through other independent receptor-dependent mechanisms that are not well understood. GHB has a half-life of 20 min, and degradation generates no active metabolites. It is almost completely oxidized to carbon dioxide and water in the lungs and then expired. [1,3]

Clinical effects primarily involve the CNS system and are dose-related. Low doses produce euphoria, nystagmus, ataxia, and dizziness; moderate doses produce sedation; and high doses produce coma, respiratory depression, apnea, and rarely, death. Under controlled conditions, 10 mg/kg results in amnesia, hypotonia, and ataxia; 30 mg/kg induces euphoria, drowsiness, and dizziness. Doses of 50 mg/kg produce unconsciousness. Doses above 50 mg/kg causes bradycardia, respiratory depression, and seizure-like activity. Since most GHB is "home brewed," dose uncertainty is guaranteed, and patients may present anywhere along this clinical spectrum. Additional symptoms reported in GHB overdose are vomiting, emergence delirium, and Cheyne-Stokes respirations. Characteristic clinical clues to GHB toxicity include marked agitation on stimulation despite periods of prolonged apnea and hypoxia. Historical features common in GHB intoxication include an abrupt onset of uncharacteristic aggressive behavior followed by sudden drowsiness, dizziness, euphoria, or coma with rapid reawakening and amnesia. [4]

Treatment is supportive for isolated GHB ingestion; aspiration precautions are recommended because of the potential for sudden changes in mental status. Bradycardia responds to atropine if simple stimulation fails to suffice. Neither naloxone nor flumazenil has been effective in treating CNS depression induced by GHB. Lavage or charcoal is of limited value because of the small amounts ingested and the drug's rapid absorption. The drug is undetectable in the urine after 12 h and missed by most routine toxicologic screens. Patients with symptoms of mild intoxication who improve rapidly (6 h of observation) and clear completely can be discharged from the ED; all others should be admitted for observation. Serious GHB intoxication complicated by coingestion of alcohol or other CNS depressants often will require emergent airway stabilization and cardiovascular support. Because GHB functions as an anesthetic induction agent, rapid-sequence intubation can proceed with paralytic agents alone. Once the airway is secured, routine gastric decontamination for coingestants is indicated. Extracorporeal elimination methods have not been evaluated in GHB overdose. A small case series indicates that dependence liability and a non-life-threatening withdrawal syndrome may exist with abrupt cessation of GHB in chronic use. [5]

When patients present to the ED seeking evaluation for possible substance-induced rape and/or assault, the best recommendation is compassionate advocacy. Currently, this is accomplished by collecting evidence, including urine samples that can be submitted for testing according to strict chain-of-custody procedures, which will be critical if the case is prosecuted. Even if the patient chooses not to report the incident to law enforcement authorities, drug testing can be important in identifying substances used. A free drug testing service has been made available to hospital EDs and rape crisis centers by Hoffmann-LaRoche, the manufacturer of Rohypnol. This testing program, accessed by calling (800) 608-6540, uses an independent forensic toxicology laboratory certified by the U.S. Department of Health and Human Services that follows strict chain-of-custody procedures. Testing for GHB and alcohol in addition to a wide range of other abused drugs was initiated in March of 1997. Results are returned in 10 days to the submitting agency to facilitate patient counseling. [6]

CHLORAL HYDRATE

Introduced in 1869, chloral hydrate was used as a popular sedative in clinical medicine until the advent of barbiturates largely supplanted their use in the early 1900s. Chloral hydrate is still used effectively for promoting sedation in children because in therapeutic doses it does not depress respiratory drive or circulatory function. Drawbacks include its narrow margin of safety, minimal analgesic activity, and propensity to develop tolerance and physical dependence. Withdrawal symptoms mimic those of alcohol abstinence. Toxic doses produce severe CNS, respiratory, and cardiovascular depression. Ethanol potentiates the sedative effects of chloral hydrate when taken in combination. This observation led to the street use of the two substances for malicious intent, as in slipping someone a "Mickey (Finn)" or "knockout drops." Chloral hydrate is a schedule III drug with recognized abuse potential.

Chloral hydrate absorption occurs rapidly and completely from the GI tract. It is a well-known mucous membrane irritant, especially when taken in quantity or undiluted. Development of GI bleeding is a useful clue in overdose. Chloral hydrate is lipid-soluble and easily transits all cell membranes. Volume of distribution and protein-binding properties are moderate. Metabolism occurs in the liver via alcohol dehydrogenanse and results in the generation of a longer-acting active metabolite, trichloroethanol, thought to be responsible for most of the drug's sedative action. Neither the parent drug nor the metabolite induces hepatic enzyme activity.

Chloral hydrate is a CNS depressant, with an unknown mechanism of action. Toxic doses also depress myocardial contractility, shorten the refractory period, and sensitize the myocardium to catecholamines. These factors create the substrate for resistant ventricular dysrhythmias that are the leading cause of mortality overdose.[7]

Clinical clues to the ingestion of chloral hydrate are a pearlike breath odor, hypotension, and cardiac dysrhythmias. Because chloral hydrate is radiopaque, abdominal x-rays may help narrow the differential diagnosis and guide decontamination. Serum levels are rarely helpful in guiding clinical management. [7]

Barring evidence of caustic injury causing perforation, gastric lavage should be considered and activated charcoal administered. Cardiac monitoring is mandatory, but treatment of ventricular dysrhythmia may prove difficult. There are anecdotal reports of successes using lidocaine and propanolol. Overdrive pacing in the setting of ventricular tachycardia may prove necessary. Avoid b-adrenergic drugs such as epinephrine, isoproterenol, and dopamine, which can potentiate dysrhythmias in the catecholamine-sensitized myocardium. If hypotension does not respond to volume loading, a-acting pressors such as norepinephrine should be used. Hemodialysis and hemoperfusion have been shown to be beneficial in severe overdose.

ETHCHORVYNOL

Ethchlorvynol, a schedule IV drug, was marketed initially in 1955 as an alternative to barbiturates, possessing a more rapid onset and shorter duration of action. However, the drug's high abuse potential, coupled with its tendency toward tolerance, physical dependence, and life-threatening withdrawal, overshadowed any claim of superior efficacy. The drug is available as a liquid-filled capsule, allowing both intravenous and oral abuse.

Ethchlorvynol is absorbed rapidly from the GI tract. It is highly lipophilic, concentrates in the CNS, and possesses a large volume of distribution. Its biphasic distribution is characterized by an initial period of adipose tissue deposition, 3 to 5 h after ingestion, with sedative effects disappearing only to resurface 7 to 10 h later when the drug redistributes from fat stores. Ethchlorvynol is moderately protein-bound and hepatically metabolized but does not induce microsomal enzymes. It also crosses the placenta and causes neonatal withdrawal symptoms. Mechanisms of CNS sedative action and hepatic degradation are unknown. Ethanol potentiates CNS depressant effects.

Distinguishing clinical clues in oral and intravenous overdose are a vinyl-like breath odor (although the patient may report a mintlike taste in the mouth), dypsnea, and dry cough. CNS effects include nystagmus, lethargy, and extremely prolonged coma. Isoelectric electroencephalographic (EEG) tracings have been reported but do not preclude full recovery. Hypothermia, hypotension, and relative bradycardia signal hemodynamic instability. Noncardiogenic pulmonary edema can be seen in massive oral overdose, although it is more characteristic of intravenous overdose. Polydrug exposures that potentiate CNS depression can result in respiratory arrest and cardiovascular collapse. Psychological and physical dependence develop rapidly. Chronic abusers may present with a variety of neurologic symptoms: ataxia, dysarthria, tremors, facial numbness, confusion, weakness, and visual disturbances (e.g., toxic amblyopia and central scotomata). Abstinence symptoms resembling those seen with alcohol withdrawal include states reminiscent of delirium tremens, with psychotic hallucinations, seizures, agitation, confusion, hypertension and tachycardia.

Successful treatment of ethchlorvynol overdose centers on the usual attention to supportive care and general decontamination. Serum levels of ethchlorvynol are not helpful in guiding management except to confirm diagnosis or trigger use of an extracorporeal elimination method in refractory cases. Charcoal hemoperfusion is superior to hemodialysis because of the drug's degree of protein binding and redistribution characteristics. Forced diuresis is not recommended because the risk of inducing pulmonary edema outweighs the minimal enhancement of drug cleared by the kidney.

GLUTETHIMIDE

Glutethimide was introduced in 1954 as a safe, nonaddicting sedative-hypnotic drug substitute for barbiturates. However, its clinical usefulness was quickly eclipsed

by recognition of its potential adverse effects, which closely resembled those of barbiturates. Similarities include its ability to induce prolonged coma, addiction, tolerance, and severe withdrawal. In large overdose, several complications (e.g., cerebral and pulmonary edema, hypotension, seizures, and sudden apnea) make treatment of this schedule II substance more difficult. Illicit abuse centers on street combinations of codeine and glutethimide that reportedly produce a similar but longer-acting euphoria than can be obtained with intravenous heroin use. Side effects with chronic use include "hangover," headaches, blurred vision, rash, bone marrow suppression, hypocalcemia, and osteomalacia.[8,9]

Poor water solubility causes glutethimide to be slowly and erratically absorbed from the GI tract. However, coingestion of alcohol markedly enhances drug dissolution and absorption. The drug is lipophilic and initially concentrates in the CNS and adipose tissue, with eventual redistribution. Drug half-lives up to 40 h have been observed in overdose. Glutethimide has a large volume of distribution, is moderately protein-bound, and is capable of inducing hepatic microsomal enzymes. Hepatic degradation results in several active metabolites that may play a role in the prolonged fluctuating coma seen in overdose. Glutethimide crosses the placenta, and fetal blood concentrations equal those of the mother. Minimal amounts of unchanged drug are excreted in breast milk.[9]

Clinical manifestations of glutethimide overdose mirror those seen with barbiturate toxicity with two exceptions. Anticholinergic symptoms are prominent, and the unique fluctuating nature of the prolonged coma complicates management. Mydriasis, dry mucous membranes, tenacious secretions, tachycardia, hypertension, ileus, urinary retention, hyperpyrexia, delirium, seizures, and agitation may be observed.[8]

Serum levels of one of the active metabolites, 4-HG, may correlate better with toxicity than do levels of the parent compound. As with ethchlorvynol, complete clinical recovery is possible despite an isoelectric EEG if the patient has been spared the insults of cerebral hypoxia and/or ischemia. Coingestion of other sedative-hypnotic drugs, prolonged coma, and age over 60 years are predictive of negative outcomes in glutethimide overdose.[10]

Late gastric lavage (12 h after ingestion) has been shown to be beneficial in obtunded patients whose overdose has resulted in delayed gastric emptying due to anticholinergic effects. In asymptomatic patients presenting 4 h or more after ingestion, the poor water solubility of glutethimide limits the effectiveness of lavage. Activated charcoal and cathartics are recommended in all patients, but the utility of multiple-dose activated charcoal (MDAC) remains unproven. The use of physostigmine to reverse anticholinergic CNS toxicity is not recommended. Forced diuresis is not effective and can precipitate the development of pulmonary edema. Improvement in clinical outcomes for the elderly and those patients with severe intoxications (serum glutethimide levels > 40 mg/L) has been documented using extracorporeal techniques to increase drug clearance. Hemoperfusion is the preferred method, but efficacy remains controversial, so hemoperfusion should be limited to patients not responding to supportive measures alone. Given the potential for delayed, erratic absorption and characteristic fluctuating mental status, admission and prolonged observation of patients with significant overdose are indicated.[8,9 and 10]

MEPROBAMATE

Meprobamate has been in clinical use as a schedule IV drug with anxiolytic and sedative-hypnotic properties since 1955. Several combination products remain available, but prescription practices have changed in recent years, favoring the safer benzodiazepine derivatives. Nonetheless, toxic exposures continue to be reported, with intentional overdose commonly implicated as the rationale. Also notable, carisoprodol (Soma), a structurally related muscle relaxant that is metabolized to meprobamate, is emerging as a street drug of abuse. Carisoprodol often is combined with Tylenol and codeine. The combination is known as "Soma-Do" and "Soma-Coma." According to the 1996 Annual Report of the American Association of Poison Control Centers, carisoprodol has a similar number of deaths due to overdose as meprobamate. However, the actual number of exposures is unknown.[11]

Absorption of meprobamate occurs in the small intestine. The compound is poorly water-soluble, stable in acidic environments, and able to decrease gastric motility. These characteristics lend themselves to the development of gastric concretions. Meprobamate has a large volume of distribution, is poorly protein-bound, and is metabolized primarily in the liver, where it can induce microsomal enzymes. Approximately 10 percent of the drug is excreted unchanged in the urine. Meprobamate crosses the placenta, and fetal blood levels approximate those of the mother. It is also excreted in breast milk.[12]

Meprobamate depresses the CNS by reducing sensory transmission, particularly in the thalamus. In overdose, meprobamate also concentrates in myocardial tissue, causing direct cardiotoxicity, manifesting as depressed contractility and hypotension often in the absence of respiratory depression.[12]

Clinical features of meprobamate toxicity are similar to those of other sedative-hypnotic agents. CNS symptoms range in mild exposures from nystagmus and dysarthria to ataxia, confusion, and deep coma in overdose. In contrast to barbiturates, hypotension may be an early sign of toxicity occurring in lesser stages of coma. Prolonged and fluctuating coma is due to continued drug absorption from concretions. Hypotension is the hallmark of serious meprobamate overdose. Seizures, cardiac dysrhythmias, and pulmonary edema have been reported rarely. Abstinence syndromes reflective of the degree of physical dependence and tolerance develop quickly, usually within 1 to 2 days of drug discontinuation, and can be severe.[12]

Utility of serum levels of meprobamate is limited but confirmative of ingestion. It may guide the need for extracorporeal removal. The treatment approach after stabilization of the airway and circulation centers on gastric decontamination given meprobamate's propensity to form concretions. Delayed gastric lavage and whole-bowel irrigation using a polyethylene glycol solution until rectal effluent is clear is advocated but not well studied. Multiple-dose activated charcoal (MDAC) also appears to be safe and effective in increasing the clearance of meprobamate, although solid clinical outcome data are lacking.[13] Gastrostomy and endoscopic removal of concretions have been reported anecdotally as successful. Hemoperfusion is the preferred extracorporeal method to enhance drug elimination when usual intensive supportive measures fail or serum levels dictate. Forced diuresis is controversial. Given the limited renal elimination of meprobamate and the risk of inducing pulmonary edema, it is not recommended. Management of hypotension should include the early use of vasopressors and inotropes to avoid fluid overload.[13]

METHAQUALONE

One of the more ubiquitous sedative-hypnotic barbiturate substitutes, methaqualone was introduced in 1965 and withdrawn from the U.S. market in 1984 because promotions of safety and nonaddictiveness proved false. High abuse potential owed to methaqualone's popularity as a street aphrodisiac. The college pastime of "luding out," slang for a standard combination of 300 mg methaqualone ingested with wine, was used for attainment of characteristic deep relaxation, disinhibition, and euphoria.[14] In the 1980s the drug was used increasingly to mitigate the unpleasant side effects of popular stimulants as a "cocaine downer." Even though the drug continues to be clandestinely manufactured abroad and smuggled into the United States, actual reports of toxicity and mortality are becoming rare. Cessation of legal synthesis and readily available benzodiazepine alternatives explain this trend.

Methaqualone is rapidly absorbed from the GI tract, is highly lipophilic, and concentrates in the brain, adipose tissue, and liver. It exists as a weak base with a large volume of distribution and is highly protein-bound. The majority of its metabolism occurs in the liver; no active metabolites are generated, and microsomal enzymes are moderately induced.

The drug is a CNS depressant like all the other sedative-hypnotics; however, its mechanism of action is more of a mystery. In contrast to other sedative-hypnotics that depress muscle tone and reflexes, methaqualone increases muscle tone and motor activity by selectively depressing polysynaptic spinal reflexes at high dose. Clinically, hypertonicity, clonus, hyperreflexia, and muscle twitching are seen along with the usual sedative-hypnotic symptom profile of lethargy, ataxia, dysarthria, seizures, and coma at escalating dose.[15] Hyperacusis is also reported and may be a helpful diagnostic clue to ingestion. More often the drug-induced dissociative "high," poor judgment, and impulsive behavior result in death due to trauma rather than from the direct toxic effects of overdose.[16]

Cardiopulmonary symptoms include hypotension due to decreased myocardial contractility and respiratory depression. However, such symptoms occur less commonly than with other sedative-hypnotics, even in comatose patients. Coingestion of other CNS depressants can lead to severe respiratory depression and sudden apnea. Pulmonary edema can be seen as a result of increased capillary permeability, a risk common to most sedative-hypnotics.

GI distress and hemorrhage have been noted in methaqualone overdose. Drug-induced platelet aggregation inhibition, prolonged prothrombin and partial thromboplastin times, and decreased factors V and VII are causative.[17] As with other sedative-hypnotic agents, decontamination and supportive care remain the mainstays of therapy. Specific management considerations for methaqualone overdose include early use of benzodiazepines to control hypertonicity and seizures along with administration of blood products (i.e., platelets, vitamin K, fresh-frozen plasma) in the setting of hemorrhage. Charcoal hemoperfusion is more effective than hemodialysis in clearing methaqualone but is reserved for patients who fail to respond to maximal supportive therapy or whose serum methaqualone levels are greater than 10 to 15 mg/dL. Severe abstinence symptoms occur in chronic users when this drug is stopped abruptly and require hospital admission for gradual

withdrawal.

BUSPIRONE

Buspirone is a prototype anxiolytic drug from the azapirone family introduced in 1984. The agent is not chemically or pharmacologically related to the other sedative-hypnotics, although its efficacy profile is comparable with that of the benzodiazepines. Clinical indications for buspirone are not fully delineated; however, it appears most useful in the treatment of conditions such as chronic anxiety, especially in the elderly, and mixed anxiety-depression states. It does not affect GABA or benzodiazepine receptors and therefore produces less sedation, euphoria, psychomotor impairment, and ethanol potentiation. It does affect CNS serotonergic, dopaminergic, and noradrenergic neurotransmission, but the mechanisms are not fully understood. Buspirone appears to have several merits when compared with the other sedative-hypnotics. It exhibits a virtual absence of potential for addiction, a wide margin of therapeutic safety, and no documented delayed toxicity or withdrawal reactions with abrupt discontinuation of chronic use. [18]

Buspirone is rapidly absorbed, highly protein-bound, and widely distributed to the tissues. Metabolism occurs in the liver, with at least one active metabolite generated. Fecal elimination accounts for 20 to 40 percent of drug clearance.

Experience in overdose may be limited by the drug's wide margin of safety. Patients have taken up to 3 g (which is 150 times the average anxiolytic dose) in overdose without lasting ill effects. Most common clinical symptoms in overdose are nonspecific drowsiness and dysphoria. Rarely, hypotension, bradycardia, seizures, GI upset, dystonia, and priapism also have been described. Spontaneous acute hypertensive reactions have developed in patients coprescribed buspirone and monoamine oxidase inhibitors. No other adverse drug interactions or unexpected toxicities have emerged with buspirone use. [18]

Treatment is supportive. Serum levels are not useful clinically, and extracorporeal methods of elimination enhancement have not been evaluated.

ZOLPIDEM

Zolpidem is a new short-acting hypnotic agent introduced in 1988 for the treatment of insomnia. It is an imidazopyridine derivative, structurally different from benzodiazepines and other sedative-hypnotics. It binds preferentially to one of the benzodiazepine receptor subtypes (omega-1, benzodiazepine-1) in the CNS. The drug is rapidly absorbed, has an onset of action within 30 min, and is effective for up to 6 h. Zolpidem is metabolized in the liver to inactive metabolites that are excreted in the urine and feces. Its advantage over the benzodiazepines is the absence of reported addiction, tolerance, or withdrawal symptoms. [19] Experience in overdose is limited.

Signs of acute overdose in larger series commonly include drowsiness and vomiting and, rarely, coma and respiratory depression. These symptoms escalate with dose and are complicated by coingestion of other psychotropic drugs and ethanol. In most cases, symptoms of intoxication remit rapidly, and therapy is usually limited to general supportive measures. [20]

Treatment is not aided by obtaining serum zolpidem levels; the utility of multidose activated charcoal and extracorporeal elimination enhancement methods has not been evaluated in overdose. Anecdotally, flumazenil has been effective in reversing the CNS and respiratory actions of zolpidem. [21] The recommended initial dose is 0.2 mg IV over 30 s. If no improvement in consciousness is observed within 30 s, an additional dose of 0.3 mg may be administered over 30 s. This dosing regimen (0.2 mg followed by 0.3 mg) can be repeated one more time, to a total dose of 1 mg, at an interval of 1 min if adequate consciousness is not obtained. Flumazenil at a total dose of 1 mg or less IV leaves 50 percent of the benzodiazepine receptors unoccupied and therefore should limit the risk of acute withdrawal so long as this dose is not exceeded. Flumazenil is best avoided in overdose settings where there is evidence that a drug capable of causing seizures has been ingested. Furthermore, the presence of any of the following contraindications would obviate the use of flumazenil in overdose: (1) suspected tricyclic overdose and/or clinical signs that could be related to tricyclic activity, (2) overdose of unknown agents, (3) known seizure disorder, and (4) history of prescribed benzodiazepines or chronic benzodiazepine dependence. In the event of a flumazenil-induced seizure, a therapeutic dose of benzodiazepine should be effective.

GENERAL TREATMENT GUIDELINES

The agents discussed in this chapter share certain generalities useful in guiding management (Table 159-3). Most overdoses of nonbenzodiazepine sedative-hypnotics are taken orally and often involve coingestants. Therefore, a diligent search for other treatable substances (e.g., acetaminophen and salicylates) is mandatory. Coingestants also may obscure expected toxidrome features or potentiate symptoms, complicating management. All the agents discussed, with the possible exceptions of buspirone, zolpidem, and GHB, cause physical dependence and tolerance in chronic use. Thus hospitalized patients who have been treated for acute toxicity subsequently may develop life-threatening abstinence states that are best anticipated from the ED.

160 ALCOHOLS

William A. Berk
Wilma V. Henderson

ETHANOL

Ethanol is the most frequently used and abused intoxicant in the United States[1] and most other societies, including those where it is proscribed. Nearly three-quarters of adult Americans consume at least one alcoholic drink each year, compared with only 36 percent who smoke at least one cigarette. Beer ranks as the fourth most popular beverage in terms of volume consumed, after soft drinks, milk, and coffee. Adult consumption of beverages containing ethanol peaked in 1980–1981 at 2.77 gallons per person of pure ethanol, but by 1993 this had declined to 2.25 gallons. [1] In recent years wine coolers have accounted for up to 25 percent of all U.S. ethanol consumption.

Distilled spirits typically contain ethanol volumes of 40 to 50 percent (80 to 100 proof), although brands with volumes of 75 percent or more exist. Wines have an ethanol volume of 10 to 20 percent, while beers range from 2 to 6 percent. Ethanol is also a constituent of mouthwashes (up to 75 percent volume), colognes (40 to 60 percent), and medicinal preparations (0.4 to 65 percent).

The medical, psychiatric, social, legal, and public health implications of ethanol use are well known to emergency physicians. Emergency departments (EDs) are expected to provide a safe haven for intoxicated individuals. Ethanol has been detected in the blood of 15 to 40 percent of unselected ED patients, depending on locale.[2] Yet emergency physicians and inpatient specialists fail to recognize 50 percent of patients with ethanol dependence. [3] The formal diagnosis of alcoholism has rested on instruments such as CAGE (see Chap. 287) and the Michigan Alcohol Screening Test. In the clinical setting, pointed questioning, when appropriate, about quantity of ethanol intake, medical complications usually caused by drinking, and whether the patient or others has ever felt he or she had a drinking problem will usually uncover such problems. There is growing evidence that the manner in which questions are understood by the patient may be culture- and gender-specific and thus may need to be specifically tailored. See Chap. 287 for a discussion of identification and referral issues.

Pathophysiology

Ethanol is a central nervous system depressant which inhibits neuronal activity, probably through its effects on cell membranes. Behavioral stimulation is often observed at low blood concentrations. Cross-tolerance exists between ethanol and other sedative-hypnotic agents, including benzodiazepines and barbiturates. Absorption occurs from the mouth and esophagus to a small extent, from the stomach and large bowel to a moderate extent, but chiefly from the proximal portion of the small bowel.

Gender-related differences in the metabolism of ethanol explain the considerably higher blood ethanol levels in women versus men after similar dosing on a gram-per-kilogram basis. Women have a smaller volume of distribution (0.6 L/kg) for ethanol than men (0.7 L/kg) and have decreased first-pass metabolism of ethanol because their gastric walls contain less alcohol dehydrogenase than do those of men. [4]

Approximately 2 to 10 percent of ethanol may be excreted by the lungs, in urine, or in sweat, the proportion being dependent on blood concentration. The remainder is metabolized to acetaldehyde in the liver by one of two pathways. In the cell, cytosol alcohol dehydrogenase with nicotinamide adenine dinucleotide as a cofactor produces acetaldehyde, which in turn is metabolized by aldehyde dehydrogenase. The second pathway, which is clinically significant at high blood ethanol concentrations and has increased activity with repeated exposures to ethanol, is a microsomal alcohol oxidizing system.

Clinical Features

Symptoms and signs of ethanol intoxication include slurred speech, nystagmus, disinhibited behavior, central nervous system depression, and decreased motor coordination and control. A lowering of usual blood pressure or even hypotension may occur secondary to ethanol-mediated decrease in total peripheral resistance or as a result of volume loss. Reflex tachycardia may also be observed. When hypotension is present, causes other than ethanol intoxication must be considered. Morbidity and mortality in association with acute intoxication are predominantly the result of accidental injuries, often motor vehicle collisions, related to ethanol-induced deficits in judgment or physical capabilities.

Because of the phenomenon of tolerance, blood alcohol levels correlate poorly with degree of intoxication. While death from respiratory depression may occur in unhabituated individuals at concentrations of 400 to 500 mg/dL, it is not uncommon for some alcoholics to appear minimally intoxicated if at all at blood concentrations as high as 400 mg/dL.[5] Although most states have adopted 100 or 80 mg/dL as the legal definition of intoxication for the purposes of driving a motor vehicle, there is considerable evidence to suggest that impairment may be seen with levels as low as 5 mg/dL, especially in unhabituated individuals.

Treatment

Management of acute ethanol intoxication consists of observation until clinical sobriety is attained and attending to associated injuries or medical illness. A careful examination should be performed to evaluate for complicating injuries or medical conditions. Ethanol levels are not necessarily required for mild or moderate intoxication where no other abnormality is suspected, but many institutions offer a blood alcohol screening panel that tests for ethanol, methanol, and isopropanol. One advantage of the alcohol screening panel is the detection of otherwise unsuspected isopropanol or methanol. The assays for each alcohol are specific and do not cross-react with each other. Hypoglycemia should be excluded by a bedside glucose determination. Ethanol does not bind to activated charcoal, so it is not needed unless other adsorbable substances have been ingested. Any alcoholic with severe CNS depression, even if apparently attributable to intoxication, should receive thiamine. Because nutritional status is often wanting, folate and other vitamin supplements are often added to the intravenous solution. Patients with mild to moderate intoxication do not necessarily require intravenous line placement, treatment with vitamin supplements other than thiamine, or intravenous fluid administration unless clinical signs of volume depletion are present. The IV solution should be 5% D/0.9% NaCl since alcoholics are often glycogen depleted. Careful and serial observation is crucial, as deterioration in mental status should be considered secondary to causes other than ethanol and managed accordingly. Unhabituated patients eliminate ethanol from the bloodstream at a rate of 15 to 20 mg/dL per hour, while alcoholics average 25 to 35 mg/dL per hour. Most patients with central nervous system depression secondary to ethanol ingestion improve within a few hours of emergency department arrival at the ED. Respiratory depression may result in

hypoventilation and carbon dioxide retention, which, if severe, may rarely require advanced airway management.

Alcoholics should be questioned about concomitant drug use. In the past, ethylene glycol or methanol was occasionally substituted for or combined with ethanol. Today cocaine has clearly become the most common concomitant drug used by alcoholics. The attraction of abusing these drugs together may relate to the formation of a metabolite, cocaethylene, which has 40 times the affinity for cocaine receptors of cocaine itself [6] and is thus an extremely potent intoxicant. The risk of sudden death among users of both drugs simultaneously may be as high as 20 times that with cocaine alone. Ethanol is the most common cause of an osmolal gap (Table 160-1), which also characterizes isopropanol, methanol, and ethylene glycol poisoning. However, a distinguishing feature of methanol and ethylene glycol is the wide-anion-gap metabolic acidosis. It is seductive to attribute the metabolic acidosis to the presence of ethanol. This can lead to missing or a significantly delay in establishing the correct diagnosis. Indeed, metabolism of alcohol in the liver leads to the formation of ketoacids, relatively depleting NAD while increasing NADH. As a consequence, high NADH diverts pyruvate, destined for glucose formation, to lactate, resulting in acidosis and hypoglycemia. However, the presence of significant acidosis should never be ascribed to alcohol intoxication alone. An alternate cause must be sought expeditiously and will invariably be found. For a discussion on other issues related to the ethanol-intoxicated patient, see Chap. 299.

Substance	Molecular Weight	mOsm/L at 100 mg/dL	Correction Factor
Ethanol	46	22	4.6
Isopropanol	60	17	6.0
Methanol	32	31	3.2
Ethylene glycol	62	16	6.2

*Molecular weight and contribution of alcohols to serum osmolality. To estimate concentration of an alcohol in mg/dL, use the following formula: (osmolal gap-10) × correction factor. This estimation is valid only if the alcohol is the only unmeasured abnormal contributor to osmolality.

TABLE 160-1   Substances That Contribute to the Serum Osmolality*

Disposition

Patients with acute ethanol intoxication rarely require hospital admission for treatment of this problem alone. However, questions frequently arise over alcoholics who appear clinically sober while still having considerable blood ethanol concentrations. Medical judgment of mental competence should not be confused with any particular blood alcohol (BAC) level. Patients whose intoxication has resolved to the extent that they do not constitute a danger to themselves or others *and* who will not be responsible for their own transport, may be discharged on their own recognizance or preferably in the company of friends or relatives who can assist them and take some responsibility for their care.

ISOPROPANOL

Isopropanol ($CH_3CHOHCH_3$), also known as isopropyl alcohol and 2-propanol, is commonly found in the home as rubbing alcohol. It is also used widely in industry as a solvent and disinfectant and is a component of a variety of skin and hair products, jewelry cleaners, detergents, paint thinners, and antifreeze. Poisoning usually results from ingestion but may also occur after inhalation in poorly ventilated areas—for example, during alcohol sponge bathing. Toxicity occurring after administration of an isopropanol enema has also been reported. Its principal metabolite, acetone, does not cause the eye, kidney, cardiac, or metabolic toxicity caused by the metabolites of methanol and ethylene glycol.

Isopropanol is approximately twice as potent as ethanol in causing central nervous system depression and has a duration of two to four times that of ethanol. As a result it is on occasion utilized as a substitute intoxicant by alcoholics as well as in suicide attempts. After ethanol, it is the second most commonly ingested alcohol. It is more toxic than ethanol, though considerably less so than methanol or ethylene glycol.

Pathophysiology

Isopropanol is a clear, volatile liquid with a bitter, burning taste and an aromatic odor. It is rapidly absorbed after being ingested, with 80 percent of an oral dose being absorbed after 30 min and complete absorption within 2 h. The substance has a volume of distribution of 0.6 to 0.7 L/kg. Small and clinically insignificant amounts are resecreted by the salivary glands and stomach.

The kidneys excrete 20 to 50 percent of an absorbed dose unchanged. However, the major pathway for metabolism of isopropanol is in the liver, where it is oxidized to acetone by alcohol dehydrogenase (Fig. 160-1). Acetone is further metabolized to acetate, to formate, and then finally to carbon dioxide. Mild acidosis may result from the conversion of acetone to acetic acid and formic acid. However, unlike methanol and ethylene glycol, significant acidoses directly ascribed to isopropanol or its metabolites is not seen. A hallmark of isopropanol toxicity is ketonemia and ketonuria, but without elevated blood glucose or glycosuria. This feature helps differentiate isopropanol ingestion from poisoning with ethylene glycol or methanol.
FIG. 160-1. Metabolic pathway of isopropanol in the liver.

Isopropanol most closely follows concentration-dependent (first-order) kinetics. The half-life of isopropanol in the absence of ethanol is 6 to 7 h, while the half-life of acetone is 22 to 28 h. The long half-life of acetone may be the cause of the prolonged symptomatology often associated with isopropanol poisoning. Ethanol administration has not been used clinically to inhibit isopropanol metabolism to acetone.

The toxic dose of 70% isopropanol is approximately 1 mL/kg, with the lethal dose in an adult approximately 2 to 4 mL/kg. As little as 0.5 mL/kg may cause symptoms, but survival has been reported following ingestions of up to 1 L. Children are especially susceptible to toxic effects and may develop symptoms with as little as three swallows of 70% isopropanol.

Clinical Features

The clinical features of isopropanol intoxication are similar to those seen with ethanol intoxication except that the duration of symptoms and signs is longer and central

nervous system depression may be more profound because of the formation of acetone. Onset of symptoms occurs within 30 to 60 min, with peak effects in a few hours. Nystagmus is usually present. Severe poisoning is marked by early onset of coma, respiratory depression, and hypotension. [7]

Massive ingestion may cause hypotension secondary to peripheral vasodilatation, with contributions possible from hemorrhagic gastritis. Serious dysrhythmias are rare.[7]

Hemorrhagic gastritis secondary to gastric irritation appears early and is a striking feature of isopropanol ingestions, resulting in nausea, vomiting, abdominal pain, and upper gastrointestinal hemorrhage. [7]

Hypoglycemia may occur secondary to depressed gluconeogenesis. Less common complications include hepatic dysfunction, acute tubular necrosis, myoglobinuria, hemolytic anemia, rhabdomyolysis, and myopathy.[7]

Isopropanol poisoning should be suspected when the smell of rubbing alcohol is present on the breath, when there is acidosis associated with ketonuria and ketonemia without glycosuria or hyperglycemia, and in the presence of an elevated osmolal gap. [7] Acidosis, if present, is mild. The use of alcohol screening panels helps detect unsuspected isopropanolism.

As previously mentioned, isopropanol has approximately twice the intoxicating effect of ethanol at the same blood concentration. Although isopropanol levels of 50 mg/dL are associated with mild intoxication in individuals who are not habituated to ethanol, alcoholic patients may be considerably more resistant to the central nervous system effects of isopropanol.

Treatment

If there is suspicion of isopropanol poisoning, intravenous access should be established with bedside testing for blood glucose, and administration of thiamine and naloxone if indicated. Patients should be monitored for central nervous system or respiratory depression. Because of the rapid absorption of isopropanol, there is no utility to performing gastric lavage. Activated charcoal binds isopropanol poorly and is not necessary in the absence of ingestion of adsorbable substances. Laboratory studies are guided by the results of examination and clinical condition. Serum electrolytes, CBC, glucose, and acetone are generally needed as a minimum.

In severely obtunded patients, airway management may require intubation and ventilatory support. Hypotension usually responds to intravenous fluids. In severe cases, support with pressors may be indicated. Patients with severe hemorrhagic gastritis may require blood transfusion. The acidosis associated with isopropanol poisoning is usually mild. If acidosis is significant, vigorous investigation for another cause must be made. For example, if the patient is hypotensive, consider lactic acidosis. Hemodialysis is indicated when hypotension is refractory to conventional therapy, resulting in hemodynamic instability, or when the predicted peak isopropanol level is greater than 400 mg/dL. Hemodialysis is effective in eliminating both isopropanol and acetone. Peritoneal dialysis is less effective.

Patients with lethargy or prolonged central nervous system depression should be admitted to the hospital. Those who remain asymptomatic for 6 to 8 h may be discharged or referred for substance abuse counseling or psychiatric evaluation.

METHANOL

Methanol (CH_3OH)—also referred to as methyl alcohol, wood spirits, or wood alcohol—is used widely in commercial, industrial, and marine solvents. It is a component of many paint removers, varnishes, shellacs, windshield washing fluids, and antifreeze formulations. It is a product of wood distillation. Methanol poisoning has resulted from the consumption of contaminated whiskey, accidental ingestion by desperate alcoholics, or intentional ingestion during suicide attempts. Methanol's toxicity is due to the formation of two toxic metabolites, formaldehyde and formic acid. Therapeutic strategies are therefore based on prevention of the formation of these metabolites or their removal from the body.

Pathophysiology

Methanol is a colorless, volatile liquid with a distinctive odor. It is well absorbed from the gastrointestinal tract, with peak levels attained 30 to 90 min after ingestion. Most incidents of toxicity occur after oral ingestion, but significant absorption may also occur through the lungs or skin. The serum half-life after mild toxicity is 14 to 20 h. With severe toxicity, this increases to 24 to 30 h. Methanol has a volume of distribution of 0.6 to 0.7 L/kg.

Following ingestion, highest concentrations are found in the kidney, liver, and gastrointestinal tract, but high levels are also found in the vitreous humor and optic nerve. Most methanol—90 to 95 percent—is eliminated by the liver, while renal excretion accounts for 2 to 5 percent; pulmonary excretion is minimal. In overdose situations, elimination follows saturation (zero-order) kinetics.

Toxicity from methanol poisoning results from the metabolism by hepatic alcohol dehydrogenase of methanol to formaldehyde and formic acid (Fig. 160-2). The accumulation of formic acid is associated with the onset of clinical symptoms. Lactate is produced from formate-induced inhibition of mitochondrial respiration, as a result of tissue hypoxia, and to a lesser extent as a result of a decrease in the intracellular NAD/NADH ratio caused by the oxidation of methanol and thus stimulation of anaerobic glycolysis and lactate production. Formaldehyde production in the retina causes optic papillitis and retinal edema, in severe cases resulting in blindness; hence the term "blind drunk." Since folate is a cofactor in the breakdown of formic acid to carbon dioxide and water, alcoholics who are folate-deficient may be especially susceptible to methanol toxicity.
FIG. 160-2. Metabolism of methanol in the liver.

The amount of methanol required to cause toxicity varies; death has been reported after ingestion of a dose as small as 15 mL of a 40% solution. Although 30 mL of a 40% solution is considered the minimal lethal dose, amounts as large as 500 to 600 mL have been ingested with survival reported.

Clinical Features

The symptoms of methanol poisoning may not appear for up to 12 to 18 h after ingestion because of the time it takes for methanol to be metabolized to its toxic metabolites. The delay in symptoms may be even longer if ethanol has been ingested. The cardinal clinical manifestations of methanol poisoning are central nervous system depression similar to that of ethanol, visual disturbances, abdominal pain, nausea and vomiting, and wide-anion-gap metabolic acidosis. As with isopropanol, the early phase of elation commonly seen in ethanol intoxication is absent.

On arrival at the hospital, the victim may be confused or, in severe cases, comatose. There may be complaints of headache or vertigo, and seizures may occur. Visual

disturbances are seen in approximately 50 percent of patients. These include diplopia, blurred vision, decreased visual acuity, photophobia, descriptions of "looking into a snow field," constricted visual fields, and blindness. The clinician may find nystagmus, fixed and dilated pupils, retinal edema, and optic atrophy or hyperemia of the optic disk. Computed tomography of the brain may reveal basal ganglia infarcts consistent with the parkinsonian syndrome, which has been reported after methanol poisoning.[7] Methanol is a potent mucosal irritant and causes severe abdominal pain as well as nausea and vomiting in over one half the cases; pancreatitis has also been commonly reported. However, serious ingestions may occur without subsequent gastrointestinal symptoms. Although an increased osmolal gap is usually present with serious methanol ingestion, methanol poisoning with a normal osmolal gap has been reported. This is due to complete metabolism of the methanol itself, while resultant toxic metabolites are exerting their effect.

Hypotension and bradycardia are late findings and suggest a poor prognosis. [7] Outcome is best correlated with the severity of the acidosis rather than serum methanol concentration.

Diagnosis of methanol poisoning rests on history, the presence of the characteristic clinical features outlined above, and the presence of a wide-anion-gap metabolic acidosis and osmolal gap. While confirmation of a tentative diagnosis depends on identification of the substance in the bloodstream, treatment should be initiated based on compatible clinical presentation to avoid morbidity resulting from delay. In any case, serum methanol determinations at many institutions depend on outside laboratories and may not be available for several hours. However if the ethanol level is known, the methanol level can be estimated from the osmolal gap (Table 160-1).

Normal methanol blood concentration from endogenous sources is 0.05 mg/dL. Asymptomatic individuals usually have peak levels below 20 mg/dL, while levels above 50 mg/dL indicate serious poisoning. Central nervous system symptoms usually appear when levels rise above 20 mg/dL; eye problems are associated with levels greater than 50 mg/dL, and the risk of fatality rises with levels greater than 150 to 200 mg/dL.

The differential diagnosis should include other potential causes of a wide-anion-gap metabolic acidosis—i.e., ethylene glycol, diabetic ketoacidosis, paraldehyde, isoniazid, salicylates, iron, lactic acidosis, phenformin, and uremia.

Treatment

Intravenous access should be established, with immediate bedside testing for blood glucose and administration of thiamine and naloxone if indicated. The general measures involved in treatment are (1) supportive care, (2) correction of acidosis, (3) administration of fomepizole (or ethanol) to decrease conversion to toxic metabolites, and (4) dialysis to eliminate the methanol. Unless the patient presents immediately after the ingestion, gastric lavage is unlikely to be of benefit. Activated charcoal has been shown to bind methanol poorly and therefore is not necessary in the absence of ingestion of other, adsorbable substances. Care should be taken to maintain an adequate airway with intubation if necessary for proper ventilatory support. Sodium bicarbonate should be administered with the goal of maintaining a near normal pH, since correction of metabolic acidosis moderates some of the toxic effects of methanol poisoning, including visual impairment.

4-Methylpyrazole (fomepizole) has been used successfully for initial treatment of methanol intoxication, [8] although case experience is not as great as that for its administration in cases of ethylene glycol ingestions (see below). A competitive inhibitor of alcohol dehydrogenase, fomepizole blocks the metabolism of methanol to its toxic metabolites. Unlike ethanol, it does not cause central nervous system depression. Many authorities recommend its use as a substitute for ethanol in initial treatment of adult methanol ingestions—specifically when methanol poisoning is suspected, in cases of high anion gap metabolic acidosis with an osmolal gap, if methanol concentration is found to be greater than 20 mg/dL, when the quantity of methanol ingested is calculated to be 0.4 mL/kg or more, or when symptoms consistent with methanol poisoning are present. Its use does not change the indications for dialysis. Some clinicians, however, still advocate the use of ethanol as the initial treatment of adult methanol intoxication. There is a lack of data on the use of fomepizole in children.

Fomepizole is administered in a loading dose of 15 mg/kg, followed by doses of 10 mg/kg every 12 h for four doses. Each dose is given by slow intravenous infusion over 30 min. More frequent dosing is required for patients requiring hemodialysis because fomepizole is removed during the procedure.

Ethanol, the traditional initial treatment of methanol intoxication, competitively inhibits the metabolism by alcohol dehydrogenase. Ethanol's affinity for the enzyme is 10 to 20 times that of methanol and its presence largely inhibits the formation of the toxic metabolites. Blood ethanol level should be maintained between 100 and 150 mg/dL to completely inhibit formation of toxic metabolites. Blood concentrations below 100 mg/dL are considerably less effective and therefore increase the risk of severe toxicity.

Ethanol may be administered intravenously, orally, or by nasogastric tube. Intravenous administration is preferred, though it may result in superficial thrombophlebitis. The intravenous solution should contain 10% ethanol in 5% D/W. A 20 to 30% ethanol concentration can be used for oral dosing. Higher concentrations have been used, but they can cause gastritis. To maintain an ethanol level of 100 to 150 mg/dL, a loading dose of 0.6 to 0.8 g/kg should be given intravenously or by mouth, with maintenance doses at approximately 0.11 g/kg per hour. If the recommended solution of 10% ethanol in 5% D/W is utilized, the loading dose is 10 mL/kg and maintenance is 1.6 mL/kg per hour. If the patient is habituated to ethanol, with enhanced hepatic elimination, the maintenance infusion should be started at 15 g/kg. When intravenous ethanol is not immediately available, oral therapy can be initiated with commercial distilled spirits. To calculate the ethanol content of distilled spirits, the following formula may be used:

$$\text{Ethanol (g)} = \text{vol of beverage (ml)} \times 0.9 \times (\text{proof}/200)$$

Ethanol levels should be assayed on a frequent basis, with the dose adjusted to maintain a concentration of 100 to 150 mg/dL. Administration should continue until the methanol level is zero. If dialysis is initiated, a higher maintenance infusion starting at 0.24 g/kg per hour will be necessary, as ethanol is dialyzable. As hypoglycemia may occur with ethanol administration, especially in children, blood glucose levels should be monitored closely.

Dialysis should be performed for methanol poisoning if there are signs of visual or central nervous system dysfunction, if peak methanol levels are greater than 25 mg/dL, if severe metabolic acidosis develops regardless of levels, and if there is a history of ingesting more than 30 mL. Hemodialysis is considerably more effective than peritoneal dialysis, but peritoneal dialysis may be utilized if hemodialysis is unavailable. Dialysis eliminates both the parent compound and its toxic metabolites. The indications for dialysis are unchanged for patients who receive treatment with fomepizole.

Folate is a cofactor for the conversion of formic acid to carbon dioxide. It is especially important to provide supplements to alcoholic patients who may be folate-deficient. Administration of folic acid 50 mg intravenously q4h for several days to all patients is recommended.

Disposition decisions are based on criteria identical to those used for ethylene glycol poisoning (see below). It should be emphasized that asymptomatic patients with history of significant ingestion should be admitted and treatment initiated, even if no acidosis is evident.

ETHYLENE GLYCOL

Ethylene glycol has many commercial uses as a coolant (antifreeze), preservative, and glycerine substitute; it has also been used in lacquers, cosmetics, polishes, and detergents. It may be ingested as an alcohol substitute by alcoholics, in suicide attempts, and accidentally by children. Ethylene glycol's toxicity is the result of the formation of two toxic metabolites, formaldehyde and formic acid. As with methanol, therapeutic strategies are based on prevention of formation of these metabolites or their removal from the body.

Pathophysiology

Ethylene glycol is a colorless, odorless, sweet-tasting substance. It is highly water-soluble and rapidly absorbed when ingested orally, but not by the lungs or skin. Peak blood levels occur within 1 to 4 h of an ingestion. The volume of distribution is 0.83 L/kg and the plasma half-life is 3 to 5 h. Ethanol at a concentration of 100 to 200 mg/dL has an increased half-life of 17 h. Ethylene glycol is metabolized in the liver and kidneys to toxic metabolites—aldehydes, glycolate, oxalate, and lactate—which, in turn, cause toxicity to the lungs, heart, and kidneys. These metabolites also cause the metabolic acidosis associated with ethylene glycol poisoning.[7]

Ethylene glycol is metabolized to glycoaldehyde by the alcohol dehydrogenase (Fig. 160-3). This conversion involves the reduction of NAD+ to NADH, which causes

inhibition of the citric acid cycle and formation of lactic acid. Glycoaldehyde is further metabolized to glycolic acid and to glyoxylic acid, which, in turn, are converted to several new compounds. Pyridoxal phosphate is a cofactor in the conversion of glyoxylic acid to glycine, which is nontoxic, while thiamine pyrophosphate is the cofactor in the conversion of glyoxylic acid to another nontoxic compound called a-hydroxy-b-ketoddipate. A deficiency of either pyridoxal phosphate or thiamine may shift the metabolism of ethylene glycol to the production of toxic metabolites.
FIG. 160-3. Metabolic pathway of ethylene glycol.

Glyoxylic acid is also metabolized to formic acid and oxalic acid. Glycolic acid contributes to the metabolic acidosis observed in ethylene glycol poisoning. Oxalate crystalluria is a striking feature caused by calcium oxalate salt deposition. Oxalate crystals are present in the urine in only about 50 percent of cases.

The potentially lethal dose in adults is 2 mL/kg, although survival has been reported after ingestions ranging from 240 to 970 mL.

Clinical Features

Ethylene glycol poisoning often exhibits three distinct clinical phases, the severity and progression of which depends on the amount ingested. The initial phase is characterized by central nervous system depression, usually within 1 to 12 h after ingestion. Patients may appear inebriated, with slurred speech and ataxia but without the odor of ethanol on their breath. Hallucinations, coma, seizures, and death may also occur during this initial phase. These central nervous system symptoms correlate with peak glycoaldehyde production. The optic fundus is usually normal, differentiating the syndrome from methanol poisoning, although nystagmus and ophthalmoplegia may be observed: Lumbar puncture may demonstrate elevated CSF pressure and protein, and a few polymorphonuclear cells.

The second, cardiopulmonary phase develops 12 to 24 h after ingestion. Tachycardia, mild hypertension, and tachypnea are the most common symptoms; congestive heart failure, adult respiratory distress syndrome, cardiomegaly, and circulatory collapse are also observed. Myositis has also been reported less commonly during this phase.

The third phase, marked by nephrotoxicity, occurs 24 to 72 h after ingestion. Early symptoms consist of flank pain and costovertebral angle tenderness. Oliguric renal failure and acute tubular necrosis ensue. Complete anuria may occur, but most patients recover without renal damage if they receive appropriate therapy. Nephrotoxicity is caused by aldehyde metabolites and oxalic acid. Two forms of urinary calcium oxalate crystals may be identified on microscopic evaluation of the urine. The dihydrate form (octahedral crystals) shows tent-shaped crystals and the monohydrate form (monclinic crystals) shows crystals that are dumbbell- or prism-shaped. The monohydrate form was at one time felt to represent a salt of hippurate, explaining previous reports of hippurate crystals in the urine.

Hypocalcemia may develop secondary to precipitation of calcium as calcium oxalate and may be severe enough to cause tetany and prolongation of the QT interval. Elevated serum creatine phosphokinase levels may accompany and explain the generalized myalgias experienced by some patients.

Ethylene glycol intoxication should be considered when a patient presents with inebriation and no ethanol scent on the breath, a wide-anion-gap metabolic acidosis with osmolal gap, and calcium oxalate crystalluria. The mechanisms of anion-gap metabolic acidosis and osmolal gap are similar to those observed with methanol.

Tentative diagnosis and initiation of treatment should be based on history and characteristic clinical presentation. As with methanol poisoning, confirmation of a tentative diagnosis depends on identification of the substance in the bloodstream, but treatment should be initiated based on compatible clinical presentation to avoid morbidity resulting from delay. Serum levels greater than 20 mg/dL are likely to result in toxicity. Survival has been reported with levels up to 650 mg/dL, while fatality has been associated with levels between 98 and 775 mg/dL.

Leukocytosis is common and should not be considered a manifestation of infection unless clinical signs are present. One-third of patients may have hypocalcemia, with shortening of the QT interval present on the electrocardiogram. Serious intoxication has been reported in the absence of an osmolal gap or calcium oxalate crystalluria. The mechanism for the absence of an osmolal gap is based on the same explanation as given for methanol (above).

As with methanol, the differential diagnosis should include other potential causes of a wide-anion-gap metabolic acidosis.

Treatment

The management of ethylene glycol poisoning is similar to that of methanol. For indications for gastric lavage and guidelines for administration of sodium bicarbonate, refer to instructions given for methanol, above. If the patient is hypocalcemic, 10 mL of calcium gluconate 10% should be given intravenously. Pyridoxine 100 mg and thiamine 100 mg intramuscularly or intravenously should be administered daily to facilitate metabolism of ethylene glycol by nontoxic pathways. Magnesium has also been shown to be a cofactor in the metabolism of toxic metabolites and should be given if patients are hypomagnesemic, as is often the case with alcoholics. Laboratory tests that may be useful in evaluating patients suspected of ethylene glycol ingestion include complete blood count, serum electrolytes, acetone, alcohol toxicology panel with ethanol, isopropanol, and methanol determinations, electrolytes, blood urea nitrogen, creatinine, salicylate level, arterial blood gases, urinalysis, serum ethylene glycol level, calcium, creatine phosphokinase (CPK), and magnesium levels. Lactate levels should also be determined if the reason for the severe acidosis is unclear.

Fomepizole has supplanted ethanol as the initial treatment of choice for adults with ethylene glycol intoxication. [9,10] Fomepizole is a potent inhibitor of alcohol dehydrogenase and has an affinity for the enzyme which is 8000 times greater than that of ethanol. Headache, nausea, and dizziness are the most common adverse effects. It has fewer side effects than ethanol, especially in regard to central nervous system depression. Fomepizole should be administered if there is strong suspicion of ethylene glycol intoxication based on clinical presentation, if ethylene glycol level is more than 20 mg/dL, or if acidosis is present. Administration and dose is described in the section on methanol. If fomepizole is not readily available, ethanol should be administered immediately in suspected cases of ethylene glycol ingestion. There is a paucity of experience with fomepizole in children. Hemodialysis is still indicated for those patients with ethylene glycol concentrations greater than 50 mg/dL and for severe metabolic acidosis or anuria.

If fomepizole is not readily available, ethanol should be administered as soon as the diagnosis is suspected. [7] Ethanol's affinity for alcohol dehydrogenase is 100 times that of ethylene glycol, resulting in a prolongation of the half-life of ethylene glycol to 17 h. Oral and intravenous dosing guidelines for ethanol are identical to those outlined for methanol, above.

Dialysis should be initiated if a history, clinical presentation, or laboratory results consistent with ethylene glycol or poisoning is present, when serum concentration of ethylene glycol is greater than 20 to 25 mg/dL, when there are signs of nephrotoxicity, or when metabolic acidosis is present. [7] Treatment with fomepizole does not change the indications for dialysis. As with methanol, hemodialysis has been shown to be considerably more effective, but peritoneal dialysis can be used if hemodialysis is unavailable.

Disposition

Any patient with the serious signs and symptoms associated with ethylene glycol or methanol intoxication or a history of significant ingestion even in absence of symptoms should be admitted to an intensive care setting. Fomepizole or ethanol administration and dialysis should be continued until serum blood levels are zero and acidosis has resolved. Suicidal patients should receive a psychiatric evaluation when their condition improves and prior to discharge from any facility.

Patients seen at facilities unable to provide hemodialysis or intensive care should be transferred (if sufficiently stable) to institutions capable of providing such care. Because the symptoms of ethylene glycol and methanol intoxication may be delayed, patients who have ingested these substances should be admitted to the hospital for observation and laboratory testing even if they are asymptomatic initially.

161 OPIOIDS

Suzanne Doyon

The term *opioids* is an all-inclusive term for antagonists, endogenous and exogenous substances that possess morphine-like activity. Opioids are classified as natural, semisynthetic or synthetic (Table 161-1). The most commonly abused opioids are heroin and methadone. The National Institute of Drug Abuse estimates that approximately 2.5 million people have a history of heroin abuse in the United States. Heroin abuse has significantly increased over the last decade because of lower street costs and easy availability. Also, street purity has increased from about 10 percent in the past to 70 percent or greater today, making nasal insufflation rather than injection a viable method. Thus, heroin has seen increased popularity on college campuses and among the affluent, rising to the status of a glamour drug. The public perception of addiction is that heroin use occurs predominantly among impoverished minorities. Heroin addiction does affects minorities disproportionately; however, its use among Caucasians is widespread. From 1990 through 1995, heroin-related emergency department (ED) visits more than doubled to 76,000, as did the rate per 100,000 population (from 15 to 33), according to data from the Drug Abuse Warning Network (DAWN).

TABLE 161-1   Classification and Characteristics of Major Opioids

PHARMACOLOGY

Opioids modulate nociception in the terminals of afferent nerves in the central nervous system (CNS), peripheral nervous system, and gastrointestinal tract. They are agonists at the mu1, mu2, kappa, delta, sigma, and epsilon receptors in these tissues. The opioids with a preference for the mu receptors are the more potent analgesics, but delta and kappa agonists are effective analgesics as well. [1] Opioids bind to the receptor sites and either decrease neurotransmitter release or open potassium channels, resulting in hyperpolarization of the neuronal membranes. Specific binding at different receptor sites located within the locus ceruleus activate the "pleasure pathway" and result in dependence and craving. The endogenous opioids—enkephalins, endorphins, and dynorphins—are the natural ligands at all the receptor sites mentioned above.

PHARMACOKINETICS

A detailed discussion of the absorption, distribution, and elimination of opioids is beyond the scope of this chapter. However, when clinically relevant, details of absorption and elimination of specific opioids are given. Knowledge of duration of action and elimination half-life is useful and is provided in   Table 161-1.

Most opioids are more effective when given parenterally than orally, owing to variable but significant first-pass effect. Opioids with good oral potency are codeine, oxycodone, levorphanol, and methadone.

The metabolism of codeine, morphine, propoxyphene, oxycodone, meperidine, and methadone is mostly hepatic. The hepatic metabolites may be pharmacologically active. Concurrent use of benzodiazepines, barbiturates, and alcohol is common in the opioid abuser either because of their additive effect or their capacity to inhibit hepatic metabolism, especially the metabolism of methadone. Cyclic antidepressants and propoxyphene also decrease methadone metabolism.

CLINICAL FEATURES

Patients present to the emergency department in one of two states: intoxication with opioids or acute withdrawal from them.

The opioid toxidrome can encompass a wide variety of signs and symptoms. Opioids cause respiratory depression, mental status depression, analgesia, miosis, orthostatic hypotension, and nausea and vomiting, histamine release resulting in localized urticaria and occasionally bronchospasm, decreased gastrointestinal motility, and urinary retention secondary to increased vesical sphincter tone. The mental status depression can be variable but may be extremely profound. The respiratory depression may also be variable. One should look for shallow respirations, cyanosis, bradypnea, hypercarbia, and hypoxia. Miosis is not universally present. In fact, normal or even enlarged pupils have been documented secondary to exposure to meperidine, morphine, propoxyphene, pentazocine, and diphenoxylate; this sign may be secondary to severe cerebral hypoxia and it may also be attributable to coingestants.

The abrupt withdrawal of an opioid causes a host of other clinical signs and symptoms. It usually starts with feelings of anxiety, insomnia, yawning, lacrimation, diaphoresis, rhinorrhea, diffuse myalgias, piloerection, mydriasis, nausea and profuse vomiting, diarrhea, and abdominal cramping.

DIAGNOSIS

The diagnosis of opioid overdose or withdrawal is clinical.

The classic triad of coma, miosis, and respiratory depression strongly suggests chronic or acute opioid intoxication. Hoffman and coworkers attempted to determine clinical criteria predictive of the presence of opioid overdose. Their criteria of respirations £12 breaths per minute, presence of miosis, and circumstantial evidence of opioid use (drug paraphernalia, needle marks, presence of a tourniquet, bystander corroboration) were highly sensitive in predicting response to naloxone (92 percent), hence establishing the diagnosis of exposure to opioids. Unfortunately in this study, a respiratory rate only was used as a measure of respiratory depression—not an assessment of depth or quality of the respirations nor a pulse oximetry or blood gas measurement. Examination of the urine for opioids may aid in the diagnosis of opioid intoxication, but the results have a high false-negative rate and are not available to the clinician prior to the need to initiate prescriptive

therapy.[2]

The diagnosis of opioid withdrawal is established when a constellation of withdrawal symptoms is temporally related to the abrupt cessation of an opioid.

Differential Diagnosis

The differential diagnosis of opioid overdose includes toxic or depressant effects of clonidine, organophosphates and carbamates, phenothiazines, sedative-hypnotic agents, and carbon monoxide. Gamma hydroxybutyrate (GHB), known as a "date rape" drug, may cause CNS depression, apnea, and occasionally miosis. Based on animal studies, GHB can potentially respond to naloxone, although this has not been shown clinically. There are no ancillary tests that will help the ED physician to differentiate GHB from opioids. Similarly, olanzapine in at least one case has caused CNS depression and miosis. Again, there is no ancillary test available to differentiate olanzapine from opioids except that olanzapine will not respond to naloxone. Clonidine overdoses are characterized by periods of apnea that respond to tactile or auditory stimulation. Organophosphate and carbamate overdoses cause muscle fasciculations, profuse vomiting and diarrhea and sweating. Phenothiazines cause intraventricular conduction delays and a partial anticholinergic toxidrome due to decreased alpha-adrenergic tone overriding anticholinergic effects, thus leading to miosis instead of mydriasis. Sedative-hypnotic agent and carbon monoxide cause profound CNS depression but are not usually associated with miosis. Hypoglycemia, hypoxia, CNS infections, postictal states, and pontine hemorrhages should also be considered in the differential diagnosis.

TREATMENT

When minute ventilation is depressed, appropriate airway measures should be undertaken. Once the airway is assured, the administration of naloxone may follow.

Naloxone was introduced in 1976. It is a specific "pure" antagonist at mu, kappa, and delta receptors. Naloxone can fully reverse the opioid-induced respiratory depression, mental status changes, and analgesia. It can be used as a diagnostic or therapeutic tool.

Naloxone can be administered intravenously, intratracheally, intramuscularly, subcutaneously, and even intralingually. The intravenous route is the most rapid and is preferred.

When the establishment of an intravenous line is difficult, these other routes are options. A recent study suggests that subcutanous (SQ) injection of 0.8 mg naloxone will have the desired effect. However, the slower absorption with SQ or intramuscular (IM) injection will likely offset the delay in establishing intravenous (IV) access. [3] Unless delay is anticipated to be inordinate and the patient's circumstances dictate immediate reversal, it is preferable to wait for IV access, even if femoral or other central venous access is required.

In the prehospital setting, there is no indication to rush reversal of the opioid's pharmacologic effects in a patient who is hemodynamically stable. In fact, early reversal may complicate transport. There are many reports of patients who regain consciousness in ambulances and become combative, rendering transport difficult and placing prehospital providers at physical risk. Patients who have regained their faculties have even invoked their "right" to decline treatment, demanding release from the ambulance, and placing prehospital providers at further risk.

A positive response to the naloxone establishes the diagnosis of opioid intoxication, acute or chronic. The recommended diagnostic dose is 0.1 to 2.0 mg IV in adults and children and 0.01 mg/kg in neonates. A full 2.0 mg IV should be administered to the patient presenting with respiratory depression. If the effect is minimal or absent, repeated doses of 2 mg every 3 min are recommended until a maximum of 10 mg IV has been reached or an effect is noted. Exposures to propoxyphene, fentanyl, pentazocine, or dextromethorphan may require these larger doses. If there is no response to 10 mg of naloxone IV, it is unlikely that an isolated opioid intoxication is the cause of the patient's altered mental status.

A smaller dose, for example, 0.1 to 0.4 mg IV, is advocated in overdose patients with a history of opioid dependence and little or no respiratory depression to avoid precipitation of withdrawal. The dose can be added to in small increments of 0.1 to 0.4 mg IV until a desired maximum or effect has been noted. The technique is to titrate 0.1 mg aliquots to effect. This particular regimen can be useful in treating the patient with chronic pain as well as chronic addicts.

The therapeutic dose of naloxone varies somewhat from the diagnostic dose. Reversal of opioid toxicity with naloxone will last 20 to 60 min. Repeated IV boluses or naloxone infusions are occasionally required in order to maintain respirations. This is especially true if the ingested opioid has a prolonged duration of action, at least more prolonged than that of naloxone. An infusion should be considered only if the patient has responded to the initial naloxone bolus and is not meant to be used in lieu of the bolus. To calculate the infusion rate and dose, first establish what initial bolus dose was successful in reversing the respiratory depression. Administer approximately two-thirds of that dose per hour by IV infusion. For example, two-thirds of a 1-mg dose is about 0.6 mg. Mix 6 mg of naloxone into 1 L of 5% D/W and run at 100 mL/h.[4] Adjustments in infusion rates may be required if the patient develops respiratory depression (renew the bolus and increase infusion rates) or withdrawal symptoms (decrease infusion rates). Patients requiring naloxone infusions should be admitted to a monitored setting capable of rapid airway intervention.

Recent literature suggests that the number of opioid receptors is similar in adults and children. Thus, the same therapeutic/diagnostic approach can be used with children as described above for adults. The traditional dose of 0.01 mg/kg of naloxone IV is probably appropriate for the neonate in the peripartum period but is inappropriate in treating the toddler with an accidental exposure to an opioid.

The most adverse effect associated with the administration of naloxone is precipitation of opioid withdrawal: anxiety, nausea, vomiting, diarrhea, abdominal cramps, piloerection, yawning, and rhinorrhea. The incidence of withdrawal can be minimized by judicious dosing. A small body of literature from the 1970s reported cases of cardiac dysrhythmias and death following the administration of naloxone IV. In most of these cases, the patients experienced a deteriorating course before naloxone was administered. Widespread clinical experience during the last 25 years suggests naloxone is one of the safest antidotes for toxicity diagnosis and reversal. Of note, large doses and rapid administration of naloxone to the neonate may induce seizure activity. In short, the administration of naloxone remains safe in the vast majority of clinical settings. [4,5]

Endotracheal intubation may be necessary for severe respiratory depression where adequate ventilation cannot be achieved by bag-valve-mask or if there is no response to naloxone.

For ingested opioids, gastric decontamination should not be performed routinely. Lavage may be considered on a patient who has ingested a potentially life-threatening amount of opioid within the previous hour. [6] Syrup of ipecac is not recommended due to the potential risk of aspiration of stomach contents in patients with altered mental status.

Administration of activated charcoal is of value: 50 g of activated charcoal orally followed by a cathartic such as sorbitol 0.5 to 1.0 g orally are standard doses. Multiple-dose activated charcoal is particularly useful in diphenoxylate and propoxyphene overdoses because of their large enterohepatic circulation.

An acetaminophen level should be obtained in cases of propoxyphene, oxycodone, or codeine overdose.

Approximately one-third of naloxone responders will relapse into opioid toxicity within 30 to 120 min. Hence, the minimum observation period is 2 h. The author recommends an observation period of 4 to 6 h in the ED for most cases of opioid intoxication. Although not a standard of care, this conservative approach is recommended to allow complete recovery and allow recognition of potential coingestants with delayed effects. Except in certain cases, illustrated below, it is acceptable to discharge the opioid-intoxicated patient after a reasonable period of observation and resolution of symptoms and signs. The moderately to severely methadone-intoxicated patient usually requires a 24 to 48 h hospital admission due to the prolonged elimination half-life of methadone. A psychiatric evaluation is mandatory in all cases of suicidal intent. [7]

SPECIAL CONSIDERATIONS

Meperidine and its metabolite, normeperidine, are proconvulsive agents. Normeperidine is reported to have twice the convulsant activity of meperidine. Use of these agents may result in seizures without underlying hypoxia. A wide range of seizure activity from multifocal myoclonus to generalized tonic-clonic seizures is reported. Normeperidine is almost entirely renally excreted. It accumulates in patients whose renal function is diminished: e.g., dialysis patients, those with cancer, the elderly, and sickle cell patients. Orally administered meperidine is more likely to lead to an accumulation of the toxic metabolite than parenterally administered meperidine

because of a large first-pass effect. Therefore, patients with underlying renal dysfunction who receive oral meperidine, especially repeated oral doses, are at increased risk of seizures. Patients with new meperidine-induced seizures should receive a full diagnostic evaluation for seizures. The proconvulsive effects of mepridine and normepridine are long lasting. Clusters of seizures over 24 h can be seen. Accordingly, patients exhibiting seizure should be admitted. Naloxone will not be useful in the treatment of meperidine induced seizures. Treatment of acute seizures is with benzodiazepines.

The combination of meperidine or dextromethophan with monoamine oxidase inhibitors can result in an increase in the amount of serotonin in the neuronal terminals in the CNS. The clinical syndrome is characterized by disorientation, severe hyperthermia, hypo/hypertension, and muscle rigidity. Deaths have been reported. Naloxone should have no effect and thus it is not indicated. Its administration could potentially complicate the patient's course by precipitating withdrawal. Treatment involves the administration of benzodiazepines and aggressive cooling (see Chap. 153).

Propoxyphene and its metabolite, norpropoxyphene, are particularly cardiotoxic and neurotoxic. Propoxyphene overdoses have been associated with intraventricular conduction disturbances, heart block, a prolonged QT interval, and ventricular bigeminy. Seizures have also been reported. Naloxone cannot reverse these effects. Treatment includes cardiac monitoring for about 6 h in the ED. If the patient remains asymptomatic and a repeat electrocardiogram is normal, discharge is appropriate. Otherwise, the patient should be admitted for continued cardiac monitoring for 24 h. The administration of hyperosmolar sodium bicarbonate, 1 mEq/kg IV, may reverse the cardiotoxic effects of propoxyphene.

The mixed agonists-antagonists include pentazocine (Talwin), butorphanol (Stadol), buprenorphine (Buprenex), and nalbuphine (Nubain). They have variable but mostly antagonist activity at the mu receptor and are agonists at the kappa receptors. They may cause significant respiratory depression in overdose situations, especially buprenorphine. Naloxone should be effective in reversing the respiratory depression. Mixed agonists-antagonists usually precipitate withdrawal when taken in excess by an opioid-dependent individual, hence reducing their potential for abuse.

Diphenoxylate is a frequently prescribed antidiarrheal agent. The medication is manufactured in a pill form containing a combination of diphenoxylate 2.5 mg and atropine 0.025 mg and is called Lomotil. It is a schedule IV drug. Anticholinergic effects predominate initially due to atropinic effects: flushing, tachycardia, hyperthermia, hallucinations, dry mucous membranes, and urinary retention. These signs and symptoms regress as the patient enters the second phase of the intoxication. Phase 2 is characterized by a predominantly opioid-like picture due to the effects of diphenoxylate. Naloxone is marginally effective in reversing the effects of diphenoxylate. There are two important clinical points to remember: first, children can be particularly sensitive to diphenoxylate; second, absorption can be delayed, up to 6 to 12 h. Current recommendations are to admit all pediatric exposures and monitor for respiratory depression. Multiple-dose activated charcoal is recommended in all cases of moderate to severe Lomotil intoxication.

Tramadol (Ultram) overdoses are associated with agitation, hypertension, respiratory depression, and seizures, especially at doses exceeding 500 mg orally in an adult. Treatment remains supportive. Naloxone is ineffective in reversing the seizures.

"Designer" opioids have included fentanyl and methylfentanyl, which are 100 and 2000 times more potent than morphine. They require large doses of naloxone, up to 10 mg IV, in order to reverse the respiratory depression. They remain undetectable in urine toxicology assays.

Recent clinical experience with heroin-cocaine (i.e., Speedball) and heroin-scopolamine (e.g., Polo, Homicide, Sting, and others) mixtures has raised issues regarding the blind administration of naloxone. Often naloxone "unmasks" the underlying cocaine or scopolamine intoxication. Cocaine has a relatively short duration of action, but the same is not true of scopolamine. Unmasked scopolamine overdoses often require control with benzodiazepines. Administration of physostigmine, to reverse scopolamine toxicity, can be considered but is best left to experienced physicians familiar with the use of this antidote. [8]

Retained drug packets pose special challenges to the clinician. Current literature supports the use of a polyethylene glycol solution (Go-Lytely) via NG tube at a rate of 2 L/h until the rectal effluent is clear. Multiple dose activated charcoal is also recommended. Large doses of naloxone may be required to reverse the respiratory depression associated with the leakage or breakage of the packets.

Special mention must be made of opioid-induced noncardiogenic pulmonary edema, a rare complication associated with heroin and methadone abuse. Acute lung injury (formerly referred to as noncardiogenic pulmonary edema) can occur immediately or be delayed up to 24 h in profoundly comatose patients and should be suspected in any patient who develops tachypnea, rales, or decreased oxygen saturation. Up to 50 percent of heroin users may experience noncardiogenic pulmonary edema at some time in their lives. Its occurrence is independent of route of exposure. The pathophysiology is poorly understood but some degree of direct capillary injury is present. Treatment includes oxygenation, consideration of airway intervention with possible use of positive end-expiratory pressure, and possible placement of a of Swan-Ganz catheter for appropriate monitoring. Diuretics and digoxin are usually not indicated. Naloxone will not reverse this complication.

Hospitalized Patients

The management of opioid dependent individuals hospitalized for medical or surgical reasons remains controversial. It is generally agreed that detoxification from opioids during the acute course of a medical illness is usually unsuccessful. Alleviation of withdrawal symptoms should be the goal of therapy. Daily administration of a verified dose of methadone orally (or half the verified dose intramuscularly if the patient is to take nothing by mouth) is recommended to inhibit withdrawal symptoms and reduce craving. This applies only to individuals who are actively enrolled in a methadone maintenance program and in whom the dose can be verified externally. The habitual user who is not on methadone maintenance therapy can receive methadone 20 mg by mouth (PO) or 10 mg IM. These dosages should inhibit withdrawal symptoms but not induce euphoria. No methadone should be administered to the habitual user until the appearance of withdrawal symptoms.

Occasionally, patients will present to the ED requesting methadone because they missed their outpatient or community program appointment. Unless the provider or clinic can be contacted and they indicate that the request is appropriate and valid, it should not be honored. Indiscriminate dispensing of methadone undermines methadone maintenance programs. Similarly, it is difficult to think of any valid rationale to prescribe methadone for outpatient use from the ED. In fact, pharmacies will generally not honor methadone prescriptions written on standard ED prescription pads. The Drug Enforcement Administration (DEA) rigidly controls how methadone is prescribed. Methadone prescriptions for detoxification programs (maximum 3 days) and maintenance therapy (longer than 3 days), can be filled only at methadone clinics sanctioned by the DEA. Reprimand and even loss of license to practice medicine has occurred for violations.

Withdrawal States

Downregulation of endogenous endorphins and dynorphins occurs from chronic usage, as does downregulation of opioid receptors. Abrupt cessation of opioid use does not allow time for upregulation of these endogenous ligands or receptors and results in increased neuronal firing and their withdrawal symptoms. Classic opioid withdrawal includes anxiety, craving, yawning, lacrimation, rhinorrhea, diaphoresis, mydriasis, nausea and vomiting, diarrhea, abdominal cramps, and diffuse myalgias. Onset of withdrawal is usually within 12 h of last heroin usage and within 30 h of last methadone exposure. It can be precipitated by the administration of naloxone or naltrexone.

Opioid withdrawal states are rarely life-threatening. They can be rendered more tolerable by the administration of the central alpha2 agonist clonidine, antiemetics, and antidiarrheal agents. Clonidine may be used at doses of 5 µg/kg PO if the blood pressure is above 90 mmHg systolic. Clonidine can be prescribed in a 0.1- or 0.2-mg oral dose tid. It is medically sound to discharge patients from the ED with a 3-day prescription until counseling can be obtained. The only concern is that some addicts abuse clonidine, as it enhances the opioid "high." One option that has merit in many situations is to discharge patients with a clonidine patch. This is the best option for patients who are not in a position to take a medication three times daily, such as those returning to a jail. The patch is effective for 7 days and has no resale value.

Contaminants

Intravenous heroin continues to contain many adulterants: strychnine, quinine, lactose, and talc. The actual role of many adulterants in the etiology of medical illnesses attributable to intravenous drug usage remains largely unknown. An exception to this statement must be made in the case of MPTP (N-methyl-4-phenyl-1,2,3,6-tetrahydropyridine). A meperidine analogue synthesized in the 1980s contained MPTP as a contaminant. When used intravenously, MPTP caused a severe form of movement disorder similar to parkinsonism. It is metabolized by monoamine oxidase B in the substantia nigra to MPP$^+$, which is directly neurotoxic.[9]

Medical Complications

Medical complications from intravenous drug use include bacterial endocarditis, septic pulmonary emboli, aspiration pneumonia, tuberculosis, venous thrombosis, nephropathy, pulmonary talcosis, tetanus, hepatitis, human immunodeficiency virus (HIV) and other blood-borne infections, pneumothorax, pseudoaneurysms, mycotic aneurysms, multiple skin abscesses, cellulitis, septic arthritis, osteomyelitis, and intestinal pseudoobstruction secondary to fecal impaction. Given the risk, a thorough history of tetanus immunization should be sought.

OVERVIEW

Cocaine, amphetamines, and other stimulants produce toxicity by activating the sympathetic nervous system. Although cocaine abuse is most prevalent and has dominated reports of stimulant toxicity, amphetamines and other substances that resemble cocaine produce unique toxic complications as well. The regional prevalence of each of these drugs of abuse may help the clinician decide which agent is present in a patient with sympathomimetic findings. The scope of toxicity is broad and includes chest pain following use of cocaine or amphetamines, blunt or penetrating trauma related to cocaine trafficking, and depression associated with chronic cocaine or amphetamine abuse.[1] This chapter focuses on cocaine abuse and its multiorgan toxic effects; it highlights unique toxicities associated with amphetamines and other stimulants.

Epidemiology

Cocaine abuse is widespread, but few data sources can provide an accurate estimate of its use. The 1996 National Household Survey on Drug Abuse reported that 71.7 million Americans were current cocaine users. Approximately 40 percent of these patients were crack users in urban areas. Cocaine use is highest among young persons aged 18 to 25 years and appears to be increasing in this age group. The National Center for Alcohol and Drug Abuse Interventions reports that there are greater than half a million new cocaine users each year (1998). Correspondingly, the Drug Abuse Warning Network (DAWN) reports that emergency department ED visits by cocaine-abusing patients tripled since 1988. Fatal injuries (homicides, suicides, falls, and overdoses) following cocaine use are a leading cause of death among young adults in New York City and probably in many other urban environments as well.[2] A recent 3-year study demonstrated cocaine metabolites in 26 percent and free cocaine in 18 percent of all patients with fatal injuries. Methamphetamine use was recently reported as a frequent cause of drug-related ED visits in the western United States, and its use is increasing in eastern states as well.

Pathophysiology

Cocaine is the naturally occurring alkaloidal extract of *Erythroxylon coca*, a plant indigenous to South America. The water-soluble hydrochloride salt is absorbed across all mucosal surfaces, including the oral, nasal, gastrointestinal, and vaginal epithelium; thus cocaine can be applied topically, swallowed, or injected intravenously. Although the hydrochloride form is most often insufflated (snorted) or injected intravenously, ether extraction yields crack cocaine, a form that is stable to pyrolysis and can be smoked, producing the popping sound that characterizes its name. The onset and duration of action vary with the route of administration. When cocaine is insufflated nasally, the peak effect occurs within 30 min and the duration of effect is 1 to 3 h. The delayed and prolonged effect is due to vasoconstrictive properties that limit mucosal absorption. A fraction of insufflated cocaine is swallowed and thus absorbed from the stomach as well. Gastrointestinal absorption is also slowed by vasoconstriction, producing a peak effect at 90 min and a duration of effect as long as 3 h. Both the intravenous and the inhalational routes produce a rapid peak effect (within 30 s to 2 min), with a duration of effect of 15 to 30 min. This rapid onset but short duration property helps explain why more crime and increased risk of human immunodeficiency virus (HIV) and other blood-borne infections are associated with the highly addictive drug. Frequent use is required to maintain the "high." Cocaine is primarily metabolized to ecgonine methyl ester by plasma cholinesterase. Relative deficiency of this enzyme may predispose affected patients to life-threatening toxicity.[3] Benzoylecgonine is the other major metabolite excreted in the urine and is the one routinely sought by most urine toxicology screens.

Cocaine is both a local anesthetic and a central nervous system (CNS) stimulant. Like other local anesthetics, cocaine inhibits conduction of nerve impulses by blocking fast sodium channels in the cell membrane. In vivo, cocaine has been demonstrated to have quinidine-like effects on conduction causing QRS widening and QTc prolongation. Thus in large doses, cocaine may exert a direct toxic effect on the myocardium resulting in negative inotropy, wide complex dysrhythmia, bradycardia, and hypotension. Central effects are mediated through activation of the sympathetic nervous system via enhanced effects of excitatory amino acids and blockade of presynaptic reuptake of norepinephrine, dopamine, and serotonin. The resultant excess of neurotransmitters at postsynaptic receptor sites leads to sympathetic activation, producing the characteristic physical findings of mydriasis, tachycardia, hypertension, and diaphoresis and predisposing the user to dysrhythmias, seizures, and hyperthermia. Cocaine use produces a euphoria associated with enhanced alertness and a general sense of well-being. It is thought that the psychological addiction, drug craving, and withdrawal effects are mediated through interference with dopamine and serotonin balance in the central nervous system. Subsequent dopamine depletion at the nerve terminals may account for the dysphoria and depression associated with long-term abuse. Many of ED visits attributed to cocaine are for the depression associated with chronic abuse.

Amphetamines

Amphetamines comprise a broad class of structurally similar derivatives of phenylethylamine. The derivative methamphetamine, also known as "ice," is abused by ingestion, intravenous injection, inhalation, or insufflation. As with cocaine, amphetamine's absorption and peak effects occur rapidly with inhalation, insufflation, and intravenous injection. However, the effects of some amphetamines such as methamphetamine (MDA) and methylenedioxymethamphetamine (MDMA) may persist for 12 h.

Amphetamines enhance the release and block the reuptake of catecholamines and may also directly stimulate catecholamine receptors. Some amphetamine metabolites inhibit monoamine oxidase, thus also increasing cytoplasmic concentrations of norepinephrine. Certain amphetamine derivatives can also induce release of serotonin and affect central serotonin receptors. The serotonergic effects account for the hallucinogenic properties of some amphetamine derivatives such as MDA, MDMA, and methylenedioxyethamphetamine (MDEA, or mescaline). Dopamine receptor activity may contribute to the withdrawal phenomenon. Mortality from amphetamine toxicity, like that from cocaine, is due to dysrhythmias, seizures, hyperthermia, hypertension (intracranial hemorrhage or infarction), and encephalopathy.

The stimulants ephedrine and phenylpropanolamine produce toxic syndromes similar to those caused by cocaine and amphetamines, although there are some distinguishing features. Phenylpropanolamine is abused as a stimulant and anorectic agent and is found in many over-the-counter diet aids and decongestants. It is primarily a peripheral alpha agonist that causes significant vasoconstriction resulting in hypertension and, often, a marked reflex bradycardia. Hypertensive encephalopathy and intracranial hemorrhage are associated with overdose. Ephedrine is a plant-derived indirect-acting sympathomimetic with both alpha- and beta-adrenergic activity due to the release of dopamine and norepinephrine from neuronal stores. Although used therapeutically for asthma in the past, it is currently promoted as a "natural" stimulant and anorectic. Significant cardiovascular and neurologic toxicity, psychosis, mania, and severe hypertension have been reported,

including several deaths.[4]

CLINICAL FEATURES

Cardiac

Cocaine induces dysrhythmias, myocarditis, cardiomyopathy and myocardial ischemia and infarction. Other vascular complications include aortic rupture and aortic and coronary artery dissection. Evidence in both animal and human experimental trials demonstrates that even at relatively low doses cocaine induces vasoconstriction in coronary arteries.[5] Vasoconstriction is one of the proposed mechanisms of cocaine-induced myocardial ischemia and infarction. Coronary vasoconstriction is exacerbated by b-adrenergic blockade and antagonized by phentolamine, suggesting that it is mediated through the stimulation of a-adrenergic receptors.[6] This effect is further potentiated by cigarette smoking. Myocardial ischemia has been demonstrated in chronic abusers undergoing cocaine withdrawal. It is thought that cocaine withdrawal is a dopamine-depleted state, resulting in intermittent coronary spasm. Animal data demonstrate increased platelet aggregation and thrombogenesis, accelerated atherosclerosis, direct myocardial toxicity, and increased myocardial oxygen demand.

A profile of the patient at risk for myocardial ischemia can be elucidated from a compilation of 91 case reports of patients with cocaine-induced myocardial infarction and a prospective evaluation of patients with cocaine-associated chest pain.[7,8] The average patient with cocaine-associated myocardial infarction was young and male (mean age 32.8, range 18 to 52; male-to-female ratio, 7:1) and most (83 to 89 percent) were cigarette smokers and regular cocaine users. Two-thirds of patients presented within 3 h of cocaine use and all routes of cocaine administration were reported. Of the patients with follow-up cardiac catheterization, coronary artery disease was present in 31 percent. Electrocardiographic (ECG) abnormalities were variably present, and both Q-wave and non-Q-wave infarctions occurred. Many studies have reported myocardial infarction in patients with atypical histories and unremarkable ECGs.

Myocardial ischemia and infarction and aortic dissection are also reported in association with ephedrine, phenylpropanolamine, or amphetamine use. Additionally, reports of mitral and aortic valve abnormalities associated with use of the amphetamine combination phentermine-fenfluramine prompted a voluntary recall of these drugs. Cardiopulmonary toxicity from other amphetamine diet aids has also been reported.

Central Nervous System

An array of neurologic syndromes are described in association with cocaine abuse, most commonly seizures, intracranial infarctions, and hemorrhages. Pathology results from the hyperadrenergic tone, inducing severe transient hypertension, hemorrhage, or focal vasospasm and sometimes, exacerbation of underlying abnormalities of cerebral blood vessels. In their studies using a dog model, Catravas and Waters demonstrated that lethal doses of intravenous cocaine initially induced seizures, lactic acidosis, hyperthermia, and death.[9] Progression of toxicity could be prevented by sedation and cooling. These authors also demonstrated that diazepam was an optimal sedative because it prevented hyperthermia and seizures in the cocaine-poisoned dog and thereby improved survival. Although coronary vasospasm has been well documented in humans exposed to cocaine, a recent study using magnetic resonance angiography also demonstrated cerebral vasoconstriction following cocaine administration. Other CNS manifestations reported include spinal cord infarctions, cerebral vasculitis, and intracranial abscesses. Acute dystonic reactions following cocaine use and withdrawal are both reported. Choreoathetosis and other repetitive movements are associated with cocaine and amphetamine intoxication, and all seem to be related to dopamine dysregulation. An interesting syndrome termed "cocaine washout" occurs in patients following a prolonged crack binge. Patients have a depressed level of consciousness but can be aroused to normal with stimulation. Resolution of lethargy can take up to 24 h. Unilateral blindness occurs secondary to central retinal artery occlusion and bilateral blindness from diffuse vasospasm. A syndrome of corneal abrasions and ulcerations secondary to smoke and irritation is known as "crack eye." Keratitis due to methamphetamine use is described as well.

Amphetamines, phenylpropanolamine, and ephedrine are also associated with intracranial hemorrhages, infarctions, encephalopathy, and seizures. Amphetamines also cause a CNS vasculitis resulting in focal neurologic deficits. A profound paranoid psychosis occurs with chronic amphetamine abuse and withdrawal.

Pulmonary

Respiratory effects of cocaine use have become more prevalent with the epidemic of crack cocaine, which is smoked. Pulmonary hemorrhage, barotrauma, pneumonitis, asthma, and pulmonary edema are described. Pneumomediastinum, pneumothorax, and pneumopericardium result from barotrauma secondary to the Valsalva maneuvers performed following inhalation or insufflation in an attempt to enhance drug effect. Pneumonitis, asthma, and bronchiolitis may be immunologic phenomena or the result of the numerous adulterants known to be present in cocaine. A recent case control study in an urban ED examined the association between bronchospasm and cocaine use.[11] The authors demonstrated a higher incidence of recent cocaine use in patients presenting with new-onset bronchospasm as compared with age- and sex-matched ED patients. Another study demonstrated bronchoconstriction following the inhalation of crack but not following intravenous injection of cocaine.[12] This suggests that such bronchospasm may be due to local airway irritation. Pulmonary edema may be catecholamine-mediated, in view of a similar syndrome described in patients with adrenergic excess from pheochromocytoma and intracranial hemorrhage. Upper airway irritation and a presumed thermal uvulitis occurs in patients smoking crack cocaine.

Gastrointestinal

Patients who are thought to have swallowed poorly packaged cocaine following police pursuit are called "body stuffers." Such patients are often brought to the hospital by police and may or may not show signs of cocaine intoxication. In contrast, the "body packer" swallows a large number of well-sealed packages of cocaine in order to smuggle drugs into this country. Because of the large quantities of relatively pure drug contained in these packages, toxicity and death can occur if even a single bag ruptures.

Cocaine-induced mesenteric vasospasm may contribute to the many reported cases of intestinal ischemia, bowel necrosis, ischemic colitis, and splenic infarctions. In addition, gastrointestinal bleeding and perforation occur in association with cocaine use.

Renal

Traumatic and nontraumatic rhabdomyolysis occurs secondary to cocaine or amphetamine use. In one series of cocaine-induced rhabdomyolysis, one-third of patients developed acute renal failure and half of those died. Risks for developing rhabdomyolysis include altered mental status, seizures, dysrhythmias, and hemodynamic instability including cardiac arrest.[13] Patients whose initial serum CK is less than 1000 U/L with normal creatinine, white blood cell count, and only one or no risks in addition to cocaine itself are unlikely to develop complications [13] and need not necessarily be admitted for this alone. In addition to renal failure resulting from rhabdomyolysis, stimulants may further exacerbate renal injury through hyperthermia, vasoconstriction, hypotension, and hypovolemia. One must be aware of this potential late complication and augment fluid resuscitation to maintain a urine output of 1 to 3 mL/kg per hour. Renal infarction has been described following intravenous cocaine use.

The Pregnant Patient

Cocaine is a potent vasoconstrictor and has been shown to alter uteroplacental blood flow. An increased incidence of spontaneous abortions, abruptio placentae, fetal prematurity, and intrauterine growth retardation results from cocaine abuse in pregnancy.[14] Both spontaneous abortions and abruptio placentae appear to occur from placental vasoconstriction and increased uterine contractility, with concomitant maternal hypertension. Intoxication of a breast-fed infant secondary to maternal cocaine use has been reported as well. Methamphetamine abuse during pregnancy has similar detrimental effects on fetal growth.

DIAGNOSIS

The cocaine- or amphetamine-intoxicated patient can often be identified initially by vital signs. Adrenergic stimulation may produce tachycardia, tachypnea, hypertension, and possibly hyperthermia. The patient's mental status can range from normal to paranoid or severely agitated to coma. Organ-system involvement may be suspected from symptoms such as chest pain, palpitations, dyspnea, headache, or focal neurologic complaints. The patient may be postictal or may present with seizures. Other physical findings may include mydriasis and diaphoresis. In the absence of an adequate history, it may be difficult to distinguish this presentation from other conditions of catecholamine excess, such as withdrawal from alcohol or sedative-hypnotics. Metabolic acidosis may be present following seizures or as a result

of vasoconstriction and hypoperfusion. As with all intoxicated patients, occult trauma and hypoglycemia must be excluded.

Concomitant use of alcohol and other drugs frequently alters the clinical presentation. For example, a patient ingesting both opioids and stimulants may present with a decreased level of consciousness and few if any other revealing findings. When the opioid is reversed with naloxone, the stimulant effects are unmasked, sometimes in dramatic fashion.

Laboratory

Laboratory studies may be helpful in diagnosing complications of cocaine or amphetamine abuse. Any patient with significant agitation or elevated temperature should have a chemistry panel and CPK obtained to screen for a metabolic acidosis, renal failure, or rhabdomyolysis. Hyponatremia of unknown etiology sometimes occurs following the use of hallucinogenic amphetamines (MDMA). Cardiac enzymes including CPK-MB or troponin are appropriate to screen for cardiac injury. A urine sample may be helpful in detecting rhabdomyolysis as well, since it may dip positive for hemoglobin with only few or no red blood cells by microscopy. Patients with hyperthermia should have baseline coagulation and liver function studies, since these values increase dramatically in the first 24 h. Most patients with altered mental status not responding to standard measures should undergo computed tomography of the head, since associated neurovascular injuries are common. A chest radiograph and ECG are fundamental to the evaluation. Laboratory confirmation of cocaine or amphetamine use is readily available but must be interpreted with caution. Urine drug screening for the cocaine metabolite benzoylecgonine is sensitive to 200 to 300 ng/mL; cocaine use within the past 24 to 72 h will typically be detected depending on dose and chronicity of cocaine use. Cocaine can be detected in chronic users by more sensitive techniques (radioimmunoassay, gas chromatography) for up to 2 weeks after last use. Although these qualitative drug screens will be positive for cocaine in the presence of the drug, they may be misleading in the chronic cocaine abuser who used the drug in the preceding several days, but now presents with a nontoxicologic condition. While most of the rapid screening tests for cocaine are fairly specific for cocaine metabolites and exhibit little cross-reactivity, the opposite is true for the amphetamine immunoassays. Interfering substances as well as false positives due to other phenylethylamine compounds may produce erroneus results. In addition, excessive use of certain nasal inhalers that contain stimulant-class drugs may cross-react with immunoassay methods and yield false-positive tests.

TREATMENT

The basic protocol specific to stimulants outlined in Chapter 151 should be followed. Charcoal may be given if appropriate. Intravenous access should be obtained in most patients and supplemental oxygen delivered to those with potential ischemia. The cornerstone of therapy is adequate sedation and close assessment of vital signs. The patient with hypertension and tachycardia will often respond to treatment with benzodiazepines, which decrease central sympathetic outflow. Lorazepam 2 mg or diazepam 5 mg can be administered intravenously and titrated with repeated doses to decrease the autonomic excess and CNS stimulation. Haloperidol and chlorpromazine should be avoided as these lower the seizure threshold. A core temperature should be measured in the evaluation of an agitated patient. Hyperthermia is potentially lethal and patients must be cooled rapidly to decrease subsequent morbidity and mortality. Ice-bath immersion produces the most rapid cooling; however, it is sometimes difficult to accomplish quickly. Cool mist spray to the skin and fans to increase heat loss by convection and evaporation may decrease temperature adequately. Application of ice packs and cooling blankets is insufficient to cool a hyperthermic poisoned patient. Aggressive fluid resuscitation is critical to maintain urine output.

Seizures may be treated with benzodiazepines as well; however, in status epilepticus, phenobarbital loading or neuromuscular blockade may be necessary to control motor activity and prevent hyperthermia, acidosis, and rhabdomyolysis. Computed tomography is recommended in all cases of stimulant-induced seizures because the finding of intracranial pathology creating a seizure focus is common.

The patient complaining of chest pain should be evaluated for possible myocardial ischemia as well as the common pulmonary etiologies mentioned in this population. Cocaine use should be considered an additional risk factor in reevaluation of any patient with chest pain. Patients suspected of myocardial ischemia should be managed with nitrates, morphine, benzodiazepines and aspirin.[15] b-adrenergic antagonist therapy is absolutely contraindicated because unopposed stimulation of a-adrenergic receptors may worsen coronary and peripheral vasoconstriction, hypertension, and possibly ischemia.[6] Although labetalol (a mixed a- and b-adrenergic antagonist) has been suggested, labetalol increased seizures and mortality in an animal model of cocaine toxicity and does not decrease cocaine-induced coronary vasoconstriction in humans. Furthermore, it has predominant b-adrenergic antagonist effects and may still lead to predominant a-adrenergic activity, thus worsening peripheral vasoconstriction and hypertension. Consultation may be helpful before administering thrombolytic therapy in cocaine-associated myocardial infarction. Despite the increased incidence of coronary atherosclerosis, vasospasm, coronary artery dissection, and severe hypertension would all be contraindications to its use.[16,17]

Wide complex tachydysrhythmias and QRS prolongation secondary to the quinidine-like effects of cocaine may be treated by alkalinizing the serum to a pH of 7.45 to 7.5 with a sodium bicarbonate infusion.[18] Although lidocaine has been used safely in this setting, some animal studies and theoretical evidence suggest that lidocaine may potentiate cocaine neurotoxicity and should be used with caution in patients with dysrhythmias who are not responsive to sodium bicarbonate.

Severe hypertension not responding to sedation may require treatment with nitroprusside infusion or phentolamine (phentolamine starting dose: 2.5 to 5 mg IV). Blood pressure may be lowered aggressively provided that the patient does not have chronic hypertensive disease. Treatment for refractory hypertension would be similar to that for hypertensive emergencies of any etiology (see Chap. 53).

The treatment of patients with cardiovascular or neurologic sequelae of amphetamine or other stimulant use is comparable to that outlined for cocaine. Acidification of the urine to increase amphetamine excretion was previously recommended but should not be done because of the increased risk of renal tubular precipitation of myoglobin in the presence of rhabdomyolysis. Dialysis is not of value.

The management of an asymptomatic cocaine "body packer" brought in by police or customs officials constitutes a new dilemma for the emergency physician. If the patient shows no signs of toxicity, we recommend a dose of activated charcoal followed by whole bowel irrigation with polyethylene glycol electrolyte lavage solution (GoLYTELY or Colyte) to gently hasten elimination of the potentially lethal packets. If the patient begins to show signs of intoxication, such as agitation, hypertension, or tachycardia, benzodiazepines should be administered while immediate surgical consultation for emergent laparatomy and packet removal is made. Neither upper nor lower endoscopy should be attempted because both routes have been associated with packet rupture. Following passage of the "last" packet, a radiologic imaging procedure (a Gastrografin upper gastrointestinal series with small bowel follow-through or abdominal CT with contrast) should be performed to ensure that the gut has been purged of all containers. In contrast to "body packers," "body stuffers" are more likely to be seen in the ED. These patients can be given a dose of activated charcoal, sedated (if indicated), and given supportive care if intoxicated, since it is known the toxicity should be shorter-lived and often involves smaller amounts of drug.

Drug Interactions

There are a few potential drug interactions to be aware of in the treatment of the stimulant poisoned patient. Since cocaine is metabolized by plasma cholinesterase, coadministration of other drugs such as succinylcholine and mivacurium, which are metabolized by plasma cholinesterase, may have a prolonged duration of effect due to decreased metabolism. This may have significant implications during a failed rapid-sequence intubation with these agents.

Both lidocaine and cocaine are local anesthetics and act as sodium channel antagonists. It is thought that neurotoxic effects from both occur by similar mechanisms. Animal studies examining cocaine and lidocaine together are inconclusive, demonstrating both synergistic neurotoxicity as well as protective effects of lidocaine pretreatment on cocaine-induced lethality. Although there may be some theoretical risk of treating cocaine-induced dysrhythmias with lidocaine, it has been used safely to date in patients with cocaine-associated myocardial infarction.

Monoamine oxidase inhibitors block the degradation of catecholamines and lead to increased levels of presynaptic catecholamines. Amphetamines are indirect-acting sympathomimetic amines and weak inhibitors of monoamine oxidase as well. Thus, patients taking monoamine oxidase inhibitors who subsequently use amphetamines or phenylpropanolamine (and to a lesser extent cocaine) may precipitate an acute syndrome of excessive catecholamine release, resulting in severe hypertension, tachycardia, hyperthermia, agitation, tremors, and possible severe neurotoxicity.

Withdrawal

Cocaine withdrawal is characterized by irritability, paranoid ideation, and delayed depression. Symptoms are generally milder than for amphetamines. Psychological addiction may be particularly strong. Amphetamine withdrawal is characterized by drowsiness, lethargy, hunger, tremor, and chills. There is considerable potential for

long-term depression and suicide.

DISPOSITION

Patient disposition depends on initial patient presentation, response to therapy, the particular stimulant involved, and expected duration of effect. Patients who present with adrenergic excess following recent cocaine use and who respond to sedation may be expected to improve completely during a period of observation in the ED secondary to the relatively limited duration of cocaine effect. In contrast, amphetamines have a longer duration of effect and may be expected to produce more prolonged toxicity, necessitating hospital admission or prolonged observation in some cases. Patients demonstrating resolution of toxicity and clear sensorium in the absence of focal complaints or end-organ damage should be advised of the medical risks of their drug abuse and referred to appropriate detoxification, counseling, and social support services. In general, patients with significantly increased creatine phosphokinase levels, hyperthermia, myoglobinuria, or ECG changes consistent with myocardial ischemia should be hospitalized in an intensive care setting. [13]

Disposition of patients who present with cocaine-associated chest pain and normal electrocardiograms may be difficult. Although several studies have examined risk factors associated with myocardial ischemia in this population, clinical parameters were not helpful in identifying those patients who subsequently did have myocardial infarctions. The incidence of myocardial ischemia in a large cohort of patients with cocaine-associated chest pain was approximately 6 percent. Admission to a telemetry or ED observation unit for serial cardiac enzymes and ECGs is sufficient, since the complication rate in stable patients is quite low. Young patients who "rule out" do not need a follow-up stress test unless there are other indications. Patients with unremitting chest pain, dysrhythmias, congestive heart failure, or evolving ECGs require hospital admission.

163 HALLUCINOGENS

Karen N. Hansen

EPIDEMIOLOGY

Modern interest in hallucinogenic drugs dates from Albert Hofman's 1943 discovery of the properties of lysergic acid diethylamide (LSD) through inadvertent ingestion.[1]

The popularity of hallucinogens as recreational drugs peaked in the 1960s, and is currently undergoing a resurgence among adolescents and young adults.[2] In the United States in 1995, 8.4 percent of high school seniors, and 6.8 percent of college students used LSD.[2] In the same year, marijuana was used by 34.7 percent of high school seniors and 31.2 percent of college students.[2] Of particular concern is the current popularity of the psychoactive amphetamine-derivative MDMA ("ecstasy" or "Adam") among college students.[3] Encouragingly, the incidence of emergency department (ED) visits due to phencyclidine (PCP) has decreased sharply in the past decade.[4] In 1995, annual prevalence of PCP use among high school seniors was 1.8 percent, and among young adults was only 0.3 percent.[2]

Terms such as "psychedelic" are sometimes preferred to "hallucinogen." Many of the drugs within this group rarely produce true hallucinations, which are sensory perceptions occurring in the absence of any external stimulus. Perceptual alterations based on some environmental cue are termed illusions, and are far more common. These effects may involve any sensory modality, but are most often visual. Users may also experience distortions of body image, and a distorted sensation of the passage of time. Alterations in mood and heightened suggestibility are common.

The "classical" hallucinogens include agents from the indole alkylamine (LSD, psilocybin), and phenylethylamine (mescaline and others) chemical families (Table 163-1). These drugs share a common proposed mechanism of action, and are capable of producing the profound psychological effects and sensory distortions characteristic of the psychedelic "trip." In addition to classical hallucinogens, a number of other drugs, such as MDMA ("ecstasy"), phencyclidine (PCP), and marijuana, possess the ability to alter sensory perceptions, and can be placed within the broader category of hallucinogens.

TABLE 163-1   Characteristics of Hallucinogens

DIAGNOSIS

LSD

LSD (lysergic acid diethylamide) can be chemically synthesized or obtained by hydrolysis of ergot alkaloids from the fungus *Claviceps purpurea*. It is one of the most potent psychoactive compounds known. Evidence suggests that the psychedelic effects of LSD are mediated through serotonergic (5-HT) systems, and that LSD acts as an agonist at 5-HT$_2$ receptors.[5]

The typical LSD dose of 50 to 300 μg is most commonly delivered through ingestion of a small square of dried "blotter" paper that has been saturated with a solution of the compound. Blotter acid is often imprinted with fanciful designs or cartoons which may serve as trademarks for the manufacturer. Other forms of LSD, including "microdots" (tiny tablets), "windowpane" (gelatin sheets), and liquid LSD, are currently uncommon. LSD is relatively inexpensive; a dose costs the user less than $15.

LSD is rapidly absorbed following ingestion. Onset of psychedelic effects occurs after about 30 minutes, peak effects occur within the first 4 hours, and the total duration of an LSD "trip" is between 8 and 12 h. The serum half-life of LSD is approximately 3 h. The physiological effects of LSD usually precede the psychedelic effects, and are dominated by sympathomimetic symptoms. These include marked mydriasis, and mild elevations of pulse, blood pressure, and temperature. Facial flushing, mild gastric distress, piloerection, increased muscle tension, and hyperreflexia may be seen. Severe or life-threatening complications are extremely uncommon. Seizures have been reported rarely. Massive overdose of LSD may produce coma, respiratory arrest, hyperthermia, and coagulopathy.[6]

The psychedelic effects of LSD may be perceived as pleasurable or horrifying, depending on the user's prevailing mood and expectations ("set"), and external environmental factors ("setting"). Acute adverse psychological effects ("bad trip") include panic attacks, extreme paranoia, acute psychotic reactions, and depressive reactions. Potential physical trauma as a consequence of dangerous or impulsive behavior is a serious hazard. Occasional suicides have been reported. Prolonged and sometimes permanent psychosis following LSD use has been well described, and affects between 0.08 percent and 4.6 percent of users.[7] The term "flashback" has been replaced by Hallucinogen Persisting Perception Disorder,[7,8] a debilitating malady in which patients experience chronic perceptual distortions reminiscent of the drug-induced state, often accompanied by anxiety or panic.

Patients who present to the ED due to effects of LSD will usually be able to give a history of the drug ingestion. In most ED settings, the available routine toxicology screen will not detect LSD, but toxicological screening may be indicated if other intoxicants are suspected. If the history is clear, and in the absence of medical complications or possible co-ingestants, observation in a quiet, safe environment, with reassurance and emotional support, are generally the only interventions required to manage a patient experiencing a "bad trip." Oral or parenteral benzodiazepines may be given if the patient is extremely agitated. Haloperidol may be used as a second choice if additional sedation is required. Patients who are lucid and medically stable may be released into the custody of family or friends. Patients with paranoid or psychotic symptoms lasting longer than 8 to 12 h may require hospital admission. Rarely do patients with medical complications due to massive overdose require hospital admission; they can be expected to recover quickly with supportive management.[6]

Psilocybin

Psilocybin and the related compound psilocin are hallucinogens of the indole alkylamine class, and are structurally related to LSD. Psilocybin and psilocin are believed to act as $5-HT_2$ agonists in a manner similar to LSD. They occur naturally in mushrooms of the *Psilocybe* genus, most notably *P. semilanceata* (liberty cap), and *P. cubensis*. Psilocybin-containing mushrooms grow naturally in many areas of the United States and Europe, and kits containing spores and the ingredients necessary for propagation are advertised in drug-oriented publications. Hallucinogenic mushrooms purchased on the street are often nonpsychoactive mushrooms that have been adulterated with LSD or PCP.[9] Psilocybin-containing mushrooms may be dried or cooked without losing potency. Because the size of the mushrooms and the concentration of psychoactive compounds varies, there is little correlation between the number of mushrooms ingested and the hallucinogenic effects. A user may ingest as few as 5 or as many as 100 mushrooms for a single "dose."

Symptom onset occurs about 30 min after ingestion of psilocybin-containing mushrooms, and the total duration of hallucinogenic effects is about 4 to 6 h. The hallucinogenic effects are similar to, although less powerful than, those produced by LSD. Other common effects include mydriasis, mild tachycardia, hyperreflexia, and nausea and vomiting. Serious medical side effects are extremely rare, but seizures and hyperthermia have occurred, and the death of a small child has been reported.

ED management of patients presenting with isolated hallucinogenic mushroom ingestion is largely supportive. Routine drug screens do not detect psilocybin or psilocin. However, a drug screen may indicate whether the ingested mushrooms were adulterated with PCP. If the patient's symptoms are not consistent with psilocybin, the possibility that the mushrooms ingested were of another more toxic variety should be considered.

Mescaline

Mescaline (3,4,5-trimethoxyphenylethylamine) is the hallucinogenic alkaloid found in the Mexican peyote cactus *Lophophora williamsii*. It is a member of the phenylethylamine class of hallucinogens, and is structurally related to amphetamines. As for LSD, the hallucinogenic action of mescaline is believed to result from HT_2 agonist properties.[10] Mescaline, however, is a much weaker hallucinogen than LSD.

The small 8-mm crowns of the peyote cactus are dried and sold as peyote "buttons," each containing approximately 45 mg of mescaline. A typical dose of 200 to 500 mg will require 3 to 12 of these "buttons." Mescaline can be extracted from peyote or be chemically synthesized, but these methods are expensive. Pills or capsules sold on the street as "mescaline" are unlikely to be genuine,[9] and may instead contain LSD or PCP.

Peyote is bitter tasting, and causes significant uncomfortable physical side effects within an hour of ingestion. Initial signs and symptoms, which often include nausea and vomiting, abdominal discomfort, diaphoresis, dizziness, nystagmus, ataxia, and headache, generally resolve after about 2 h. Adrenergic stimulation causes mydriasis, and mild elevations in pulse, blood pressure, and temperature. The hallucinogenic effects, which are very similar to those produced by LSD, begin several hours after ingestion and persist for 6 to 12 hours. Death due to aberrant behavior while under the influence of the drug has occurred, but reports of significant morbidity or mortality due to physiological effects of mescaline are absent from the literature. Patients presenting to the ED due to peyote ingestion can generally be managed supportively. Mescaline is not detected by routine drug screens.

MDMA

MDMA (3,4-methylenedioxymethamphetamine; "Ecstasy" or "Adam") is a synthetic phenylethylamine derivative that is structurally related to both amphetamines and mescaline. MDA (3,4-methylenedioxyamphetamine) and MDEA (3,4-methylenedioxymethamphetamine; "Eve") are related compounds with similar properties. The effects of MDMA are believed to result from stimulation of 5-HT release from central serotonergic nerve terminals.[11]

MDMA is usually ingested in doses of 50 to 200 mg. Tablets are typically round and white, often imprinted with bird motifs. Acute effects last about 4 to 6 hours. MDMA rarely causes actual hallucinations, but can produce sensory effects such as alterations in the intensity of colors or sensation of textures. Users often report feelings of euphoria, enhanced sociability, verbosity, and heightened sexual interest. Common physical manifestations of MDMA include sympathomimetic effects, particularly mydriasis and mild elevations of pulse and blood pressure, as well as nausea, jaw tension, bruxism, dry mouth, muscle aches, and ataxia.

The increase in popularity of MDMA has been accompanied by an increase in reports of serious complications and death related to its use. Fatal dysrhythmias and death due to cardiac effects have been reported in patients with and without underlying cardiac disease.[12] Severe hypertension and intracranial hemorrhage have been reported.[12] A pattern of toxicity manifested by hyperthermia, seizures, disseminated intravascular coagulation (DIC), rhabdomyolysis, and renal failure has been increasingly recognized.[13] This pattern shares many features of the serotonin syndrome.[14] Hepatic toxicity and possibly long-term damage to serotonergic neurons may result from chronic MDMA use.[15]

Patients presenting to the ED with complications due to MDMA should receive activated charcoal if the ingestion was recent. Dysrhythmias are managed with standard therapy. Hypertension and tachycardia will often respond to benzodiazepines alone, but if hypertension is severe, phentolamine or nitroprusside can be used. b-Blockers, such as propranolol, should probably be avoided due to the risk of possible unopposed a stimulation. Hyperthermia should be managed aggressively with active cooling measures and hydration. Dantrolene has been recommended for treatment of hyperthermia,[13] and has been used successfully in sporadic cases. Because of the similarity of the hyperthermic MDMA syndrome and the serotonin syndrome, the use of 5-HT antagonists such as methysergide or cyproheptadine has been suggested.[14]

Phencyclidine

Phencyclidine is a synthetic piperidine derivative. It is a dissociative anesthetic agent structurally related to ketamine. PCP is unlike the classic hallucinogens in that it causes clouding of the sensorium rather than heightened sensory awareness. PCP is believed to act as a glutamate antagonist at the NMDA (*N*-methyl-*d*-aspartate) receptor.[16]

PCP can be easily and inexpensively synthesized. Powdered drug ("angel dust") is most often combined with tobacco, marijuana, or other vegetable matter and smoked, but PCP can be ingested orally, sniffed intranasally, or injected intravenously. Unfortunately, PCP is often sold as another drug, or used to adulterate another drug, and thus may be unknowingly ingested.[9] The onset of action depends on the mode of administration; onset of action is about five min if PCP is smoked. Acute effects generally last 4 to 6 h, but can persist much longer. The half-life is very variable, possibly due to the significant enterohepatic circulation and high lipid solubility of the drug. PCP is a weak base, and is concentrated in acidic environments. It is largely metabolized by the liver, and metabolites are excreted in the urine.

Because of the remarkable variability of clinical effects produced, recognition of PCP intoxication can be challenging. Patients may present with CNS stimulation or depression, and may be physically violent, catatonic, or comatose. A combination of cholinergic, anticholinergic, and sympathomimetic effects may be present. Many patients have taken a combination of drugs, compounding the clinical picture.[17] In a series of 1000 PCP-intoxicated patients, nystagmus and hypertension were the most common findings, each occurring in 57 percent of patients.[17] Hypertension was generally mild. Other prevalent manifestations were: acute brain syndrome (37 percent); violent (35 percent), agitated (34 percent), or bizarre (29 percent) behavior; hallucinations or delusions (19 percent); and tachycardia (30 percent).[17] Diaphoresis, muscle rigidity, dystonic reactions, ataxia, and a decreased response to painful stimuli have also been described. Pupil size is variable; unlike classic hallucinogens, widely dilated pupils are not common.[17]

Medical complications due to PCP use occur frequently. Coma has been seen in 10.6 percent,[18] and seizures in 3.1 percent,[17] of PCP-intoxicated patients. Elevated serum creatinine phosphokinase (CPK), due to increased muscle activity and/or a possible direct toxic effect of PCP, was found in 70 percent of patients in one study.[17] Frank rhabdomyolysis may occur, and sometimes results in renal failure requiring dialysis.[18] Hypoglycemia, sometimes severe, was found in 22 percent of PCP-intoxicated patients.[17] Hypertension causing intracerebral hemorrhage, and hyperthermia causing hepatic necrosis, have also been reported. In addition, significant traumatic injury, and sometimes death, may occur as a result of the violent or aberrant behavior characteristic of PCP use.

The ED evaluation of a patient with known or suspected PCP intoxication should include examination for occult trauma and evaluation for the possibility of hypoglycemia or rhabdomyolysis. If the urine dipstick is positive for occult blood, but microscopic urinalysis shows no red blood cells, myoglobinuria should be

suspected, and a total CPK level obtained. Results of toxicological screening for PCP can be misleading. Tests can be falsely negative due to fluctuations in serum and urine drug levels. Conversely, chronic PCP users may test positive for weeks following their last use, [19] so a positive test does not necessarily indicate acute PCP intoxication.

Violence and agitation are common features of PCP intoxication, and sedation or physical restraints are frequently required to prevent patients from harming themselves and to protect ED personnel. Pharmaceutical intervention is preferable to physical measures because the muscular activity a patient expends while fighting against restraints may contribute to the development of rhabdomyolysis. Parenteral benzodiazepines are recommended, but haloperidol can also be used.

Gastric lavage is only indicated for patients with very recent oral ingestions of large amounts of PCP, or who may have significant co-ingestions. Patients who are comatose should be endotracheally intubated for airway control prior to gastric lavage. Regardless of the original mode of drug administration, circulating PCP is secreted into the stomach, and becomes trapped in the acidic environment. Therefore, continuous gastric suction or multiple-dose charcoal administration can help facilitate drug removal; either is recommended for patients with significant PCP intoxication. Administration of multiple doses of charcoal is probably preferred to continuous gastric suction, as it is likely to be easier and safer to accomplish in this patient population. Urinary acidification is of theoretical benefit, but is contraindicated because it may exacerbate myoglobin precipitation in the kidneys. Due to the large volume of distribution of PCP, hemodialysis is not effective.

Management of patients with PCP intoxication is generally supportive, but patients with severe CNS toxicity, or who have specific medical complications, require appropriate intervention. Patients in coma require endotracheal intubation and evaluation for other causes of altered consciousness, including hypoglycemia and head injury. Seizures should be treated with benzodiazepines, and patients in status epilepticus may require endotracheal intubation and neuromuscular blockade. Hyperthermia is treated with rapid cooling, and possibly dantrolene. Hypertension usually responds to sedation, but severe hypertension can be treated with nitroprusside. Treatment of rhabdomyolysis includes aggressive hydration. Administering intravenous sodium bicarbonate to alkalinize the urine may help prevent acute tubular necrosis in this setting.

Based on a large study of patients presenting with acute PCP intoxication, four major and five minor clinical patterns of PCP intoxication have been described. [18] The major clinical patterns are coma, catatonia, toxic psychosis, and acute brain syndrome. Most patients presenting with one of the major patterns of PCP intoxication require hospital admission for medical or psychiatric reasons. Patients exhibiting one of the minor clinical patterns of PCP intoxication (lethargy, bizarre behavior, violent behavior, or agitation) can often be discharged if their condition improves after observation. [18]

Marijuana

Dried leaves and flowers from the hemp plant *Cannabis sativa* are called marijuana, and dried resin from the flower tops of this plant is known as hashish. The psychoactive ingredient of marijuana is d^9-tetrahydrocannabinol (d^9-THC). d^9-THC binds to a specific brain receptor for which an endogenous ligand has been discovered.[20]

Marijuana is usually smoked, but it can be ingested. Symptoms persist for 2 to 4 hours, or longer if ingested. Drowsiness, euphoria, heightened sensory awareness, paranoia, distortions of time and space, and feelings of unreality are described. Hallucinations do not normally occur at usual doses. Common physiological effects of marijuana are mild tachycardia, injected conjunctiva, bronchodilation, orthostatic hypotension, and impaired motor coordination. Although significant medical complications occur rarely, if at all, users may experience panic reactions, or even brief toxic psychoses due to d^9-THC.

Acute psychiatric symptoms due to marijuana use can usually be managed with reassurance alone, but benzodiazepines can be used if medication is warranted. Urine tests are unreliable indicators of acute marijuana intoxication because it is detectable for days after use in novice users, and for weeks after the last use in chronic users.[21]

Other Hallucinogens

Seeds of the morning glory plant (*Ipomoea violacea, Ipomoea tricolor,* and others) contain lysergic acid amide (ergine), a compound closely related to LSD. They are sometimes intentionally ingested for the hallucinogenic effects. Several hundred seeds may be taken as a "dose." Physical and psychological manifestations closely resemble effects of LSD, and patients can be managed similarly.

Accidental or intentional ingestion of large amounts of nutmeg can cause delirium with hallucinations. Nutmeg is the dried seed from the tropical *Myristica fragrans* tree. The hallucinogenic properties of nutmeg may be due to a component, myristicin, but the mechanism is not well understood. Ingestion of 1 to 3 nutmegs or 5 to 15 g of the ground spice produces psychological effects, which begin 3 to 6 h later and last for 6 to 24 h. Uncomfortable physical symptoms are prominent, and may include tachycardia, flushing, dry mouth, nausea, and abdominal pain. Signs and symptoms may resemble anticholinergic poisoning, but pupils are usually small or midsize. Management is generally supportive.

Jimson weed (*Datura stramonium*) and angel's trumpet (*Datura candida*) plants grow naturally in the United States, and contain the anticholinergic alkaloids atropine, scopolamine, and hyoscyamine. Seeds or other parts of the plant can be ingested or smoked, and cause the anticholinergic toxic syndrome. Delirium, hallucinations, and seizures can occur, along with other classic anticholinergic effects, such as mydriasis, tachycardia, dry mouth and skin, blurred vision, urinary retention, and hyperthermia. Gastric emptying can be delayed, so gastric decontamination is an important part of the management of such patients. Medications with anticholinergic properties, such as phenothiazine, should be avoided. Use of physostigmine should be reserved for patients with severe anticholinergic toxicity who do not respond to supportive measures.

TREATMENT

The initial ED management of a patient presenting with hallucinations, bizarre behavior, or altered thought processes should concentrate on assessing the patient's general medical condition and stabilizing the patient's airway, breathing, and circulation. Hypoglycemia should be considered in all patients with altered mental status. Among the many conditions that can mimic hallucinogen intoxication are alcohol or benzodiazepine withdrawal, anticholinergic poisoning, thyrotoxicosis, and acute psychosis. Numerous prescription and nonprescription medications can also cause hallucinations.

Hallucinogens are usually taken intentionally, so in most cases a history of what was taken and the mode of administration is available. Because the identity of street drugs is often misrepresented,[9] the possibility that the substance used was adulterated or substituted by another, more toxic drug, particularly PCP, should be considered. Drug testing is of limited utility because most hallucinogens will not be detected by routinely available drug screens. In addition, a positive test for PCP or marijuana can be misleading, as it may be indicative of use days or weeks prior to testing.

Patients under the influence of hallucinogens may present with severe anxiety, agitation, or violent behavior. In many cases, calm reassurance in a supportive environment is sufficient to soothe the patient. In other cases, pharmacological intervention, and possibly physical restraints, may be necessary to ensure the safety of the patient and the ED staff, and to facilitate evaluation and treatment of the patient. Benzodiazepines are considered the mainstay of treatment. Diazepam, 5 mg po or IV, or lorazepam, 1 to 2 mg po, IM, or IV, can be given depending on the severity of symptoms and the clinical situation. Repeated doses can be given as needed, provided the patient is monitored for the possibility of respiratory depression. Phenothiazine should not be used. Use of haloperidol, a butyrophenone, or droperidol may be considered in the unlikely event that a second sedating agent is required. Haloperidol and droperidol, however, lower the seizure threshold, have anticholinergic properties, and can cause dystonias. They should be used with caution, and should be avoided completely if the patient is exhibiting significant anticholinergic symptoms. Haloperidol or droperidol can be administered IM or IV in 5 mg increments. Physical restraints are sometimes necessary. Physical restraints may cause injury, may exacerbate paranoia and agitation, and may contribute to the development of rhabdomyolysis in patients who struggle against them.

Most hallucinogens are rapidly absorbed. Patients experiencing adverse effects usually present several hours after the drug was administered. Therefore, gastric decontamination is of limited utility in most cases. Gastric lavage should only be considered for very recent large ingestions, or if significant toxic co-ingestions are suspected. Administration of oral activated charcoal is sufficient in the majority of cases. PCP is secreted into the stomach from the systemic circulation, so continuous gastric suction or, preferably, multiple doses of activated charcoal are recommended for patients exhibiting significant toxicity from PCP.

Hemodialysis is not indicated, as it does not effectively remove hallucinogens from the body. Although urinary acidification would theoretically enhance elimination of

PCP and the hallucinogenic amphetamines, it can also cause renal injury due to myoglobin precipitation, and is therefore contraindicated.

The management of patients with hallucinogen intoxication is largely supportive, but medical complications can occur, and should be treated appropriately. Tachycardia and hypertension often respond to sedation with benzodiazepines alone. Significant dysrhythmias are treated using standard protocols. Severe hypertension can be treated with nitroprusside. The dose of a nitroprusside infusion starts at 0.5 μg/kg per minute, and can be titrated to a maximum of 10 μg/kg per minute as needed. Propranolol should probably be avoided because many of the hallucinogens cause significant adrenergic stimulation, and use of a b-blocker may lead to paradoxical hypertension due to unopposed a stimulation. Rapid cooling measures should be initiated for patients with significant hyperthermia. Treatment of severe hyperthermia may require neuromuscular paralysis with endotracheal intubation and possibly the administration of dantrolene. Seizures are treated with benzodiazepines and standard anticonvulsants. Patients with rhabdomyolysis require aggressive IV hydration and IV sodium bicarbonate to achieve a urinary pH of 7 to 8.

DISPOSITION

Most patients seen in the ED due to adverse reactions from hallucinogen use can be discharged into the custody of family or friends if they are lucid and medically stable after a period of observation. Patients with persistent psychotic symptoms or other significant psychiatric disturbance may require psychiatric evaluation and possible hospital admission. Patients with significant medical complications of hallucinogen use, such as severe hypertension, hyperthermia, seizures, or rhabdomyolysis, should be admitted to the hospital for continued treatment and observation. All patients should be assessed for suicide wish.

164 SALICYLATES

Richard C. Dart

EPIDEMIOLOGY

The widespread availability of aspirin (acetylsalicylic acid, or ASA) in prescription and over-the-counter preparations, confusion between product names and brand names, and the ease with which incremental chronic dosing can cause toxicity make salicylism a common and sometimes fatal occurrence. Data from the American Association of Poison Control Centers Toxic Exposures Surveillance System showed that, in 1996, aspirin was implicated in 25,281 exposures, with 12,385 cases (49 percent) treated in a health care facility; 48 deaths (0.2 percent of cases) were attributed to salicylate toxicity. [1]

Many people use over-the-counter medications without realizing that they may contain significant amounts of salicylate. For example, Pepto Bismol (261 mg of salicylate per 30 mL) will deliver large amounts of salicylate in patients who overuse the product. Children may become salicylate toxic from extensive application of keratolytic agents or other agents containing oil of wintergreen (methyl salicylate). One milliliter of a 98% methyl salicylate contains 1400 mg of salicylate. Liniments and products used in hot vaporizers have high concentrations of methyl salicylate, and an ingestion of 5 to 10 mL can be lethal for an infant or a toddler.

PATHOPHYSIOLOGY

Absorption of salicylate may be delayed or erratic, depending on the product. After ingestion of large amounts of non-enteric-coated ASA, absorption from the gastrointestinal (GI) tract may be slowed because of the inhibitory effect of ASA on gastric emptying and the impaired dissolution of tablets in gastric fluids at high concentrations. Peak serum salicylate levels may not be reached for 18 to 24 h, although toxic levels are usually evident within 6 h. Methyl salicylate is a liquid that produces peak levels earlier, whereas peak levels following enteric-coated or sustained-release ASA overdose have been reported to occur 10 to 60 h after ingestion.[2] Some formulations of ASA may coalesce to form a gelatinous gastric mass, and significant amounts of ASA may remain in the stomach long after an intentional overdose, providing a source for continued absorption.

After absorption, ASA is hydrolyzed to salicylic acid (salicylate) and is distributed throughout body tissues. The severity of toxicity depends on the cellular salicylate concentration. Salicylate is responsible for both the therapeutic and the toxic effects of ASA. At higher salicylate concentrations, a lesser percentage of the drug is protein bound and more free drug is available to diffuse into tissues and cause toxicity. The pK_a of salicylate is 3.0 and, at physiologic pH (7.40), almost all salicylate molecules are ionized. If the systemic pH decreases, the change in equilibrium will form a greater portion of nonionized molecules. This is an important concept because nonionized molecules will cross cellular membranes, such as the blood-brain barrier. Thus, for a given salicylate level, brain salicylate levels will be substantially higher in the presence of acidemia.[3] Although the precise mechanism remains to be determined, the concentration of salicylate in the brain is correlated directly with mortality rate.[3]

The ionized state of salicylate can be used to enhance its elimination. If the urine pH is above 8.0, more salicylate molecules in the urine will be ionized compared with the renal tubular cell pH of 7.4 and reabsorption across the urinary tubule will be reduced. [4]

Acute salicylate overdose may produce nausea and vomiting as a result of local gastric irritation and stimulation of the chemoreceptor trigger zone. [5] Vomiting may result in volume depletion, which reduces renal perfusion and urine flow, adversely affecting renal salicylate elimination and contributing to acid-base and electrolyte disturbances.

Salicylate initially increases respiratory rate through a direct stimulatory effect on the medullary respiratory center in the central nervous system (CNS), [6] but very high levels of salicylate depress respiration, a finding usually seen later in the course. Salicylate also stimulates skeletal muscle metabolism, which causes an increase in oxygen consumption and carbon dioxide production.[6] The clinical manifestation of the initial respiratory center stimulation (the dominant component) and the increase in carbon dioxide production causes an increased respiratory rate resulting in respiratory alkalosis. [6] Initially, this will counter the enduring metabolic acidosis. If ventilatory compensation fails to keep pace with increased carbon dioxide production, respiratory acidosis will develop and will compound the metabolic acidosis.

The loss of the respiratory buffering effect is very dangerous, because the kidneys, even under ideal conditions, cannot react with sufficient rapidity to counter the acidosis meaningfully. Also, the critical alkalemia seen early when respiratory alkalosis predominates causes the kidneys to increase bicarbonate and potassium excretion. The urinary bicarbonate loss will eventually decrease the body's bicarbonate stores and impair compensation for the metabolic acidosis of salicylism.

Salicylate enhances lipolysis, uncouples oxidative phosphorylation, and inhibits various Krebs cycle enzymes involved in energy production and amino acid metabolism, resulting in (1) increased catabolism that leads to increased carbon dioxide production, (2) increased heat production, (3) increased glycolysis and peripheral demand for glucose, and (4) production of metabolic intermediaries (organic acids, lactate, pyruvate, and keto acids), which contribute to the metabolic acidosis of salicylate toxicity.[7] Overall, the acid-base disturbance associated with salicylate poisoning is mixed and includes respiratory alkalosis, metabolic alkalosis (due to volume contraction) and a wide-anion-gap type metabolic acidosis.

Salicylate-induced noncardiogenic pulmonary edema has been observed in humans [8,9,10 and 11] and studied in animals. Salicylate toxicity causes increased pulmonary vascular permeability, whereas pulmonary vascular pressures and cardiac performance are unaffected. This vascular injury may also involve the kidneys. Proteinuria is a prominent early finding in salicylate toxicity, starting at a serum salicylate level greater than 30 mg/dL, and it is directly related to salicylate levels. [9]

Salicylate also affects both central and peripheral glucose homeostasis. Salicylate causes mobilization of glycogen stores, resulting in hyperglycemia. However, salicylate is also a potent inhibitor of gluconeogenesis. Therefore, normoglycemia, hyperglycemia, or hypoglycemia may occur in salicylate toxicity. The brain involves a unique problem with glucose delivery. Animal studies demonstrate that toxic doses of salicylate produce a profound decrease in brain glucose concentration despite normal serum glucose levels.[12] This finding suggests that the supply of glucose to the brain in salicylate poisoning may be inadequate, even though serum glucose levels are normal.

Antiplatelet activity is a well-known effect of ASA, but hemorrhage is a rare complication of acute, single, massive overdose of salicylate. Salicylate has a molecular structure similar to both vitamin K and dicumarol. *Chronic* administration of large doses of salicylate may cause significant hypoprothrombinemia when the serum salicylate concentration exceeds 60 mg/dL.[13] This is presumably due to salicylate's competitive inhibition of the vitamin K effect.

Salicylate ototoxicity is characterized by a reversible sensorineuronal hearing loss, which is not idiosyncratic; it is related to serum salicylate concentrations. [14] When serum salicylate concentrations exceed 40 mg/dL, hearing loss reaches its maximum of 40 decibels.[14]

CLINICAL FEATURES AND DIAGNOSIS

Clinical manifestations of salicylism depend on the dose of salicylate ingested, duration of exposure, and age of the patient. In general, acute ingestion of less than 150 mg/kg may produce "mild" toxicity, with nausea, vomiting, and GI irritation, but significant toxicity is not expected. Acute ingestion of 150 to 300 mg/kg may produce "mild to moderate" toxicity, with vomiting, hyperpnea, diaphoresis, tinnitus, and acid-base disturbances. Acute ingestion of more than 300 mg/kg may produce "severe" toxicity.

The features of pediatric and adult salicylate intoxication differ. *Acute* pediatric salicylate intoxication is characterized by a known history of ingestion and onset of symptoms within a few hours of ingestion. Patients usually present soon after the ingestion. Symptoms are usually mild and the intoxication well tolerated. [15] The acid-base disturbance on presentation may be related to the patient's age. When the duration of salicylate intoxication is between 12 to 24 h, metabolic acidosis and acidemia (pH < 7.38) occur primarily in children younger than age 4, and nearly all children younger than age 1 have acidosis. [16] The acid-base disturbance in older children (age 4 or older) changes to a mixed disturbance with respiratory alkalosis, and increased anion-gap metabolic acidosis; alkalemia (pH > 7.42) tends to be observed.

Chronic or "therapeutic" (repeated dose) pediatric salicylate poisonings are generally more serious and are fatal more frequently than are acute ingestions. [15,17] Often, several days elapse between the initial administration of salicylate and the onset of symptoms. [17] There is often a coincidental illness that prompted the salicylate administration, and children usually appear more ill than those with acute intoxication. The presenting signs are hyperventilation, volume depletion, acidosis, severe hypokalemia, and CNS disturbances.[15] Chronic salicylism is often mistaken for an infectious process. Young children are prone to develop hyperpyrexia, which indicates a worse prognosis.[17] Renal failure may be a significant complication, but pulmonary edema is unusual in the pediatric population. [17] The delay in diagnosis may account for the more severe clinical picture with "therapeutic" salicylism.

Acute salicylate intoxication in adults is usually due to intentional ingestion, most often occurs in young women, and the patient frequently has a psychiatric or drug overdose history.[16] The typical clinical presentation includes nausea, vomiting, tinnitus, sweating, and hyperventilation, which are reported to occur when the serum salicylate concentration is above 30 mg/dL.[19] However, tinnitus may develop when the serum salicylate concentration exceeds 19.6 mg/dL.[19] Most patients have a mixed acid-base disturbance of respiratory alkalosis and metabolic acidosis.[20] However, when patients have also ingested sedative drugs that impair the hyperpneic response associated with salicylate toxicity, their acid-base profile is altered. Respiratory acidosis, rather than respiratory alkalosis, is more likely to occur. [20] Patients with mixed ingestions had a normal anion-gap metabolic acidosis 40 percent of the time compared with patients who had a larger mean anion gap when salicylate was ingested alone.[20] Therefore, salicylate intoxication in adults who present with a normal anion-gap metabolic acidosis should raise the suspicion that a coingestion including a CNS depressant has occurred. A normal anion gap does not rule out salicylate toxicity in patients with an unknown ingestion.

The complex triple-mixed acid-base disturbance of wide-anion-gap acidosis, metabolic alkalosis, and respiratory alkalosis may not be seen frequently in salicylate toxicity but, when it is noted, the differential diagnosis is quite limited. The only other wide-anion-gap acidosis seen with the other two components is sepsis (lactic acidosis, contraction metabolic alkalosis, and respiratory alkalosis). The main contribution to the metabolic acidosis in sepsis is lactate. In contrast, any lactic acidosis associated with salicylate poisoning should be mild unless there is significant hypotension and impaired tissue perfusion. The presence of significant lactic acidosis should always prompt a search for an alternate etiology (see Chap. 21).

Uncommon features of acute adult salicylism include fever, neurologic dysfunction, renal failure, adult respiratory distress syndrome (ARDS), noncardiogenic pulmonary edema, and hypoglycemia. Each of these uncommon manifestations indicates more severe poisoning, with associated greater morbidity and mortality rates. Hyperpyrexia appears to be an adverse prognostic indicator, and death is usually preceded by a predominant metabolic acidosis and neurologic deficits. [18,20] Other rare complications may include rhabdomyolysis, gastric perforation, and GI hemorrhage. Risk factors for death from acute salicylate toxicity include unconsciousness on presentation, fever, severe acidosis, seizures, cardiac dysrhythmias, and advanced age. The development of respiratory acidosis is usually a premorbid event.

The diagnosis of chronic salicylate intoxication (supratherapeutic misadventures or chronic excessive dosing) in adults is different, particularly in the elderly. These patients are more likely to have underlying medical conditions that they are treating with salicylates. [18] Signs and symptoms of chronic intoxication include hyperventilation, tremor, papilledema, agitation, paranoia, bizarre behavior, memory deficits, confusion, and stupor. [21] Neurologic abnormalities are much more common in chronic salicylate poisoning and often mislead physicians. [18] Chronic salicylism should be considered in any patient with unexplained CNS dysfunction, especially in the presence of a mixed acid-base disturbance, tachypnea or dyspnea, unexplained noncardiogenic pulmonary edema, or nonfocal neurologic or behavioral abnormalities. Adults with chronic salicylate toxicity have a higher morbidity rate, including pulmonary edema, seizures, and renal failure, as well as higher mortality rate.[18]

The distinction between acute and chronic salicylate toxicity may not always be clear. A patient may present many hours after an acute severe salicylate overdose, when altered mental status, acidosis, elevated prothrombin time, and serious toxicity with a "therapeutic" serum salicylate level are signs consistent with a chronically poisoned patient. Significant toxicity may be evident despite "therapeutic" or declining salicylate levels. In these situations, the patient's clinical status is the most important parameter in the assessment of the severity of toxicity.

Chronic salicylism may develop in patients taking carbonic anhydrase inhibitors for treatment of glaucoma. [22] The non-wide-anion-gap (hyperchloremic) metabolic acidosis produced by carbonic anhydrase inhibitors increases the volume of distribution for salicylate and facilitates its entry into the CNS, causing toxicity at a "therapeutic" salicylate blood level.

SPECIFIC ISSUES

The Done nomogram was created to assist in clarifying the level of salicylate intoxication that should prompt intervention: "This (nomogram) provides only a rough guide to a single criterion of severity in previously well patients ... it obviously does not supplant clinical judgement." [23] Although widely taught and used for almost 40 years, the Done nomogram is typically misunderstood and often misused. Thus, it is strongly recommended that the patient's clinical condition and early course, rather than the nomogram, guide clinical therapy. The nomogram was based primarily on previously healthy pediatric patients with acute single salicylate ingestion. [23] The patients' presentations were clinically graded. The initial serum salicylate concentration was extrapolated based on toxicokinetic data. The clinical grade was then correlated to the extrapolated initial salicylate concentration. The potential usefulness of the nomogram is to assist in predicting the degree of toxicity after an acute, single ingestion of ASA in patients who have not been taking salicylate recently. However, there are severe limitations to the usefulness of the Done nomogram. The nomogram is *not* useful when (1) salicylate has been ingested over several hours or days, (2) the preparation is an enteric-coated or a sustained-release tablet, (3) the compound is oil of wintergreen, which is rapidly absorbed, (4) the patient has renal insufficiency or failure, (5) the time of ingestion is unknown or uncertain, (6) the patient is acidemic, or (7) a salicylate level drawn before 6 h after ingestion returns nontoxic. In such situations, the clinical condition of the patient should be considered paramount and not the salicylate level. The degree of toxicity is determined by serial evaluation of a patient's clinical condition and serial salicylate levels. Evolution of a "nontoxic" salicylate level into severe salicylate intoxication has surprised many physicians. Failure to anticipate worsening intoxication is generally due to reliance on a single salicylate level, without regard to the formulation or the time of ingestion. If the level was drawn before 6 h, it may underestimate the severity. It is prudent in most patients to draw serial serum salicylate levels every 1 to 2 h until the levels are declining and the patient's clinical status stabilizes. Acidemia must alter estimation of the severity of the intoxication. Due to its limitations and deceptive utility, use of the Done nomogram is not recommended and, as such, a description of its use is not provided in this text.

The presence of salicylate may be determined with the ferric chloride test, which uses several drops of 10% ferric chloride added to 1 mL of urine. A purple color will be seen in the presence of salicylic acid, acetoacetic acid, or phenylpyruvic acid. This test is very sensitive to small quantities of salicylic acid, and a positive test result does not indicate salicylate poisoning or toxicity. False-negative results have not been reported. However, false-positive results may occur when a small quantity of urine that has been used for dipstick analysis with the N-multistix or Bili Labstix is then used for ferric chloride testing. Presumably, some impregnated chemical from the dipstick dissolves in the urine and causes a false-positive reaction. Another bedside test for salicylic acid utilizes the Ames Phenistix, which turns brown when either salicylic acid or phenothiazines are present in the urine or serum. Adding one drop of 20 *N* sulfuric acid to the strip bleaches out the color in the case of phenothiazines but not in the case of salicylic acid. The color change is often difficult to interpret. Both the ferric chloride and Ames Phenistix tests are qualitative tests. All positive urine results must be confirmed with serum salicylate level. There are severe limitations associated with bedside detection techniques for salicylic acid, and we do not advocate their use in the clinical setting.

Assessing the condition of patients who have ingested enteric-coated or a sustained-release aspirin preparation is difficult. These products are formulated to remain intact in the acidic gastric environment, but to dissolve in the alkaline intestinal fluids. Drug release is therefore primarily a function of gastric emptying, and peak levels may not be apparent until 10 to 60 h after ingestion. [2]

Another problem with enteric-coated and sustained-release tablets is their large size, which makes them difficult to remove from the stomach even through a 40-French gastric lavage tube. A plain radiograph of the abdomen has been recommended for enteric-coated medications, but not all are radiopaque. [24] Thus, a positive radiograph can confirm that pills are present, but a negative radiograph does not rule out an enteric-coated or sustained-release ASA in the GI tract. If a

potentially lethal number of enteric-coated or sustained-release tablets have been ingested, the patient should be observed for a minimum of 24 h and serial serum salicylate levels obtained until a declining level is assured. [2]

Many standard texts assert that urinary alkalinization is impossible until hypokalemia has been corrected. [16,25,26] The kidneys will attempt to excrete H^+ in order to retain potassium, leading to paradoxical aciduria despite alkalemia. However, there seem to be little or no clinical data specifically regarding the role of potassium replacement in alkalinization of urine during salicylate intoxication. In one human study, no correlation was found between serum potassium levels and urinary pH, and the patients' urines remained acidic in spite of alkalemia and normokalemia. [27] Although it is important to administer supplemental potassium to hypokalemic patients, it is inappropriate to delay the administration of sodium bicarbonate until normokalemia is achieved. Potassium and sodium bicarbonate should be administered simultaneously.

When aggressive management for ARDS with endotracheal intubation, mechanical ventilation, and sedation becomes necessary, hyperventilation must be maintained or acute deterioration may occur as a result of iatrogenic respiratory acidosis, causing a rapid shift of salicylate into the CNS.

TREATMENT

There is no specific antidote for salicylate toxicity. The main goals of therapy are immediate resuscitation; maintenance of airway, breathing, and circulation; correction of volume depletion and metabolic derangements; GI decontamination; and reduction in body salicylate burden.

The first step is to determine that clinically significant salicylate toxicity exists. This decision is made based on serial clinical assessment of the patient and serial serum salicylate concentrations. Recommended laboratory tests include serum electrolytes, glucose, blood urea nitrogen, creatinine, liver function tests, complete blood count, chest x-ray, electrocardiogram, and urinalysis with urine pH determination.

Reducing a patient's salicylate burden involves minimizing further absorption of salicylate from the GI tract and hastening elimination of salicylate already absorbed. Salicylate absorption is effectively reduced by the administration of activated charcoal (AC) both for regular and for sustained-release forms. [28] AC, 1 to 2 g/kg, should be administered to patients who have ingested potentially toxic amounts of salicylate. In contrast, no convincing data support the use of repeated doses or multiple doses of AC. Evidence supports the use of whole bowel irrigation as a more effective means of GI decontamination when dealing with enteric-coated or sustained-release ASA in the GI tract. [29]

Patients with severe salicylate intoxication are usually volume depleted and have acid-base disturbances that require general supportive and specific measures to enhance elimination. Careful assessment of a patient's volume and electrolyte status is important particularly in the elderly and in patients with a history of cardiac disease. Fluid replacement of volume deficits should be undertaken while preparations are made for other measures. A glucose-containing crystalloid (e.g., 5% D/0.9% NaCl) should be used in most patients because hypoglycemia has been implicated in the pathophysiology of salicylate CNS injury. [12] When hypokalemia is evident, potassium should be added to the intravenous fluids after urine output has been established. Note that correction of acidemia might further exacerbate hyopkalemia due to a shift of potassium into cells.

Urinary salicylate clearance is directly proportional to urine flow rate, but, more importantly, it is logarithmically proportional to urine pH. [30] Urine alkalinization is more effective than forced diuresis or forced alkaline diuresis, and it avoids the potential complication of fluid overload that may result from forced diuresis, especially in those with marginal cardiac reserve or cardiac performance. [30]

Opinions differ on the approach to initial fluid resuscitation and alkalinization of the urine. In practice, often both hydration and urine alkalinization are initiated simultaneously. Our approach has been to volume replete patients with normal saline with a target urine output of 1 to 2 mL/kg/h. Concurrently, in a second intravenous line, administer an intravenous bolus of sodium bicarbonate (1 to 2 meq/kg), followed by a continuous infusion of 5% D/W, to which 3 ampules (either 44 or 50 meq/ampule) of sodium bicarbonate have been added, starting at 1.5 to 2.0 times the maintenance rate and then adjusted to maintain the urine pH above 7.5. Except for the fluids used for hydration, all intravenous fluids administered should contain a minimum of 50 g/L glucose (5% D/W). [31] When hypoglycemia or neurologic symptoms are present, a minimum of 100 g/L glucose (10% D/W) has been suggested. [31] It is important to monitor the patient's clinical course diligently. The patient's urine pH, and serum salicylate concentration, as well as volume, acid-base and electrolyte status, and cardiopulmonary and neurologic status should be evaluated at least every hour. Potassium (40 meq/L) should be supplemented in the normal saline after adequate urine output has been established.

Patients with salicylate-induced (noncardiogenic) pulmonary edema should be managed as are patients with ARDS from other causes. Pulmonary edema begins to improve concomitantly with the lowering of serum salicylate levels. [8,18] This would suggest that aggressive efforts toward rapid elimination by hemodialysis may be beneficial in this subset of patients. In addition, early hemodialysis enables removal of salicylate without the volume challenge that accompanies sodium bicarbonate administration, and it avoids the possibility of aggravating pulmonary edema.

Although bleeding diathesis is frequently mentioned in texts, hemorrhagic complications are rarely seen in single massive salicylate overdoses. Salicylate has a molecular structure similar to both vitamin K and dicumarol. Chronic administration of large doses does cause significant hypoprothrombinemia when serum salicylate concentration exceeds 60 mg/dL. [13] Hemorrhage, even under this scenario, however, is rarely seen in clinical practice or in animal experiments. When bleeding does occur, it rarely appears to be a contributing factor in death from salicylate poisoning. Patients who are actively bleeding should have judicious administration of fresh-frozen plasma and vitamin K_1. Observations in animals and humans indicate that administering large doses of vitamin K after the development of hypoprothrombinemia has little or no effect on the plasma prothrombin time when salicylate concentration is high. After discontinuing salicylate, the prothrombin time rapidly returns to normal.

Hemodialysis is considered the extracorporeal technique of choice for the treatment of serious salicylate toxicity, because hemodialysis can normalize acid-base and electrolyte abnormalities while rapidly reducing the salicylate burden. [32] Indications for hemodialysis include (1) clinical deterioration despite intensive supportive care and an alkaline diuresis, (2) unsuccessful attempts to detect clinical deterioration and an alkaline urine, (3) renal insufficiency or renal failure, (4) severe acid-base disturbance, (5) altered mental status, and (6) patients with ARDS.

Determination of the serum salicylate concentration may be helpful but should not be the sole determinant in the decision to initiate hemodialysis. A level of 100 mg/dL after an acute ingestion in a healthy patient may not require hemodialysis, whereas a patient with a level of 30 mg/dL in a chronic ingestion may be moribund. One should err on the side of hemodialysis in patients who are elderly, have ingested ASA chronically, have altered mental status, have acidemia, or have a severe underlying disease (e.g., coronary artery disease or chronic obstructive pulmonary disease).

In significant ingestions, serum salicylate levels should be monitored at least every 2 h until a peak has been reached and then every 4 to 6 h until the peak falls into the nontoxic range. In severe ingestions, serum salicylate levels should be determined hourly and clinical decisions should be based on the trend of the serum salicylate levels as well as the patient's clinical status.

DISPOSITION

A patient may be discharged following adequate GI decontamination, if there is progressive clinical improvement, no significant acid-base disturbance, and a documented serial decline in serum salicylate levels toward the therapeutic range. If there is any doubt, the patient should be admitted to an appropriate setting.

In the management of salicylism, "knee jerk" responses should be avoided when assessing salicylate level. Therapeutic decisions should not be based solely on the serum salicylate concentration. Although the determination of serial salicylate levels offers valuable information regarding the effectiveness of the treatment implemented, it is a poor substitute for clinical evaluation of a patient. The final decision when considering management options should be individualized according to the clinical condition of the patient and not depend on a particular salicylate level. Early consultation with a clinical toxicologist is prudent.

165 ACETAMINOPHEN

Oliver Hung
Lewis S. Nelson

Acetaminophen (*N*-acetyl-*p*-aminophenol, or APAP) is the most popular over-the-counter analgesic used in the United States. As an ingredient found in a wide variety of prescription and over-the-counter remedies, acetaminophen is one of the most common toxic exposures reported to poison centers nationwide. Because of its ubiquitous presence, acetaminophen poisonings often occur because of the erroneous belief that this medication is benign or because the victim was unaware that it was an ingredient in the ingested preparation. According to the Toxic Exposure Surveillance System in 1996, acetaminophen accounted for 5 percent of all toxic exposures, but also accounted for 11 percent of reported fatalities. [1]

PHARMACOLOGY

The recommended dosing of acetaminophen is 650 mg every 4 to 6 h up to 4 g a day in adults and 10 to 15 mg/kg every 4 to 6 h in children. After ingestion, acetaminophen is rapidly absorbed from the gastrointestinal (GI) tract. In therapeutic doses, peak serum levels are usually achieved within 30 min to 2 h. Even in overdose, peak serum levels are usually achieved within 2 h. However, delayed absorption of acetaminophen has been reported with overdoses of acetaminophen propoxyphene preparations and overdose of a new acetaminophen preparation, Tylenol Extended Relief.

Acetaminophen is primarily metabolized by the liver through sulfation (20 to 46 percent) and glucuronidation (40 to 67 percent). A small percentage (less than 5 percent) of acetaminophen undergoes direct renal elimination. A small percentage is also oxidized by cytochrome P-450 to a toxic metabolite, *n*-acetyl-*p*-benzoquinoneimine (NAPQI), which is quickly detoxified by hepatic stores of glutathione to a nontoxic acetaminophen-mercaptate compound that can be eliminated through renal excretion (Fig. 165-1A).
FIG. 165-1A and B. Acetaminophen (*N*-acetyl-*p*-aminophenol, or APAP) metabolism.

However, during acetaminophen overdose, hepatic metabolism through glucuronidation and sulfation is quickly saturated. A larger proportion of acetaminophen is metabolized by cytochrome P-450 to NAPQI, depleting glutathione. When hepatic stores of glutathione decrease to less than 30 percent of normal, hepatic toxicity occurs. A reactive metabolite, NAPQI readily binds to other sulfur containing amino acids, primarily hepatic proteins and enzymes (Fig. 165-1B). Within the hepatic lobule, cytochrome P-450 is concentrated within hepatocytes surrounding the terminal hepatic vein and least concentrated within hepatocytes surrounding the portal triad. As a result, acetaminophen-induced hepatic injury results in the characteristic feature of hepatic centrilobular necrosis (Fig. 165-2).
FIG. 165-2. Hepatic centrilobular necrosis. THV, terminal hepatic vein.

Although the clinical manifestations of acetaminophen toxicity are classically delayed, hepatic injury actually occurs very early. In an animal model of acetaminophen hepatic toxicity, early signs of hepatic necrosis occurred within 12 h of exposure. [2] This was based on microscopic evidence of hepatic cellular necrosis and immunofluorescent staining of NAPQI-hepatic protein adducts (3-Cys-A) within hepatocytes. Hepatic necrosis continues to progress until day 2, when cell lysis occur, releasing hepatic enzymes such as transaminases and NAPQI-hepatic protein adducts into the circulation where they can be detected in the serum. This corresponds to the development of clinical toxicity in humans (Fig. 165-3).
FIG. 165-3. Acetaminophen (APAP) toxicity time course. *Abbreviations:* 3-Cys-A, APAP-hepatic protein adduct; ALT, alanine aminotransferase. From Roberts et al,[2] with permission.

CLINICAL PRESENTATION

The clinical presentation of human acetaminophen toxicity can be roughly divided into four stages. During the first 24 h after exposure (stage 1), patients often have minimal signs and symptoms of toxicity. Many patients may be asymptomatic and appear normal. Some may have minor, nonspecific GI signs and symptoms, such as anorexia, nausea, vomiting, and malaise. By days 2 to 3 (stage 2), clinical signs of hepatotoxicity that may be discerned in hepatotoxic patients include right upper quadrant abdominal pain and tenderness, and abnormal laboratory test results, such as elevated serum aspartate aminotransferase (AST), alanine aminotransferase (ALT), and bilirubin. Even without treatment, most of these patients will recover without sequelae. By days 3 to 4 (stage 3), however, the condition of some patients will progress to fulminant hepatic failure. Characteristic findings include metabolic lactic acidosis, coagulopathy, renal failure, encephalopathy, and recurrent GI symptoms. Those patients who survive the complications of fulminant hepatic failure will begin to recover over the next week (stage 4), with complete resolution of hepatic dysfunction in survivors.

Patients with insufficient glutathione stores (alcoholics and AIDS patients) and patients with induced cytochrome P450 enzymatic activity (alcoholics and those taking concurrent anticonvulsant or anti-tuberculous medications) may be at greater risk for developing acetaminophen-induced hepatotoxicity following overdose. In contrast, children, because of their greater ability to metabolize acetaminophen through hepatic sulfation, may be at decreased risk for developing hepatotoxicity when compared with adults.[3]

Acetaminophen may also cause acute, extrahepatic toxic effects, presumably due to the presence of cytochrome P-450 present in other organs. Ingestion of massive doses of acetaminophen (4-h acetaminophen level greater than 800 μg/mL) has been associated with the acute development of altered sensorium (coma or agitation) and metabolic acidosis.[4] Acetaminophen overdose has also been infrequently associated with the direct development of renal insufficiency. In rare cases, cardiac toxicity and pancreatitis have also been reported.

DIAGNOSIS

A toxic exposure to acetaminophen is possible when more than 140 mg/kg is ingested in a single dose or when more than 7.5 g is ingested within a 24-h period. Unlike other types of poisoning, the diagnosis of acetaminophen toxicity depends on laboratory testing, because the initial clinical presentation is unhelpful and nonspecific. Also, the initial manifestations of toxicity (GI signs and symptoms) are usually delayed.

The diagnosis of acetaminophen toxicity depends solely on obtaining a serum acetaminophen level and estimating the time of ingestion. The acetaminophen level should be determined for all patients arriving at the emergency department (ED) with overdose of any drug. Acetaminophen is widely available in many single and multidrug over-the-counter and prescription medications. Consequently, many patients are unaware of their ingestion of acetaminophen. In one study, one in 500 patients arriving at the ED after an overdose and denying a history of acetaminophen ingestion was determined to have potentially toxic acetaminophen levels. [5] In economic terms, empirical testing of all patients with intentional overdoses may be cost effective. The cost of treatment of one patient for complications of acetaminophen-induced hepatotoxicity is commonly estimated to outweigh the cost of laboratory testing for 500 patients with nontoxic acetaminophen levels.

The interpretation of a measured acetaminophen level depends on plotting the level on the Rumack-Matthew nomogram [6] (Fig. 165-4). This nomogram was empirically based on a retrospective analysis of previous acetaminophen overdose patients and their clinical outcomes. The original nomogram line was based on a 4-h acetaminophen level of 200 μg/mL, but was subsequently modified in the United States by the FDA to increase the safety margin by moving the line to a 4-h acetaminophen level of 150 μg/mL. More importantly, the nomogram only applies to an acetaminophen level measured after 4 h following ingestion and before 24 h after ingestion. It cannot be applied to acetaminophen levels determined outside of that 20-h period.
FIG. 165-4. Rumack-Matthew nomogram. *Abbreviation:* APAP, *N*-acetyl-*p*-aminophenol (acetaminophen). From Rumack and Matthew,[6] with permission.

Measuring multiple acetaminophen levels is not indicated. The nomogram cannot interpret multiple levels because it is not based on acetaminophen kinetics. In addition, the calculation of acetaminophen kinetics by measuring multiple levels over a short period is usually mathematically inaccurate because of the intrinsic laboratory error present in the acetaminophen assay.

Based on historical data before the widespread use of antidotal therapy, patients with serum acetaminophen levels above the original 200 μg/mL nomogram were observed to have a 60 percent risk of developing hepatotoxicity (AST >1000 IU/mL), 1 percent risk of renal failure, and a 5 percent risk of death. [7] In addition, patients with extremely high serum acetaminophen levels (above a parallel line coinciding with a 300 μg/mL 4-h level) were observed to have a greater risk (90 percent) of developing hepatotoxicity (Fig. 165-5). The safety level below the US nomogram line (4-h level corresponding to 150 μg/mL) was confirmed in a prospective study involving 11,195 patients.[8] The risk of hepatotoxicity in patients with acetaminophen levels below the nomogram was 1 percent. No patients received antidotal therapy, and all recovered without any complications (Fig. 165-6).
FIG. 165-5. Outcomes of acetaminophen overdose (no antidote treatment). *Abbreviations:* APAP, *N*-acetyl-*p*-aminophenol (acetaminophen); AST, aspartate aminotransferase. Adapted from (1) from Prescott[7] and (2) Smilkstein et al,[8] with permission.

TREATMENT

Treatment for acetaminophen toxicity consists of GI decontamination, the timely use of the antidote— *N*-acetylcysteine (NAC)—and supportive care. For most cases of acetaminophen poisoning, adequate GI decontamination consists of the early administration of activated charcoal orally or through nasogastric tube. Emesis induced by administering syrup of ipecac is undesirable because it delays the administration of the antidote, NAC. In addition, more aggressive forms of decontamination such as orogastric lavage or whole bowel irrigation, are unnecessary because of the rapid GI absorption of acetaminophen and the great success of treating acetaminophen poisoning with NAC. However, aggressive GI decontamination should be considered in cases of polydrug overdose in which a coingestant is likely to be life-threatening (e.g., a cyclic antidepressant or a sustained-release calcium-channel blocker).

The mainstay of treatment for acetaminophen toxicity is the administration of the antidote, NAC. Although its mechanisms of action are not fully understood, NAC is thought to have two important beneficial effects. In early acetaminophen toxicity (less than 8 h after ingestion), NAC prevents toxicity by inhibiting the binding of the toxic metabolite NAPQI to hepatic proteins. NAC may act as a glutathione precursor or substitute, act as a sulfate precursor, or it may directly reduce NAPQI back to acetaminophen. In late acetaminophen toxicity (more than 24 h after ingestion), NAC diminishes hepatic necrosis by nonspecific mechanisms. NAC may act as an antioxidant, decrease neutrophil proliferation, improve microcirculatory blood flow, and increase tissue oxygen delivery and extraction.

The standard 72-h oral NAC regimen used in the United States is a loading dose of 140 mg/kg followed by maintenance doses 70 mg/kg every 4 h for 17 doses. If treatment is initiated within 8 h of acetaminophen ingestion, NAC is nearly 100 percent effective in preventing the development of hepatotoxicity, as defined by an AST level of greater than 1000.[8] The longer NAC therapy is delayed past 8 h after ingestion, the greater is the risk of developing hepatotoxicity. Even by 24 h after acetaminophen ingestion, however, NAC treatment is associated with a lower risk of hepatotoxicity than are historical controls [7] (Fig. 165-6).

The major complications of oral NAC therapy are nausea and vomiting due to its foul odor and taste of rotten eggs. To hide these disagreeable characteristics, the standard 10% or 20% NAC solution should be diluted to a 5% concentration in a chilled beverage such as fruit juice or a soft drink prior to administration. NAC's disagreeable odor may be further minimized by having the patient sip the drink through a straw from a covered cup or by administering the dose by nasogastric or duodenal tube. Some patients with persistent nausea and vomiting may require concomitant antiemetic treatment with intravenous (IV) metoclopramide (Reglan), 0.1 mg/kg up to 1.0 mg/kg, ondansetron (Zofran), 0.15 mg/kg, or granisetron (Kytril), 0.01 mg/kg, to prevent vomiting and to administer NAC successfully.

Alternative IV NAC regimens have been used successfully in other countries for over 20 years but remain experimental in the United States. [9,10] These regimens possess potential limitations. IV NAC administration may be less effective for the treatment of acetaminophen overdoses in patients arriving more than 10 h after ingestion and is also associated with anaphylactoid reactions. [11] At this time, the clinical experience of IV NAC usage in the United States remains too limited to recommend it as a replacement for the traditional oral NAC regimen used for early acetaminophen poisoning. However, IV administration of NAC may be required for patients with refractory vomiting and for patients with contraindications to oral therapy (e.g., caustic ingestions). IV NAC may also be preferable to oral NAC for the treatment of acetaminophen-induced fulminant hepatic failure. [12]

Currently, there is no IV NAC formulation available in the United States. If it is to be used, the oral NAC formulation, which is sterile, can be made into an IV formulation. Clinical experience suggests that patients with poor glutathione reserves have similar excellent clinical outcomes when the standard treatment guidelines are applied to their care. Thus, the dosage of NAC should not be modified for these patients.

In many clinical situations, NAC therapy is often started in close temporal proximity to the administration of activated charcoal. Although NAC is adsorbed by activated charcoal, there is no evidence that activated charcoal inhibits the clinical effectiveness of NAC. [13] Most authorities believe that NAC dosing is probably excessive. NAC dosing is based on a patient's weight and bears no relationship to the dose of acetaminophen ingested. In addition, NAC appears to be equally effective in preventing hepatotoxicity following the largest acetaminophen overdose. [14] Separating the first dose of NAC and activated charcoal by 1 to 2 h, when possible, is a reasonable method to minimize potential NAC and activated charcoal interaction.

There are no data on which order is superior, and there is no evidence that administration of activated charcoal and NAC in a closer time frame is a problem.

Finally, the weight of clinical evidence suggests that NAC therapy is safe to use during pregnancy and that the approach to treating a pregnant patient following an acetaminophen overdose should remain the same. An ovine model demonstrated that NAC was unable to cross the placenta. [15] Finally, fetal demise and malformations have been described when NAC treatment was delayed for acetaminophen overdose in first-trimester pregnant women. [15]

TREATMENT GUIDELINES

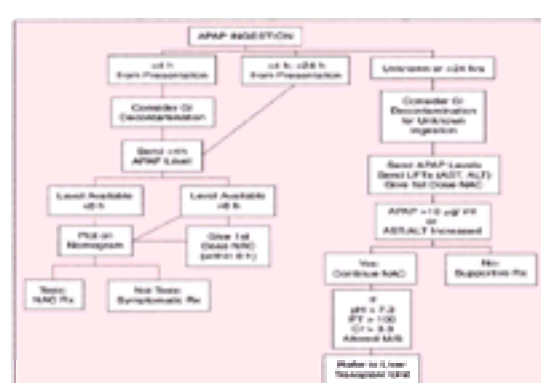
Treatment guidelines for acetaminophen poisoning are based on the time to presentation to the ED after ingestion: acetaminophen ingestions less than 4 h prior to presentation, acetaminophen ingestions longer than 4 h but less than 24 h ago, and acetaminophen ingestions of unknown time or longer than 24 h prior to presentation (Fig. 165-7). No further acetaminophen serum measurements are necessary once the need for NAC therapy has been determined. Treatment with NAC should continue for the full 72-h course (18 doses).


FIG. 165-7. Treatment guidelines for acetaminophen ingestion. *Abbreviations:* ALT, alanine aminotransferase; APAP, *N*-acetyl-*p*-aminophenol (acetaminophen); AST,

aspartate aminotransferase; GI, gastrointestinal; LFTs, liver function tests; M/S ; NAC, *Ν*-acetylcysteine; PT, prothrombin time; Rx, treatment.

For patients with acetaminophen ingestions who present within less than 4 h to the ED, treatment begins with GI decontamination (usually activated charcoal) and awaiting the determination of a 4-h postingestion acetaminophen level. If the hospital laboratory can determine the acetaminophen level within 8 h after ingestion, the clinician should wait for that measurement and plot it on the nomogram to determine whether NAC therapy is necessary. If the hospital laboratory cannot determine the acetaminophen level within 8 h, the clinician should empirically administer the first dose of NAC (within 8 h of acetaminophen ingestion) without waiting for the measurement. Subsequently, when the acetaminophen level is determined, it should be plotted on the nomogram to determine whether additional NAC therapy is necessary.

For patients with acetaminophen ingestions who present longer than 4 h but less than 24 h to the ED, the serum acetaminophen level should be determined by the laboratory as soon as possible. GI decontamination may be performed, but it may have limited effectiveness because of the delay in presentation. It should be considered more in light of possible coingestions. Similarly, if the hospital laboratory can determine the acetaminophen level within 8 h after ingestion, the clinician should wait for the serum acetaminophen level and plot it on the nomogram to determine whether NAC therapy is necessary. Otherwise, the first dose of NAC (within 8 h of acetaminophen ingestion, if possible) should be administered without waiting for the measurement. When the acetaminophen level is determined, it should be plotted on the nomogram to determine whether additional NAC therapy is necessary.

Finally, for acetaminophen ingestions of unknown time or longer than 24 h ago, the clinician should consider whether GI decontamination is required. A serum acetaminophen level should be determined and liver function tests (AST and ALT) should be performed by the hospital laboratory. In addition, the first dose of NAC therapy should be started as soon as possible. In this scenario, a detectable acetaminophen level (>10 µg/mL) suggests that the patient may be at risk for developing hepatotoxicity. Similarly, elevated AST and ALT enzymes suggest the possibility of ongoing hepatic toxicity. Therefore, continued NAC therapy is indicated if the acetaminophen level is measurable or if the serum AST or ALT is elevated.

Supportive therapy for acetaminophen poisoning, as in all overdose presentations to the ED, should include obtaining early IV access and a 12-lead electrocardiogram interpretation to exclude cardiac toxins (e.g., cyclic antidepressants, digoxin, b blockers, and calcium-channel blockers). Hypoglycemia and hypoxemia should be quickly considered and excluded for all patients presenting with altered sensorium. All patients requiring NAC therapy should be admitted to the hospital until the completion of the therapy. In general, admission to an unmonitored hospital bed is adequate unless a patient is hemodynamically unstable or a patient is suicidal and 24 h direct observation cannot be arranged. Patients who are not at risk for developing acetaminophen-induced hepatotoxicity (acetaminophen level below the nomogram, unmeasurable acetaminophen level with normal liver function test results) should be observed in the ED for a minimum of a 4 to 6-h period to exclude potentially toxic coingestants. This observation period is sufficient to exclude untoward events. Psychiatric evaluation should be considered for all patients with intentional acetaminophen overdose.

FULMINANT HEPATIC FAILURE

Unfortunately, a small percentage of patients with toxic acetaminophen ingestions will develop fulminant hepatic failure. The mortality rate for these patients (without NAC therapy) is estimated to be 58 to 80 percent. Most fatalities occur on days 3 to 5 after overdose and are attributed to hepatic complications such as cerebral edema, hemorrhage, shock, acute respiratory distress syndrome, sepsis, and multiorgan failure. Patients who eventually survive fulminant hepatic failure generally begin to show evidence of their recovery by days 5 to 7. Eventually, all survivors will develop complete hepatic regeneration without any persistence of hepatic impairment.

NAC also appears to be beneficial in the treatment of acetaminophen-induced fulminant hepatic failure. When compared with controls, NAC therapy was associated with increased survival (48 vs 20 percent), decreased cerebral edema (40 vs 68 percent), and decreased vasopressor requirements (40 vs 80 percent). [12] NAC appears to be beneficial in the treatment of other forms of hepatic failure, too, including viral hepatitis and alcoholic cirrhosis. [16]

Prognostic indicators have been developed to determine those patients with the highest risk of mortality from acetaminophen-induced fulminant hepatic failure. As a result, they also serve as early predictors of patients who will subsequently require liver transplantation. A variety of laboratory and clinical markers have been used, including serum pH, prothrombin time (PT), serum creatinine, and mental status evaluation. The presence of a metabolic acidosis, pH < 7.3, despite fluid and hemodynamic resuscitation, or a combination of coagulopathy (PT > 100), renal failure (creatinine > 3.3 mg/dL), and encephalopathy (grade III or IV) is extremely useful in predicting patients who will die without liver transplantation. [17]

Treatment for acetaminophen-induced fulminant hepatic failure includes NAC therapy, aggressive correction of coagulopathy and acidosis, monitoring for and aggressive treatment for cerebral edema, and early patient referral to a liver transplant center. Unlike the treatment of early acetaminophen toxicity, NAC therapy should be continued past the 72-h standard regimen until the patient recovers, receives a liver transplant, or dies. Since all clinical studies supporting the use of NAC to treat fulminant hepatic failure utilized the IV administration of NAC, IV NAC therapy may be preferable to oral NAC. IV NAC should be administered at the same dosage as oral NAC. Because of the risk of anaphylactoid reaction, IV NAC infusions should be administered slowly and adjusted based on repeated blood pressure measurements to prevent hypotension.

SPECIAL CONSIDERATIONS: MULTIPLE-DOSE ACETAMINOPHEN INGESTIONS AND TYLENOL EXTENDED RELIEF

Multiple-dose acetaminophen ingestions and Tylenol Extended Relief ingestions represent two unique aspects of acetaminophen poisoning since the Rumack-Matthew nomogram does not apply to these two scenarios. In addition, since there is little clinical data regarding multiple-dose acetaminophen ingestions and Tylenol Extended Relief, treatment guidelines remain conservative.

The scenario of multiple ingestions of acetaminophen over a period of time is problematic because the acetaminophen level measured cannot be interpreted by the nomogram since a specific single time of ingestion cannot be determined. Theoretically, an ingestion of multiple doses of acetaminophen over a period of time should be less toxic than a single ingestion of the same total dose of acetaminophen. In the case of multiple doses, the liver may be able to regenerate glutathione stores between ingestions to lessen the possibility or severity of hepatic toxicity. However, the approach to multiple acetaminophen ingestions remains conservative. A single ingestion is assumed to occur at the earliest possible time stated by the patient. Based on this artificial time, an acetaminophen level is plotted on the Rumack-Matthew nomogram and treatment decisions are made accordingly. For example, if a patient ingests five doses of 50 mg/kg of acetaminophen over a 4-h period beginning 8 h earlier, a single acetaminophen ingestion is assumed to have occurred 8 h earlier and the serum level is plotted on the nomogram.

Tylenol Extended Relief (Tylenol ER) represents a new acetaminophen formulation by McNeil Pharmaceuticals. [18] These caplets consist of a bilayered formulation containing a total of 650 mg acetaminophen. One side of the caplet contains 325 mg of "regular" immediate-release acetaminophen. The other side consists of 325 mg acetaminophen placed within a slowly releasing matrix. Ingestion of these caplets results in prolonged GI absorption that may delay peak acetaminophen levels when compared with the original formulation. In addition, there are case reports describing Tylenol ER ingestions in which the initial acetaminophen level was below the nomogram line, but a second acetaminophen level was found to "cross the nomogram line." [19] These reports should be interpreted with caution since the Rumack-Matthew nomogram was not meant to apply and cannot be applied to ingestions of Tylenol ER.

Currently, no data suggest that Tylenol ER is more toxic than regular acetaminophen. Theoretically, Tylenol ER could be less toxic than an equivalent amount of regular acetaminophen since the prolonged GI absorption may allow additional time for hepatic regeneration of glutathione. Because of the continued uncertainty, however, the approach remains conservative. Two additional hours are added to the estimated time of ingestion to increase the safety margin and to account for potential ingestions that might "cross the nomogram" (i.e., the 6-h postingestion level is read as a 4-h postingestion level). The acetaminophen level and the "revised" time of ingestion are plotted on the nomogram to determine risk of toxicity.

166 NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

G. Richard Bruno
Wallace A. Carter

Nonsteroidal anti-inflammatory drugs (NSAIDs) are among the most widely used and prescribed drugs in the United States. They are effective antipyretics, nonnarcotic analgesics, and anti-inflammatory agents. There are between 35 and 70 million NSAID prescriptions written in United States each year, and several agents are now available over the counter.[1] The world market for NSAIDs is reported to be a 6 billion dollars per year industry. Given the tremendous use and easy availability of NSAIDs, they are relatively safe agents with respect to acute ingestion and overdose. The American Association of Poison Control Centers (AAPCC) reports 261,795 NSAID exposures resulting in 2130 major outcomes (life-threatening signs and symptoms or significant residual disability) and 26 deaths between 1992 and 1996. These cumulative data compare favorably to aspirin and acetaminophen, with fewer major outcomes and deaths per exposure (Table 166-1). The morbidity from NSAIDs in acute overdose is far overshadowed by complications of NSAIDs at therapeutic doses. It is estimated that NSAID-related gastrointestinal (GI) bleeding accounts for 7500 deaths and 75,000 hospitalizations annually in the United States. [2] NSAIDs have also be reported to account for a substantial proportion of drug-induced renal failure. This chapter reviews basic pharmacology of NSAIDs, significant interactions of NSAIDs with other drugs, side effects of chronic NSAIDs use, clinical presentation of acute overdose, and management of overdose.

5-Year Cumulative AAPCC Data, 1992-1996	NSAIDs	Acetaminophen	Aspirin
Number of exposures	261,795	357,866	79,754
Major outcomes*	634	2,130	721
Deaths	26	248	213

*Major outcomes are defined as signs or symptoms that are life threatening or result in significant disability.
Abbreviations: AAPCC, American Association of Poison Control Centers; NSAIDs, nonsteroidal anti-inflammatory drugs.

TABLE 166-1   Major Outcomes and Deaths

PHARMACODYNAMICS

NSAIDs are a structurally varied group of compounds with common therapeutic effects (Table 166-2). NSAIDs inhibit the enzyme cyclooxygenase (COX), which is responsible for the production of prostaglandins from arachidonic acid. NSAIDs mediate inflammation through inhibition of prostaglandin production but may also inhibit neutrophils via nonprostaglandin mechanisms. NSAIDs work as antipyretics through inhibition of prostaglandin E $_2$ (PGE$_2$) in the hypothalamus. The mechanism of NSAID-mediated analgesia is less clear than anti-inflammatory and antipyretic effects, but NSAIDs appear to attenuate prostaglandin-mediated hyperalgesia and local pain-fiber stimulus.

Salicylates
 Aspirin
 Salsalate (Salflex, Disalcid)
 Diflunisal (Dolobid)
Acetic acids
 Tolmetin (Tolectin)
 Ketorolac (Toradol)
 Diclofenac (Voltaren)
 Indomethacin (Indocin)
 Sulindac (Clinoril)
 Nabumetone (Relafen)
 Etodolac (Lodine)
Fenamic acids
 Mefenamic acid (Ponstel)
 Meclofenamate (Meclomen)
Propionic acids
 Ibuprofen (Advil, Motrin, Nuprin)
 Naproxen (Naprosyn, Aleve)
 Ketoprofen (Orudis)
 Fenoprofen (Nalfon)
 Flurbiprofen (Ansaid)
 Oxaprozin (Daypro)
Pyrazolones
 Phenylbutazone
Oxicams
 Piroxicam (Feldene)

TABLE 166-2   Classes of Nonsteroidal Agents Available in the United States

There are at least two forms of cyclooxygenase: COX I and II. COX I is found predominately in blood vessels, stomach, and kidneys at steady levels. COX II is not usually found at significant levels in human tissue; rather, production of the enzyme is induced by local inflammatory mediators. Most NSAIDs inhibit both COX I and COX II. Inhibition of COX I is believed to be responsible for much of the unwanted side effects of NSAIDs. Work is currently under way to develop selective inhibitors

of COX II, which may be better anti-inflammatory agents and have fewer ill effects on the renal/GI and vascular system.

PHARMACOKINETICS

All NSAIDs are rapidly absorbed from the GI tract and are highly protein bound in the plasma. Most NSAIDs undergo at least partial metabolism in the liver via glucuronic acid conjugation or oxidation in the microsomal enzyme system before elimination in the urine or feces. Plasma half-lives of NSAIDs range from 2 to 4 h for ibuprofen to longer than 50 h for the long-acting agents piroxicam and phenylbutazone.

SIGNIFICANT DRUG-DRUG INTERACTION

Warfarin

Warfarin and NSAIDs have important interactions. Two NSAIDs (phenylbutazone and naproxen) have been reported to displace warfarin from plasma proteins, leading to increased warfarin levels in serum and elevated prothrombin times. Phenylbutazone has also been shown to decrease elimination of warfarin. Other NSAIDs have not been reported to change warfarin protein binding or elimination, but the use of any NSAID is contraindicated in warfarin users because NSAID inhibition of platelet aggregation may significantly increase the risk for bleeding.

Diuretics and Other Antihypertension Agents

NSAIDs may decrease the effectiveness of some antihypertensives, including diuretics, a-adrenergic blockers, angiotensin-converting enzyme inhibitors, and b-adrenergic blockers. The blood pressure change when both NSAIDs and antihypertensives are used ranges from little effect to hypertensive urgencies. Inhibition of prostaglandin synthesis is believed to be central to the attenuation of antihypertensive effects. Lower prostaglandin levels result in decreased renal sodium clearance, water retention, changes in vascular tone, and alterations in the renin-angiotensin system, all which may attenuate the effectiveness of antihypertensive agents. [3]

Decrease Renal Clearance of Drugs

NSAIDs may also decrease the renal clearance and elimination of certain drugs. NSAID use inhibits renal clearance of lithium and leads to elevated serum lithium levels. Methotrexate elimination is also decreased with coadministration of NSAIDs and has resulted in fatal toxicity.

CLINICAL PRESENTATION OF TOXICITY

Toxicity of NSAIDs at Therapeutic Doses

NSAIDs are relatively safe drugs that have a number of well-documented side effects at therapeutic doses. Given the huge number of NSAID prescriptions written by emergency department physicians, it is important to be aware of common side effects. Morbidity and death from renal insufficiency and GI bleeding with chronic NSAID use far overshadow that of acute NSAID overdose. Other organ systems that may show toxicity at therapeutic doses include the central nervous system (CNS), cardiovascular, respiratory, hepatic, and dermatologic. It is generally believed that indomethacin and the long-acting agents phenylbutazone and piroxicam are responsible for a greater proportion of side effects, and that the propionic acid agents such as ibuprofen are responsible for fewer side effects.

Central Nervous System

Toxic CNS side effects of NSAIDs are far less frequent than GI or renal toxicity; however, various CNS effects include headache, cognitive difficulties, behavioral change, and aseptic meningitis. Acute psychosis has been reported with indomethacin and sulindac use and is hypothesized to result from the structural similarity of these NSAIDs to serotonin.

One of the most interesting side effects of NSAID use is aseptic meningitis. The literature reports cases in which patients repeatedly present with symptoms of headache, fever, neck stiffness, and fever within hours of taking NSAIDs. Cerebrospinal fluid analysis in these patients reveals elevated white blood cell, elevated protein, and normal or decreased glucose levels. Symptoms resolve after NSAID use is stopped and can be elicited with repeat NSAID challenges. This phenomenon is most often seen with patients who have underlying autoimmune diseases, such as systemic lupus erythematosus. The phenomenon is thought to be a hypersensitivity reaction. A complete workup to rule out infectious meningitis must be undertaken before the diagnosis of NSAID-induced aseptic meningitis is entertained.[4]

Pulmonary System

NSAIDs have been responsible for various adverse pulmonary reactions, including hypersensitivity pneumonitis, bronchospasm in asthmatics, and pulmonary edema. Patients with NSAID-related hypersensitivity pneumonitis present with symptoms of fever, cough, shortness of breath, pulmonary infiltrates on chest x-ray, leukocytosis, and often-peripheral eosinophilia. Cessation of NSAIDs results in the resolution of symptoms, whereas readministration causes a recurrence of symptoms. NSAIDs implicated in hypersensitivity pneumonitis include naproxen, diflunisal, piroxicam, sulindac, and diclofenac. The mechanism of NSAID-mediated pneumonitis is believed to be an immune-mediated hypersensitivity reaction.

NSAID-induced bronchospasm is a well-described phenomena in patients with reactive airway disease. The spectrum of hypersensitivity reaction varies from rhinitis to severe bronchospasm with laryngeal edema. Patients with underlying reactive airway disease and nasal polyps appear to be at greater risk for these complications. Aspirin is most often involved in hypersensitivity reactions. Aspirin-induced bronchospasm occurs in 8 to 20 percent of all asthmatics and in 14 to 23 percent of asthmatics with nasal polyps.[5] Cross-sensitivity between aspirin and other NSAIDs is believed to be as high as 90 percent. [6] The mechanism of this hypersensitivity to NSAIDs in asthmatics has not been identified but does not appear to be an immunoglobulin E-mediated event.

Gastrointestinal-Hepatic System

Perhaps the greatest morbidity from NSAID use is bleeding from the GI tract. At therapeutic doses, NSAIDs inhibition of cytoprotective gastric prostaglandins (PGI_2 and PGE_2) increases the risk of gastric erosion, gastritis, and GI bleeding. There is a two- to fivefold increased risk of perforation or hemorrhage in NSAID users over the non-NSAID-using population. Data suggest that the risk for life-threatening bleeding is between 1.3 and 4 percent per year among NSAID users. It is estimated that NSAID-related GI bleeding contributes to 7500 deaths and 75,000 hospitalizations annually in the United States. The prostaglandin analogue misoprostol is effective at preventing NSAID-related gastric erosions at doses of 200 μg qid. Recently, the proton-pump inhibitor omeprazole has been shown to be effective at treating NSAID-related ulcers, but its role in prophylactic therapy is less clear. [7]

Hepatic System

NSAIDs may cause a spectrum of hepatic dysfunction from asymptomatic elevation of transaminases to fulminant hepatic failure. NSAIDs that have caused idiosyncratic fulminant hepatic failure include diclofenac, bromfenac, ibuprofen, sulindac, naproxen, phenylbutazone, and oxaprozin. Hepatic toxicity can occur at any time during NSAID administration and is most common in patients with underlying liver disease, in the elderly, and in patients with preexisting autoimmune diseases.

Renal System

The inhibition of prostaglandin synthesis by NSAIDs has specific effects on the kidneys. These effects range from mild changes in fluid and electrolyte homeostasis to acute renal insufficiency. NSAIDs promote sodium and water retention by attenuating prostaglandin-mediated inhibition of chloride reabsorption. NSAIDs may lead to hyperkalemia either by increased potassium reabsorption secondary to decreased sodium concentration at the distal tubule or by decreased secretion of renin. There is at least one report in the literature of cardiac arrest secondary to NSAID-induced hyperkalemia. [8]

Prostaglandins have a vasodilatory effect on the renal vasculature. The most important of these renal vasodilatory prostaglandins are PGI_2 and PGE_2.

Prostaglandin-mediated vasodilatation is probably of little importance in euvolemic patients with normally functioning kidneys. However, prostaglandins appear to attenuate the vasoconstricting affects of the renin-angiotensin system and sympathetic nervous system during times of stress, during periods of decreased intravascular volume (sepsis, hemorrhage, and diuretic therapy), [9] and in disease states that predispose patients to sodium retention (congestive heart failure, cirrhosis, and nephrotic syndrome). [9] The lack of these vasodilatory prostaglandins, due to COX inhibition by NSAIDs, may put stressed kidneys at risk for azotemia and renal insufficiency. The aforementioned comorbid states are speculated to contribute to the risk of NSAID-mediated renal insufficiency.

Hematologic System

NSAIDs inhibit platelet formation of thromboxane A_2, a potent stimulator of platelet aggregation. This leads to qualitative platelet deficiencies. Most NSAIDs decrease platelet aggregation only when significant concentrations of the drug are present. Increased bleeding tendencies secondary to NSAIDs are not widely reported in the literature. However, patients taking aspirin are at risk for increased bleeding during surgery and patients maintained on coumadin are advised to avoid all NSAIDs.

NSAIDs may cause other blood disorders. Bone marrow suppression is a rare but reported hematological complication with use of NSAIDs. Aplastic anemia has been reported with almost all classes of NSAIDs, but phenylbutazone, indomethacin, and diclofenac are responsible for most cases. [10] NSAID use has also resulted in agranulocytosis, red cell aplasia, thrombocytopenia, and hemolytic anemia.

Dermatologic System

NSAIDs account for approximately 10 percent of cutaneous drug reactions. [11] Agents most frequently involved in dermatologic complications include phenylbutazone, piroxicam, and benoxaprofen.[12] Drug reactions to NSAIDs range from benign maculopapular rashes to the severe Stevens-Johnson syndrome and toxic epidermal necrolysis. NSAIDs are some of the most often-implicated drugs in cases of toxic epidermal necrolysis, accounting for up to one-third of drug-related cases in one series.[13] NSAIDs of all types (oral and topical) can cause photosensitivity reactions, including increased sensitivity to sun exposure (phototoxic) and true photoallergic reactions. Piroxicam and ketoprofen are the NSAIDs most frequently involved in photoallergic reactions. One NSAID of the oxicam family, isoxicam, was removed from the US market after fatal skin reactions.

Pregnancy

Prostaglandins are found in high concentration in the term uterus and have a stimulatory effect on normal labor. NSAIDs inhibit uterine motility through COX-mediated inhibition of prostaglandin synthesis. Indomethacin is sufficiently effective at slowing uterine contractions that it has been used to treat preterm labor. Although NSAIDs are not believed to be teratogenic in humans, they do cross the placenta later in pregnancy. One of the most significant effects of fetal exposure to NSAIDs is premature constriction of the ductus arteriosus, which may result in pulmonary hypertension. Other reported effects of in utero exposure to NSAIDs include oligohydramnios, renal dysfunction, necrotizing enterocolitis, and CNS hemorrhage.

NSAID-induced inhibition of platelet aggregation may place the fetus and the mother at increased risk for bleeding. Mothers who take NSAIDs during the latter part of pregnancy appear to be at risk for increased peripartum hemorrhage. The safest recommendation is to avoid NSAID use during pregnancy, especially during the third trimester.

PRESENTATION OF ACUTE OVERDOSE

Most patients with acute overdoses suffer little morbidity, but patients with significant overdoses may present with CNS, metabolic, hemodynamic, GI, or renal dysfunction.[14] It is generally accepted that patients taking NSAIDs of the pyrazolone (phenylbutazone and oxyphenylbutazone) and the fenamic acid (mefenamic acid) families may present with the most severe clinical symptoms. It does not appear that NSAID metabolism is changed after acute overdose, and symptoms of acute overdose are usually apparent within 4 h of ingestion.

Central Nervous System

CNS manifestation of acute NSAID overdose is usually minimal, but patients with significant overdose may present with altered mental status. Other CNS manifestations of acute overdose have included diplopia, nystagmus, and headache. Seizures have been reported after large overdoses and appear to be of special concern after ingestion of mefenamic acid.

Cardiovascular System

Acute NSAID overdose has resulted in hypotension and bradydysrhythmia. NSAIDs are not known to be primary causes of dysrhythmias, but fluid and electrolyte abnormalities may place patients at risk for cardiac dysrhythmias. Cardiovascular dysfunction is responsive to conventional critical care management.

Electrolytes

Electrolyte and acid-base abnormalities have been reported in acute NSAID overdoses. Alterations in serum electrolytes may occur secondary to decreased prostaglandin synthesis or from NSAID-induced renal failure. Sodium and water retention may lead to volume overload, with patients having preexisting renal failure, cirrhosis, or congestive heart failure. Hyperkalemia, hypocalcemia, and hypomagnesemia have been reported in NSAID overdoses complicated by acute renal failure.[15]

Increased anion-gap acidosis has been observed in large overdoses of the propionic acid NSAIDs ibuprofen and naproxen. Prostaglandin inhibition is not directly responsible for the anion-gap acidosis; rather, acidosis is likely to be related to lactic acidosis. Case reports of large overdoses suggest that the acidosis is related to large quantities of these mildly acidic NSAIDs and their metabolites in serum. [16] However, these studies neither measured nor considered lactate as the possible mechanism. Concurrent lactic acidosis in the setting of NSAID-induced seizures may worsen the acidosis in some cases.

Gastrointestinal-Hepatic System

Patients presenting after acute NSAID overdose may have abdominal pain, nausea, and vomiting. Life-threatening GI hemorrhage is not a typical finding after acute overdoses. Overdose may also result in hepatic injury, as witnessed by elevated transaminase level and cholestasis.

Renal Failure

Acute renal failure is rare after NSAID overdose, but NSAID overdose may place a stressed renal system at risk for failure. Clinical presentation may include hematuria, elevations in blood urea nitrogen/creatine, and oliguria. The mechanism of renal insufficiency in acute overdose is believed to be renal vascular changes secondary to COX-mediated prostaglandin inhibition. Patients with underlying renal insufficiency appear to be at greatest risk for acute renal failure. Most patients have recovery of renal function, but the need for long-term dialysis has been reported.

TREATMENT

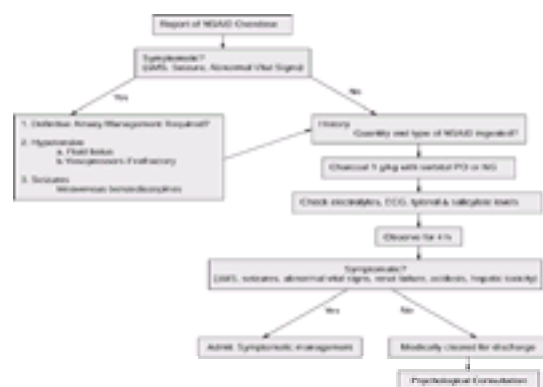
Most patients who present with NSAID overdose will be asymptomatic. Patients who present with symptomatic ingestions (altered mental status, seizure, electrolyte disturbances, anion-gap acidosis, or renal insufficiencies) should be treated with supportive care using emergency medicine and toxicology principles (Fig. 166-1). Airway management should be initiated in obtunded or apneic patients, hypotension should be managed with fluid boluses or vasopressor agents when refractory, and seizures should be treated initially with intravenous benzodiazepines.


FIG. 166-1. Approach to treatment of acute NSAID overdose. *Abbreviation:* DMS, change in mental status.

Patients who present as hemodynamically stable with a report of acute ingestion should have a directed history and physical examination with attention focused on mental status, GI symptoms, and any signs of renal dysfunction (Fig. 166-1). The history should include amount and type NSAID ingested and questions about coingestants. Ibuprofen is the most common NSAID encountered in acute ingestion, and it is generally accepted that an ingestion of less than 100 mg/kg is unlikely to result in toxicity and that greater than 400 mg/kg places the patient at greatest risk for toxicity. Most authorities believe that patients with acute ingestions will show symptoms within 4 h.

Laboratory Evaluation

Laboratory evaluation of patients with acute ingestions should focus on acid-base status, electrolyte level, and renal function. Electrolyte panel, determination of hepatic profile, complete blood count, coagulation profile, and aspirin and acetaminophen levels should also be sent. Evaluation of drug levels for specific NSAIDs are not indicated. A nomogram for ibuprofen intoxication does exist but is not clinically useful. NSAID levels do not correlate well with observed toxicity or outcomes. [17]

Decontamination and Enhanced Elimination

Gastric decontamination should be initiated in all patients with suspected NSAID overdoses. Activated charcoal with the cathartic sorbitol should be given orally or through a nasogastric tube. Repeated doses of activated charcoal without sorbitol are indicated in symptomatic patients. Dialysis and charcoal hemoperfusion are not effective in enhancing elimination, because NSAIDs are highly protein bound. Manipulation of serum and urine pH through alkalinization is not helpful in enhancing elimination.

DISPOSITION OF PATIENTS WITH ACUTE OVERDOSES

Most patients with asymptomatic NSAID ingestions can be safely discharged after screening for coingestants and a 4- to 6-h period of observation. Any patient with symptomatic overdose (altered mental status, abnormal vital signs, electrolyte abnormalities, or acute renal failure) should be admitted for observation and supportive care. The psychosocial situation within which the overdose occurred requires careful evaluation.

Prognosis

The majority of NSAID overdoses will not cause significant sequelae. Even patients with major symptoms have a good prognosis if they overcome the initial insult (Table 166-1).

167 XANTHINES

Daniel J. Kranitz
Charles L. Emerman

Theophylline use is complicated by its narrow therapeutic window, with a metabolism that depends on the patient's coincident medical problems and use of other medications. The 1996 Annual Report of the American Association of Poison Control Centers Toxic Exposure Surveillance System reported 3100 exposures to aminophylline or theophylline, resulting in major toxicity in 76 patients and death in 11. There were 7316 exposures to caffeine, resulting in major toxicity in 16 patients with 2 deaths.[1] Most consider a theophylline level greater than 20 µg/mL (110 µmol/L) toxic, although side effects may be seen at lower levels.[2] Recent changes in the US Food and Drug Administration dosing guidelines have been aimed at reducing the likelihood of developing toxic levels. Life-threatening toxicity from theophylline poisoning can result in significant cardiac, neurologic, and metabolic abnormalities.[3] Toxic side effects of caffeine have many similarities to those of theophylline, but serious side effects are rare. Several modalities are available for treating theophylline toxicity, but indications for their use in patients without life-threatening symptoms is controversial.

PHARMACOLOGY

Theophylline and related products (Table 167-1) have a complex mechanism of action that has not been entirely elucidated.[4] Although traditional teaching is that theophylline acts by inhibiting the action of phosphodiesterase, the concentration required for effective in vivo inhibition far exceeds the concentration usually produced by clinical dosages. Others have suggested that theophylline may act by affecting the binding of cyclic adenosine monophosphate, cyclic glucose monophosphate phosphodiesterase inhibition, prostaglandin antagonism, modification of intracellular calcium, stimulation of catecholamine release, or adenosine antagonism. In addition to its bronchodilatory effect, theophylline affects both the immune and inflammatory mechanisms.[5]

Drug	Theophylline Content, %
Aminophylline	80–85
Oxtriphylline	65
Dyphylline	50

TABLE 167-1   Theophylline Content of Related Drugs

Theophylline is readily absorbed after oral administration, with peak levels occurring 90 to 120 min after ingestion. Oral absorption is enhanced by fasting or ingestion of large volumes of fluid and is decreased following ingestion of certain foods. Enteric-coated tablets and sustained-released preparations reach peak plasma levels between 6 and 8 h. The newer, once-daily preparations have an erratic absorption rate, particularly after eating, which may lead to drug "dumping" (rapid absorption) and elevated theophylline levels. Peak levels are reached within 30 min after intravenous administration of aminophylline. The absorption of intramuscularly and rectally administered drug is erratic and unpredictable. Consequently, these routes should not be used.

Theophylline is approximately 60 percent protein bound, with less binding in neonates and patients with cirrhosis. The volume of distribution ranges from 0.3 to 0.7 L/kg, with an average of 0.5 L/kg. Theophylline is primarily (85 to 90 percent) eliminated by the hepatic P450 cytochrome system, and the remaining 10 to 15 percent is eliminated by urinary excretion. Metabolism generally follows first-order elimination. The half-life is 4 to 8 h in young, healthy, nonsmoking adults and shorter in children and smokers. Some authors have recommended a lowering of the target serum concentration from 20 to 15 µg/mL, since most bronchodilation occurs by that level.

A number of factors affect theophylline's half-life, including cigarette use, diet, cardiac and liver disease, and medications that interfere with the cytochrome P450 pathway (Table 167-2). Theophylline acts as an adenosine antagonist. It markedly inhibits the coronary vasodilating effects of adenosine and may interfere with the usefulness of pharmacologic stress tests. Theophylline has been reported to reverse adenosine-induced bronchoconstriction. Few studies have examined the effects of theophylline on the therapeutic use of adenosine to reverse supraventricular tachycardia. One study reported on the successful conversion from supraventricular tachycardia in two patients with therapeutic theophylline levels. A few case reports describe the use of adenosine in theophylline-induced arrythmias, but experience on which to base recommendations is inadequate.

Decreased Half-Life	Increased Half-Life
DRUGS	
Carbamazepine	Cimetidine
Phenobarbital	Allopurinol
Phenytoin	Efavirenz
Rifampin	Ticlopidine
	Interferon
	Methotrexate
	Estrogen
ANTIBIOTICS	
Sulfapyrazone	Erythromycin
	Clarithromycin
	Quinolones
	Thiabendazole
ANTIDYSRHYTHMICS	
	Mexiletine
	Propranolol
	Tocainide
	Propafenone
CONDITIONS AND OTHER FACTORS	
Smoking	Cirrhosis
Charcoal-broiled foods	Congestive heart failure
Children	Pneumonia
Hyperthyroidism	Severe COPD
	Viral illness in children
	Obesity
	Cholecystitis

TABLE 167-2   Factors Affecting Theophylline Half-Life

Caffeine is probably the most commonly used drug in the world. It is readily absorbed after oral administration, with an onset of action of 30 min and peak effect at 60 to 120 min (Table 167-3). Caffeine is also metabolized by demethylation in the liver, forming L-methyluric acid and L-methyl xanthine, the active agents. As with theophylline, about 10 percent of the drug is eliminated by urinary excretion. Many of the factors that affect the half-life of theophylline, such as severe liver disease,

also affect that of caffeine.

Product	Caffeine Content, mg
No Doz Maximum, Vivarin	200
Espresso coffee	120
Regular coffee	103
No Doz	100
Jolt Cola	72
Aspirin-free Excedrin	65
Excedrin ES	65
Instant coffee	57
Black tea	53
Most sodas	35–55

TABLE 167-3   Caffeine Content of Various Products

TOXIC EFFECTS

Theophylline has a range of toxic effects from minor gastrointestinal symptoms to life-threatening dysrhythmias. Although it is commonly thought that symptom severity is serum-level dependent, in fact, life-threatening adverse effects may occur with little warning and before minor symptoms are evident.

Cardiovascular

Even at therapeutic levels (10 to 20 μg/mL), theophylline can cause cardiac side effects. Sinus tachycardia may occur after administration, and increased atrial automaticity, with premature atrial contractions, atrial tachycardia, multifocal atrial tachycardia, atrial fibrillation, and atrial flutter, occurs more frequently with levels above 20 μg/mL. Ventricular dysrhythmias with premature ventricular contractions and self-limited runs of ventricular tachycardia may also occur. Sustained ventricular tachycardia may occur in older patients with chronic overdose at levels of around 40 to 60 μg/mL. Younger patients with acute intentional overdose may tolerate levels above 100 μg/mL without developing life-threatening cardiac effects. [6] Patients with a history of dysrhythmias may experience a recurrence of dysrhythmias with levels less than 40 μg/mL. Hypotension has also been associated with acute ingestion but may also occur with chronic overmedication.

Neurologic

Even with therapeutic levels, theophylline use can be associated with agitation, headache, irritability, sleeplessness, tremors, and muscular twitching. Seizures, including both generalized tonic-clonic and focal motor, have been reported in patients with therapeutic levels. Patients with a history of epilepsy are particularly susceptible to aminophylline-induced seizures. The incidence of seizures increases as toxic levels increase. [7] Status epilepticus resistant to treatment can occur as the level rises above 25 μg/mL. When seizures occur at only mildly elevated levels, there are usually underlying neurologic deficits. The occurrence of seizures does not appear to correlate with prognosis. Theophylline toxicity has also been associated with hallucinations and psychosis.

Metabolic

Theophylline produces a dose-dependent increase in circulating catecholamines. There is a concomitant increase in glucose, free fatty acid, and insulin levels and white blood cell count. Hypokalemia may occur, with the fall in serum potassium level inversely related to the theophylline concentration. Hypokalemia appears to be a particular problem in patients with acute overdose or acute overdose superimposed on chronic use. Administration of a b agonist may also be associated with hypokalemia and, with the hypokalemia produced by theophylline overdose, may lead to cardiac dysrhythmias. Lactic acidosis (tissue ischemia) may also be present.

Gastrointestinal

TOXIC EFFECTS OF THEOPHYLLINE   Theophylline has a direct central nervous system effect, leading to nausea and vomiting. In addition, theophylline increases gastric acid secretion. Nausea and vomiting can be seen with therapeutic levels, although the incidence of nausea and vomiting increases markedly with levels above 15 μg/mL. Approximately 25 percent of patients with levels greater than 20 μg/mL have nausea or vomiting. Gastrointestinal bleeding, with epigastric pain, may also occur. Esophageal reflux has also been reported.

TOXIC EFFECTS OF CAFFEINE   Caffeine shares many effects with theophylline. Gastrointestinal symptoms generally occur with overdose and include abdominal pain, vomiting, and occasional hematemesis. Central nervous system effects include agitation, seizures, and coma. Ventricular dysrhythmias other than premature ventricular contractions are rare, but paroxysmal atrial tachycardia may occur. Rhabdomyolysis, hyperglycemia, leukocytosis, and metabolic acidosis have been reported. Toxicity is seen after 1-g doses in adults. Doses of around 80 mg/kg may lead to symptoms in children.

TREATMENT

Following acute ingestion (2 to 4 h) of potentially toxic doses of aminophylline or theophylline, gastric emptying with gastric lavage should be considered. Gastric lavage is probably not indicated for patients whose dose is calculated to have raised their levels to less than 30 μg/mL (approximately 15 mg/kg), unless coingestion of other medications is suspected. Ipecac may complicate the use of other therapies for enhancing the elimination of theophylline and, given the seizure potentiation, should not be used. In addition, vomiting is usually a prominent symptom in theophylline toxicity.

Cathartics should be administered to enhance the passage of ingested theophylline through the gastrointestinal tract. Some investigators have found magnesium citrate not to be effective in lowering the theophylline level. Further, there have been reports of magnesium toxicity after the use of magnesium cathartics.

Sorbitol may be a better choice. A 70% sorbitol solution (100 mL) can be used either alone or in combination with activated charcoal for patients with potentially toxic ingestions. There have been reports of the successful use of whole-bowel irrigation with polyethylene glycol, but this treatment is controversial.

Theophylline undergoes hepatobiliary enteric circulation. Administration of repeated doses of activated charcoal at 2- to 4-h intervals significantly decreases the half-life of theophylline. [8] Doses of 30 to 60 g should be used in adults. Charcoal may also be administered as a continuous nasogastric infusion at rates of 0.25 to 0.5 g/kg/h. In patients with markedly elevated theophylline levels, the administration of charcoal is complicated by repeated episodes of emesis. In one study, patients with levels greater than 50 μg/mL could not tolerate any of their charcoal doses because of repeated episodes of emesis. Patients who cannot tolerate oral administration of activated charcoal should be pretreated with ranitidine.

Treatment of theophylline toxicity is hindered by the recurrent nausea and vomiting produced by toxic levels. Administration of ranitidine, 50 mg intravenously, is useful when nausea and vomiting are present. It permits the use of repeated doses of activated charcoal to enhance drug elimination.

Diazepam, phenobarbital, and phenytoin have been used in the treatment of theophylline-induced seizures. Unfortunately, status epilepticus may be resistant to those drugs. The airway should be protected in patients with theophylline-induced status epilepticus, particularly after administration of oral activated charcoal. Patients with status epilepticus resistant to traditional therapy may require general anesthesia for more aggressive measures to lower the serum theophylline level.

Although it is less effective at drug removal than hemoperfusion, hemodialysis may be used for patients with toxicity. [9] The clearance rate induced by hemodialysis is approximately 200 mL/kg/h. Charcoal hemoperfusion with resin or charcoal filters produces extraction ratios above 0.85 with clearance rates of up to 300 mL/kg/h. Recent prospective studies, however, indicate that hemoperfusion is associated with a higher complication rate without any signficant increase in clinical efficacy over hemodialysis.[10] The indications for hemoperfusion or hemodialysis are controversial (Table 167-4). In the view of some investigators, hemoperfusion or hemodialysis

is not absolutely indicated at any theophylline level in the absence of life-threatening symptoms, such as status epilepticus or resistant ventricular dysrhythmias. Others have felt that patients with increased half-lives, advanced age, or theophylline levels above 40 μg/mL may be candidates for hemoperfusion or hemodialysis. Young, healthy patients with an acute ingestion may be able to tolerate levels over 100 μg/mL without adverse incident. The decision to use hemoperfusion or hemodialysis should be made considering the potential for life-threatening toxicity.

Clinical Conditions	Recommendation
Life-threatening toxicity (i.e., seizures, tachydysrhythmias) not responsive to other therapy	Hemoperfusion or dialysis indicated
Acute overdose with level >100 μg/mL	Hemoperfusion or dialysis possibly indicated
Chronic overdose with level >60 μg/mL	Hemoperfusion or dialysis possibly indicated
Elderly patient with prolonged half-life, severe liver or severe cardiac disease, or level >40 μg/mL	Hemoperfusion or dialysis controversial
Theophylline level <30 μg/mL	Hemoperfusion or dialysis not indicated

TABLE 167-4   Indications for Hemoperfusion

Hypotension or life-threatening cardiac dysrhythmias may be an indication for b-blocker therapy when symptoms do not respond to other therapy. The use of b blockers may be complicated by further cardiac depression or exacerbation of airway obstruction. They should be administered cautiously in low doses and monitored for adverse effect. Propanolol may be used, given in 1-mg doses up to a total of 10 mg. Alternatively, one of the newer b-blocker agents, such as labetalol or the short-acting esmolol, may be used.

In addition to being treated with b blockade, cardiac dysrhythmias may be treated with other antiarrhythmics. Verapamil has been effective in animal studies. The use of digoxin, lidocaine, and phenytoin has been reported for treatment of venticular dysrhythmias. Adenosine may be considered for supraventricular dysrhythmias, but it may induce bronchospasm. The contributory effect of hypokalemia should be considered in treating patients with resistant ventricular dysrhythmias, and correction of serum electrolyte abnormalities may be effective in terminating recurrent dysrhythmias.

INDICATIONS FOR TREATMENT AND ADMISSION

Although theophylline toxicity can lead to life-threatening side effects, toxic theophylline levels are common, and most patients tolerate them with only minor toxic manifestations.[11] Serum theophylline concentrations do not correlate well with severity of toxicity in chronic exposures. However, serum levels for acute exposures are more valuable in predicting toxicity and clinical course. No well-conducted studies have demonstrated that prophylactic use of antiarrhythmics or antiepileptics decreases morbidity or mortality rates. Similarly, while hemodialysis, hemoperfusion, and oral activated charcoal therapy enhance theophylline clearance, there is no compelling evidence that their use lowers morbidity or mortality rates for patients with only mild toxic symptoms or minimally elevated levels.

On the other hand, ventricular dysrhythmias or seizures may occur in patients before the manifestation of other minor toxic effects, leading some authors to advocate aggressive therapy. Older patients with concomitant medical problems are more susceptible to life-threatening theophylline toxicity following chronic overmedication than are younger patients with an acute overdose. [12] Prophylactic use of hemoperfusion has been reported to decrease rates of major morbidity in elderly patients.

In general, patients with a history of seizures or ventricular dysrhythmias should be monitored until their theophylline level returns to normal. Patients with levels below 25 μg/mL and minor symptoms do not require specific therapy other than discontinuation or modification of theophylline administration. Such patients generally do not require hospitalization. Patients with levels above 30 μg/mL should be treated with oral activated charcoal (repeated) and monitored for toxic side effects. Hemoperfusion or hemodialysis use is controversial but may be indicated for older patients with levels above 30 μg/mL or for younger patients with acute intentional overdose with levels above 100 μg/mL.

PREVENTION

Theophylline toxicity is only rarely a result of intentional overdose. Physician prescribing errors, patient self-overmedication, and variations in plasma clearance due to deteriorating cardiac or hepatic status, smoking cessation, or concomitant administration of drugs that affect theophylline clearance all may lead to elevated levels. Aminophylline infusions should be started using standard guidelines with close monitoring of serum levels. Because the history of outpatient theophylline use has been found to be a poor guide to the serum concentration, loading doses of aminophylline should be calculated using the initial theophylline level. As a rough approximation, each milligram per kilogram of aminophylline will raise the theophylline level by 2 μg/mL. The initial dose of oral theophylline should not exceed 900 mg/day. Patients should be started at a much lower dose (400 mg/day) to avoid the nausea and vomiting frequently accompanying initial theophylline use. Levels should be determined in order to monitor therapy. The presence or absence of mild side effects is not a good predictor of drug levels. [13] Patients should be cautioned not to alter their medication regimen without physician guidance. Patients being started on erythromycin or cimetidine should have their theophylline dose decreased by approximately 25 percent, with monitoring of the effect on levels.

168 DIGITALIS GLYCOSIDES

William H. Dribben
Mark A. Kirk

EPIDEMIOLOGY

For centuries, digitalis glycosides have been recognized for their medicinal benefits and potential toxicity. Digitalis preparations are used most commonly in the treatment of supraventricular tachydysrhythmias and congestive heart failure. In addition to their availability as pharmaceuticals, cardiac glycosides are also found in plants such as foxglove, oleander, and lily of the valley. It is important that physicians recognize digitalis toxicity because potentially fatal cardiac dysrhythmias can be reversed with prompt administration of a highly specific antidote, digoxin specific Fab fragments. [1] According to the American Association of Poison Control Centers, 2963 exposures to cardiac glycosides were reported in 1997. Of these exposures, 416 (34 percent) patients demonstrated moderate or major morbidity with 12 (1 percent) deaths.[2] Even though digitalis use has declined due to newer modes of therapy, reported exposures and morbidity and mortality have remained constant over the past 5 years.

PHARMACOLOGY AND PATHOPHYSIOLOGY

Digoxin is currently the most widely used digitalis preparation. It is rapidly absorbed from the gastrointestinal tract and is primarily eliminated through renal excretion. It has a volume of distribution of 6 L/kg. The half-life of a therapeutic dose is 36 to 48 hours.

Digitalis has a narrow therapeutic-toxic margin. Toxicity results from an exaggeration of its therapeutic actions. Digitalis binds to a specific receptor site on the cardiac cell membrane, inactivating the sodium-potassium adenosine triphosphate pump (Na-K ATPase). [3] This pump concentrates sodium extracellularly and potassium intracellularly to maintain the electrochemical membrane potential vital to conduction tissues. When Na-K ATPase is inhibited, the sodium-calcium exchanger removes accumulated intracellular sodium in exchange for calcium. This exchange increases sarcoplasmic calcium and is the mechanism thought to be responsible for the positive inotropic effect of digitalis. Inhibition of the Na-K ATPase pump also results in an increase in extracellular potassium. [3] Digitalis increases vagal tone and decreases conduction through the AV node. In toxic doses, these effects result in various bradydysrhythmias. Automaticity is increased due to slowing of conduction in the electrical system along with a shortened refractory period in the myocardium. Intracellular calcium overload can create delayed after-depolarizations, causing electrical oscillations in cell membranes that give rise to triggered dysrhythmias. [4]

CLINICAL FEATURES

When a poisoned patient presents to the emergency department, the clinician should determine if toxicity is due to an accidental ingestion, massive intentional ingestion, or chronic toxicity from therapeutic use of digitalis. If the ingestion is intentional, historical information may be inaccurate or incomplete, and coingestants should be suspected. The time of ingestion is extremely helpful in interpreting laboratory information. Because various plants contain digitalis glycosides and cause similar toxicity to medicinal forms, an attempt should be made to accurately identify any ingested plants.

Preexisting medical conditions and current medications may identify risk factors that potentiate digitalis toxicity. Increased susceptibility is seen in patients who are elderly, have coexisting diseases (heart disease, renal dysfunction, hepatic dysfunction, hypothyroidism, and chronic obstructive pulmonary disease), electrolyte disturbances (hypokalemia, hypomagnesemia, and hypercalcemia), and hypoxia.[5] Drug interactions, most notably class IA antidysrhythmics, calcium channel blockers, and b blockers, potentiate digitalis toxicity. Carefully evaluate the cardiac, neurologic, and gastrointestinal systems for clues of developing toxicity.

Cardiac dysrhythmias in digitalis toxicity are nonspecific and may be life-threatening. Suspect digitalis toxicity in patients with any dysrhythmia or junctional escape rhythms and AV block. The most common dysrhythmia is frequent premature ventricular beats, especially in a diseased heart. Bidirectional ventricular tachycardia, a narrow complex tachycardia with right bundle branch morphology, is rare but specific for digitalis toxicity. [6]

In addition to cardiac manifestations, gastrointestinal distress, dizziness, headache, weakness, syncope, and seizures may occur. Reported psychiatric symptoms include confusion, disorientation, delirium, and hallucinations. Any elderly patient taking digitalis presents with mental status changes should be evaluated for toxicity. Patients with toxicity have reported seeing yellow-green halos around objects. [7] No single clinical feature or laboratory value is diagnostic of digitalis toxicity.

DIAGNOSIS

Digitalis glycoside toxicity is determined by evaluating the entire clinical presentation. The history, physical examination, and laboratory studies provide important clues, with no single element that excludes or confirms the diagnosis.

Laboratory Evaluation

Serum potassium and digoxin levels will assist in providing information necessary to make adequate therapeutic decisions. Acute poisoning of the Na-K ATPase pump may result in markedly elevated serum potassium levels.[3] A high incidence of hyperkalemia has been noted in patients with severe acute poisoning. The serum potassium may be a better indicator of end organ toxicity and a better prognostic indicator than the serum digoxin level in the acutely poisoned patient. Hyperkalemia is less common in chronically poisoned patients. Potassium status may be less predictive in patients with renal insufficiency or dehydration, or who are receiving diuretic therapy.

Accepted therapeutic digoxin levels are 0.5 to 2.0 ng/mL. In most laboratories, the serum digoxin level is not part of the routine toxicologic screen and must be specifically requested.

Serum digoxin levels in both acute and chronic toxicity should be interpreted in the overall clinical context, and not relied upon as the sole indicator of the presence or absence of toxicity. In acute exposures, digoxin is absorbed into the plasma compartment and then redistributed slowly into the tissue compartment. Hence, high digoxin levels are not always associated with clinical signs and symptoms of poisoning. Serum levels are most reliable when obtained six hours after ingestion, when distribution is complete. In patients with clinical evidence of chronic digitalis toxicity, a "therapeutic" level does not exclude toxicity, especially when predisposing factors are present. Conversely, levels above the upper limits of normal do not always cause symptoms. Given the above limitations, it is still most common that the higher the serum level, the greater the likelihood of toxicity. [8]

A positive serum assay is diagnostic of acute ingestion if the patient has not received digitalis glycosides therapeutically. The rare exception is in the presence of digoxin-like immunoreactive substance that has been detected in neonates and patients with renal insufficiency or hepatic dysfunction. In addition, naturally occurring

digitalis glycosides from plants and animals may cross-react with the digoxin assay. The degree of cross-reactivity is unknown and no correlation has been established between serum levels of these glycosides and toxicity.

Additional laboratory evaluation includes the determination of adequate oxygenation, renal and hepatic function, and electrolyte determinations in addition to potassium. Continuous electrocardiographic monitoring is essential to detect dysrhythmias and evidence of hyperkalemia.

Differences in the Presentation of Acute and Chronic Toxicity

A distinct clinical presentation exists for both acute and chronic digitalis glycoside toxicity (Table 168-1). Acute poisoning most often results from accidental or intentional ingestion. There may be an asymptomatic period of several hours prior to development of symptoms. Gastrointestinal symptoms are often the earliest manifestation of toxicity. In the early period of toxicity, increased central vagal tone produces cardiac dysrhythmias that are typically bradydysrhythmias, or supraventricular dysrhythmias with AV block; however, life-threatening ventricular dysrhythmias may develop at any stage in an acute massive ingestion. [6] Acute toxicity most closely correlates with hyperkalemia, and correlates poorly with the serum digoxin level. [9]

Acute Toxicity
  Clinical History: Intentional or accidental ingestion
  GI Effects: Nausea and vomiting
  CNS Effects: Headache, dizziness, confusion, coma
Cardia effects: Predominately supraventricular tachydysrhythmias with AV
block; bradydysrhythmias
  Electrolyte Abnormalities: Hyperkalemia
  Digoxin Level: Marked elevation

Chronic Toxicity
  Clinical History: Typically an elderly cardiac patient taking diuretics.
  May have renal insufficiency
  GI Effects: Nausea, vomiting, diarrhea, abdominal pain
  CNS Effects: Fatigue, weakness, confusion, delirium, coma
  Cardiac Effects: Ventricular dysrhythmias are common.
  Almost any ventricular or supraventricular dysrhythmia can occur.
  Electrolyte Abnormalities: Hypokalemia or normal serum K
  hypomagnesemia
  Digoxin Level: Minimally elevated or therapeutic range

TABLE 168-1   Clinical Presentation of Digitalis Toxicity

Chronic toxicity occurs most typically in the elderly cardiac patient taking digoxin and diuretics. Signs and symptoms may mimic more common illnesses such as influenza and gastroenteritis. An altered mental status or psychiatric symptoms may not be recognized as signs of digitalis toxicity. Almost any cardiac dysrhythmia may be seen, but ventricular dysrhythmias occur more frequently in chronic than in acute poisonings. [6] The serum digoxin level is not an accurate predictor of toxicity, and the serum potassium is usually decreased, normal, or may even be elevated in the setting of renal failure.

Differential Diagnosis

Other toxins and medical illnesses may present with a clinical picture similar to digitalis toxicity. Other toxins causing bradydysrhythmias include calcium and b-blocker overdoses, class IA antidysrhythmics (procainamide and quinidine) overdoses, clonidine overdoses, organophosphate insecticide poisoning, and cardiotoxic plants (e.g., rhododendron, monkshood, tobacco, false hellebore, and yew berry). Sinus node disease can also mimic digitalis toxicity.

Factors Enhancing Toxicity

A variety of factors increase susceptibility to digitalis toxicity. True end organ sensitivity is seen with myocardial disease or ischemia, and metabolic or electrolyte abnormalities. Hypokalemia, hypomagnesemia, and hypercalcemia all predispose to increased toxicity. [3] The elderly are more susceptible to toxicity. Decreased renal function, hepatic disease, hypothyroidism, chronic obstructive pulmonary disease, and drug interactions can all augment toxic effects. [5] Drug interactions potentially resulting in digitalis toxicity include quinidine, procainamide, b blockers, calcium channel blockers, amiodarone, spironolactone, indomethacin, clarithromycin, and erythromycin.

EMERGENCY DEPARTMENT CARE

The basic emergency department management of any poisoned patient includes general supportive care, treatment of specific complications of toxicity, prevention of further drug absorption, enhanced drug elimination, antidote administration, and safe disposition (Table 168-2). Patients with intentional or accidental ingestions may present with no symptoms. Still, life-threatening complications of toxicity should be anticipated. The management of the asymptomatic patient should focus on preventing drug absorption and closely monitoring for development of toxicity. Continuous cardiac monitoring, intravenous access, and frequent reevaluations should be provided for any patient with a potentially toxic ingestion of digitalis. Toxicity may not develop for several hours after an acute ingestion; therefore, extended observation (12 h) is required for anyone with a confirmed ingestion. [8] Admission to the intensive care unit and frequent reassessment is required for any patient developing signs of toxicity.

TABLE 168-2   Treatment of Digitalis Glycoside Poisoning

Treatment of Life-Threatening Conditions

Approach the symptomatic patient methodically. Ensure a patent airway, adequate ventilation, and effective circulation. Rapidly correct conditions such as hypoxia, hypoglycemia, hypovolemia, and electrolyte abnormalities.

Conventional and antidote therapies are available to treat digitalis-induced dysrhythmias. Atropine and cardiac pacing (external and transvenous) have been used successfully in treating bradydysrhythmias. Both phenytoin and lidocaine depress ventricular automaticity and increase the fibrillation threshold. Because of phenytoin's ability to accelerate conduction at the AV node, it has been considered the antidysrhythmic of choice by some for digitalis-induced ventricular dysrhythmias. Bretylium has effectively suppressed dysrhythmias in the clinical setting, although in a digitalis-toxic animal model, it was found to enhance dysrhythmias. [10] IA antidysrhythmics, such as quinidine and procainamide, are contraindicated because they depress AV nodal conduction, which in turn may enhance digitalis-induced cardiac toxicity. Intravenous magnesium has been reported to counteract ventricular irritability in digitalis toxicity. [11] Electrocardioversion may induce intractable ventricular fibrillation and should be considered only as a last resort. If necessary, use a low setting (10 to 25 W-s) and prepare to treat resulting ventricular fibrillation. In severe toxicity, conventional treatment may be unsuccessful. When available, digoxin-specific Fab fragments are the treatment of choice for

those dysrhythmias that are life-threatening and do not respond immediately to conventional therapy. [12]

Hyperkalemia may be life-threatening and needs immediate treatment. Treatment includes intravenous administration of dextrose, insulin, sodium bicarbonate, and enteral administration of a potassium-binding resin. [12] Calcium chloride administration in the face of digitalis-induced hyperkalemia may promote cardiac toxicity and should be avoided. If digitalis-induced hyperkalemia is not rapidly corrected by conventional therapy, then Fab fragments are indicated for reversal (see below). [12]

Gastrointestinal Decontamination and Enhanced Elimination

Ipecac clearly has no role in the emergency department management of digitalis glycoside poisoning. After initial stabilization, administer activated charcoal to prevent further drug absorption. [13] The use of gastric lavage is controversial. Because activated charcoal is so effective, lavage has a minimal role, if any. Asystole has been reported in a digoxin-toxic patient presumably from vagal stimulation during lavage. If lavage is contemplated, pretreatment with atropine prior to performing gastric lavage has been suggested. Forced diuresis, hemodialysis, or hemoperfusion have no role in enhancing elimination of digitalis.

Antidote Therapy

Digoxin specific Fab (Digibind, Burroughs-Wellcome) is derived from the IgG fragment of sheep antidigoxin antibodies. Fab fragments distribute widely throughout tissues and remove digitalis from tissue binding sites. [12] In a series of 150 severely poisoned patients, 90 percent showed reversal or significant improvement in life-threatening dysrhythmias and hyperkalemia after Fab fragment administration. [12] In most cases, clinical improvement in cardiac rhythm occurs within one hour of antidote administration. Those patients developing cardiac arrest prior to Fab administration had a 50 percent survival, which is significantly improved from survival by treatment with conventional therapies. [12] Fab fragments have also been reported to be beneficial in treating digitoxin and oleander poisonings. [14]

Indications for digitalis specific Fab fragments are: ventricular dysrhythmias; hemodynamically significant bradydysrhythmias unresponsive to standard therapy; and hyperkalemia in excess of 5.5 mEq/L [12] associated with a toxic digitalis level or a presumptive diagnosis of overdose. Elevated serum digoxin levels should not be the sole indication for Fab fragment administration.

Fab fragment administration has resulted in few adverse effects. [12] Cardiogenic shock has been reported in patients dependent upon digoxin for inotropic support. [15] In addition, ventricular response to atrial fibrillation may be increased. Hypokalemia may develop rapidly as digitalis toxicity is reversed. Only mild, acute hypersensitivity reactions including rash, flushing, and facial swelling have been reported. No incidences of serum sickness or anaphylaxis have been observed, even in patients with repeated administration. [15] Because Fab is derived from sheep protein, skin testing should be considered in patients with a strong history of allergies, especially to antibiotics, or those with asthma. If cardiac arrest is imminent, Fab fragment infusion should not be delayed for skin testing. Failures to Fab fragment therapy have been attributed to inadequate dosing, moribund state prior to administration, and incorrect diagnosis of digitalis toxicity. [15]

The Fab fragment dosage is based on an estimation of total body load of digoxin. [12] This can be determined from the serum digoxin level or based on the estimated dose ingested (Table 168-3). Clinical series have reported that an average of 200 to 480 mg (5 to 12 vials) were required to effectively treat severely digitalis toxic patients. [12] When the ingested dose is unknown, 5 to 10 vials are recommended as initial treatment in life-threatening situations. Fab fragments are administered intravenously through a 0.22-μm filter over 30 minutes, except in a cardiac arrest, where it may be given as a bolus.

1) Calculate total body load
    Based on history of amount ingested:
    Total body load = amount ingested (mg) × 0.80 (bioavailability)
    Based on serum digoxin concentration:

$$\text{Total body load} = \frac{\text{serum digoxin level} \times 5.6 \text{ L/kg} \times \text{Patient's weight (kg)}}{1000}$$

2) Calculate number of vials of digoxin-specific Fab fragments needed to neutralize the calculated total body load:
    It is assumed that an equimolar dose of Fab fragments is required for neutralization.
    One vial (40 mg) of Fab fragments binds 0.6 mg of digoxin.

$$\text{Number of vials required} = \frac{\text{Total body load}}{0.6}$$

A simple and accurate variation of the above calculations:

$$\text{Number of vials of Fab} = \frac{\text{serum digoxin level} \times \text{Patient's weight (kg)}}{100}$$

TABLE 168-3   Calculating Digoxin-Specific Fab Fragment Dosage

The serum digoxin level has no correlation with clinical toxicity following Fab administration because most laboratories use assays that measure both bound and unbound digoxin, although there are some laboratories that measure only free digoxin levels. Minutes after Fab fragment administration, the free digoxin level falls to zero, but the total serum digoxin level (bound to Fab fragments) increases 10- to 20-fold. [12] The Fab-digoxin complex is eliminated by renal excretion. [16] In the case of renal failure, the complex may persist in the circulation for prolonged periods. Recurrent toxicity can occur up to 10 days after Fab fragment administration in patients with renal failure. Hemodialysis does not enhance the elimination of the digoxin-Fab complex. [16]

DISPOSITION

Patients with signs of toxicity or a history of a large, ingested dose, especially if coexisting risk factors increase susceptibility to digitalis toxicity should be admitted to a monitored unit. Contacting the local poison center and medical toxicologist can facilitate difficult management and treatment decisions regarding when to administer Digibind. Any patient receiving Fab fragments requires ICU observation for at least 24 h. All suspected suicidal patients should have a psychiatric evaluation prior to discharge. Accidental exposures with no signs of toxicity after 12 h can be discharged home.

169 b-BLOCKER TOXICITY

William P. Kerns II

b-adrenergic receptor antagonists, or b-blockers, alleviate such manifestations of cardiovascular disease as hypertension, tachydysrhythmias, and myocardial infarction. Considering the high prevalence of cardiovascular disease and the widespread use of b-blockers, it is not surprising that accidental and intentional poisoning is common. Poison control center data from 1996 demonstrate over 7200 exposures to b blockers. Of these, 134 were serious poisonings, resulting in 16 deaths.[1] These data probably underestimate the true prevalence of b-blocker toxicity due to underreporting of poisonings.

PHYSIOLOGY

The b receptor is a glycoprotein within the cell membrane whose stimulation ultimately results in increased cytosolic calcium, which is integral for excitation-contraction coupling. The b receptor is coupled to an intracellular second messenger, cyclic adenosine monophosphate (cAMP), by a regulatory protein within the cell membrane called the G protein. Upon b-receptor stimulation, the G protein undergoes a conformational change that activates adenyl cyclase, increasing intracellular cAMP. Cyclic AMP stimulates protein kinase, which phosphorylates calcium channels, leading to calcium entry into the cell. Calcium entry into the cell triggers additional calcium release from storage organelles. Phosphodiesterase then hydrolyzes cAMP.

Three b-receptor subtypes have been identified: the b_1 subunit in the myocardium, kidney, and eye; the b_2 subunit in adipose tissue, pancreas, liver, and muscle; and the b_3 subunit in adipose tissue. Stimulation of each subunit serves a unique function. For example, b_1 stimulation increases the force and rate of myocardial contraction. b_2 stimulation relaxes vascular smooth muscle. b_2 activation also increases metabolic substrate availability needed for stress by stimulating lipolysis and glycogenolysis. The b_3 subunit alters lipid metabolism.

TOXICOPHYSIOLOGY

Excessive b-receptor blockade predictably decreases inotropy, chronotropy, and metabolic effects that are expected from subunit stimulation, resulting in hallmark bradycardia and hypotension.

Other mechanisms may contribute to b-blocker toxicity. Several b-blocker drugs antagonize myocardial sodium channels (Table 169-1) in a manner similar to the effects of quinidine or cyclic antidepressants. Impedance of sodium entry slows phase zero of the action potential, resulting in prolonged QRS duration and myocardial depression. Thus, patients may present with wide-complex bradycardia.

Agent	B_1 Selective	Partial Agonist	Na+ Channel Blockade
Acebutolol	Yes	Yes	Yes
Atenolol	Yes	No	No
Esmolol	Yes	No	No
Labetolol	No	Yes	No
Metoprolol	Yes	No	No
Nadolol	No	No	No
Oxprenolol	No	Yes	Yes
Pindolol	No	Yes	Yes
Propranolol	No	No	Yes
Sotalol	No	No	No
Timolol	No	No	No

TABLE 169-1   b-Blocker Pharmacologic Profile

Experimental evidence implicates altered calcium and potassium homeostasis as a contributing mechanism of toxicity.[2]

PHARMACOLOGY AND PHARMACOKINETICS

Many b blockers are available. They differ slightly in pharmacologic (Table 169-1) and pharmacokinetic (Table 169-2) properties. Pharmacologic differences among drugs influence expression of toxicity. Highly lipid-soluble agents penetrate the blood-brain barrier to a greater extent than do water-soluble b blockers, resulting in more central nervous system toxicity. Propranolol, acebutolol, labetolol, oxprenolol, and pindolol inhibit myocardial sodium channels, making these drugs potentially more cardiotoxic. Several b blockers have partial agonist activity, and thus weak stimulation of the b receptor occurs concurrently with blockade. Thus, partial agonist activity may have a protective effect in overdose. Labetolol has the potential to cause profound hypotension due to combined a_1- and b-receptor antagonism.

Agent	Absorption, %	Protein Binding, %	Onset of Action, h*	Volume of Distribution, L/kg	Metabolism and Half-Life, h	Lipophilicity
Acebutolol	90	25	4–3	3	Renal, 3–4	Moderate
Atenolol	50	45	3–4	0.6–4.1	Renal, 6–9	Weak
Esmolol	NA	55	3 min	3.4	Blood esterase, 9 min	Weak
Labetolol	90	50	4–3	5.1–9.6	Hepatic, 3–4	Weak
Metoprolol	90	12	4–2	5.6	Hepatic, 3–4	Moderate
Nadolol	30	30	3–4	1.9–2	Renal, 14–24	Weak
Oxprenolol	90	80	3–2	1.2	Hepatic, 2–3	Moderate
Pindolol	90	57	10	1.2–2	Renal, 3–4	Moderate
Propranolol	90	93	1–1.5	3.6–4	Hepatic, 3–4	High
Sotalol	70	4	2–4	0.23–0.7	Renal, 9–16	Weak
Timolol	90	10	1–2	1.3–3.6	Renal, 4–5	Weak

New York, McGraw-Hill, 1996.

TABLE 169-2   b-Blocker Pharmacologic

Clinically relevant pharmacokinetic characteristics include drug formulation (regular versus sustained release), rate of drug absorption, lipid solubility, and volume of distribution (Vd). Absorption of normal-release b blockers occurs rapidly, with peak effect in 1 to 4 h. For this reason, toxic symptoms begin soon after ingestion. The high degree of protein binding, the large Vd, and lipid solubility predict that extracorporeal drug removal will not be useful for most b blockers. Hemodialysis may be

beneficial for atenolol, nadolol, and sotalol because these agents have lower protein binding, are hydrophilic, and have Vds similar to that of water.

CLINICAL PRESENTATION

Patients who ingest b blockers manifest a spectrum of clinical presentations ranging from minimal symptoms to profound bradycardia, hypotension, and cardiogenic shock. The majority of serious cases result from ingestion of propranolol. [3] Symptoms typically develop within 1 to 3 h after acute ingestion, but the onset may range from 15 min to 10 h. Delays are expected following ingestion of sustained-release formulations. Systemic toxicity has been reported following instillation of ophthalmic preparations. [4]

Slowing of the heart due to sinus node suppression or conduction abnormalities occur in all significant b-blocker intoxications except overdoses of b blockers that have partial agonist activity, in which case bradycardia may not be present. QRS widening may occur with b blockers that antagonize sodium channels, such as propranolol, pindolol, and acebutolol.

Ventricular dysrhythmias are common with sotalol poisoning. Sotalol has properties consistent with the Vaughan Williams class III antidysrhythmic drugs that prolong action potential duration in His-Purkinje tissue, resulting in a prolonged Q-T interval. Premature ventricular contractions, bigeminy, ventricular tachycardia, ventricular fibrillation, and torsades de pointes have been reported.

Hypotension results from poor contractility. Together, bradycardia and depressed contractility may produce severe cardiac failure.

Depressed consciousness, seizures, and psychosis may occur due to poor perfusion or direct neuronal toxicity. Lipophilic agents are more likely to cause coma and seizures. Seizures are generalized and tend to be brief, lasting seconds to minutes. Status seizures are rare but may be refractory to treatment. [5] Acute psychosis preceded myocardial manifestations in a case of propranolol overdose. [6] When patients survive, neurologic recovery appears to be complete.

Bronchospasm following overdose is infrequent despite potential b$_2$ antagonism but has been reported with atenolol, metoprolol, oxprenolol, and propranolol poisoning.

Hypoglycemia is rare, despite potential for altered glucose homeostasis.

Rare complications of poisoning include esophageal spasm, mesenteric ischemia, and acute renal failure.

DIAGNOSIS

A limited number of other medications, chemicals, and natural toxins potentially result in bradycardia and hypotension. Common drugs include calcium channel antagonists, centrally acting a-agonists, and digoxin. Many plants (e.g., oleander, digitalis, and rhododendron) contain cardiac glycosides that may cause symptoms following ingestion of plant parts or consumption of teas brewed from the plant. Chinese medicinal preparations and aphrodisiacs often contain animal-derived cardiac glycosides (e.g., bufotoxin) that may cause bradycardia and hypotension. Such chemicals as organophosphate insecticides, cyanide, or hydrogen sulfide cause bradycardia.

Diagnostic Studies

A twelve-lead electrocardiogram and continuous rhythm monitoring are essential in evaluation and ongoing assessment. Laboratory testing is directed at supportive monitoring of renal function, glucose level, oxygenation, and acid-base status. Specific drug levels may be determined to confirm an exposure, but the results will not alter acute management, since symptoms do not necessarily correlate with levels and levels are not rapidly available. Radiographs to detect b-blocker pills in the gastrointestinal tract are not useful, since these drugs are not radiopaque. [7]

TREATMENT

Initially, all b-blocker exposures should be evaluated in a high-acuity area of the emergency department. For serious cases, treatment begins by establishing adequate airway patency, ventilation, and oxygenation. Multiple intravenous access sites, as well as central venous access, may be required.

The goal of specific cardiovascular drug therapy is to restore perfusion to critical organ systems by improving myocardial contractility, increasing heart rate, or both. Current therapy is derived principally from reports of case studies and includes glucagon, adrenergic agonists, atropine, and phosphodiesterase inhibitors. Overall, these therapies have met with variable success. Figure 169-1 is an algorithm for use of these drugs based on review of available human cases and limited experimental studies.

FIG. 169-1. Algorithm for drug therapy for b-blocker overdose.

Glucagon is widely accepted as first-line therapy. It enhances myocardial performance by increasing cAMP concentrations in a manner identical to that of catecholamines but is thought to act via its own receptor. [8] Thus, glucagon may bypass the blocked b receptor. Clinical experience with this antidote has generally produced favorable results, often after other treatments have failed. However, only two cases report glucagon as the sole pharmacologic agent to resuscitate severely toxic propranolol overdoses. [9] In several instances, glucagon failed to reverse toxicity. [10,11] A limited number of animal models directly comparing glucagon to other therapies support the use of glucagon. [12]

The initial glucagon dose is 50 to 150 μg/kg intravenous bolus. For a 70-kg patient, this represents 3.5 to 10 mg. The bolus may be repeated as needed. Because the duration of action of glucagon is 15 min, a constant infusion of 1 to 10 mg/h may be necessary to sustain its effect. There is no defined maximum therapeutic dose of glucagon. Cumulative bolus doses ranged from 1 to 30 mg. [13,14] Infusions have been continued for up to 26 h. [15]

Compared to the potential benefits of increasing heart rate and blood pressure, the adverse effects of glucagon are minimal. Nausea and vomiting may occur due to esophageal sphincter relaxation. Mild, transient hyperglycemia may develop. When using large amounts of glucagon, excessive exposure to phenol, the manufacturer's diluent, may occur, resulting in seizures, hypotension, or dysrhythmias. [16] To avoid these unwanted effects, discard the supplied diluent and reconstitute glucagon with normal saline solution.

Unfortunately, sufficient amounts of glucagon are frequently unavailable in hospital pharmacies. [17] If glucagon is not available or fails to restore organ perfusion, the

next step is to add a catecholamine.

b-adrenergic receptor agonists (catecholamines) are a logical therapy for b-blocker toxicity. Nevertheless, their use has met with disappointing results, restoring heart rate in only two-thirds of cases and blood pressure in only half. Results may not have been optimal because of inadequate dosing. For example, in humans, the dose of isoproterenol required to maintain heart rate and blood pressure had to be increased 26-fold following an infusion of labetolol. [18] In canines, isoproterenol and dopamine had to be increased 15 and 5 times, respectively, to overcome the depressant effects of propranolol. [19]

When faced with significant b-blocker toxicity, dopamine or norepinephrine are the catecholamines of choice. These agents may be preferable to epinephrine for two reasons. First, in animal models of propranolol toxicity, epinephrine had no effect on mortality rates. [20] Second, in similar calcium channel blocker toxicity models, epinephrine failed to provide optimal myocardial energy substrates needed during shock. [21] Dopamine or norepinephrine is administered as a constant infusion. Dopamine is more likely to work for mildy toxic cases. For severe toxicity, one may need to start with norepinephrine. Potential adverse effects of catecholamines include dysrhythmia, tissue necrosis, and increased myocardial oxygen demand.

Phosphodiesterase inhibitors have been used to treat b-blocker toxicity. In theory, they inhibit cAMP breakdown, thereby facilitating maintenance of intracellular calcium levels. In propranolol-induced heart failure, amrinone demonstrated positive inotropic effects without increasing myocardial oxygen demands. [22] However, other animal studies are not encouraging. Amrinone and milrinone increased cardiac output but had no appreciable effect on heart rate. [12] When administered with glucagon, neither amrinone or milrinone provided any additional benefit over that of glucagon. [23] Thus, phosphodiesterase inhibitors have no advantage over glucagon. However, if glucagon is not available, phosphodiesterase inhibitors can be reasonable alternatives.

Atropine is unlikely to be effective in the management of bradycardia and hypotension.

Treatment of ventricular dysrhythmias due to sotalol requires pharmacologic measures different from those required for other b blockers. Isoproterenol, lidocaine, and overdrive pacing have been successfully used. Magnesium may also be of benefit. [24]

Extrinsic pacing may be required to maintain heart rate. However, electrical capture is not always successful, and, if capture does occur, blood pressure is not always restored. Cardiac pacing may be most beneficial in treating torsades de pointes associated with sotalol. [24]

Occasionally, extreme means of resuscitation, including extracorporeal circulation [25] and aortic balloon pump, [26] have been successful. Insulin-dextrose was superior to standard antidotes in animals [16] and was used successfully in a combined amlodipine and atenolol overdose. [27]

Gastrointestinal decontamination with 1.0 g/kg plain activated charcoal should be initiated unless oral intake is contraindicated. Gastric lavage may be beneficial prior to instillation of charcoal if it can be accomplished within 1 to 2 h of ingestion. Syrup of ipecac is contraindicated, since b-blocker intoxicated patients may experience a rapid decline in mental status, with risk of aspiration during vomiting.

Based on previously described pharmacokinetic properties, hemodialysis would not be expected to effectively remove lipophilic b-blocker drugs that have a large volume of distribution or extensive protein binding. Hemodialysis may be useful for atenolol, nadolol, and sotalol overdose because these drugs have a lower volume of distribution and less protein binding than do other b blockers.

DISPOSITION

Patients who develop altered mental status, bradycardia, conduction delays, or hypotension should be managed in the intensive care unit. Overdose patients who present initially without symptoms can be safely discharged to psychiatric care after an observation period of 8 to 10 h provided they remain asymptomatic with normal vital signs and electrocardiogram, receive gastrointestinal decontamination, and are not expected to develop delayed complications from sustained-release formulation or coingested drugs.

170 CALCIUM CHANNEL BLOCKERS

Jeffrey A. Kline

EPIDEMIOLOGY

Each year for the past decade, calcium channel blocker poisoning required hospital treatment for over 5000 persons and caused 30 to 50 mortalities in the United States.[1] Calcium channel blockers (CCBs) are one of the most commonly prescribed classes of cardiovascular drugs. It is likely that toxicity from these drugs will increase in the next decade.

PATHOPHYSIOLOGY AND PHARMACOLOGY

Intracellular calcium is the primary stimulus for smooth and cardiac muscle contraction and for impulse formation in sinoatrial pacemaker cells. At therapeutic concentrations, organic CCBs bind to the alpha subunit of the L-type calcium channel, causing the channel to favor the closed state and thereby decreasing calcium entry during phase II depolarization. At very high concentrations, some CCBs (verapamil) may occupy the channel canal and completely block calcium entry through the L-channel. The result is profound smooth muscle relaxation, weakened cardiac contraction, and blunted cardiac automaticity. Clinically, these effects are recognized as hypotension and bradycardia. When circulatory shock supervenes with severe overdose, lactic acidosis and hyperglycemia are common manifestations. Hyperglycemia results from a suppressive effect of CCBs on pancreatic beta-cell insulin release, together with whole-body insulin resistance. [2,3] Severe poisoning also can cause hyperkalemia, which augments the negative inotropy of CCBs in two ways. First, hyperkalemia reduces the action potential duration and shortens the phase II plateau, and second, hyperkalemia enhances the binding of organic CCBs to the L-type calcium channel. [4,5] Verapamil overdose also impairs myocardial carbohydrate intake, which contributes to the negative cardiac inotropy. [6]

Table 170-1 reviews the three major classes of CCBs that are widely used in the clinical setting: the phenylalkylamines (verapamil), the benzothiazepines (diltiazem), and the dihydropyridines (nifedipine). Verapamil is the most potent negative inotrope of all CCBs, causing at least equal depression of heart contraction compared with smooth muscle dilatation at any concentration. This is one reason that verapamil overdose causes more deaths than all other CCBs combined. [1] Dihydropyridines bind more selectively to vascular smooth muscle calcium channels compared with cardiac calcium channels and therefore relax smooth muscle at concentrations that produce almost no negative inotropy. Dihydropyridines have been structurally modified to make them more lipid soluble in an effort to prolong their durations of action. These modified dihydropyridines are known as *second-generation dihydropyridines* (amlodipine and felodipine). They cause more gradual smooth muscle relaxation, producing less reflex baroreceptor activation and less reflex tachycardia than is observed with first-generation dihydropyridines.

Class	Trade Name	Vascular Selectivity*
Phenylalkylamines:		
Verapamil	Calan, Verelan, Isoptin	1.0
Benzothiazepines:		
Diltiazem	Cardizem, Dilacor	1.0
Dihydropyridines:		
Nifedipine	Procardia, Adalat	0.1
Amlodipine	Norvasc	0.1
Nicardipine	Cardene	0.01
Isradipine	DynaCirc	0.01
Felodipine	Plendil	0.01
Nisoldipine	Baymycard (in U.K.)	0.0001

Note: An index number closer to 1.0 indicates that the drug causes an equal degree of reduction in cardiac function compared with vasodilation.
*Ratio of percent negative inotropy to percent vasodilatation at 10^{-7} M.

TABLE 170-1 Relative Negative Inotropic Effect versus Vascular Smooth Muscle Relaxing Effect of Calcium Channel Antagonists in Humans

PHARMACOKINETICS

The use of sustained-release and second-generation dihydropyridine CCB preparations is now widespread. [1] These preparations provide a larger drug dose per tablet (especially in children), can extend the duration of clinical toxicity, and can lead to a delay in clinical manifestation of toxicity. Drawing from available case reports that provide plasma drug levels, several management guidelines can be asserted for overdose of any long-acting CCB preparation. First, if significant toxicity occurs, it will be manifested within 6 h of overdose[7] although a 12-h delay in overt toxicity after a sustained-release verapamil overdose treated with charcoal administration has been reported.[8] Peak drug levels and associated toxicity will occur within 12 h of overdose. Finally, chronic use of the drug will worsen and prolong toxicity of acute overdose.

CLINICAL FEATURES

Information about the clinical effects of CCB overdose is drawn largely from case reports, retrospective case series, and animal studies. It is not disputed that CCBs cause a decrease in systemic vascular resistance at all degrees of toxicity. Thus the patient with CCB poisoning will exhibit evidence of poor organ perfusion (Table 170-2). Inadequate cerebral perfusion may produce dizziness, lethargy, agitation, confusion, seizures, or hemiplegia suggestive of stroke early in the course of CCB poisoning. Compensatory tachypnea can be expected with a major overdose. Mild CCB toxicity usually causes sinus bradycardia, whereas more severe intoxication causes variable degrees of conduction blocks. The most severe CCB intoxication causes complete sinus arrest, at which point the dominant cardiac rhythm is an escape rhythm from the ventricle, which may show a wide QRS complex on surface ECG. Generally, the degree of impairment in cardiac conduction and overall heart function is difficult to predict based on the reported amount or type of CCB ingested. There appears to be a narrow CCB dose range (3–7 mg/kg for nifedipine, 5–10 mg/kg for diltiazem or verapamil) where the cardiotoxic manifestations of CCB are highly variable between individuals. One patient with a "moderate" CCB ingestion will exhibit only sinus bradycardia, whereas another patient with a reportedly similar ingestion will exhibit complete sinus arrest. Similarly, the degree of impairment of cardiac conduction and global cardiac function cannot be tightly correlated with plasma CCB concentrations. Indeed, dihydropyridines in moderate doses are well recognized to produce reflex increases in heart rate with an increase in left ventricular stroke volume, leading to an increase in cardiac output in healthy subjects. Preliminary reports suggest that patients with moderate CCB overdose who are treated with adrenergic agents usually show an *increased* cardiac output.[9] This finding has been verified experimentally in healthy animals as well, and has been attributed to physiologic reflexes and neurohumoral adaptations. Undoubtedly, however, with severe overdose, all CCBs exert a negative inotropic effect with depressed cardiac contraction, conduction block, and hypotension with shock. Thus it is possible

with overdose of sustained-release preparations that the patient will pass through a brief period of good cardiovascular compensation only to deteriorate later as drug absorption increases and hepatic and renal perfusion decrease. Urine output will be minimal with severe poisoning as a result of poor renal perfusion. The combination of hypotension and bradycardia can help differentiate CCB toxicity from hypovolemia, sepsis, cyclic antidepressant toxicity, and causes of circulatory shock such as pulmonary embolism or cardiac tamponade, all of which cause hyperdynamic shock in early stages.

Bradycardia with hypotension

Altered mental status (range from agitation to coma)

Generalized weakness

Metabolic acidosis with hyperglycemia

Sinus arrest on ECG

Refractory shock

TABLE 170-2   Key Diagnostic Features of Calcium Channel Antagonist Overdose

Other clinical manifestations of CCB toxicity stem from multiorgan hypoperfusion and inhibition of metabolic processes and may indicate impending severe shock. Physical examination (and intuition) may provide the best initial evidence of incipient severe toxicity. Most patients with significant toxicity are drowsy and asthenic. However, muscular weakness does not occur from a direct effect of CCBs on skeletal muscle excitation contraction even with massive overdoses. Mydriasis is not a key feature of CCB poisoning, although some patients do exhibit dilated pupils. Mental function is often altered, with behavior ranging from agitation to coma. Noncardiogenic pulmonary edema is sometimes seen. Hypoxemia also has been reported, presumably from intrapulmonary ventilation-perfusion mismatch. Metabolic (lactic) acidosis with hyperglycemia is described in multiple case reports and in laboratory reports. Hypokalemia is observed frequently but carries little prognostic meaning. However, hyperkalemia is an ominous finding, suggesting severe poisoning. Hypercalcemia is not caused by CCB overdose, although hypocalcemia has been reported.[10]

DIAGNOSIS

Initial Measures

Any patient with suspected CCB toxicity should have cardiac monitoring, supplemental oxygen, and at least one 18-gauge or larger intravenous catheter inserted with a normal saline infusion begun. A 10 to 20 cc/kg bolus should be administered to otherwise healthy patients with a systolic blood pressure below 90 mmHg or to patients with a history of hypertension who demonstrate a systolic blood pressure less than 100 mmHg. Venous blood should be drawn for electrolyte and creatinine determinations. In hypotensive patients with suspected drug overdose who remain very drowsy despite administration of naloxone, endotracheal intubation should be considered to ensure airway protection and facilitate further treatment measures. Cuff sphygmomanometry frequently produces inaccurate estimations of arterial blood pressure with shock. Accordingly, an intraarterial catheter should be inserted for persistent hypotension. Arterial blood gases and electrolytes should be examined to determine acid/base status and to guide the rate of oxygen delivery and minute ventilation based on Pa_{O_2} and Pa_{CO_2} measurements. A widened anion gap indicates significant systemic hypoperfusion. Central venous catheterization should be performed for any patient who remains hypotensive after normal saline bolus or for any patient with documented congestive heart failure or anuric renal failure who manifests CCB toxicity. Patch-stick electrodes should be placed on the anterior and posterior chest to facilitate transcutaneous electrical pacing, should it be necessary.

Secondary Evaluation

The shock state from CCB overdose is characterized by hypotension from profound vascular smooth muscle relaxation with decreased left ventricular contractility and bradycardia. Patients with severe CCB poisoning typically manifest heart rates of 45 to 55 beats per minute with no evidence of sinus node depolarization on surface ECG. The metabolic acidosis is caused by lactate accumulation. Each of these manifestations can be quantified at the bedside to help gauge the severity of overdose. Transthoracic echocardiography can be performed to estimate the left ventricular ejection fraction as an index of contractile function. Arterial blood gas analysis may reveal hypoxemia. Compensatory hypocarbia can be expected as the patient hyperventilates in an effort to offset CCB-induced metabolic acidosis. The arterial base deficit and the lactate concentration can provide indexes of overall toxicity with CCB overdose. Precise cause of the lactic acidosis remains to be elucidated but likely occurs as a combination of skeletal muscle hypoperfusion with impaired oxidative metabolism and reduced hepatic lactate uptake. Lactic acidosis may be important for diagnostic and therapeutic reasons. A lactate concentration greater than 2.0 mmol/L may portend a severe overdose that will lead to hemodynamic decompensation. Also, severe lactic acidosis can itself impair heart function and metabolism, thereby potentiating the negative inotropy of CCB poisoning. As mentioned earlier, hyperkalemia also can worsen the negative inotropy of severe CCB overdose. Hyperkalemia probably develops as a result of systemic insulin resistance and acidosis.

TREATMENT

Treatment of CCB overdose consists of three basic objectives: providing supportive care, decreasing drug absorption, and improving cardiac function with cardiotonic agents. Many patients are alert and cooperative, describe a nontoxic CCB overdose (<3 mg/kg for nifedipine, <5 mg/kg for diltiazem or verapamil), and demonstrate sinus rhythm with essentially normal arterial blood pressure. These individuals can be closely monitored noninvasively for 6 to 12 h. Patients who are drowsy and manifest hypotension despite a 15 mL/kg normal saline bolus or show sinus arrest on ECG should be managed aggressively, as outlined below.

General Measures

Supportive care consists of airway protection, adequate ventilation, and hemodynamic monitoring. Patients who are drowsy after an unquantified CCB overdose should receive naloxone and fingerstick glucose determination. If the patient still does not follow verbal commands, endotracheal intubation is advised, regardless of hemodynamic status. Endotracheal intubation may help prevent pulmonary aspiration during gastric instillation of charcoal, should vomiting occur. Mechanical ventilation eliminates work of breathing, which can translate into improved cardiac output. The minute ventilation can be adjusted to produce a slight respiratory alkalosis (Pa_{CO_2} 25–30 mmHg), which may reduce negative inotropy. Additionally, the patient can be positioned safely (and administered skeletal muscle paralytic agents, if necessary) for central venous cannulation. A #8.5 French central venous catheter is quite useful for managing CCB overdose because it can provide a portal for pulmonary artery catheterization and can be used to administer calcium salts, which are irritating to peripheral veins. All patients require Foley catheterization to monitor urine production as a key index of organ perfusion.

Reducing drug absorption and enhancing elimination are the next objectives in treating CCB overdose. All CCBs bind to activated charcoal, which should be administered after the patient's airway is secured. With massive overdose, sustained-release preparations can form gastrointestinal concretions (with ileus) that can persist for days, rendering charcoal less useful. Accordingly, whole-bowel irrigation with polyethylene glycol has been advocated to accelerate removal of sustained-release CCB pill fragments.[8] Drug elimination can be enhanced by extracorporeal removal. For example, charcoal hemoperfusion may lower verapamil and diltiazem concentrations but may have less use for nifedipine or other dihydropyridine poisoning. [11,12]

No firm rules can dictate the selection and sequencing of cardiotonic agents to treat CCB toxicity. A guideline algorithm is offered in Fig. 170-1 . Several basic resuscitation efforts should be addressed prior to or simultaneously with the use of an inotropic agent. These include administration of a volume bolus (10–20 mL/kg), correction of acidemia (keep arterial pH above 7.20 by hyperventilation or with sodium bicarbonate infusion), and rapid correction of hyperkalemia with a bolus infusion of calcium chloride (1 g 10% w/v, diluted to 100 cc in normal saline, IV) simultaneously with a bolus of insulin (0.2 unit/kg, IV). Although the treatment objective is to establish normal sinus rhythm with normal blood pressure, with severe poisoning, treatment goals should focus on *stabilization* rather than on normalization of heart rate, arterial blood pressure, urine output, arterial base deficit, and cardiac output (if available) or left ventricular ejection fraction. There are no

reports of perminant cardiomyopathy or central nervous system (CNS) dysfunction from direct CCB effect.

FIG. 170-1. Treatment guidelines for severe CCB ingestion.

Calcium

Calcium salts are recommended by many toxicologists for the first-line treatment of CCB overdose. As a guideline, calcium chloride should be initiated as a 10 to 20 mg/kg bolus injection. Calcium chloride may be preferable to gluconate preparations because it produces more reliable plasma ionized calcium concentrations. Calcium chloride is available in a 10-mL 10% solution, which may be diluted to 100 mL in normal saline and infused over 5 min via central venous catheter as a test bolus in adults. If this infusion improves heart rate or conduction on ECG or increases the arterial blood pressure, then a constant infusion at 20 to 50 mg/kg/h $CaCl_2$ should be initiated. As a general end point, ionized plasma calcium concentrations should be maintained between 2.0 and 3.0 meq/L. The elevated plasma calcium concentration improves cardiac conduction and contraction simply by increasing the driving force of the calcium ion's entry through L-type channels that are not closed. If the calcium channels are uniformly saturated by a CCB (in particular, verapamil), then the proportion of L-channels that are closed will be nearly 100 percent. In this situation, even the highest of plasma calcium concentrations will not improve cardiac function. Calcium infusion also may cause vomiting, acute rhythm disturbances including asystole, and local irritative effects that may result in serious sequelae, including upper extremity compartment syndromes.

Glucagon

If calcium infusion provides inadequate clinical response, glucagon should be tested next. Glucagon is capable of inducing an immediate and remarkable positive chronotropic and inotropic response in mild to moderate toxicity. Glucagon binds to at least one specific membrane receptor, which is distinct from the b-adrenergic receptor. The glucagon receptor activates the stimulatory G-protein, leading to an elevation in cytosolic cyclic adenosine monophosphate (cAMP). The increased cAMP signals for the activation of protein kinases that phosphorylate the cytosolic domain of the L-channel. Channel phosphorylation increases the probability of channel opening, even if an organic CCB is bound to the channel. However, the degree of recruitment in channel opening is entirely dependent on the proportion of channels that have CCB bound to them. If binding is widespread, then the net increase in channel opening will be very low, even with maximal cAMP–protein kinase stimulation. Thus, with severe CCB poisoning, glucagon may be ineffective.

Glucagon should be diluted in normal saline, as opposed to using the phenol provided in the package, and a 0.1 mg/kg intravenous test bolus should be administered. In general, one of two responses occurs with glucagon injection with CCB overdose. The patient may show immediate evidence of improvement, both on ECG and in blood pressure. Alternatively, the patient may vomit, and deteriorate. [13,14 and 15] If a benefit is observed, a constant infusion of glucagon should be initiated, starting at 0.1 mg/kg/h. The infusion rate should be minimized to maintain sinus rhythm or a systolic blood pressure above 100 mmHg with urine production above 1 mL/kg/h. Note that wholesale cost of glucagon is about $20/mg.

Catecholamines

Catecholamines should be tested as the next step for refractory CCB overdose. The predominant mechanism by which all catecholamines increase cardiac function and systemic vascular resistance is through binding to two membrane receptors. Activation of the b$_1$ adrenoreceptor increases cardiac cAMP in a postreceptor manner identical to glucagon and causes increased heart rate and force of cardiac contration. Activation of the a$_1$ receptor causes an increase in vascular smooth muscle tone and increases cardiac inotropy via a mechanism separate from the cAMP–protein kinase pathway. Dopamine is the most commonly used agent and can be given in doses standard for cardiogenic shock (1–20 µg/kg/h). [16] Other catecholamines such as dobutamine, norepinephrine, and isoproterenol have been used in patients and animal studies with variable success. Epinephrine also has shown benefit in CCB-intoxicated humans and animals. [17,18 and 19] However, in one clinically relevant dog model of verapamil toxicity, epinephrine tended to worsen heart function and did not improve survival compared with saline treatment. [20] If epinephrine is used, a trial of 0.1 µg/kg/min can be titrated to a maximum of 1.0 µg/kg/min. If there is no satisfactory improvement within 5 min of the maximum infusion rate, then epinephrine should be discontinued in favor of an alternative agent.

Other Cardioactive Agents

Amrinone also has been reported to be successful in treating refractory CCB overdose. Amrinone inhibits the action of the cardiac phosphodiesterase (known as the peak III PDE), which leads to an elevation in cytosolic cAMP. Amrinone's main benefit is its positive inotropic action. Amrinone requires a loading bolus of 750 µg/kg, followed by a constant infusion at 1 to 20 µg/kg/h.

Atropine also is used frequently for treating CCB overdose. [16] Although atropine probably has no adverse effects in this setting, it seldom produces any benefit as a sole treatment.

Insulin

High-dose insulin infusion also has provided benefit in two models of verapamil toxicity. [18,20] Insulin appears to improve myocardial mechanical efficiency and contractility by accelerating carbohydrate oxidation. Insulin is also potent a positive inotrope that operates through a mechanism similar to the postreceptor action of the a$_1$ adrenoreceptor. Insulin does not produce a sharp improvement in hemodynamic indexes when bolus infused. Instead, insulin slowly but steadily improves heart contractility. Insulin has no direct effect on cardiac conduction but may lower plasma potassium concentrations and indirectly improve automaticity and conduction. Perhaps the best role of insulin is as an adjunctive therapy for suspected massive overdose, and it is more effective in humans when administered before profound hypodynamic shock supervenes. [21] A suggested infusion dose is 1.0 unit/kg/h for the first hour, followed by 0.5 unit/kg/h. [21] Depending on the severity of overdose, resistance to insulin-mediated glucose clearance may be significant; in general, adults require 20 to 30 g of glucose per hour to maintain euglycemia with a high-dose insulin infusion. The concomitant use of catecholamines should not deter the use of insulin. When insulin infusion is added to catecholamine infusion, an additional positive inotropic effect is observed, even in the depressed heart. [22]

RESCUE TREATMENTS

For patients with cardiogenic shock that is refractory to the preceding treatments, several options remain open. Electrical cardiac pacing may help restore heart rate and should be considered for patients with shock and a heart rate below 40 beats/min. At the level of the heart cell, CCBs delay both systolic calcium transients and diastolic calcium reuptake. The heart cell cannot be forced into normal rhythmicity and electrical depolarization. In fact, ventricular stroke volume tends to be maximized at a heart rate of 45 to 50 beats/min. Electrical pacing faster than this rate actually may reduce stroke volume. As a result, electrical pacing at too rapid a rate may not improve cardiac output.

4-Aminopyridine (4-AP) is a potassium channel blocking agent that is now available for the treatment of multiple sclerosis. Based on several animal studies of

verapamil toxicity, (4-AP) can be considered for a patient who is dying despite all efforts. [23,24] 4-Aminopyridine should be infused in doses of 10 to 50 μg/kg/h.

Venovenous hemodialysis or venovenous charcoal hemoperfusion can lower the plasma concentration of verapamil and diltiazem. However, these procedures should be considered with caution. Both require insertion of a large-bore dialysis catheter, and both require heparin anticoagulation. Hemodialysis—and to a lesser extent hemoperfusion—can worsen cardiovascular instability in a patient already suffering hypodynamic shock. First, to achieve adequate drug removal, relatively high rates of blood flow across the artificial kidney may be required. Second, hemodialysis can remove plasma catecholamines. Third, approximately 10 percent of patients develop an idiosyncratic hypotensive response to the polysulphone membrane used in most hemodialysis and hemoperfusion circuits. Thus, when the pump is started, the patient's blood pressure may drop. Also, with large ingestions, a mass of drug usually is present in the patient's intestine for at least 12 h, which allows ongoing drug absorption. For these reasons, continuous hemoperfusion is advised over episodic dialysis.

Intraaortic balloon counterpulsation also has been reported to improve shock from verapamil poisoning. [25,26] Extracorporeal cardiopulmonary bypass also may provide a bridge to survival, especially if used in conjunction with hemodialysis or hemoperfusion.

DISPOSITION

Patients with trivial ingestions (<3 mg/kg of a first-generation dihydropyridine, <0.2 mg/kg of a second-generation dihydropyridine, or <5 mg/kg of diltiazem or verapamil), a normal heart rate and blood pressure, and no symptoms can be observed for approximately 6 h and discharged. Patients who report a large overdose of a sustained-release preparation (>10 mg/kg of verapamil or diltiazem) or a dihydropyridine derivative with a half-life over 12 h (Table 170-3) should be admitted for ECG monitoring for at least 12 h, even if they exhibit no symptoms. All patients with signs and symptoms of CCB toxicity should be admitted to an appropriate setting. Any patient who requires inotropic support (including bolus doses of calcium salts) should be admitted to an intensive care unit.

Drug	Peak Toxicity [h]	$t_{1/2}$ [h]
Verapamil	1–2	5–7
Verelan SR	6–7	>12
Calan SR	2–3	7–12
Diltiazem	1–2	8–9
SR, CD, XR	3–5	5
Nifedipine	1	3
Adalat retard	3–10	20–25
Procardia XL	3–5	12–18
Amlodipine	6–12	>24
Felodipine	6–12	>12

171 ANTIHYPERTENSIVES

Arjun Chanmugam

Hypertension is one of the most common diseases in the United States, affecting almost 24 percent of the population.[1] Medications used to control hypertension are among the most commonly prescribed drugs. As a result, the potential for overdose, inadvertent or intentional, is quite high. In 1997, according to the Toxic Exposure Surveillance System, cardiovascular drugs, including antihypertensive medications, accounted for nearly 3 percent of all adult toxic exposures.[2]

There are many classes of antihypertensive medications available for use, with new agents introduced into the market routinely. The initial management of patients with an acute overdose of antihypertensive medication remains relatively uniform. Airway, breathing, and circulation remain the initial priorities, so oxygen, cardiac monitoring, and intravenous access remain the key initial interventions. If mental status changes are present glucose and naloxone should be also be considered as initial interventions. If no contraindications are present, antihypertensive-induced hypotension should be treated initially with volume expansion, using normal saline or an equivalent crystalloid solution (such as Ringer lactate solution). In most adults, initial fluid therapy should consist of bolus challenges of 500 mL or 10 to 20 mL/kg over 10 to 15 min. If hypotension persists despite fluid challenges, the use of a vasopressor may be warranted. In most cases, dopamine is the vasopressor of choice, with infusion rates started at 2 to 5 μg/kg/min and increased as necessary.

Supportive measures and appropriate monitoring should be instituted as early as possible. The use of activated charcoal is indicated in most overdose situations, but gastric decontamination should be considered only in appropriate patients. The management of patients with antihypertensive poisonings rarely depends on serum levels of medications but instead depends on symptoms. However, a key to managing these patients is to determine the medication involved and target interventions specific for that class of antihypertensive agent (Table 171-1). In the following discussion, antihypertensive toxicology is divided into sections based on the class of medications. b Blockers, monoamine oxidase inhibitors, and calcium-channel blockers are discussed in separate chapters.

TABLE 171-1   Specific Antihypertensive Medications

DIURETICS

Diuretics are among the most commonly prescribed of all antihypertensives because they are recommended as a first-line medication in the treatment of hypertension.[1] Depending on their mechanism of action, diuretics can be subdivided into several groups.

Thiazides and Loop Diuretics

Thiazides and loop diuretics are two classes of diuretics commonly used. The classic thiazide diuretic is hydrochlorothiazide, which can be used as single-drug therapy or as part of a multidrug regimen. Combination products are becoming more common in the treatment of hypertension, and hydrochlorothiazide is often used as a component of these fixed-combination medications. In general, toxicity associated with thiazides is rare.

The diuretic action of thiazides is due to its ability to inhibit reabsorption of sodium and chloride at the distal convoluted tubule. This results in a greater excretion of water and other essential electrolytes, including potassium and bicarbonate. At higher doses, thiazides can act as carbonic anhydrous inhibitors. Calcium regulation is also affected by thiazides by two separate mechanisms: (1) They inhibit synthesis of vitamin D to decrease calcium absorption from the gastrointestinal tract. (2) They inhibit renal excretion of calcium.

Loop diuretics include such drugs as furosemide, bumetanide, and ethacrynic acid. These drugs act on the ascending limb of the loop of Henle to decrease reabsorption of sodium, chloride, and water. They act similarly to the thiazides in that they alter the regulation of other essential electrolytes, particularly potassium and calcium. Loop diuretics also increase venous capacitance and are used in acute situations with elevated cardiac filling pressures.

The toxicity associated with thiazides and loop diuretics involves two basic processes: volume contraction and electrolyte derangements. Symptoms associated with intravascular volume depletion include hypotension, tachycardia, and altered mental status. Common electrolyte derangements include hyponatremia, hypokalemia, hypocalcemia, hypomagnesemia, and hypochloremic metabolic alkalosis. Other adverse reactions from thiazides and loop diuretics may include rash, pruritis, hearing loss, leukopenia, and thrombocytopenia.

Normal saline administration is the preferred therapy for hypovolemia, hyponatremia, and alkalosis. The use of vasopressors is rarely indicated for hypotension. Potassium replacement should be instituted early, although renal function should be assessed and monitored during therapy to avoid inducing iatrogenic hyperkalemia in acute or chronic renal failure. In general, if comorbid conditions are not present, most asymptomatic individuals can be medically cleared after therapy and observation. Poisonings sufficient to cause significant electrolyte abnormalities are likely to be associated with total body deficits of various elements and may require prolonged therapy. Elderly patients and individuals at suicide risk need to be monitored carefully.

Potassium-Sparing Diuretics

The most common medications of this subclass are spironolactone, triamterene, and amiloride. Spironolactone, a competitive inhibitor of aldosterone, acts to allow

potassium retention while inducing sodium and water excretion. Triamterene has direct effects on the renal tubule to inhibit sodium exchange for potassium and hydrogen. Amiloride's mechanism of action, also independent of aldosterone, is to promote potassium retention in exchange of sodium and water. Volume depletion, hyperkalemia, hyponatremia, and hypochloremia are common manifestations of toxicity for this class of medication. Treatment for potassium-sparing diuretic toxicity is directed at maintaining intravascular volume, repleting sodium, and reversing the hyperkalemia. Hypotension is best initially treated with intravenous fluids, usually normal saline. If hypotension is persistent, a vasopressor such as dopamine is warranted. The most serious manifestations of hyperkalemia include neurologic and cardiovascular dysfunction. Treatment of hyperkalemia should remain a priority, and can be serious enough to warrant dialysis.

Carbonic Anhydrase Inhibitors

The prototype for this subclass of diuretic is acetazolamide, which is a nonbacteriostatic sulfonamide whose adverse reactions include severe allergic reaction and Stevens-Johnson syndrome. The primary action of this class of diuretic is to inhibit carbonic anhydrase in the kidney to prevent the reversible reaction of carbon dioxide and water to form carbonic acid. This results in loss of bicarbonate ions in the urine, along with sodium, potassium, and water. Overdose with this class of medication can lead to volume depletion and electrolyte disturbances, as well as non-anion-gap metabolic acidosis. Treatment is directed at reversing volume depletion, monitoring electrolytes, and restoring normal pH balance.

Osmotic Agents

Osmotic agents, such as mannitol, are not absorbed by the nephron. Rather, they induce diuresis by raising the osmolarity of the glomerular filtrate, thereby attracting more water in the tubules to increase urine volume. The main effect of osmotic agents is to decrease intravascular volume, but toxicity can result in pulmonary edema, anaphylaxis, and acute renal failure. Overdoses can cause profound volume loss, accompanied by electrolyte imbalances. Treatment is aimed at repleting the intravascular volume and correcting any electrolyte imbalances. Other adverse reactions—such as pulmonary congestion, acidosis, electrolyte loss, dryness of mouth, thirst, marked diuresis, urinary retention, edema, headache, blurred vision, convulsions, nausea, vomiting, rhinitis, skin necrosis, thrombophlebitis, chills, dizziness, urticaria, dehydration, fever and angina-like chest pains—have been reported during or following mannitol infusion.

CLONIDINE

This centrally acting antihypertensive has long been a favorite for the acute management of hypertension. Two forms of clonidine are commonly prescribed, including an oral version and a transdermal patch. Clonidine has gained prominence in recent years because of its ability to mitigate opiate and alcohol withdrawal symptoms. Although it has not been approved by the Food and Drug Administration for this use, clonidine has been used as standard clinical practice for the treatment of narcotic withdrawal for almost 2 decades.[3] With the advent of the clonidine patch in 1986, drug delivery could be reliably maintained for 7 days at a variety of doses, which increased its attractiveness for prescribers. However, plasma concentrations of clonidine remain high enough to maintain a hypotensive effect for approximately 8 h after the removal of the patch. Regardless of the route of administration, clonidine's most common adverse effects are dry mouth and drowsiness.

Clonidine is an imidazoline whose principle site of action is on the a_2 receptors in the lower brainstem. Stimulation of the central a_2-receptor decreases norepinephrine release in the central nervous system (CNS), resulting in a lower heart rate and blood pressure. Although clonidine acts as a central a_2 agonist, it has other effects. For example, it reduces noradrenergic output in the locus ceruleus, which is stimulated by the cessation of narcotic use, thereby mitigating the symptoms of opioid withdrawal. At higher doses, clonidine can act as a partial peripheral a agonist, resulting in a paradoxical increase in blood pressure and heart rate. However, this effect is relatively short-lived and the antihypertensive effects usually predominate.

The primary symptoms associated with clonidine toxicity include hypotension and bradycardia, which can lead to cardiac ischemia and congestive heart failure. Mental status changes range from agitation and hallucinations to sedation and coma. Respiratory depression and recurrent apnea can occur, especially in children. The other symptoms of clonidine toxicity include seizures, diarrhea, hypothermia, and miosis.

Treatment of clonidine overdoses is centered on maintaining adequate blood pressures. In the acute phase of toxicity, a brief blood pressure elevation may occur. This paradoxical hypertensive response is due to peripheral adrenergic stimulation but usually evolves rapidly into hypotension as central a_2-agonist stimulation predominates. Treatment is rarely indicated for transient blood pressure elevation, but if aggressive intervention is warranted, nitroprusside is the drug of choice due to its rapid onset and dissipation. The peak effects of clonidine usually occur in 1 to 3 h. Intravenous fluids are usually adequate for the treatment of hypotension, but in cases of persistent hypotension, a dopamine infusion beginning at a midlevel (dose) rate of 2 to 5 µg/kg/min can be initiated.

The other serious cardiovascular condition caused by clonidine toxicity—sinus bradycardia—must be monitored closely. Symptomatic bradycardia should be treated with repeated doses of atropine sulfate. The other toxic effects of clonidine occur less commonly but may be serious. Respiratory depression is rare, but recurrent apnea, especially in children, may require intubation. Seizures require supportive measures and usually respond to standard anticonvulsant therapy. Hypothermia associated with clonidine toxicity also responds to standard interventions.

In cases of severe refractory hypotension or CNS depression, the use of naloxone has been suggested, although its mechanism of action is not well understood. Tolazoline, 10 mg intravenously titrated every 30 min, is only recommended after intravenous fluids, dopamine, atropine, and naloxone have failed to reverse the cardiovascular effects of clonidine. There is also a single case report of clonidine toxicity being successfully treated with yohimbine, a CNS a_2-adrenergic antagonist.[4]

Clonidine's range of toxicity has not been well established. Severe toxicity has been reported in children at doses as low as 0.1 mg, whereas adults have survived with levels exceeding 15 mg. Symptoms of clonidine toxicity can persist for up to 72 h, so admission should be considered for any patient suspected of clonidine overdose.

Abrupt cessation of clonidine therapy can result in withdrawal. Signs and symptoms range from hypertensive encephalopathy to jitteriness and headache. This rebound hypertensive state results from elevated catecholamine concentrations in the plasma and, in rare cases, has been reported to be fatal. However, clonidine-related rebound hypertensive states are usually associated with high-dose therapy. If end-organ damage results, clonidine withdrawal should be managed as a hypertensive emergency (see Chap. 53). If no evidence of hypertensive emergency is found, resumption of clonidine therapy or the administration of labetolol, 200 mg orally, is adequate intervention. The use of other b blockers should be avoided in clonidine withdrawal states, as the unopposed a-adrenergic effects may worsen the hypertension.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

Angiotensin-converting enzyme (ACE) inhibitors come in two basic forms: an active drug form, best represented by captoril, and a prodrug form, represented by enalapril. Recently, enalaprilat, the active form of enalapril, became available for intravenous use. However, there are many ACE inhibitors available today, and all work to inhibit the conversion of the prohormone, angiotensin I, to the potent endogenous vasoconstrictor, angiotensin II. Besides being a vasoconstrictor, angiotensin II stimulates aldosterone release to increase sodium and water retention. Aside from these two effects, ACE inhibitors have other mechanisms of action to decrease total peripheral resistance without increasing heart rate or cardiac output. For example, by inhibiting ACE (also known as bradykininase), the degradation of the vasodilator peptide, bradykinin, is prevented.

Adverse effects of ACE inhibitors include hypotension, angioedema, rash, anaphylactoid reactions, cough, drug fever, proteinuria, glomerulopathy, neutropenia, and agranulocytosis. With overdoses of ACE inhibitors, the most important concern is hypotension, which can be profound. The preferred therapy to reverse the hypotension is the administration of normal saline, and, if necessary, vasopressors, such as intermediate or high-dose dopamine, can be added. Although ACE inhibitors are dialyzable, peritoneal dialysis and hemodialysis are not recommended at this time. Naloxone has been reported to be useful in reversing the hypotension induced by captopril, although its mechanism is unclear.

ANGIOTENSIN II RECEPTOR ANTAGONIST

The antihypertensive medications of this relatively new class are reversible, competitive inhibitors of the angiotensin II receptor. Losartan, the first drug of this class to be approved, has no effect on ACE but is a selective blocker of the AT_1 receptor found in vascular smooth muscle. Experience is limited with losartan, but adverse effects have been reported to be minimal. Toxicity includes hypotension and bradycardia. Supportive measures, including intravenous normal saline, adequate

monitoring, and close observation is indicated for anyone who may have ingested an overdose of an angiotensin II receptor antagonist.

OTHER CENTRALLY ACTING ANTIHYPERTENSIVES

Centrally acting antihypertensives all work by decreasing sympathetic outflow in the CNS. The importance of many of these medications has decreased as other classes of medications have gained in prominence. Two medications in particular are considered in this section: guanabenz and methyldopa. Overdoses of these medications result in similar effects, including hypotension, symptomatic bradycardia, dry mouth, and potential mental status changes. Hypotension should be treated with intravenous fluids; if necessary, vasopressors such as norepinephrine or dopamine should be considered. Bradycardia can be treated with atropine. Methyldopa can be dialyzed, but there is no clear evidence that guanabenz can be dialyzed. A rebound hypertensive condition, similar to that of clonidine withdrawal, may occur with the abrupt cessation of any centrally acting antihypertensive medication.

PERIPHERAL VASODILATORS AND GANGLIONIC BLOCKERS

The toxic manifestations of these classes of medications include hypotension and bradycardia. Hypotension is best treated with intravenous fluids and, if necessary, vasopressors. If symptomatic bradycardia develops, atropine should be used. Seizures are a potential complication and should be treated with standard anticonvulsant therapy.

In addition to hypotension, a-adrenergic antagonists such as phentolamine may also cause CNS effects. No deaths have been attributed to the acute toxicity of phentolamine or to the ganglionic blocker trimethaphan. Other specific vasodilators are discussed below.

Prazosin

Prazosin is an arteriolar dilator whose mechanism of action involves competitive blockade of postsynaptic a $_1$-adrenergic receptors. Reported toxicity associated with this drug is uncommon. A first-dose phenomenon has been reported with prazosin use that results in an unanticipated sudden hypotensive episode potentially leading to syncope. Inadvertent hypotension generally occurs within 30 to 60 min after the first dose has been given and is usually preceded by tachycardia. The first-dose phenomenon usually occurs in individuals with impaired hepatic function or congestive heart failure.

Other toxic symptoms include headache, vertigo, paresthesias, gastrointestinal discomfort, and weakness. Case reports have indicated that priapism, pulmonary edema, and acidosis can also occur as a result of overdose with prazosin. However, the most common manifestation of prazosin overdose remains hypotension and tachycardia. Treatment is supportive with intravenous fluids, careful monitoring, and vasopressors, if necessary.

Hydralazine

Hydralazine, a smooth muscle vasodilator whose mechanism of action is poorly understood, is available both in tablet form and in parental form. Acute toxicity with hydralazine is uncommon, and no fatalities due to acute poisoning have been reported. Chronic use does lead to a hydralazine-induced systemic lupus erythematosus syndrome, but this generally occurs in individuals who have slow hepatic acetylation. Treatment is supportive; the hypotension associated with hydralazine responds well to intravenous fluids. Vasopressors should be used with caution in order to avoid precipitating dysrhythmias. Dopamine should be used judiciously if a vasopressor is necessary. Symptomatic tachycardia can be cautiously treated with b blockers.

Minoxidil

Minoxidil is a direct-acting peripheral vasodilator that lowers systolic and diastolic blood pressure without much affect on the CNS. It also has the advantage of not interfering with vasomotor reflexes and therefore does not induce orthostatic hypotension.

Minoxidil, in tablet form, is usually reserved for the treatment of severe or refractory hypertension, and reported toxicity has been rare. A common side effect of minoxidil is hirsuitism. In 1988, a 2% topical solution of minoxidil was approved for the treatment of baldness. At least one case report exists involving ingestion of the topical solution. Regardless of the preparation, the most common symptoms of toxicity include hypotension and tachycardia. In patients with renal failure, fluid retention and pericardial effusion have been reported. Treatment is supportive and includes intravenous fluids. If the hypotension is persistent, dopamine or phenylephrine should be considered. Vasopressors with b-adrenergic activity, such as epinephrine, should be avoided because of the potential for excessive cardiac stimulation. b blockers can be used for symptomatic tachycardia.

Sodium Nitroprusside

This is the drug of choice for hypertensive emergencies. It is a rapidly absorbed and rapidly dissipated drug whose principle action is to lower blood pressure by relaxing smooth muscle in arteries and veins. Sodium nitroprusside causes toxicity by three primary mechanisms: (1) The most common adverse effect is direct vasodilation resulting in hypotension and dysrhythmias. (2) Thiocyanate toxicity occurs infrequently, resulting in tinnitus, altered mental status changes, nausea, and abdominal pain. (3) In rare cases, cyanide toxicity can occur, resulting in coma, metabolic acidosis, or respiratory arrest. In very rare cases and in susceptible patients, methemoglobinemia can occur, which, if levels reach greater than 15 percent, can result in symptomatic cellular hypoxia. Toxicity associated with sodium nitroprusside is usually related to prolonged administration or occurs in patients with renal or hepatic failure.

Nitroprusside reacts with hemoglobin to form cyanomethemoglobin and cyanide. Methemoglobin is derived from hemoglobin and will bind cyanide until the intraerythrocyte methemoglobin has been saturated. Thiosulfate will react with the remaining cyanide to form thiocyanate, which is excreted in the urine. A limiting factor in cyanide metabolism is the amount of thiosulfate in the body, and that limit is usually achieved at a nitroprusside infusion rate of 5 μg/kg/min.

The direct vasodilatation effects of nitroprusside can result in excessive hypotension, resulting in mental status changes and dysrhythmias. Thiocyanate toxicity causes anorexia, fatigue, and mental status changes, including psychosis, weakness, seizures, tinnitus, and hyperreflexia. Cyanide toxicity is often associated with the odor of almonds on breath and can result in acidosis, tachycardia, mental status changes, and death.

Excessive hypotension secondary to nitroprusside administration can be avoided by careful monitoring using an arterial line and frequent clinical evaluations. In general, blood pressure reduction should not exceed a 25 percent reduction in mean arterial pressure. Thiocyanate toxicity can be minimized by avoiding prolonged administration of nitroprusside and by limiting drug use in patients with renal insufficiency. If necessary, thiocyanate can be removed by dialysis. Cyanide toxicity can be avoided by the coadministration of sodium thiosulfate or by limiting the administration of nitroprusside. Details of the treatment of cyanide toxicity are discussed in Chapter 182, "Cyanide."

172 PHENYTOIN AND FOSPHENYTOIN TOXICITY

Harold H. Osborn

It is estimated that over 2 million Americans suffer from epilepsy, and as many as 10 percent of the population may suffer at least one seizure in their lifetime. Phenytoin is a primary anticonvulsant for all types of epilepsy except absence. It is useful in the treatment of status epilepticus in conjunction with other more rapidly acting anticonvulsants.[1] Phenytoin has been used prophylactically in a variety of settings (head trauma, alcohol withdrawal, and drug overdose) but has so far only proven useful in the setting of head trauma.

Phenytoin has been employed in the management of chronic pain syndromes. Historically, it has also been used as an antidysrhythmic agent, especially in the setting of digoxin toxicity, but it is no longer considered a first-line agent. Morbidity or mortality is unusual following intentional phenytoin overdose if good supportive care is provided. Most phenytoin-related deaths have been caused by rapid intravenous administration or hypersensitivity reactions.

Data from the American Association of Poison Control Centers (AAPCC) regarding exposures are almost certainly underestimates, in that major toxicity related to oral preparations is more likely to be reported from parenteral adverse events and minor drug reactions related to oral preparations. Still, in 1997, a total of 4630 exposures were reported, of which 56 percent were unintentional, 32 percent intentional, 8 percent adverse reactions, and the rest "other." Among these exposures, 25 percent were considered inconsequential, 22 percent minor, 13 percent moderate, and less than 2 percent major. Only two deaths were reported. [2]

MECHANISM OF ACTION

Phenytoin exerts its anticonvulsant effect by blocking voltage-sensitive and frequency-dependent sodium channels in the neurons. Phenytoin stabilizes sodium channels in an inactive state, and this inhibitory effect, similar to the action of local anesthetics, is dependent on the voltage and frequency of firing of the neuron. Phenytoin has no effect on the amplitude or duration of the action potential. Rather, it limits the ability of the neuron to fire trains of action potentials at high frequency by delaying recovery. In this fashion, it suppresses repetitive neuronal activity and prevents the spread of a seizure focus. At higher concentrations, phenytoin delays activation of outward potassium currents in nerves and prolongs the neuronal refractory period. It may also exert an anticonvulsant effect by influencing calcium channels or g-aminobutyric acid (GABA) receptors, although this is not yet fully established.

PATHOPHYSIOLOGY

The toxic effects of phenytoin vary with route administration, duration of exposure, and dosage used. Of these determinants of toxicity, the most important is the route of administration. The intravenous administration of phenytoin carries the greatest risk, in large part due to the other constituents of the parenteral vehicle (see the section "Effects of Propylene Glycol and Ethanol Diluents"). The most serious reactions following intravenous administration are cardiovascular (bradycardia, hypotension, and asystole), although tissue necrosis and sloughing following extravasation have been described. [3] Major cardiac toxicity occurs only following parenteral administration; in general, oral overdose does not lead to cardiovascular morbidity. [4] It is more common in the elderly and those with underlying cardiac disease but has been described in young healthy patients, as well.

Many of the side effects of the oral preparation are dose related and are predictable at higher plasma concentrations. Still, different people have differing tolerance profiles, and adverse effects can be evident in some at seemingly therapeutic doses, whereas others may display untoward effects well beyond the therapeutic range. Early toxicity is manifested by vestibular/ocular/cerebellar signs: nystagmus, dysdiadochokinesia, and ataxia. At higher levels, central nervous system (CNS) depression and other cognitive effects (confusion, dizziness, and loss of concentration and memory) are seen. Only two areas of the brain normally exhibit spontaneous neuronal burst discharge: the hippocampus and the cerebellum. Phenytoin's ability to suppress these areas may result in impaired memory and balance, respectively. Paradoxically, very high levels of phenytoin may be associated with seizures. Acute oral overdose is usually manifested by nystagmus, nausea and vomiting, ataxia, dysarthria, choreoathetosis, opisthotonos, and CNS depression or excitation. [5] Deaths from oral ingestion of phenytoin are extremely rare and occur in association with ingestion of other substances.[6] The chronic administration of phenytoin is associated with numerous side effects that involve a variety of organ systems. Many of these are dose and duration dependent, but some are idiosyncratic. Hypersensitivity reactions to phenytoin usually occur within the first few months of therapy and include fever, skin rashes, blood dyscrasia, and, rarely, hepatitis. Deaths due to Stevens-Johnson syndrome have occurred, and anyone with this syndrome should never receive phenytoin again.

PHARMACOKINETICS

Phenytoin is a weak acid with a pKa of 8.3. Thus, in the acid milieu of the stomach, and even at physiologic pH, its aqueous solubility is limited. The parenteral form of phenytoin is adjusted to pH 12 to keep the drug in solution, but it is very irritating to the tissues, and intramuscular injections result in local precipitation of phenytoin with erratic absorption and is, therefore, not recommended. Absorption after oral ingestion is slow, variable, and often incomplete, especially following an overdose. Consequently, it is necessary to obtain serial levels in suspected overdose, to determine peak levels. Significant differences in bioavailability exist among different phenytoin preparations. Peak levels typically occur anywhere from 3 to 12 h after a single oral dose.

Following absorption, phenytoin is distributed throughout the body with a volume of distribution of 0.6 L/kg. Brain tissue concentrations equal those in plasma within about 10 min of intravenous infusion and correlate with therapeutic effects, whereas cerebrospinal fluid and myocardium equilibrate within 30 to 60 min. At steady state, concentrations are higher in neural tissue than in the serum. Within the CNS, concentrations are higher in the brainstem and cerebellum than in the cerebral cortex.

PROTEIN BINDING AND FREE PHENYTOIN FRACTIONS

Phenytoin is extensively (90 percent) bound to plasma proteins, especially albumin. The free, unbound, form is the biologically active moiety responsible for the drug's clinical effect and toxicity. The free phenytoin fraction normally constitutes 10 percent of the plasma level. The unbound fraction of the drug is greater in the following groups of patients: neonates; the elderly; pregnant women; individuals with uremia, hypoalbuminemia (cirrhosis, nephrosis, malnutrition, burns, trauma, or cystic fibrosis), and hyperbilirubinemia; and individuals taking drugs that displace phenytoin from binding sites (salicylate, valproate, phenylbutazone, tolbutamide, and sulfisoxazole).

Although patients with decreased protein binding may have higher levels of free phenytoin and a greater biologic effect, they may have lower levels of total phenytoin, since more of the drug is available for metabolism. Theoretically, such patients may become toxic with total phenytoin levels in the therapeutic range. Patients who exhibit toxic signs in the therapeutic range and those with decreased protein binding should have free phenytoin levels measured.

Phenytoin concentrations are most commonly measured by an enzyme-mediated immunoassay (EMIT) technique, which is specific and sensitive to less than 1 µg/mL. If available, free phenytoin concentrations are more useful to predict toxicity. Corrected serum phenytoin levels can be calculated in hypoproteinemic patients with a known serum albumin level. To calculate the phenytoin concentration (C_{norma}) that would be present if a patient's serum albumin were normal, the following equation is used:

$$C_{normal} = \frac{C_{measured} \times 4.4}{\text{albumin concentration}}$$

where phenytoin concentrations are in micrograms per milliliter and albumin concentration is in grams per deciliter.

METABOLISM

Following absorption and distribution, only 4 to 5 percent of phenytoin is excreted unchanged in the urine. The remainder is metabolized by hepatic microsomal enzymes. The drug is primarily hydroxylated to a series of inactive compounds. The major (60 to 70 percent) metabolite is the parahydroxyphenyl derivative. It is glucuronidated, secreted in the bile, reabsorbed, and subsequently excreted in the urine. Phenytoin is not appreciably removed by hemodialysis or hemoperfusion. The metabolism of phenytoin is capacity limited (dose dependent). At plasma concentrations below 10 µg/mL, elimination is first order (a fixed percentage of drug metabolized per unit of time). However, at higher concentrations, including those in the therapeutic range (10 to 20 µg/mL), the metabolic pathways may become saturated, and the elimination may change to zero-order kinetics (a fixed amount metabolized per unit of time). This change in kinetics can markedly prolong the half-life of phenytoin, which is normally 6 to 24 h. An understanding of capacity-limited kinetics is essential to the proper dosing of phenytoin, the avoidance of side effects with chronic therapy, and the management of overdoses. At higher levels in the therapeutic range, any increase in the daily dose may result in a disproportionate increase in the plasma level. Thus, incremental doses should be limited to 30 mg and levels should be carefully monitored when it is necessary to raise phenytoin doses above 300 mg (about 5 mg/kg) per day.

Because phenytoin's half-life is 24 h or less, once-a-day regimens may result in erratic levels and become problematic for patients requiring tight control. Only one phenytoin preparation (Phenytoin Kapseals) is approved by the Food and Drug Administration for once-a-day use. Concomitant use of drugs that either inhibit or enhance hepatic microsomal activity may result in an increase or decrease of phenytoin level, respectively. Phenytoin also affects the metabolism of various other agents (Table 172-1).

Phenytoin increases serum level of	
Acetaminophen	
Oral anticoagulants	
Primidone	
Phenytoin decreases serum level of	
Amiodarone	Disopyramide
Carbamazepine	Mexiletine
Levodopa	Doxycycline
Methadone	Furosemide
Contraceptives	Quinidine
Glucocorticoids	Theophylline
Cyclosporine	Valproic acid
Phenytoin levels are increased by	
Amiodarone	Fluconazole
Oral anticoagulants	Phenylbutazone*
Chloramphenicol	Sulfonamides*
Isoniazid	Valproic acid*
Cimetidine	High-dose salicylates*
Disulfiram	Tolbutamide*
Trimethoprim	
Phenytoin levels are decreased by	
Antineoplastic drugs	Theophylline
Diazoxide	Phenobarbital
Folic acid	Diazepam
Rifampin	Ethanol
Sucralfate	Calcium

*These drugs displace phenytoin from its protein-binding sites, thus increasing the free phenytoin fraction, although the total phenytoin level may decrease.

TABLE 172-1 Phenytoin-Drug Interactions

EFFECTS OF PROPYLENE GLYCOL AND ETHANOL DILUENTS

The acute cardiovascular toxicity seen with intravenous phenytoin infusion has frequently been ascribed to its diluent. The vehicle for the older parenteral formulation of phenytoin (Dilantin) is 40% propylene glycol and 10% ethanol, adjusted to a pH of 12 with sodium hydroxide. The glycol component has been shown to cause coma, seizures, circulatory collapse, ventricular dysrhythmias, atrioventricular (AV) node depression, and hypotension in human and animals. [7] Propylene glycol is a strong myocardial depressant and vasodilator and increases vagal tone. Other toxic effects of propylene glycol include hyperosmolality, hemolysis, and lactate-associated metabolic acidosis. Louis and colleagues compared the acute toxicities of intravenous phenytoin and propylene glycol both alone and in combination in a feline model. Phenytoin alone did cause hypotension but did not cause significant electrocardiographic effects and instead partially reversed the toxic effects that occurred when propylene glycol was given. [8] Acute toxic effects of propylene glycol are also strongly related to the rate of infusion. This is further evidence for its role in intravenous phenytoin toxicity, a phenomenon that is almost always related to infusion rate. The ethanol diluent fraction of parenteral phenytoin may also precipitate a reaction in patients taking disulfiram. The preparation with glycol is still available in the United States (although the original manufacturer no longer makes it). With intravenous infusion pumps controlling rate of administration, adverse effects are not as common, and phenytoin is less expensive compared with the alternative (see below).

The limitations of this parenteral form of phenytoin (incomplete aqueous solubility, irritating nature of the vehicle, and tendency to precipitate in intravenous solutions) have prompted a search for a more suitable preparation. Recently, a prodrug of phenytoin (fosphenytoin) has been synthesized that is more soluble and less irritating to the tissues. Fosphenytoin is the disodium phosphate ester of phenytoin. It is freely soluble in aqueous solutions and is formulated with TRIS buffer only at a pH of 8.8. Fosphenytoin is converted to phenytoin by phosphatases in the blood and various organs. For simplicity, the concentration and dose of fosphenytoin are expressed in phenytoin equivalents (PEs). The conversion half-life is 10 to 15 min. [9] Fosphenytoin is tolerated intravenously and intramuscularly, and patients can be successfully loaded within 30 min with one or more intramuscular injections without significant side effects. [10]

Given intravenously, fosphenytoin can cause pruritis and hypotension. It is not clear whether fosphenytoin administered intravenously can result in therapeutic levels more quickly and with fewer side effects than intravenous phenytoin. Blood pressure and cardiac monitoring are recommended when loading with fosphenytoin intravenously but not intramuscularly. The adverse and toxic effects of fosphenytoin are the same as with phenytoin, except that the effects of glycol and ethanol are not present with fosphenytoin.

SERUM LEVELS AND RANGE OF TOXICITY

Therapeutic phenytoin levels are described as being 10 to 20 µg/mL (40 to 80 µmol/L), with a free phenytoin level of 1 to 2 µg/mL. [11] Although 50 percent of seizure patients achieve reduction of seizure frequency with amounts below these levels, some patients require levels above 20 µg/mL for adequate seizure control. The therapeutic range for phenytoin is rather narrow. However, some patients have a greater propensity for side effects than others. Individual variation in toxicity is a function of baseline neurologic status, individual response to the drug, and free drug fraction. Patients with underlying brain disease are predisposed to toxicity and may become toxic at low levels. Long-term therapy must be individualized and based on clinical response, drug levels, and signs of toxicity. In general, toxicity correlates fairly well with increasing plasma levels (Table 173-2), but this is not a universal tenet as some patients tolerate levels above 40 µg/mL quite well. Nystagmus usually appears first at a phenytoin level of 20 µg/mL but may occur at lower or higher levels. Almost all patients with phenytoin-induced seizures will have levels well above 30 µg/mL. Signs of toxicity occur at free phenytoin levels of 2.0 µg/mL and are consistently severe above 5.0 µg/mL.

Plasma Level (μ/mL)	Side Effects
<10	Usually none
10–20	Occasional mild nystagmus
20–30	Nystagmus
30–40	Ataxia, slurred speech, nausea and vomiting
40–50	Lethargy, confusion
>50	Coma, seizures

TABLE 172-2   Correlation of Plasma Phenytoin Level and Side Effects

CLINICAL FEATURES

Central Nervous System Toxicity

As toxic phenytoin levels are reached, both inhibitory cortical and excitatory cerebellar-vestibular effects begin to occur. The usual initial sign of toxicity is nystagmus, which is seen first on forced lateral gaze and then becomes spontaneous. Vertical, bidirectional, or alternating nystagmus may occur with severe intoxication. A decreased level of consciousness is common with initial sedation, lethargy, ataxic gait, and dysarthria progressing to confusion, coma, and even apnea in large overdose. Chronically impaired cognitive function or acute encephalopathy may occur. Nystagmus may disappear at levels sufficient to cause coma and complete ophthalmoplegia and loss of corneal reflexes may occur. Therefore, absence of nystagmus does not exclude severe phenytoin toxicity. Nystagmus then returns as serum drug levels decrease and coma lightens.

Phenytoin-induced seizures are usually brief and are usually generalized. They are quite rare and almost always preceded by other signs of toxicity, especially in acute overdose.[12] Cerebellar stimulation and alteration in dopaminergic and serotonergic activity may be responsible for acute dystonias and movement disorders such as opisthotonos and choreoathetosis. Either depressed or hyperactive deep tendon reflexes, clonus, and extensor toe responses may also be elicited. Some signs of neurologic toxicity may outlast the presence of drug by months, especially mild peripheral neuropathy or acute reversible cerebellar degeneration with ataxia.

Cardiovascular Toxicity

Cardiac toxicity after oral phenytoin overdose in an otherwise healthy patient has not been reported and, if observed, requires assessment for other causes (e.g., hypoxia and other drugs). Cardiovascular complications have been almost entirely limited to cases of intravenous administration. Complications include hypotension with decreased peripheral vascular resistance, bradycardia, conduction delays progressing to complete AV nodal block, ventricular tachycardia, primary ventricular fibrillation, and asystole. Electrocardiographic changes include increased PR interval, widened QRS interval,and altered St-segments and T-waves. Bradycardia, hypotension, and syncope in healthy volunteers have been reported even after small undiluted intravenous doses. Some of these complications can be attributed to rapid intravenous administration of the preparation containing propylene glycol and are avoidable with cautious administration (Table 172-3). Even slowly administered intravenous phenytoin (less than 25 mg/min) has also been reported to cause arrest in critically ill patients receiving dopamine infusions to support blood pressure.

Intravenous
   Loading dose is 18 mg/kg phenytoin or phenytoin equivalents (PEs)
   Mix total dose in 150–200 mL of normal saline (keep concentration ≤6.7 mg/mL)
   Administer phenytoin through Millipore filter using an infusion pump
   Rate of administration should not exceed 30 mg/min (less in patients with cardiovascular disease)
   Monitor the blood pressure and cardiac rhythm continually during the infusion
   In the event of complications, immediately stop the infusion and administer isotonic crystalloid and other treatment as indicated

Intramuscular
   Administer 15 mg/kg PEs of the fosphenytoin preparation in either one or multiple intramuscular sites

Oral*
   Loading dose is 20 mg/kg
   Phenytoin tablets or suspension may be used
   Patient must be conscious with an intact gag reflex and not actively seizing or vomiting
   Administer the total amount in one dose

*Unlike intravenous loading, not all patients orally loaded will reach a therapeutic level.

TABLE 172-3   Guidelines for Safe Phenytoin Loading

Vascular, Extravasation, and Soft Tissue Toxicity

Intramuscular injection of phenytoin results in localized crystallization of the drug, and hematoma, sterile abscess, and myonecrosis at the injection site. Complications after intravenous infusion have included skin and soft tissue necrosis requiring skin grafting, and compartment syndrome, gangrene, amputation, and death. A syndrome of delayed bluish discoloration of the affected extremity, followed by erythema, edema, vesicles, bullae, and local tissue ischemia, has also been described.[13] The propylene glycol diluent, strong alkalinity of the intravenous solution, and crystallization of the drug contribute. Fosphenytoin by contrast, is well tolerated when given IV or IM.

Hypersensitivity Reactions

Hypersensitivity reactions usually occur within 1 to 6 weeks of beginning phenytoin therapy and can include fever, systemic lupus erythematosus, erythema multiforme, toxic epidermal neurolysis, Stevens-Johnson syndrome, hepatitis, rhabdomyolysis, acute interstitial pneumonitis, lymphadenopathy, leukopenia, disseminated intravascular coagulation, and renal failure. One should always ask about a history of previous hypersensitivity reactions before deciding to restart phenytoin in the emergency department setting.

Miscellaneous Effects

Other side effects from phenytoin include gingival hyperplasia, hirsutism, hypocalcemia, megaloblastic anemia responsive to folate administration, lymphoma, and hemorrhagic disease of the newborn responsive to vitamin K (Table 172-4). Gingival hyperplasia is so common, its absence should suggest poor compliance. Another clinically significant effect in some is hyperglycemia, felt to be secondary to inhibition of insulin release. This can lead to diabetic ketoacidosis or nonketotic hyperosmolar coma in diabetics. The teratogenic fetal hydantoin syndrome is well described, so oral phenytoin therapy in a pregnant patient should never be initiated or continued by an emergency physician without consultation and close follow-up from an attending neurologist and obstetrician.

TABLE 172-4   Toxicity of Phenytoin

DIFFERENTIAL DIAGNOSIS

Intoxication with almost any CNS-active or sedative-hypnotic drug may mimic early phenytoin intoxication, especially ethanol, carbamazepine, benzodiazepines, barbiturates, and lithium. Disease states resembling phenytoin toxicity include hypoglycemia, Wernicke encephalopathy, and posterior fossa hemorrhage or tumor. Although seizures may be caused by phenytoin at toxic levels, other epileptogenic drug overdoses and seizures due to trauma and to drug and alcohol withdrawal should be considered first.

TREATMENT

Initial general treatment of severe oral phenytoin overdose, including intravenous access and airway management, is similar to that for other ingested drugs. Respiratory acidosis due to ventilatory insufficiency or metabolic acidosis from any cause should be corrected to decrease the active free phenytoin fraction. Multiple doses of oral activated charcoal (1 g/kg) within the first 24 h may be of benefit, given the known poor solubility and resultant extended absorptive phase of oral phenytoin in overdose.[14] Hemodialysis and hemoperfusion are of no clinical benefit in phenytoin poisoning. Seizures may be treated with intravenous benzodiazepines or phenobarbital, again with the caution that seizures are not common in phenytoin overdose and other causes must be ruled out. Cardiovascular toxicity is extremely rare in oral overdose and should suggest other etiologies.

Prolonged cardiac monitoring after oral ingestion is unnecessary. Atropine and temporary cardiac pacing may be used for symptomatic bradydysrhythmias associated with intravenous phenytoin. Hypotension that occurs during intravenous administration of phenytoin usually responds to discontinuation of the infusion and the administration of isotonic crystalloid. Hospital admission and appropriate orthopedic or plastic surgery consultation should be obtained for patients with any significant extravasation of intravenous phenytoin or other signs of local vascular or tissue toxicity after infusion. To minimize complications due to infusion, intravenous phenytoin and fosphenytoin should be administered under close observation, with constant cardiac and blood pressure monitoring. The infused solution should be given slowly (less than 30 mg phenytoin or 150 mg fosphenytoin PEs/min) through a large, well-positioned catheter.

ADMISSION CONSIDERATIONS

Patients with serious complications following an oral ingestion (seizures, coma, altered mental status, ataxia, etc.) should be admitted for further evaluation and treatment. Others with only mild symptoms may be treated with activated charcoal in the emergency department and discharged after their levels have returned to normal, provided they are not actively suicidal. Prolonged observation and frequent assessment of levels is not practical in many emergency departments. Thus, patients with continuing symptoms may need to be admitted or their case followed in an observation unit. Given the long and erratic absorption phase of phenytoin after oral overdose, the decision to discharge or medically clear a patient for psychiatric evaluation cannot be based on a single serum level. Patients with symptomatic chronic intoxication should be admitted for observation unless signs are minimal, adequate care can be obtained at home, and they are 8 to 12 h from their last therapeutic dose. Phenytoin therapy should be stopped in all cases and, if toxicity continues to resolve, a serum level may be reassessed in 2 to 3 days to guide resumption of therapy.

Patients with significant or persistent complications following the intravenous administration of phenytoin should be admitted. Those with transient effects need not be.

PHYSIOLOGY

Iron is essential to life for humans. Iron is incorporated into red cells, hemoglobin, myoglobin, cytochromes, and other enzymes and cofactors. Since excess iron is toxic, the body utilizes several mechanisms to maintain appropriate iron availability while preventing toxicity. These mechanisms include serum protein binding, intracellular storage and, most importantly, regulation of gastrointestinal (GI) absorption.

The oral bioavailability of inorganic iron is less than 10 percent, and ferrous iron (Fe^{+2}) is better absorbed than ferric (Fe^{+3}) iron. Chelated iron, most readily found in heme, is best absorbed, accounting for one beneficial effect of eating meat. In the duodenum and jejunum, a mucosal carrier protein takes up iron and immediately stores it as ferritin. In times of iron need, the body produces transferrin, which removes iron from the cells. Alternatively, the iron is stored in the intestinal cell and is eventually eliminated from the body when the mucosa is sloughed. This is the principle mechanism for limiting absorption, and failure of this mechanism is critical following iron overdose.

Transferrin, the carrier protein that binds ferric iron, is the major mechanism for safe iron transport through the body. The total iron-binding capacity (TIBC) primarily measures the amount of serum transferrin. The TIBC is generally two to three times the normal iron concentration.

Ferritin is a large intracellular storage protein that can reversibly bind as many as 4500 molecules of iron. When an iron deficit exists, iron is transported from ferritin and the GI tract to the liver, spleen, and bone marrow, where it is incorporated into appropriate molecules. [1]

PATHOPHYSIOLOGY

Iron is a direct GI irritant and causes vomiting, diarrhea, and abdominal pain soon after a significant ingestion. Mucosal ulceration and bleeding, as well as intestinal perforation, may also occur. Hypovolemia from GI losses may produce hypotension, tissue hypoperfusion, and metabolic acidosis (based on tissue ischemia). As the mucosal surface is injured, iron passes unimpeded into the blood. When the ability of transferrin to combine with iron is exhausted, *free iron* becomes available. Free iron enters the mitochondria and inhibits oxidative phosphorylation to produce metabolic acidosis. Iron also participates in the production of toxic hydroxyl free radicals and subsequent membrane lipid peroxidation. Other systemic findings of iron poisoning include coagulopathy through inhibition of serum proteases, [2] myocardial dysfunction,[3] and encephalopathy. Coagulopathy may be biphasic, with prolonged prothrombin time and partial thromboplastin time within the first 24 h [2] that appear reversible with chelation therapy as free iron initially interferes with the activity of factors in the coagulation cascade. Later, as iron poisoning causes hepatic injury, factor production decreases, potentially worsening the coagulopathy.

TOXIC DOSE

Similar to most exposures, larger ingestions are more likely associated with greater toxicity. However, it is the amount of ingested elemental iron that determines a patient's potential for experiencing toxicity. Since the fraction of elemental iron varies with different preparations, it is important to determine which of these was ingested. These fractions may range from 12 to 33 percent, with ferrous sulfate containing 20 percent elemental iron (e.g., a 325-mg tablet of ferrous sulfate contains 60 mg of elemental iron). Pediatric multivitamins may contain from 10 to 18 mg of elemental iron per tablet. Toxic effects have been reported following oral doses as low as 10 and 20 mg/kg elemental iron.

In general, moderate toxicity occurs at doses of 20 to 60 mg/kg, and severe toxicity can be expected following doses of greater than 60 mg/kg. [4] These guidelines can be useful in predicting potential toxicity based on the history of ingestion. The majority of exposures, however, involve children under age 6, who mostly remain asymptomatic or develop only minimal toxicity.

LABORATORY ASSESSMENT

Serum iron levels have been used to determine toxicity and to direct management, but this use is limited, since excess iron is toxic intracellularly and not in the blood. In general, serum iron levels between 300 and 500 µg/dL correlate with significant GI toxicity, and mild systemic toxicity and serum iron levels between 500 and 1000 µg/dL correlate with moderate systemic toxicity. Levels greater than 1000 µg/dL are associated with significant morbidity. Although high serum iron levels support the potential for toxicity, low levels do not connote its absence. Other potential pitfalls in utilizing serum iron levels to predict toxicity include variable times to peak level following ingestion of different iron preparations [5,6] and artifactually lower measured iron levels in the presence of deferoxamine.

Leukocytosis and hyperglycemia have also been examined for their ability to predict iron toxicity. One early study found that a white blood cell count (WBC) of greater than 15,000/µL with glucose level of greater than 150 mg/dL correlated with an iron level of more than 300 µg/dL. [7] This study, however, assumed that a serum iron level of greater than 300 µg/dL denoted toxicity, which is not true in all cases. Subsequent studies were unable to validate the association between these laboratory values and also did not correlate these laboratory values with clinical illness. [8,9]

It was previously accepted that toxicity was not likely when the serum iron level did not exceed the TIBC. Although conceptually valid, TIBC has little value in the assessment of iron-poisoned patients, because it becomes falsely elevated in the presence of elevated serum iron levels or deferoxamine. [10] Additionally, in conditions of chronic iron overload (e.g., thalassemia and hemochromatosis), significant organ pathology occurs despite the TIBC remaining higher than serum iron level.

Use of radiographic studies can lead to diagnostic problems, as well. Radiopaque iron tablets are visible on x-ray and can guide GI decontamination when visualized. However, many iron preparations are not routinely detected, including pediatric chewable and liquid preparations, and negative radiographs do not exclude iron ingestion.[9]

CLINICAL FEATURES

Clinically, five stages of toxicity have been described corresponding to the pathophysiology of iron poisoning although, more practically, acute iron toxicity manifests in two clinical stages: local GI toxicity and systemic toxicity.

Abdominal pain, vomiting, and diarrhea characterize stage 1 of iron poisoning. Iron is directly irritating and corrosive to the GI tract and typically induces vomiting within the first few hours following ingestion. The absence of these symptoms within 6 h of ingestion essentially excludes a diagnosis of significant iron ingestion.

Vomiting is the clinical sign most consistently associated with acute iron toxicity. [7,8 and 9]

Stage 2, or the "latent" stage, of iron poisoning is not always seen. Occurring within the 6- to 24-h period following ingestion, GI symptoms may resolve, so a patient may have few, if any, symptoms, which may falsely reassure a physician. However, this is not a truly quiescent phase. Patients who have significant toxicity will have ongoing and perhaps progressive systemic deterioration due to volume loss and worsening metabolic acidosis, despite the absence of GI symptoms. Patients may not vomit but will still be clinically ill, and may have abnormal vital signs and evidence of poor tissue perfusion. Patients with large ingestions may progress directly from GI distress (stage 1) to signs of systemic toxicity (stage 3). Alternatively, symptoms in patients with limited ingestions may resolve completely prior to this phase. These latter patients will have normal vital signs and normal findings on physical examination.

Systemic toxicity characterizes stage 3 of iron toxicity. During this stage, intracellular iron disrupts cellular metabolism with resultant shock and (lactic) acidosis. Iron-induced coagulopathy may worsen bleeding and hypovolemia. Hepatic dysfunction, renal failure, and cardiomyopathy may also occur.

The hepatic stage of iron poisoning (stage 4) develops 2 to 5 days after ingestion. Thought to result from iron uptake by the reticuloendothelial system, it manifests as elevation of aminotransferases and may progress to frank hepatic failure.

Stage 5 of iron poisoning refers to delayed sequelae, including gastric outlet obstruction secondary to the corrosive effects of iron on the mucosa. These changes present only rarely and are seen 4 to 6 weeks after ingestion.

TREATMENT

Evaluation and Supportive Care

Iron poisoning is a clinical diagnosis. Patients who arrive at an emergency department asymptomatic and with normal findings on physical examination, and who remain so for 6 h following ingestion, do not require specific medical treatment for iron poisoning. Patients who are symptomatic from their ingestion should first be stabilized with attention to airway, breathing, and circulation, after which GI decontamination and chelation therapy may proceed. Dialysis is not effective in clearing iron.

In general, patients whose vomiting resolves after two or three episodes, and who have normal vital signs, are mildly iron toxic and require only supportive care. Patients who continue to vomit (i.e., five to six or more times), or who have moderately abnormal vital signs, have moderate iron toxicity, and deferoxamine therapy may be indicated. Those patients with persistent vomiting and severely abnormal vital signs or other signs of poor perfusion or shock should be aggressively fluid resuscitated and treated with deferoxamine.

Intravenous (IV) fluid resuscitation and medication, as appropriate, should be initiated in those patients who are symptomatic or show signs of hypoperfusion or shock. Coagulopathy should be addressed with parenteral vitamin K_1 (5 to 25 mg) and fresh-frozen plasma (10 to 25 mL/kg in adults; 10 mL/kg in pediatric patients). Significant blood loss may require transfusion.

Laboratory tests should include complete blood cell count and determination of serum electrolyte level, blood urea nitrogen, and coagulation parameters, as well as serum glucose and serum iron levels, with the understanding that the importance of these values may be limited.

Arterial blood-gas (ABG) determination is usually unnecessary in mild cases because determination of serum electrolytes will yield all important information. However, in the moderately to severely toxic patient, or in those with respiratory compromise, ABG determination, often more rapidly available, will yield vital information regarding the patient's acid-base status. Typing, screening, and crossmatching should be requested from the blood bank in anticipation of potential need.

Gastrointestinal Decontamination

In general, syrup of ipecac is not used, because it may obscure the initial signs of clinical toxicity. Additionally, ipecac-induced vomiting is not thought to be more effective at gastric emptying than is iron-induced vomiting. Activated charcoal does not adsorb significantly to iron, and its use is not recommended in cases of isolated iron ingestion. Its use may also complicate endoscopy, should that be necessary. Cathartics should not be used. Orogastric lavage may not be effective if the ingested tablets are large or if several hours have elapsed since ingestion, but it may be used early after ingestion. Installation of bicarbonate solution following gastric lavage has been advocated on the basis that free ferrous salt is converted into poorly absorbed ferrous carbonate. There are no data to support the efficacy of sodium bicarbonate or phosphosoda instillation during lavage to prevent iron absorption. Pills located on radiograph may indicate a potential for progressive toxicity and may guide decontamination.

Whole bowel irrigation with a polyethylene glycol solution has demonstrated efficacy in several pediatric patients with large iron ingestions. Administration of 250 to 500 mL/h in children and 2 L/h in adults via nasogastric tube may clear the GI tract of iron pills before absorption can occur. Endoscopy has been used to remove large iron loads but may not be practical where there are large numbers of pills requiring multiple endoscope insertions. Gastrotomy may also be an option where other measures are unsuccessful or impractical. [11] Antiemetics such as metoclopramide or ondansetron can be used to treat nausea and vomiting.

Deferoxamine

Deferoxamine is a specific chelating agent derived from *Streptomyces pilosus* and has been used to treat iron toxicity since the 1960s. Deferoxamine binds directly to free iron and indirectly to iron from ferritin, hemosiderin, and non-protein-bound ferric salts, as well as to intracytoplasmic and mitochondrial free iron to form the complex ferrioxamine, which is renally excreted. It is safely administered to children and pregnant women. Complete complexation of ingested iron is not the goal of therapy. Indeed, only a small fraction of the total amount of ingested iron is found in the urine following chelation. Deferoxamine administration may be a clinically effective treatment by removing a critical amount of intracellular iron from its target, restoring cellular function.

Deferoxamine can be administered by various routes. Oral deferoxamine is not recommended due to the risk of increased GI absorption of iron-deferoxamine complex and enhanced toxicity. Deferoxamine may be administered subcutaneously but only in cases of chronic iron overload. Patients with mild iron toxicity from an acute ingestion may be treated with intramuscular (IM) administration of deferoxamine 90 mg/kg up to 1 g in children and 2 g in adults. The dose may be repeated every 4 to 6 h as clinically indicated (see below). This route of administration, however, can become difficult due to the volume of injected material required when used in children.

In patients with severe iron poisoning, fluid loss and hypovolemia may become significant. Since these patients require aggressive fluid resuscitation and since more consistent absorption of deferoxamine is achieved parenterally, therapy should be given IV, because this addresses both issues at once. Additionally, IM deferoxamine is not reliably absorbed in hypotensive patients. Hypotension is the rate-limiting factor in IV administration, and it is recommended to begin the infusion slowly (5 mg/kg/h). A second IV access will likely be required so as not to impede simple volume resuscitation. Deferoxamine can be increased to 15 mg/kg/h within the first hour of treatment, as tolerated. In fact, much higher doses have been used safely to achieve appropriate chelant excess before systemic toxicity occurred. However, it is generally not recommended to exceed a total daily dose of 6 to 8 g, although there are no specific data supporting this limit in acutely iron-poisoned patients. Administering deferoxamine at this rate will achieve a total of 6 g in about 6 h in an average-sized adult. Once this amount is reached, it is prudent to decrease the rate of deferoxamine administration, because of several associated risks. Adverse effects may include mucormycosis infection, [12] renal insufficiency, [13] pulmonary toxicity, [14] and sepsis from *Yersinia enterocolitica,* which may be related to duration of therapy.

The determination of the efficacy and duration of deferoxamine therapy involves acquisition of serial urine samples. As ferrioxamine is excreted, the urine color changes to what is classically called *vin rosé* but may actually appear brown or rusty. Theoretically, the disappearance of the *vin rosé* means that a patient no longer has a significant toxicity. It is important to obtain a urine sample prior to initiating treatment, because patients who are hypovolemic will likely produce concentrated urine, which may also be somewhat dark and may be confused with the *vin rosé* appearance. False negatives, color-change latency, and difficulty visualizing a color change can limit the utility of this test.

There is some controversy surrounding how long deferoxamine therapy should continue. Recommended end points range from clinical recovery and normal iron levels, to measurement of iron-to-creatinine ratios, [15] to clinical recovery with normal iron level in conjunction with normal urine color. [4] Since measured iron levels are

artificially depressed by the presence of deferoxamine and urine color change can be unreliable, and since iron toxicity is a clinical diagnosis, clinical recovery of the patient is probably the most important factor in terminating therapy. For patients who continue to exhibit severe iron toxicity after 24 h of deferoxamine therapy, the therapy should continue carefully at a decreased dose, for reasons mentioned earlier.

Previously advocated was the *deferoxamine challenge test,* a *half-dose* of 50-mg/kg IM injection of deferoxamine followed by examination of urine samples for change in color that would indicate the presence of chelated free iron and therefore confirm iron toxicity. More recently, a *first dose* of 90 mg/kg IM has been used, also utilizing change in urine color to verify toxicity. There may be several problems with this management strategy. Single-dose deferoxamine can be unreliable in eliciting a visible color change in urine, especially if a pre-deferoxamine urine sample was not obtained, and should not be the sole factor in deciding toxicity. [4] Additionally, IM therapy does not address the issue of fluid resuscitation, which these patients very frequently require even if they do not require the antidote.

Pitfalls

Common errors in managing iron-toxic patients are many. The traditionally accepted indication of significant poisoning included a WBC of greater than 15,000/µL glucose level of more than 150 mg/dL, a 4-h serum iron level of more than 300 µg/dL, a serum iron level greater than TIBC, a positive deferoxamine challenge test, and a history of significant ingestion. However, reliance on iron levels and TIBC, WBC, serum glucose levels, and negative radiographs can lead physicians away from the proper diagnosis and increase time to treatment. Equating the so-called latent stage with clinical recovery when vital signs and clinical appearance are abnormal is an error in assessment and may lead to morbidity. Waiting for iron levels before beginning deferoxamine therapy is a misuse of time better spent aggressively caring for the patient. Withholding chelation therapy from a pregnant patient for fear of fetal toxicity from deferoxamine is not supported in the literature and should not occur.

PROGNOSIS

Patients who ingest small amounts and remain asymptomatic through the first 6 h after ingestion generally will recovery fully. Symptomatic patients are at higher risk for morbidity. Coma or shock is indicative of a grave prognosis, with approximately a 10 percent mortality rate. Most patients with shock or coma should survive with appropriate care. Generally, prognosis is improved with early recognition and initiation of treatment. Long-term sequelae include strictures, which may occur in patients with minimal symptoms.

DISPOSITION

Only those patients without a history of significant ingestion, and not symptomatic after at least 6 h of observation, can be considered for discharge. Patients in whom deferoxamine treatment is initiated should be admitted to an intensive care unit–type setting. All patients should be assessed for suicide risk, and child abuse or neglect should at least be considered in pediatric cases.

174 HYDROCARBONS AND VOLATILE SUBSTANCES

Paul M. Wax

INTRODUCTION

Hydrocarbons are a diverse group of organic compounds consisting primarily of carbon and hydrogen atoms arranged in various aliphatic and aromatic configurations. Products containing hydrocarbons are found in many household and occupational settings. Examples include fuels, lighter fluids, lamp oil, paints, paint removers, cleaning and polishing agents, spot removers, degreasers, lubricants, and solvents. Volatile liquid chemicals or gases are substances sometimes abused for their euphoric effects. Examples of commonly abused volatiles include many hydrocarbon-containing substances such as glue (which contains toluene), propellants (e.g., butane, trichloroethylene, Freon), and gasoline. Other volatile chemicals not generally classified as hydrocarbons, such as nitrites (e.g., isobutyl nitrite) and nitrous oxide, are also subject to abuse. Hydrocarbon and volatile substance exposure may cause life-threatening toxicity and, in some cases, sudden death.

Classification

Most hydrocarbons are produced from petroleum distillation, which results in predominantly aliphatic (open-chain) mixtures of hydrocarbons of different chain lengths. Gasoline, for instance, consists of approximately 80 percent saturated and unsaturated aliphatic hydrocarbons of chain length C_4 to C_{10} and 20 percent aromatic hydrocarbons. Chain length determines the phase of the hydrocarbon at room temperature. Short-chain aliphatic compounds, such as methane, propane, or butane, are gases; long-chain aliphatic compounds, such as tar, are solids. Intermediate-chain (C_5 to C_{15}) aliphatic compounds are in liquid form and account for most hydrocarbon exposures seen in the emergency department (Table 174-1). Pulmonary toxicity secondary to aspiration is the most common complication from ingesting liquid aliphatic hydrocarbons.

Substance	Commercial Use
Gasoline	Motor fuel
Kerosene	Stove and lamp fuel
Mineral seal oil	Furniture polish
Naphtha (petroleum ether)	Lighter fluid
Diesel oil	Lubricant
N-Hexane	Plastic cement, rubber cement
Methane, butane, propane	Fuel

TABLE 174-1   Substances that Predominantly Contain Aliphatics

The wood distillates (e.g., turpentine and pine oil) are derived from pine, consist mainly of cyclic terpene derivatives, and comprise another class of hydrocarbons. Gastrointestinal (GI) absorption of wood distillates tends to be greater than that of aliphatic petroleum distillates, increasing the risk for central nervous system (CNS) depression.

Aromatic hydrocarbons (containing a benzene ring; Table 174-2) and halogenated hydrocarbons (aliphatics with at least one substituted halogen group; Table 174-3) are widely used industrial solvents. Freon is the trade name for a group of halogenated hydrocarbons that contain fluoride such as dichlorodifluoromethane and bromochlorodifluoromethane. Although many of these chlorofluorocarbons (CFCs) are thought to cause atmospheric ozone changes and are being replaced by more environmentally friendly compounds, Freon may still be found as a refrigerant gas and component of fire extinguishing systems. Inhalational exposure is the usual route of toxicity for aromatic and halogenated hydrocarbons, although ingestion of these chemicals may also be problematic. Substance abusers and workers in certain occupational settings are most often affected. Such exposures may result in significant systemic toxicity.[1] Along with their potent CNS effects, specific cardiovascular, hepatic, renal, and hematologic toxicity are attributed to aromatic and halogenated hydrocarbons. Finally, some hydrocarbons have toxicity related to an additive, such as lead in gasoline and pesticides. With these, the toxic additive usually dictates the clinical approach.

Substance	Commercial Use
Benzene	Chemical intermediate, gasoline (small amount; average 0.8%)
Toluene	Airplane glue, plastic cement, acrylic paint
Xylene	Solvent, cleaning agent, degreaser

TABLE 174-2   Common Aromatic Hydrocarbons

TABLE 174-3   Common Halogenated Hydrocarbons

Substance	Commercial Use
Carbon tetrachloride	Solvent, refrigerant, aerosol propellant
Chloroform	Solvent, chemical intermediate
Methylene chloride	Paint stripper, varnish remover, aerosol paint, degreaser
Trichloroethylene (TCE)	Spot remover, degreaser, typewriter correction fluid
Trichloroethane (TCA)	Spot remover, degreaser, typewriter correction fluid
Tetrachloroethylene (perchloroethylene)	Dry cleaning agent, degreaser

Epidemiology

Exposures to hydrocarbons and volatiles most commonly occur in one of two settings: ingestion or inhalation. Hydrocarbon ingestions account for approximately 3 to 10 percent of all unintentional childhood poisonings in the United States. Ingestions of gasoline, kerosene, lighter fluid, mineral seal oil, and turpentine are most frequent. In less-developed countries kerosene ingestion accounts for 33 to 59 percent of unintentional childhood poisonings. [2] It is estimated that 3.5 to 10 percent of young people have experimented with volatile substance inhalation to produce inebriation. [3]

Most hydrocarbon exposures have a benign clinical course. The 1997 American Association of Poison Control Centers Toxic Exposure Surveillance System revealed that 66,645 potential hydrocarbon exposures were reported to poison control centers (3 percent of all reported exposures). Of these, 3.6 percent involved aromatic hydrocarbons and 12.2 percent involved halogenated hydrocarbons and/or propellants. Three thousand and fifty-eight (4.6 percent) developed moderate to severe toxicity, and 12 died.[4] Nine of the 12 deaths followed inhalational exposure; 8 involved intentional inhalational abuse and 7 occurred in teenagers. Two of the other fatalities were in toddlers who ingested and aspirated gasoline and paint thinner. An epidemiologic study of volatile substance abuse in the United Kingdom revealed that 605 people under age 18 years died from volatile substance abuse during the period 1981 to 1990. [5] The most commonly implicated volatiles were butane (39 percent), aerosols (26 percent), cleaners (16 percent), and glue (10 percent).

PATHOPHYSIOLOGY AND CLINICAL FEATURES

Determinants of Toxicity

The toxic potential of hydrocarbons depends on physical characteristics (volatility, viscosity, and surface tension), chemical characteristics (aliphatic, aromatic, or halogenated), presence of toxic additives such as pesticides or heavy metals, route of exposure, concentration, and dose. Viscosity, defined as the resistance to flow, and surface tension, denoting "creeping" ability, both play a major role in determining the aspiration potential. Viscosity is measured in Saybolt Seconds Universal (SSU). Patients ingesting substances with viscosities less than 60 SSU (e.g., gasoline, kerosene, mineral seal oil, turpentine, and aromatic and halogenated hydrocarbons) are at greater risk for aspiration than those ingesting substances with viscosities greater than 100 SSU (e.g., diesel oil, grease, mineral oil, paraffin wax, and petroleum jelly). Low surface tension also increases the risk of aspiration. Volatility denotes the ability of a substance to vaporize. Inhalation of highly volatile agents, such as aromatic hydrocarbons, halogenated hydrocarbons, or gasoline, results in systemic absorption and the potential for significant toxicity.

Dermal exposure to hydrocarbons causes local toxicity, and occasionally leads to systemic absorption. Dermal toxicity secondary to intravenous administration of hydrocarbons has also been reported. When used intravenously, hydrocarbons may cause pulmonary toxicity by their first-pass exposure through the lungs.

Toxicity from hydrocarbon exposure can be divided into different clinical syndromes based on the organ system(s) predominately affected. Characteristic presentations usually affect one or more of the following systems: pulmonary, neurologic (central and/or peripheral), GI, cardiac, hepatic, renal, hematologic, or dermal.

Pulmonary Toxicity

Pulmonary complications, especially aspiration, are the most frequent adverse effects of hydrocarbon exposure. Typically, this involves the unintentional childhood ingestion of small amounts of aliphatic hydrocarbon mixtures commonly stored in the household. Aliphatic hydrocarbons have a limited GI absorption; toxicity usually results from aspiration of the low-viscosity compounds or inhalation (intentional or inadvertent) of compounds with high volatility. Although ingestion of aromatic or halogenated hydrocarbons may also result in aspiration, GI absorption is greater. Hence, CNS and other systemic toxicity secondary to GI absorption often predominate after aromatic and halogenated hydrocarbon ingestion.

Aspiration is not dependent on volume ingested. Experimentally in rats, as little as 0.2 mL instilled intratracheally has caused pneumonitis. Pulmonary toxicity does not result from GI absorption but occurs from direct aspiration of the hydrocarbon into the pulmonary tree. This occurs at the time of ingestion when the hydrocarbon migrates from the hypopharynx into the airway. There is no evidence that hydrocarbons reflux from the stomach into the airway. Spontaneous vomiting, however, does increase the risk of aspiration.[6] Pulmonary toxicity manifested as acute bilateral pneumonitis has also been reported from the inhalation of an aerosolized aliphatic hydrocarbon such as gasoline or kerosene.

Hydrocarbon aspiration causes chemical pneumonitis by direct toxic injury to the pulmonary parenchyma and altered surfactant function. Destruction of alveolar and capillary membranes results in increased vascular permeability and edema. Early distal airway closure and alveolar collapse produces clinical bronchospasm and ventilation/perfusion mismatch. The CNS manifestations seen after ingestion of a poorly GI-absorbed aliphatic hydrocarbon are thought to be from hypoxia secondary to the hydrocarbon induced pneumonitis and/or direct CNS toxicity following the pulmonary absorption of a volatile hydrocarbon. Studies performed in animals in which hydrocarbons were instilled into the stomach after ligation of the esophagus demonstrate negligible absorption of aliphatic compounds from the GI tract with no evidence of subsequent pneumonitis.[7] Pneumatoceles, pneumothoraces, and/or pneumomediastinum are occasionally associated with hydrocarbon aspiration. Other complications include bacterial superinfection, acute respiratory distress syndrome, and death. Long-term pulmonary dysfunction may occur.

In one study of 950 children who ingested products containing hydrocarbons and who were brought to the hospital, 19 percent had clinical or radiographic evidence of pulmonary aspiration.[8] In another study of 184 pediatric hydrocarbon ingestions called to a poison center, 35 percent had initial symptoms, but only 3 percent had progressive pulmonary symptoms.[9] The clinical manifestations of pulmonary aspiration are usually apparent almost immediately on ingestion. The early effects result from irritation of the oral mucosa and tracheobronchial tree. Symptoms include coughing, choking, gasping, dyspnea, and burning of the mouth. Patients with these symptoms should be assumed to have aspirated until proven otherwise. Physical examination may reveal grunting respirations, retractions, tachypnea, tachycardia, and cyanosis. An odor of the hydrocarbon may be noted on the patient's breath. An elevated temperature of 39°C (102.2°F) or greater is common and may occur upon initial presentation or be delayed for 6 to 8 h.

Auscultation may be normal, or reveal wheezing, and decreased, or absent breath sounds. Arterial blood gas analysis may demonstrate a widened alveolar-arterial oxygen gradient or frank hypoxemia. The development of a necrotizing pneumonitis and hemorrhagic pulmonary edema usually occurs within hours in severe aspiration.

Most fatalities from these complications occur within 24 to 48 h. With less severe damage, symptoms usually subside within two to five days, except with pneumatoceles and lipoid pneumonias whose symptoms may persist for weeks to months.

Although most patients with clinically significant aspiration have abnormal chest x-rays, the time course of radiographic changes varies and correlation with physical examination may be poor. Changes may be seen as early as 30 min after aspiration, but the initial radiograph in the symptomatic patient may be deceptively clear. Radiographic changes usually appear by 2 to 6 h and are almost always present by 18 to 24 h if they are to occur. The infiltrates range in appearance from streaking to flocculent to homogeneous, and are usually located in the dependent lobes. Multilobar involvement is more common than single-lobe involvement and right-sided involvement is more common than left-sided involvement. Radiographic changes limited to bilateral perihilar regions with clear lung bases are also common.

High-viscosity compounds such as lubricants, mineral oil, or tar, are not aspirated readily and tend to be less toxic when ingested. Occasionally, however, aspiration occurs that results in the development of lipoid pneumonia. Deaths from hydrocarbon lipoid pneumonia have been reported.

Central Nervous System Toxicity

Central nervous system toxicity may result from either a direct toxic response to the systemic absorption of the hydrocarbon, as an indirect result of severe hypoxia secondary to aspiration, or as a result of simple asphyxiation. Systemic absorption usually occurs through the inhalation of highly volatile petroleum distillates, which may be absorbed inadvertently, for example as an occupational risk, or deliberately associated with solvent abuse.

Volatile solvent abuse most often occurs in teenagers and younger adults, especially from lower socioeconomic backgrounds and in particular cultures (e.g., Native Americans).[10] These patients are described as "huffers" or "baggers" depending on whether they inhale through a rag soaked with the hydrocarbon held to the mouth or rebreathe into a plastic bag containing the hydrocarbon. The act of rebreathing to facilitate inhalation may also contribute to toxicity by producing significant hypercarbia and hypoxia. Many of the most commonly abused volatiles are listed in Table 174-4.

Product	Volatile Agent
Acrylic spray paint	Toluene
Adhesive/glue	Toluene, trichloroethylene
Aerosol propellants	Propellants and butane
Cigarette lighter refills	Butane
Degreasing agents	Trichloroethylene
Dry-cleaning agents	Tetrachloroethylene
Fire extinguishers	Bromochlorodifluoromethane
Inhalational anesthetics	Nitrous oxide, halothane
Lighter fluid	Naphtha
Nitrites (poppers)	Isobutyl nitrite, amyl nitrite
Paint stripper	Methylene chloride
Petrol	Gasoline
Plastic modeling cement	Methyl ethyl ketone, toluene
Spot removers	Trichloroethylene, trichloroethane
Typewriter correction fluid	Trichloroethane, trichloroethylene

TABLE 174-4   Commonly Abused Volatile Substances

Many of the hydrocarbons that affect the CNS are organic solvents and have a natural affinity for the lipid-rich neural tissue. They behave similarly to the inhalational anesthetic agents. Hydrocarbon intoxication may be confused with ethanol inebriation. CNS depression ranges in severity from dizziness, slurred speech, ataxia, and lethargy to obtundation and coma. Depression of the central ventilatory drive may also occur. These effects are usually dose-dependent. Although hydrocarbons are CNS depressants, they often have an initial excitatory effect manifested as euphoria, exhilaration, and giddiness, effects sought by those who abuse them. More severe excitatory features include tremor, agitation, and convulsions. Perceptual changes, such as confusion, hallucinations, and psychosis, may occur.

Chronic CNS sequelae may result from recurrent inhalational exposure to hydrocarbons in the workplace or with solvent abuse. [11] These sequelae are seen among house painters and solvent abusers exposed to toluene-containing substances. Recurrent headaches, cerebellar ataxia, and a chronic encephalopathy consisting of tremors, emotional lability, mental status changes, cognitive impairment, and psychomotor impairment, characterize the syndrome. These effects may be transitory or permanent. The development of encephalopathy, ataxia, tremor, chorea, and myoclonus also is associated with the habitual sniffing of leaded gasoline. In this case, symptoms are thought to be secondary to the effects of tetraethyl lead and its toxic metabolites.

Peripheral Nervous System Toxicity

Exposure to *n*-hexane, methyl *n*-butyl ketone, and other six-carbon aliphatic hydrocarbons is associated with the development of a characteristic peripheral polyneuropathy caused by demyelinization and retrograde axonal degeneration. [12] Onset of symptoms may be delayed for months to years after initial exposure. Toxicity is attributed to a metabolite, 2,5-hexanedione, produced by the cytochrome P-450-mediated biotransformation of the parent compounds. This neurotoxic metabolite is thought to inhibit glutaraldehyde-3-phosphate dehydrogenase, which supplies energy for axonal transport. Long, distal nerves seem to be most vulnerable, characteristically producing foot and wrist drop with numbness and paresthesias. The electromyelogram typically shows a decrease in nerve conduction velocity.

Gastrointestinal Toxicity

Most hydrocarbons act as intestinal irritants, resulting in burning in the mouth and throat, abdominal pain, belching, nausea, vomiting, and diarrhea. Vomiting, which occurs in about one-third of the patients with aliphatic hydrocarbon ingestions, is particularly troublesome because of the increased risk of pulmonary aspiration.

Cardiac Toxicity

Life-threatening dysrhythmias, such as ventricular tachycardia and ventricular fibrillation, may occur with systemic absorption (gastrointestinal or inhalational) of a variety of hydrocarbon compounds.[13] Most commonly, dysrhythmias occur after exposure to halogenated hydrocarbons and aromatic hydrocarbons. Exposures to predominantly aliphatic mixtures, such as gasoline or mineral spirits, and exposure to butane have also been reported to cause dysrhythmias and sudden death. [14] The mechanism of toxicity is believed to be secondary to a sensitization of the heart to catecholamines. The term "sudden sniffing death" describes solvent abusers who die suddenly after exertion, panic, or fright.[13] The sudden release of catecholamines in these situations is thought to induce these fatal dysrhythmias. [14] Cardiac dysrhythmias as a consequence of industrial exposure to volatile hydrocarbons have also been described. Other mechanisms for sudden death include asphyxia, respiratory depression, and vagal inhibition. The use of exogenous catecholamines, such as epinephrine, may precipitate sudden dysrhythmias and should be avoided except if required for cardiac resuscitation. Decreases in myocardial contractility and peripheral vascular resistance as well as bradycardia and atrioventricular conduction blocks have also been associated with volatile solvent abuse.

Hepatic Toxicity

Hydrocarbon-induced hepatic damage resulting from halogenated hydrocarbons is well described. [15] Carbon tetrachloride toxicity has been used as a model for toxin-induced hepatic dysfunction. As little as 3 mL of carbon tetrachloride has been associated with the development of fatal liver injury. [16] Other halogenated hydrocarbons, such as chloroform, are also associated with liver dysfunction. Free-radical metabolites of these agents that cause lipid peroxidation are apparently responsible for hepatocellular destruction.

Pathologic examination reveals acute fatty degeneration of the liver with areas of centrilobular necrosis. Phenobarbital, ethanol, and other agents that induce cytochrome P-450 enzymes are contraindicated because of the propensity to increase the production of the toxic metabolites. The time-course of hepatic dysfunction with acute exposures appears similar to acetaminophen hepatotoxicity. Liver function tests may be elevated within 24 h after ingestion, with the development of liver

tenderness and jaundice in 48 to 96 h. Chronic exposure to carbon tetrachloride may be associated with the development of cirrhosis and hepatomas.

Renal and Metabolic Toxicity

Solvent abuse and occupational exposure to hydrocarbons may result in renal dysfunction. Exposure to hepatotoxic halogenated hydrocarbons, such as carbon tetrachloride and trichloroethylene, has caused acute renal failure as well as centrilobular hepatic necrosis. [15] Occupational hydrocarbon exposures have been associated with a variety of glomerulonephritides including Goodpasture's syndrome. [17,18]

Renal tubular acidosis may occur in patients who abuse toluene-containing substances. [1] Patients present with a non-anion gap metabolic acidosis, hypokalemia, and hypophosphatemia. The serum potassium may be so low (<2 meq/L) that severe muscle weakness develops, occasionally resulting in quadriparesis. Significant rhabdomyolysis may also result. Toluene toxicity may also cause a high anion gap metabolic acidosis as a result of the accumulation of hippuric acid and benzoic acid metabolites. Proteinuria and renal insufficiency can occur in patients who abuse toluene.

Hematologic Toxicity

Chronic exposure to benzene, the prototypical aromatic hydrocarbon, is associated with an increased incidence of hematologic disorders including aplastic anemia, acute myelogenous leukemia, and multiple myeloma. [19] This association has received much attention because of the extensive use of benzene in the workplace. The etiology of these blood dyscrasias is probably not benzene itself but rather a toxic metabolite. Although aplastic anemia is associated with glue sniffing, this is most likely due to the benzene fraction of the glue and not the toluene. Hydrocarbon-induced hemolysis has occurred following the acute ingestion of gasoline, kerosene, and tetrachloroethylene, and inhalation of mineral spirits. [20] Consumptive coagulopathy has also been reported.

A peculiar complication of methylene chloride exposure is the endogenous production of carbon monoxide. [21] This is unlike ordinary carbon monoxide exposure from exogenous sources where maximum carboxyhemoglobin level occurs at the time of the exposure. With methylene chloride exposure, carbon monoxide formation may continue after cessation of exposure due to slow release of methylene chloride from the tissues prior to its metabolism to carbon monoxide. When patients exposed to methylene chloride present with CNS and cardiac symptoms, impairment due to significant carbon monoxide production must be considered.

Dermal Toxicity

Dermal exposure to hydrocarbons may also result in toxicity. Cutaneous injury is most often associated with the short-chain aliphatic, aromatic, and halogenated hydrocarbons. These agents act as primary irritants and as sensitizers. Clinically, skin findings can range from local erythema, papules, and vesicles to a generalized scarlatiniform eruption and an exfoliative dermatitis. A "huffer's rash" may be noted over the face of patients who chronically abuse the volatile hydrocarbons. Pruritus may also be present. A defatting dermatitis, similar to a chronic eczematoid dermatitis, may occur. Frostbite of the face may develop during the inhalational abuse of fluorinated agents. Cellulitis and sterile abscesses have been associated with the injection of hydrocarbons. Extensive partial-thickness and full-thickness burns following immersion in hydrocarbons may also occur.

Exposure to heated high-viscosity, long-chain aliphatics, such as tar, asphalt, or bitumen, present a particularly challenging problem because of their association with burns and hyperthermia, and difficulty with decontamination. [22]

TREATMENT

Prehospital

Not all patients who have ingested hydrocarbons require emergency department evaluation. In a retrospective study of 211 patients with hydrocarbon ingestions called to a poison center, fewer than one percent required physician intervention. [9] This data suggests that patients who are asymptomatic or quickly become asymptomatic after ingestion can be watched safely at home. This approach of home observation for asymptomatic patients can be supported when the ingestion is accidental, the ingredients are known and do not cause significant systemic toxicity when ingested, and reliable follow-up can be ensured. All symptomatic patients and intentional exposures should be referred to the hospital for further evaluation. Patients who ingest hydrocarbons that may cause significant systemic toxicity (e.g., aromatic, halogenated hydrocarbons, or toxic additives), whether or not symptomatic, should also be referred to the hospital. Volatile substance abusers and others exposed to volatiles should have immediate cardiac monitoring and advanced life support transport, if available, due to the potential for life-threatening dysrhythmias.

Emergency Department

General principles of poison management apply to the initial approach to patients once they reach the hospital. Establishing the airway and maintaining ventilation is the critical first maneuver in any patient who presents with respiratory depression and/or significant CNS depression. The detection of a sweet odor may be associated with certain halogenated hydrocarbon exposures (especially chloroform or trichloroethylene) while a petrol odor suggests gasoline or some other petroleum derivative. The patient should be connected to a continuous cardiac monitor and an electrocardiogram should be obtained. Hydrocarbon-induced dysrhythmias, if present, would generally occur shortly after the exposure, especially with inhalational use. Hypotension should be treated with aggressive fluid resuscitation. Catecholamines, such as dopamine, norepinephrine, or epinephrine, should be avoided to prevent precipitating dysrhythmias, especially following exposure to halogenated hydrocarbons and aromatic hydrocarbons. The administration of glucose, thiamine, and naloxone should be considered in cases of altered mental status. (See Table 174-5.)

TABLE 174-5   ED Management of Hydrocarbon Exposures

The patient needs to be fully undressed to prevent ongoing contamination from hydrocarbon-soaked clothes. Dermal decontamination with soap and water, and eye decontamination with saline irrigation, should be performed. Pre-hospital decontamination is preferable. The staff should wear protective gloves and aprons to prevent possible secondary exposure. Specific antidotal treatment directed at the complications of toxic additives, such as organophosphates or heavy metals, may also be needed.

Useful diagnostic tests include the chest x-ray and arterial blood gas to detect pulmonary aspiration and hypoxemia. Abdominal radiographs may show evidence of chlorinated hydrocarbon ingestions, such as carbon tetrachloride, because of the radiopaque nature of these substances. [23] Tests of liver and renal function should be obtained in all aromatic and halogenated hydrocarbon exposures to check for the development of hepatic and renal injury. A blood lead level may be helpful when evaluating patients with chronic gasoline exposure. A carboxyhemoglobin level is useful to evaluate the extent of endogenous carbon monoxide production following methylene chloride exposure. Pulse oximetry will not differentiate between oxyhemoglobin and carboxyhemoglobin. Routine drug screens are not useful for the detection of hydrocarbons, but as in all intentional ingestions, an acetaminophen level, ethanol level, anion gap, and osmolality may be helpful in assessing for the

presence of other coingestants.

Gastrointestinal Decontamination

For most hydrocarbon ingestions, gastrointestinal decontamination would provide little benefit; supportive care and appropriate treatment of coexisting ingestions are all that is required. The necessity for GI decontamination depends on the type of hydrocarbon and route of exposure. The risk of systemic toxicity by intestinal absorption has to be weighed against the risks of aspiration associated with gastric emptying. The majority of hydrocarbon ingestions, which consist of aliphatic hydrocarbons mixtures (see Table 174-1), do not require GI decontamination. These agents have poor GI absorption and their toxicity is limited primarily to pulmonary aspiration. In the typical childhood accidental ingestion, the actual amount ingested is usually one swallow or about 5 mL. Suicidal ingestions, which involve larger amounts of hydrocarbons, frequently are associated with spontaneous emesis, and further decontamination is usually not required. Some recommend GI decontamination if emesis has not occurred and the dose is greater than 1 to 2 mL/kg, although this strategy has not been studied.

GI decontamination may be warranted when the ingested hydrocarbon is known to have good GI absorption and may cause significant systemic toxicity (e.g., toluene, chloroform, wood distillates) or an additive in the toxic agent (e.g., organophosphate pesticides are often mixed in petroleum distillates). The CHAMP mnemonic (camphor, halogenated hydrocarbons, aromatic hydrocarbons, metals, pesticides) is helpful in remembering most situations where GI decontamination should be considered. Unfortunately, little data is available that evaluates the clinical benefits of gastrointestinal decontamination in these settings.

If the patient presents to the ED shortly after the ingestion of these toxic hydrocarbons, aspiration with a small nasogastric tube may be useful. In patients who present with an altered mental status, the airway should be protected with a cuffed endotracheal tube, although in smaller children under eight years of age, the cuff should be kept inflated only during the period of lavage because of cuff-related injury from prolonged inflation. Ipecac-induced emesis has been advocated in the past but its risks appear to outweigh any potential benefits.

Although activated charcoal may adsorb some hydrocarbon compounds, its use is not recommended for most hydrocarbon ingestions. Charcoal instillation may distend the stomach increasing the risk for vomiting and aspiration. The use of charcoal should only be considered if one of the CHAMP-type hydrocarbons has been ingested.

The use of cathartics to hasten GI transit and facilitate decontamination has no proven efficacy in hydrocarbon ingestions. Many patients will already have diarrhea from the hydrocarbon, and further catharsis is not required. Oil-based cathartics, which had been used in the past to thicken the ingested hydrocarbon to increase its viscosity and decrease the subsequent risk of aspiration, are contraindicated. They may actually increase GI absorption and are associated with an increased risk of lipoid pneumonia when aspirated.

Pulmonary Treatment

Nebulized oxygen is helpful in the treatment of pulmonary aspiration. Inhaled b_2 agonists may also be useful, especially in the setting of bronchospasm, but their role in the treatment of hydrocarbon pneumonitis has not been studied. Positive end-expiratory pressure (PEEP) or continuous positive-airway pressure (CPAP) may sometimes be required, but because of the potential for further injury from barotrauma, one should observe for the development of pneumatoceles or pneumothoraces. In cases of severe pulmonary aspiration resulting in refractory hypoxemia, treatment with extracorporeal membrane oxygenation (EMCO) and high frequency jet ventilation (HFJV) has proved successful.[24,25] Consensus remains that corticosteroids are contraindicated because they impair the cellular immune response and increase the chance of bacterial superinfection.[26] Antibiotics have no proven role in prophylaxis and are usually not required except in cases of continued pulmonary deterioration because of the risk of a superimposed bacterial pneumonitis.

Other

There are few antidotes to counteract the actions of hydrocarbons. N-Acetyl cysteine[16] and hyperbaric oxygen[27] may have a role in preventing hepatic toxicity after carbon tetrachloride (and possibly chloroform) exposure, but more studies are needed. Hyperbaric oxygen therapy is indicated for patients who develop significant carbon monoxide toxicity after exposure to methylene chloride. b blockers may be useful in the treatment of hydrocarbon-induced malignant dysrhythmias.[28] Although extracorporeal removal with hemodialysis, hemoperfusion, or peritoneal dialysis has been attempted for severe intoxications, clinically controlled evidence of efficacy is lacking.

The treatment of tar and asphalt injuries is a particular problem because of the difficulty in removing these substances without causing further tissue injury. Immediate cooling with cold water for at least 30 min is critical. Debridement of blistered skin can aid in the removal of adherent substances. De-Solv-It, a surface-active petroleum-based solvent, has proven both nonirritating and effective in removing these agents.[29] Polyoxyethylene sorbitan-containing ointments, such as Polysorbate 80 or Tween 80, have also proven useful. Petrolatum-containing preparations, such as Neosporin (although occasionally sensitizing) or Polysporin, may also work and are readily available. In some instances, early excision and skin grafting are required to treat the more significant hot tar burns.

Undoubtedly, the best therapy begins with preventive measures to reduce accessibility of these compounds to young children. Proper labeling of containers that store hydrocarbons, mandatory use of safety closures, and public education on the risks of hydrocarbons also limit the potential for inadvertent hydrocarbon toxicity.

DISPOSITION

A medical toxicologist or regional poison control center should be consulted on most symptomatic hydrocarbon exposures and asymptomatic exposures that involve halogenated, aromatic, and hydrocarbon exposures with toxic additives. Hospitalization is required for patients who have ingested aliphatic hydrocarbons who are symptomatic at the time of evaluation. After a six-hour observation period, asymptomatic patients with a normal chest x-ray may be discharged home.[8] Similar disposition of asymptomatic patients, with abnormal chest x-rays has also been suggested if reliable follow-up can be ensured. However some physicians prefer to watch these patients for 24 h in the hospital. Hospitalization is advisable for those who ingest hydrocarbons capable of producing delayed complications (e.g., halogenated hydrocarbons causing hepatic toxicity) and those with toxic additives (organophosphates). All patients taking ingestions with suicidal intent or presenting with complications of solvent abuse should have psychiatric evaluation following medical clearance.

175 CAUSTICS

G. Richard Bruno
Wallace A. Carter

The American Association of Poison Control Centers (AAPCC) reports approximately 100,000 potentially caustic exposures in the United States annually (Table 175-1).[1] Caustic exposures include dermal, ocular, and oral ingestions. Most exposures are unintentional, with a large portion occurring in children younger than age 6. In 1996, there were approximately 167 exposures that resulted in significant morbidity and 16 in death. Intentional adult ingestions with suicide intent account for a greater percentage of serious injuries than unintentional oral ingestions by curious children.

TABLE 175-1   Epidemiology of Caustic Ingestions Reported to the American Association of Poison Control Centers, 1996

Many chemicals used in industry have caustic potential. Alkali substances used in industry include sodium hydroxide and potassium hydroxide in cleaning fluids, calcium hydroxide in concrete, lithium hydroxide in photography, and ammonium hydroxide in fertilizers (Table 175-2). Common acids used in industry include hydrochloric acid and sulfuric acids as cleaners, hydrofluoric acid in etching and metal cleaning, chromic acid in metal plating, and formic acid in leather/textile tanning. Industrial strength cleaners and chemicals accounted for approximately 8000 alkali exposures and 12,000 acid exposures in the 1996 AAPCC data (Table 175-1).[1]

TABLE 175-2   Common Caustic Compounds

Household caustics are common, and many are less concentrated forms of industrial strength cleansers. Alkali caustics found in the home include sodium hydroxide in drain cleaners, oven cleaners, and Clinitest tablets (Table 175-2). Caustic ammonium compounds are found in glass, tub, and tile cleaners. Household bleach (sodium hypochlorite) is the most common alkali exposure reported in AAPCC data, accounting for more than 50,000 exposures per year. Most bleach exposures are benign, but 44 patients reported in the 1996 data suffered major morbidity. Common household acids include sulfuric acid in drain cleaners and automobile batteries, hydrochloric acid in cleaners, formic acid in airplane glue, and hydrofluoric acid in rust removers.

PATHOPHYSIOLOGY OF CAUSTIC INJURIES

Alkali

Alkali injuries can induce deep tissue injury from liquefaction necrosis. After caustic alkali exposures, proteins are rapidly denatured and lipids undergo saponification. Initially, there is direct cellular destruction from contact with the alkali. This is followed by thrombosis of local microvasculature that leads to further tissue necrosis. Solid or granular alkali caustics often injure the oropharynx and proximal esophagus. Liquid alkali ingestions are characterized by esophageal injuries. Severe intentional alkali ingestion may cause multisystem organ injuries, including gastric perforation, and necrosis of abdominal viscera. Severe injuries to the pancreas, gallbladder, and small intestine after intentional ingestion have been reported. [2]

The most common household alkali is bleach, a 3% to 6% sodium hypochlorite solution with a pH of approximately 11. Household liquid bleach is not corrosive to the esophagus, but ingestion may cause emesis secondary to gastric irritation or pulmonary irritation related to chlorine gas production in the stomach or when mixed with other substances.[3] Other injuries reported with bleach include pneumonitis after aspiration and sight-limiting ocular injuries. Industrial strength bleach may contain much higher concentrations of sodium hypochlorite, and ingestion may result in esophageal necrosis.

Solid alkali ingestions may have greater potential for proximal esophageal tract injury and less for distal injury.

Acids

Injuries by strong acids produce coagulation necrosis. Tissue destruction and cell death result in eschar formation, which is believed to protect against deeper injury. Ingested acids settle in the stomach, where gastric necrosis, perforation, and hemorrhage may result. It was previously thought that acids were esophagus sparing, with most tissue injury concentrated in the stomach, but a study by Zargar and colleagues [4] reported a similar incidence of gastric and esophageal injury (85.4 percent gastric and 87.8 percent esophageal) after acid ingestion. Despite relatively less tissue destruction, strong acid ingestion results in a higher mortality rate than does strong alkali ingestion. This higher mortality rate after acid ingestion is hypothesized to result from complications of systemic absorption of acid (metabolic acidosis, hemolysis, and renal failure).

CLINICAL FEATURES

Patients who present after caustic ingestion may have severe pain, odynophagia, dysphonia, oral/facial burns, respiratory distress, and/or abdominal pain, and be drooling, coughing, or vomiting. Dysphonia, stridor, and respiratory distress may indicate laryngotracheal injury, whereas dysphagia, odynophagia, epigastric pain, and vomiting may indicate esophageal and gastrointestinal (GI) injury.

Conflicting data exist on the reliability of presenting signs and symptoms to predict upper GI injuries. An early retrospective study of caustic ingestions by Gaudreault and colleagues[5] reported 12 percent of patients who presented without initial signs or symptoms of upper GI injury were subsequently found to have serious esophageal injuries of grade 2 or higher (Table 175-3). A subsequent prospective study by Gorman and coworkers found that no single symptom, or group of symptoms, had 100 percent positive or negative predictive value for esophageal injury. [6] All patients with serious esophageal injuries (grade 2 or 3) in the study by Gorman and colleagues[5] had some initial sign or symptom (drooling, abdominal pain, etc.).

Grade 0	Normal examination findings
Grade 1	Edema and hyperemia of mucosa
Grade 2a	Friability, hemorrhages, erosions, blisters, whitish membrane, exudates, and superficial ulcerations
Grade 2b	Grade 2a plus deep discrete or circumferential ulceration
Grade 3a	Small scattered necrosis
Grade 3b	Extensive necrosis

TABLE 175-3   Endoscopic Grading of Upper Gastrointestinal Caustic Injuries

MANAGEMENT

Initial Assessment

During the initial and subsequent evaluations, the emergency department (ED) staff should take precautions to prevent personal injury secondary to caustic exposure (Fig. 175-1).

FIG. 175-1. Guidelines for treatment of caustic exposures.

The first step is immediate airway evaluation. Patients with respiratory distress may have significant oral, pharyngeal, and/or laryngotracheal injury, and may require emergency airway management. Ideally, patients with potential airway injuries should have fiber-optic evaluation of the airway prior to intubation to determine the extent of the damage, but this may not always be possible. Blind nasotracheal intubation is contraindicated secondary to the potential for exacerbating airway injuries. Oral intubation with direct visualization is the first choice for definitive airway management, but surgical cricothyrotomy may be required if oral intubation is not possible. When in doubt, it is prudent to establish an airway early rather than risk greater difficulty later as secondary effects of injury, such as edema, complicate the situation.

A directed history and physical examination should be performed to determine the type and amount of caustic ingested. It should also be determined whether the ingestion was intentional or unintentional. Patients should be assessed for hemodynamic instability. Etiologies for shock in these patients include GI bleeding, complications of GI perforation, and volume depletion. Patients should be examined for peritoneal signs from hollow viscous perforation, and mediastinitis should be considered in patients complaining of chest discomfort. Examinations should be performed to detect dermal and ocular caustic exposures.

Laboratory/Ancillary Test

Laboratory evaluation should include arterial blood-gas level, electrolyte panel, hepatic profile, complete blood count, and coagulation profile. Strong acid ingestions may cause severe acid-base disorders, and an arterial line may be indicated if serial blood-gas determinations are required. Special attention should be given to serum calcium and magnesium levels after hydrofluoric acid exposures (vide infra). All patients should have an upright chest radiograph to screen for peritoneal and mediastinal air. After intentional ingestions, electrocardiography should be done and aspirin and acetaminophen levels should be obtained to screen for potential coingestants.

Gastric Decontamination

Gastric decontamination is a difficult issue because much of the morbidity and death related to caustic ingestion is secondary to destruction of the GI tract. Caustics do not bind well to activated charcoal, and charcoal is not useful in either alkali or acid ingestions. Gastric lavage and ipecac are also not used. They may increase the risk for repeat exposure to the ingested caustics secondary to vomiting. Nasogastric (NG) tube placement is also controversial. The use of an NG tube is contraindicated in obvious gastric or esophageal perforation. An NG tube is also not used after alkali ingestions, because the risk of GI perforation is considered too great. In cases of strong acid ingestion, the risk for perforation is considered lower because coagulation necrosis may protect deeper tissue from injury. Placement of a small NG tube under endoscopic guidance has been recommended by some to aspirate residual acid from the stomach.

Neutralization and Dilution

Recommendations about dilution and or neutralization therapy after caustic ingestions vary. Dilution of caustic alkalis with water or milk has been shown to decrease tissue destruction in animal models.[7] The literature generally recommends dilution therapy with 1 to 2 cups of water or milk early after alkali exposures. The toxicology literature suggests a greater theoretical benefit to dilution in treating solid alkali ingestions, because dilution might wash off adherent particles. Potential dangers of such therapy include vomiting, which may lead to further exposure of the esophagus and airway to caustic material and/or aspiration. Dilution therapy is contraindicated with patients who have obvious signs of perforation or airway injury. Most sources do not recommend dilution therapy for the treatment of acid ingestion. Rather, placement of a small NG tube with aspiration of gastric contents appears to be the chief means of gastric decontamination.

Neutralization therapy has long been considered contraindicated in caustic ingestions, because neutralization of strong bases with acids (and the reverse) are exothermic reactions. It is feared that the heat generated during neutralization could worsen injuries. Recently, a series of animal studies by Homan and colleagues [8] has questioned the significance of heat generated during neutralization therapy. Currently, the best recommendation with respect to dilution or neutralization therapy is small volumes of water or milk in alkali ingestions without signs of perforation. Neutralization of alkali with weak acids is contraindicated until further study and data are available.

Endoscopy

Endoscopy is an important tool used to evaluate the location and severity of injury to the esophagus, stomach, and duodenum after caustic ingestion. Indications for endoscopy vary. Some authorities recommend endoscopy in all cases of caustic ingestions, whereas others advocate endoscopy based on signs and symptoms. [9] Endoscopy is generally indicated in the presence of any signs or symptoms of serious injury (vomiting, drooling, dyspnea, or stridor), in the presence of oral-pharyngeal burns, and after intentional ingestions.

Zargar and colleagues[4] developed the most commonly referenced system for endoscopic staging of upper GI tract caustic injuries and prospectively demonstrated the safety of using the endoscope in caustic ingestions. Injuries are divided into four grades (Table 175-3). Patients with grade 2b and 3 injuries are at risk of long-term sequelae, including stricture formation. Patients with grade 3 lesions are at greatest risk of perforation, fistula, and hemorrhage.

Traditionally, endoscopists terminated their examination at the first sign of severe esophageal injury (grade 2b or 3). However, a more complete exam to document all injuries to the esophagus, stomach, and duodenum may outweigh the risk of perforation. Most experts agree that the timing of the endoscopy should be within the first several hours of ingestions and that follow-up exams should be avoided between days 5 and 15. Other noninvasive diagnostic means to evaluate and follow caustic GI injuries include abdominal computed tomography (CT) and ultrasonography. For patients not requiring emergent laparotomy, CT may be used to screen for intraabdominal necrosis outside the GI tract or in areas not reachable with the endoscope. Sonographic evaluation, both transabdominal and endoscopic, has been advocated for evaluation and follow-up of gastric injury after caustic ingestion. [10]

Steroids

One of the most controversial aspects of caustic ingestion management is the use of steroids to potentially decrease the risk of stricture formation. The ability of steroids to inhibit the inflammatory response led to the hypothesis that steroids may decrease stricture formation after caustic ingestion. The largest study of steroid use in human caustic ingestions was not able to demonstrate a benefit from steroid use.[11] Opponents of steroid use believe that steroids may increase the risk of infection, perforation, and hemorrhage. However, no compelling data support these fears in caustic ingestions. [12,13] Steroid use has never been recommended in acid ingestions, because the risk of esophageal stricture formation is believed to be lower. Recommendations vary for steroid use after alkali caustic ingestions from not using steroids at all to using them only in endoscopic grade 2b lesions (circumferential deep ulcerated lesions). Steroids are not indicated in grade 1 and grade 2a lesions because these lesions do not form strictures and grade 3 lesions are probably best handled by surgical resection. Steroids, if used, should be used early, within the first 6 h, at a dose approximately equivalent to 2 mg/kg/24 h of prednisolone for 3 weeks, followed by a taper.

Antibiotics

Most caustic ingestions do not require prophylactic antibiotics. If steroids are to be used after caustic ingestion, some evidence indicates that antibiotics may help to reduce rates of infection. Antibiotics used in these cases are penicillin, ampicillin, or clindamycin in penicillin-allergic patients.

Systemic Toxicity

Morbidity or death from alkali injuries usually results from the complications of direct tissue necrosis, but acid ingestions may result in systemic toxicity from absorption of the acid in addition to local tissue destruction. Significant acid-base disorders, hemolysis, and renal failure may result. In cases of systemic toxicity, traditional critical care principles should be applied to optimize the patient's hemodynamics. Manipulation of serum pH with sodium bicarbonate may be required if the serum pH is consistently below 7.10.

Ocular Exposures

Ocular injuries after caustic exposures can be devastating to vision. The Eye Bank Association of America reports that 300 of the 1000 corneal transplants in the United States in 1995 were secondary to eye injuries caused by chemicals.[14] Caustic alkali injuries to the eye are generally more severe than acid-related eye injuries. Alkali injuries penetrate deep into ocular tissue and continue to be destructive after superficial removal, whereas acidic injuries are usually superficial. The coagulation necrosis after acid injury limits the penetration of acid into ocular tissue.

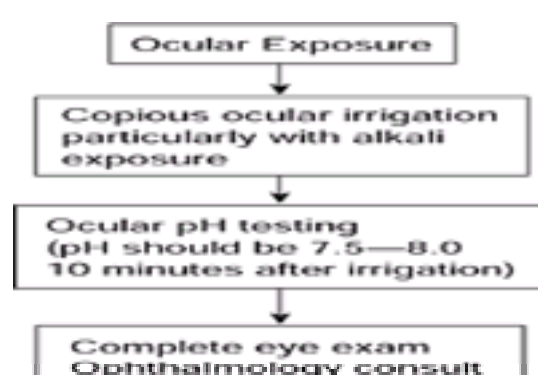
Ocular injuries should be immediately treated with copious irrigation (Fig. 175-2). Patients should have continuous irrigation with at least 2 L of normal saline per affected eye. Nitrazine (pH) paper should be utilized to ensure that the offending acid or base is eliminated. The expected pH after irrigation should be between 7.5 and 8.0, and irrigation should continue until this pH range is achieved. A waiting period of 10 min before checking the pH will more accurately reflect the pH of the eye and not the irrigation fluid. After irrigation, all patients should have a complete eye exam, including fluorescein staining, and all except the most superficial exposures should have ED ophthalmology consultation.


FIG. 175-2. Guidelines for treatment of caustic ocular exposures.

A recently reported ocular injury that ED clinicians should be aware of is alkali keratitis after deployment of motor vehicle airbags. A small amount of aerosolized sodium hydroxide and sodium carbonate is released during airbag deployment. These caustic alkalis may enter the eye and cause significant injury. The recommendation is to treat these injuries as other caustic ocular exposures, with copious irrigation, pH testing, and ophthalmology consultation. [15,16]

Treatment of Dermal Exposures

Caustic injuries to the skin most frequently occur on the extremities. Most acid injuries, excluding hydrofluoric acid, respond well to local copious saline irrigation. Alkali dermal exposures may appear deceptively superficial, yet burn more deeply and for extended periods. [17] Management of these injuries should include copious irrigation and local wound debridement to remove residual compound (Fig. 175-3). In cases of lime exposure and other caustic powders, patients should brush off the dry compound and remove contaminated clothing before irrigating.

FIG. 175-3. Guidelines for treatment of caustic dermal exposures.

Portland or ready-mix cement is an alkali mixture of lime that warrants special mention. When water is added to the dry mixture, calcium, sodium, and potassium hydroxide are produced. Patients may initially present with severe pain without obvious injury but eventually develop blisters and skin necrosis if the affected area is not irrigated early. All cutaneous caustic injuries require close follow-up or early referral to a plastic surgeon to ensure the injuries are not progressing.

Experimental Therapies

Many different therapies have been tried to decrease the toxic effects of caustic ingestions. Most experiential therapies have been aimed at preventing esophageal strictures after caustic alkali ingestion. Animal data have showed decreased stricture formation with drugs that affect collagen deposition, including b-aminopropionitrile, *N*-acetylcysteine, and D-penicillamine. Pentoxifylline, a local inflammatory and microcirculation mediator, has also been used experimentally. Oral agents to coat and protect the GI tract from insult, including sulcrafate, bismuth subsalicylate, and sodium polyacrylate, have been tried experimentally with some success. None of these agents have been evaluated in controlled clinical trials in humans, and more data are needed before a recommendation with respect to their use can be made.

Surgery/Stents/Dilation

Major ingestions of caustic agents may result in immediate perforation of the GI tract and require emergency surgery. The indications for emergency laparotomy include peritoneal signs or free intraperitoneal air. Esophageal perforation diagnosed by mediastinal air on plain films or by endoscopy is also an indication for emergent surgery. More controversial is the management of severe esophageal injuries, grade 2b and 3, without obvious perforation. Some authorities recommend early dilation therapy (in the first 3 weeks) with or without stenting, whereas others report good results with early surgical resection. [18,19]

DISPOSITION

All patients with symptomatic caustic ingestions should be admitted to the hospital. Patients with grade 1 and 2a lesions will do well but warrant hospitalization to ensure that symptoms do not progress. The majority of ocular injuries will require ED ophthalmology consultation and follow-up. Mild to moderate dermal injuries can be safely discharged after local wound irrigation, aseptic dressings, and close follow-up. The following dermal exposures may warrant admission: injuries that cross flexor or extensor surfaces, facial injuries, injuries to the perineum, partial-thickness injuries greater than 10 to 15 percent of body surface area, all full-thickness injuries, and less severe injuries in patients at the extremes of age.

SPECIAL CASES

Disc Batteries

Disc batteries are a common, potentially caustic ingestant. Each year, there are approximately 2000 disc battery ingestions in the United States, mostly by children younger than age 6 (Table 175-1). Batteries may contain manganese dioxide, zinc, mercuric acid, silver oxide, or lithium in an alkaline medium. Most disc batteries pass through the GI tract without incident. Batteries have the potential for alkali injury if they leak secondary to casing damage or from hydroxide production related to external current from intact batteries. Pressure necrosis may also play a role in injury if the disc battery becomes lodged in the GI tract. Heavy-metal toxicities, while a theoretical consideration in disc battery ingestion, have not been documented. [20]

With patients who present after disc battery ingestion, chest and abdominal radiographs should be obtained to determine the position of the battery. Batteries in the airway or esophagus should be removed by endoscopy/bronchoscopy immediately. If a battery has passed the gastroesophageal junction and appears to be in the stomach, then a follow-up film should be obtained in 24 to 48 h to ensure that the battery has passed through the pylorus. Batteries in the intestines should pass without difficulty, but checking the stools and follow-up film are used to ensure passage.

Hydrofluoric Acid

Hydrofluoric acid is a relatively weak acid (p K_a = 3.8) used in industry for glass etching, metal cleaning, and petroleum processing. It may also be found in household products such as chrome wheel cleaner and rust remover. Despite being a relatively weak acid, hydrofluoric acid has great potential for causing morbidity and death. The major mechanism of injury with hydrofluoric acid is not coagulation necrosis; rather, the free fluoride ion complexes with body calcium and magnesium, resulting in cellular death. Most injuries are to the upper extremities. Patients often present with benign-appearing wounds but complain of a tremendous amount of pain. These wounds often have a slight white discoloration but may become black and necrotic as cellular damage results. Severe injuries may result in hypocalcemia, hypomagnesemia, hyperkalemia, acidosis, and ventricular dysrhythmias. Ventricular fibrillation and death have been reported with dermal exposure of between 2.5 and 22 percent of body surface area.

Treatment of minor hydrofluoric acid injuries consists of first thoroughly irrigating the affected area with water and then placing the area in a paste of calcium gluconate or benzalkonium chloride solution. Paste can be made with surgical lubrication and calcium gluconate powder (2.5 percent wt/vol) or alternately with a

commercial preparation of benzalkonium chloride (Zephiran) is available. The affected area is soaked in the gel, with pain relief being used as end point for therapy. Other effective treatments include intradermal injections of 5% calcium gluconate or magnesium sulfate around the affected area (not to exceed 0.5 mL/cm ^{2}). For distal upper extremity injuries that do not respond to the aforementioned treatments, intraarterial infusion of calcium gluconate has been used. It is recommended that 10 mL of 10% calcium gluconate diluted in 40 mL of normal saline be infused over 4 h or until pain resolves. The use of calcium chloride should be avoided for fear of skin necrosis if extravasation occurs. The use of calcium gluconate with a Bier block has been advocated for treating serious hydrofluoric injuries. [21]

Oral ingestion of hydrofluoric acid has a high mortality rate. NG tube placement and gastric lavage with normal saline are recommended. Oral magnesium or calcium should be given in hydrofluoric ingestions on a milliequivalent-for-milliequivalent basis. If the amount of hydrofluoric acid ingested is not known, then 300 mL of magnesium citrate or calcium salts should be given. In serious exposures of any type, attention should be focused on hemodynamic monitoring for dysrhythmias. Serum calcium and magnesium levels should also be followed closely. Intravenous supplementation with large amounts of calcium and magnesium may be required.

LONG-TERM MORBIDITY

Most long-term sequelae from caustic exposure are related to injuries to the GI tract. Acid ingestions may scar the pylorus and result in gastric outlet obstruction. Caustic alkali ingestions may result in esophageal strictures, which may result in dysphagia, odynophagia, and malnutrition. Controversy exists on the appropriate treatment—long-term dilation therapy versus surgery—for strictures. [22]

Patients with caustic injuries to the esophagus are at risk for cancer of the esophagus. Increased risked for esophageal malignancy is up to 1000 times greater in patients with a history of caustic ingestion and is often seen decades after the initial ingestion and resulting esophageal injury. Some authorities advocate prophylactic esophagectomy in grade 3 lesions to decrease risk of potential future malignancy.

176 INSECTICIDES, HERBICIDES, RODENTICIDES

Walter C. Robey III
William J. Meggs

Pesticides are used to kill pests but also can be harmful or deadly to humans. Compounds considered to be pesticides include insecticides, herbicides, and rodenticides. In the United States, over 85,225 pesticide exposures were reported to poison centers in 1997. [1] About 45,390 of these involved children under 6 years of age. There were 14 deaths.

Pesticide intoxication results from intentional, accidental, and occupational exposures. Because of the number of chemical compounds marketed as multiple formulations and brand names and the complex clinical syndromes that result from exposure to their active ingredients, management often necessitates consultation with a poison center. Many pesticides contain inactive ingredients, such as petroleum distillates, that also can have harmful effects and modify management. Each class of pesticides has specific toxicologic properties that may produce predictable clinical findings after excessive exposure. However, there may be very nonspecific, subtle syndromes early on or in the case of chronic exposure. Many of the pesticides are responsible for both local and systemic effects. Supportive measures play an important role in most toxic exposures, even though specific antidotal therapy occasionally may be available. Broad-spectrum insecticides are responsible for most human pesticide intoxications.

INSECTICIDES

Chemical insecticides exert their toxic action by affecting the nervous system. Toxicity may include acute, chronic, and delayed sequelae of acute exposure. The four major classes of insecticides in use today are the organophosphates, carbamates, organochlorines, and pyrethroids. Organophosphate and carbamate cholinesterase inhibitors have replaced organochlorine insecticides because of their improved effectiveness and lack of persistence in the environment and human tissues. In 1997, 70,739 insecticide exposures were reported by the American Association of Poison Control Centers. [1] Children younger than 6 years of age were involved in 30,317 of these. Of the total, 66,217 were unintentional, 13,249 were treated in health care facilities, and 2365 patients had moderate to major clinical toxicity associated with exposure. Insecticide poisoning is worldwide. In a Jordanean study of 52 patients with insecticide poisoning, mixed organophosphate and carbamate exposure was responsible in 34.5 percent and isolated organophosphate or carbamate each was responsible for 25 percent. [2]

Organophosphates

Commonly used organophosphates include diazinon, orthene, malathion, parathion, and chlorpyrifos. In addition to their use as insecticides, organophosphates have been used as chemical warfare agents since World War II. Most recently, the organophosphate sarin was used in the terrorist attack on the Tokyo subway in 1995. [3] Organophosphates and carbamates are the most common insecticides associated with systemic illness. Potency does vary, however. Highly potent compounds such as parathion are used primarily in agriculture. Those of intermediate potency include coumaphos and trichlorfon, which are used in animal care. Low-potency products used in the household and on golf courses include diazinon and malathion. These compounds are very toxic at higher exposures. Poisoning results primarily from accidental exposure in the home, in agriculture, in industry (in workers involved in the manufacture and transport of these products), and in areas of insect control. Exposure to flea-dip products has been reported in pet groomers and children. Widespread food contamination and the potential for mass toxic exposure are always a risk. In addition, these chemicals are involved in intentional poisonings and occasionally in homicides. Systemic absorption of organophosphates occurs by inhalational, transdermal, transconjunctival, and gastrointestinal exposure.

PATHOPHYSIOLOGY   The mechanism of action of organophosphates involves the inhibition of the enzyme cholinesterase in the nervous system. Acetylcholinesterase (true or red blood cell acetylcholinesterase) is found primarily in erythrocytes and in nervous tissue. Plasma cholinesterase (pseudocholinesterase) is found in the serum, liver, heart, pancreas, and brain. Acetylcholine is a major neurotransmitter in the central, autonomic, and somatic nervous systems. The role of the cholinesterases is to hydrolyze acetylcholine into the inactive components choline and acetic acid after neurochemical transmission. Inhibition of cholinesterase leads to acetylcholine accumulation at nerve synapses and neuromuscular junctions, resulting in overstimulation of acetylcholine receptors. This initial overstimulation is followed by paralysis of cholinergic synaptic transmission in the central nervous system (CNS), in autonomic ganglia, at parasympathetic and some sympathetic nerve endings (e.g., sweat glands), and in somatic nerves. A *cholinergic crisis* results in a central and peripheral clinical toxidrome.

Organophosphates bind irreversibly to cholinesterase, thus inactivating the enzyme through the process of phosphorylation. A concept known as "aging" is used to describe the latency of permanent, irreversible binding of the organophosphate to the cholinesterase. This takes approximately 24 to 48 h to occur. The organophosphate-cholinesterase bond is irreversible without pharmacologic intervention. This time period of 24 to 48 h after exposure is therefore the critical interval during which administration of an antidote can reverse the process. Once "aging" occurs, however, the enzymatic activity of cholinesterase is permanently destroyed, and new enzyme must be resynthesized over a period of weeks before clinical symptoms resolve and normal enzymatic function returns. Therapeutic agents that remove the organophosphate and reactivate the cholinesterases are ineffective after "aging" is complete.

CLINICAL FEATURES   Clinical presentations depend on the specific agent involved, the quantity absorbed, and the type of exposure. A number of organophosphates are associated with local irritation of the skin and respiratory tract with resulting dermatitis and wheezing, respectively, without evidence of systemic absorption. A few cases of persistent reactive airway disease independent of cholinesterase inhibition have been reported. [4]

Acute systemic organophosphate poisoning results in a variety of clinical CNS, muscarinic, nicotinic, and somatic motor manifestations. In mild to moderate poisoning, symptoms occur in various combinations. Time to onset varies with route and chemical but usually occurs within 12 to 24 h. Onset is most rapid with inhalation and least rapid with transdermal absorption; however, dermatitis or skin excoriation may hasten this. Symptoms can occur within minutes with massive ingestion.

CNS symptoms of cholinergic excess include anxiety, restlessness, emotional lability, tremor, headache, dizziness, mental confusion, delirium, hallucinations, and seizures. Coma with depression of respiratory and circulatory centers may result. Aggressive behavior has been described.

Muscarinic receptor stimulation by acetylcholine is usually predominant and leads to salivation, lacrimation/sweating, urinary incontinence, diarrhea, gastrointestinal distress, emesis (SLUDGE), and bradycardia. Bradycardia is usually predominant, but tachycardia may occur. [5] Bradycardia may present as rate-related dizziness or syncope. Bronchospasm and bronchorrhea resulting from acetylcholine excess can lead to hypoxia and tachycardia. Miotic pupils and blurred vision are due to cholinergic effects on the pupillary constrictors and ciliary body.

Acetylcholine is the presynaptic neurotransmitter that stimulates nicotinic receptors in the sympathetic ganglia and adrenal medulla. Overstimulation results in pallor, mydriasis, tachycardia, and hypertension. Parasympathetic stimulation usually dominates, but sympathetic domination with tachycardia and hypertension are seen. Nicotinic stimulation at neuromuscular junctions results in muscle fasciculations, cramps, and muscle weakness. This syndrome may progress to paralysis and areflexia. Respiratory muscle paralysis results in acute respiratory failure and death. Miosis and muscle fasciculations are considered by some as reliable clinical signs of toxicity.

An intermediate syndrome may occur 1 to 4 days following an acute organophosphate poisoning. [6] The patient appears to be recovering from an acute poisoning when this manifests. Clinically, there is paralysis of neck flexor muscles, muscles innervated by the cranial nerves, and proximal limb and respiratory muscles to the extent that some patients may require respiratory support. Electromyography (EMG) may assist in making the diagnosis by indicating a problem at the neuromuscular junction. Aggressive, early antidote therapy and supportive measures may prevent this syndrome. Symptoms usually resolve within 4 to 18 days.

A non-cholinesterase-related neurotoxic syndrome known as *organophosphate-induced delayed neuropathy* (OPIDN) may occur 2 to 3 weeks after acute poisoning with a flaccid paralysis of the lower limbs. This is thought to be due to the inhibition of a neuropathy target enzyme. Delayed bilateral recurrent laryngeal nerve paralysis has been reported as a manifestation of this syndrome.

Chronic neurologic and neurobehavioral sequelae after acute organophosphate poisoning include neuropsychiatric deficits and paralysis. [7] More lipid-soluble organophosphates may not produce immediate symptoms of toxicity, and symptoms may persist for several weeks. Low-grade chronic organophosphate exposures occur among farm workers, pesticide manufacturing plant workers, and exterminators. Symptoms and signs are often less dramatic and nonspecific, with varying degrees of headache, nausea, weakness, or fatigue and a subtle cholinergic syndrome. Neuropsychological effects have been described with chronic exposure.

Special Considerations   Organophosphates are the principal toxins found in nerve gases. Chemical warfare nerve agents referred to as *G agents* were synthesized in search of better insecticides. Their mechanism involves the inactivation of acetylcholinesterase. These chemicals, however, produce "aging" within minutes, thus making them particularly toxic. They are rapid acting and extremely potent, and death occurs within minutes of inhalation or dermal exposure. Accordingly, those exposed are unlikely to present to the emergency department (ED) alive.

DIAGNOSIS   Suspicion of exposure to organophosphates is based on the history, the presence of a suggestive toxidrome, and laboratory cholinesterase assays. Diagnosis is often difficult owing to a constellation of clinical findings that may be vague in both acute and chronic poisonings. Toxicity may masquerade as a nonspecific flulike syndrome. Degree of toxicity may be based on the presence of specific signs and symptoms. Mild, moderate, and severe toxicities are described.

Clinically, noting a characteristic petroleum or garlic-like odor may assist in diagnosis. The cholinergic toxidrome may vary depending on the predominance of muscarinic, nicotinic, and CNS manifestations of the toxin and the severity of the intoxication. An initial test dose of intravenous atropine that does not result in the expected improvement in signs and symptoms in the case of poisoning may assist in making a diagnosis. Differential diagnosis of CNS alterations includes all nontoxic causes of mental status changes, coma, and seizures. Muscarinic manifestations may imitate asthma, exacerbation of chronic obstructive pulmonary disease, cardiogenic pulmonary edema, acute gastroenteritis, and primary cardiac brachycardia or hypotension. Miosis may appear late, whereas the presence of mydriasis may indicate hypoxia. Ocular exposure may cause persistent miosis. Nicotinic manifestations may imitate other causes of striated muscle dysfunction and respiratory failure. Sympathomimetic toxins and other causes of sympathetic hyperactivity should be considered when signs and symptoms of nicotinic stimulation predominate.

Functional assays of plasma and red blood cell (RBC) cholinesterases are helpful for diagnosis and as a guide for therapy but may not be readily available. Clinical toxicity is predominately due to the toxic effect of the organophosphate on RBC acetylcholinesterase; therefore, this enzyme assay is a more accurate indicator of synaptic cholinesterase inhibition. However, plasma cholinesterase is easier to assay and more available. The degree of cholinesterase inhibition necessary to produce symptomatic illness is variable, with symptoms generally occurring only after more than 50 percent inhibition from baseline determinations. Although there is patient variability, a high-normal cholinesterase level excludes acute systemic poisoning. The degree of depression from baseline cholinesterase levels is thought to correlate with toxicity. A patient may show mild clinical toxicity with normal levels. With a 60 percent decrease in cholinesterase level, headache and parasympathetic stimulation develop. Moderate symptoms develop, including muscle weakness, tremor, and neuropsychiatric symptoms, with a 60 to 90 percent decrease. After a 90 percent decrease, severe symptoms include seizures, cyanosis, pulmonary edema, respiratory failure due to muscle weakness, and coma, and death may occur.

Without treatment, plasma cholinesterase takes up to 4 to 6 weeks and RBC acetylcholinesterase as long as 90 to 120 days to return to baseline after exposure. Plasma cholinesterase levels have poor prognostic value in patients with acute organophosphate poisoning. Levels do not correlate with the amount of atropine required or the need for mechanical ventilation. [8] When the rate of cholinesterase falls gradually, as in chronic exposure, clinical symptoms may be minimal. Plasma cholinesterase levels may be depressed in genetic variants, chronic disease states, liver dysfunction, cirrhosis, malnutrition and low serum albumin states, neoplasia, infection, and pregnancy. RBC acetylcholinesterase is affected by factors that influence the circulating life of erythrocytes such as hemoglobinopathies.

Routine laboratory test abnormalities are nondiagnostic but may include evidence of pancreatitis, hypo- or hyperglycemia, and liver function abnormalities. A chest radiograph may show pulmonary edema in severe cases.

The electrocardiogram (ECG) may be abnormal and correlate with degree of toxicity and outcome. Common abnormalities include ventricular dysrhythmias, torsade de pointes, and idioventricular rhythms. Heart blocks and prolongation of the QT_c interval are common.[9]

TREATMENT   Treatment consists of intensive respiratory support, general supportive measures, decontamination, and prevention of absorption. Therapy includes the administration of antidotes and is based on the degree of toxicity. Therapy should not be withheld pending determination of cholinesterase levels.

Secondary contamination of health care workers must be prevented during patient resuscitation. Protective gloves and gowns must be worn. Patients with suspected exposure must be removed from the contaminated environment. All clothes and accessories must be removed completely and placed in plastic bags for disposal. The patient is immediately decontaminated externally with copious amounts of soapy water and possibly a second washing with dilute ethanol. Decontamination must include the scalp, hair, fingernails, skin, and conjunctivae. Abrasion or irritation of the skin should be avoided. Contaminated runoff water should be drained and discarded separately and safely.

The patient is placed on 100% oxygen, a cardiac monitor, and pulse oximeter. A 100 percent non-rebreather mask will optimize oxygenation in the patient with excessive airway secretions and bronchospasm and may reduce the chance of ventricular dysrhythmias during antidote therapy. Gentle suction will assist in clearing airway secretions from hypersalivation, bronchorrhea, or emesis. Coma, seizures, respiratory failure, excessive respiratory secretions, or severe bronchospasm may necessitate endotracheal intubation. A nondepolarizing agent should be used when neuromuscular blockade is needed. An intravenous line is established, and baseline blood sampling and determination of cholinesterase levels should be done. Hypotension may necessitate initial fluid boluses of normal saline. Substrates such as dextrose and naloxone should be considered. In a recent or large ingestion, gastric lavage may be of value. Activated charcoal is recommended. Protection of the airway must be ensured before lavage in the event a hydrocarbon vehicle is involved. When there is significant diarrhea due to cholinergic effects, catharsis is withheld. Hemodialysis and hemoperfusion are of no proven value.

Pharmacologic intervention consists of concomitant atropine and pralidoxime (2-PAM) therapy in significant poisonings. Atropine, a competitive antagonist of acetylcholine at CNS and peripheral muscarinic receptors, is used to reverse muscarinic and central effects secondary to excessive parasympathetic stimulation. The dose is titrated to dry copious tracheobronchial secretions. Pupillary dilatation is not a therapeutic end point. Atropine should not be withheld in the face of a tachycardia that may be the result of hypoxia due to secretions, respiratory muscle paralysis, or ganglionic stimulation. In moderate to severe poisoning, atropine is administered in a dose of 2 to 4 mg intravenously in the adult and 0.05 mg/kg in children as a test dose. Intramuscular administration is possible, if not ideal. Failure to respond to a trial dose of atropine is indicative of organophosphate poisoning. If no effect is noted, this dose is doubled every 5 to 10 min until muscarinic symptoms are relieved. The dose necessary to dry secretions may be on the order of hundreds of milligrams in massive overdoses, and prolonged therapy may be necessary. Atropine infusion for as long as several weeks has been reported. [10] The most common cause of treatment failure is inadequate atropinization.

Compounds called *oximes* are used to displace organophosphates from the cholinesterases. Pralidoxime, or 2-PAM, is a specific antidote available in the United States. This antidote restores acetylcholinesterase activity by regenerating phosphorylated acetylcholinesterase and appears to prevent toxicity by detoxifying the remaining organophosphate molecules. Clinically, this compound ameliorates muscarinic, nicotinic, and CNS symptoms and can reverse organophosphate-related muscle paralysis. The cholinergic nicotinic effects not reversed by atropine are reversed by pralidoxime. After blood samples are obtained for determination of

cholinesterase levels, it is important that pralidoxime is administered early before permanent and irreversible binding or "aging" occurs. It is ideal to administer this within 24 to 36 h of acute exposure. If there is a strong clinical suspicion of organophosphate toxicity, administration of 2-PAM should not be delayed. It is more effective in acute than in chronic intoxications. The recommended dose is 1 g for adults and 20 to 40 mg/kg up to 1 g for children. It should be infused in normal saline over 30 min. This may be repeated in 1 h, and multiple doses may be needed. Administration of 2-PAM should occur every 6 to 8 h for 24 to 48 h, or until signs and symptoms resolve. A continuous infusion may be administered. Combination therapy does reduce atropine requirements. This antidote is not administered to asymptomatic patients or to patients with known carbamate exposures presenting with minimal symptoms.

Response to 2-PAM therapy with a decrease in muscle weakness and fasciculation and relief of muscarinic effects with atropine usually occurs within 10 to 40 min of administration. Use of 2-PAM may prevent later subacute or chronic sequelae. [11]

Seizures are treated with airway manipulation, oxygen, benzodiazepines, and antidotal therapy. Pulmonary edema and bronchospasm are treated with oxygen, intubation, positive-pressure ventilation, atropine, and 2-PAM. Altered heart rate is treated with supportive therapy and antidotes. Management of dysrhythmias follows advanced cardiac life support guidelines. Succinylcholine, ester anesthetics, and beta blockers may potentiate poisoning and should be avoided.

DISPOSITION   Mild exposure may require only decontamination and 6 to 8 h of observation in the ED. Reexposure must be avoided until cholinesterase activity returns to baseline. Patients may return to work if it does not involve reexposure risk. Admission to the intensive care unit is necessary for all significant exposures. Most patients respond to 2-PAM therapy within 48 h. If toxins are fat soluble, the patient may be symptomatic for prolonged periods of time and dependent on 2-PAM. [12] During a period of weeks while awaiting resynthesis of new enzyme, supportive care and respiratory support may be needed. The end point of therapy is determined by the absence of signs and symptoms on withholding 2-PAM therapy. Following an acute exposure, the patient may have a variety of neurologic sequelae and nonspecific symptoms lasting days to months. Chronic exposure may necessitate serial enzyme determinations to identify a trend. Death from organophosphate poisoning usually occurs in 24 h in untreated patients. If there is no posthypoxic brain damage, and if the patient is treated early, symptomatic recovery occurs in 10 days. Respiratory failure secondary to paralysis of respiratory muscles or CNS depression and bronchorrhea is the usual cause of death.

Carbamates

EPIDEMIOLOGY   *N*-Methyl carbamates are cholinesterase inhibitors that are structurally related to the organophosphates. Commonly used carbamates are Sevin, Baygon, Lannate, and Aldicarb.

PATHOPHYSIOLOGY   Carbamates transiently and reversibly inhibit the cholinesterase enzyme through carbamoylation. Regeneration of enzyme activity by dissociation of the carbamyl-cholinesterase complex occurs within minutes to a few hours. This involves rapid, spontaneous hydrolysis of the carbamate from the cholinesterase enzymatic site. Unlike organophosphate poisoning, it is not necessary for new enzyme to be synthesized for normal function to be restored.

CLINICAL FEATURES   Symptoms of acute intoxication are similar to the cholinergic crisis observed with organophosphates but are of shorter duration. Because carbamates do not effectively penetrate the CNS, less central toxicity is seen, and seizures do not occur. Presentation of carbamate poisoning in childhood with a predominance of CNS depression and nicotinic effects differs clinically from that of adults. [13]

DIAGNOSIS   Cholinesterase levels and thus enzymatic activity may return to normal spontaneously 4 to 8 h after exposure. Measurement of RBC cholinesterase activity is therefore not useful unless done shortly after poisoning.

TREATMENT   Initial treatment is the same as for organophosphates. Atropine is the antidote of choice and is administered for muscarinic symptoms. This is usually all that is necessary while waiting for the carbamoylated acetylcholinesterase complex to dissociate and recover function. Therapy is usually not needed for more than 6 to 12 h. The use of 2-PAM in carbamate poisoning is controversial. The carbamate-binding half-life to cholinesterase is approximately 30 min, and irreversible binding does not occur; therefore, there is little need for 2-PAM. The older literature suggests that 2-PAM may potentiate toxicity of the carbamate carbaryl, but a recent study found benefit. [14] Thus, it should not be avoided in severe carbamate poisonings. 2-PAM is indicated in mixed poisonings with an organophosphate and a carbamate or if the type of insecticide is unknown.

DISPOSITION   Morbidity and mortality are limited because of the transient cholinesterase inhibition and rapid enzyme reactivation. These are less toxic and the clinical course more benign. Most patients recover completely within 24 h. In mild poisonings, observation suffices, and the patient may be discharged with follow-up. Moderate poisonings necessitate 24-h observation that includes ruling out concomitant exposure to or toxicity from inactive ingredients or vehicles such as hydrocarbons.

Chlorinated Hydrocarbons

EPIDEMIOLOGY   Dichlordiphenyltrichloroethane (DDT) is the prototype pesticide of the chlorinated hydrocarbons. Chlordane is an example of an organochlorine that was used for termite and roach control. Most have been restricted or banned in the United States because of their persistence in the environment, long half-life in the human body, and moderate toxicity. Hexachlorocyclohexane (lindane) is a general garden insecticide that is used commonly to control ticks, scabies, and lice. This compound is well absorbed on ingestion, by inhalation, and to a minimal extent transdermally unless the skin is abraded or repeated applications are used. Children and the elderly are prone to developing CNS toxicity and seizures with therapeutic use of 1% lindane.

PATHOPHYSIOLOGY   These agents are CNS stimulants absorbed primarily by the transdermal route, but they can be ingested or inhaled. The physical state, whether a liquid or solid, and the type of vehicle affects the transdermal absorption of organochlorines. Toxicity results from a decrease in permeability of membrane sodium channels following the action potential, which causes repetitive neuronal discharges. These agents are highly lipid soluble and are stored indefinitively in human tissues, and most are capable of inducing the hepatic microsomal enzyme system. Therefore, therapeutic efficacy of other chemicals and drugs that use this system is reduced in the presence of organochlorines.

CLINICAL FEATURES   Neurologic symptoms predominate in the acute intoxication. Mild poisoning presents with dizziness, fatigue, malaise, headache, neurologic stimulation with hyperexcitability, irritability, and delirium, apprehension, tremulousness, myoclonus, and facial paresthesias. Fever is common. More severe exposure may result in seizures that occur occasionally without prodromal symptoms, coma, respiratory failure, and death. Respiratory findings may indicate aspiration of an inactive hydrocarbon ingredient. In addition, these agents may induce myocardial irritability with ventricular fibrillation. Chronic neurotoxic effects associated with low-level exposure to the organochlorine compound chlordane have been noted to include deficits in tests of balance, reaction time, and verbal recall. [15]

DIAGNOSIS   History is important, and valuable information can be obtained from the package label regarding the product and vehicle involved. Laboratory evaluation is generally not helpful, but these agents can be detected in the serum and urine.

TREATMENT   Treatment includes administration of oxygen, with intubation indicated to treat hypoxia secondary to seizures, aspiration, and respiratory failure. Benzodiazepines are indicated for seizure control. Dysrhythmia control may be indicated, but atropine and epinephrine should be avoided in the organochlorine-sensitized myocardium. Hyperthermia must be managed. Skin decontaminated with soap and water is important. Avoid using oils on skin because they promote absorption. Activated charcoal and possibly gastric lavage are indicated for ingestions. The exchange resin cholestyramine should be administered to symptomatic patients exposed to Chlordecone.

DISPOSITION   Patients are observed for 6 h and admitted to the hospital if signs of significant toxicity develop or if ingestion involved a hydrocarbon.

Pyrethrins

EPIDEMIOLOGY   Pyrethins are naturally occurring botanic substances found in the chrysanthemum plant. They have potential insecticidal activity but are less toxic than other insecticides. Pyrethroids are synthetic analogues of pyrethrins. These agents are used commonly as aerosols in automated insect sprays in public areas; therefore, inhalation is the most common source of exposure. These agents are available as dusts and liquids in a hydrocarbon base.

PATHOPHYSIOLOGY   Pyrethrins block the sodium channel at the neuronal cell membrane, causing repetitive neuronal discharge. There is an additional effect on gamma-aminobutyric acid receptors. Other effects include increased nicotinic cholinergic transmission, norepinephrine release, and interference with sodium-calcium

exchange across membranes.

CLINICAL FEATURES   These compounds are responsible for dermal, pulmonary, gastrointestinal, and neurologic findings. Allergy, however, is their most common effect. Allergic reactions manifest as dermatitis, asthma, allergic rhinitis, hypersensitivity pneumonitis, and anaphylaxis. Dermal absorption is minimal, but these compounds are well absorbed from the gastrointestinal tract. Skin contact may lead to tingling and burning within 30 min of exposure and persisting up to 8 h. Contact dermatitis syndromes and allergic rhinitis result from both compounds. Allergic reactions including fatal asthma attacks have been reported. Upper and lower airway irritation occurs with local inhalation exposure. When absorbed, these compounds are metabolized rapidly in the liver, thus resulting in minimal systemic toxicity. These compounds are responsible for occasional systemic occupational poisonings. Systemic symptoms of paresthesias, hyperexcitability, tremors, incoordination, seizures, muscle weakness, respiratory failure, dizziness, headache, and nonspecific nausea, vomiting, diarrhea, and fatigue are seen with significant intentional ingestions. Alteration of consciousness, muscle fasciculations, pulmonary edema, and seizures may occur in severe poisonings.

DIAGNOSIS   Differential diagnosis includes asthma-like and neurologic diseases. Laboratory tests are of little assistance clinically.

TREATMENT   Treatment includes removal from exposure, decontamination, treatment of allergic manifestations, and supportive care.

DISPOSITION   Disposition is usually related to the severity of asthmatic and allergic manifestations. The clinical course is usually benign and hospitalization not necessary.

HERBICIDES

Herbicides are pesticides used to kill weeds. There are several classes in general use that pose a health hazard to humans despite their low acute toxicity in mammals. Toxicity in plants is due to inhibition of photosynthesis, respiration, protein synthesis, or growth stimulation mimicking plant hormones called *auxins*. Herbicides may be classified as chlorophenoxy, bipyridyl, and urea-substituted compounds. There were 10,379 exposures to herbicides reported by the American Association of Poison Control Centers in 1997.[1] Of these, 139 were intentional, with 2820 occurring in children under 6 years of age. About 2300 patients were treated in health care facilities, and 339 exposures resulted in moderate to major morbidity, including 5 deaths.

Chlorophenoxy Herbicides

EPIDEMIOLOGY   *Dioxins* and *furans* are the common names of these chemicals. The most commonly used compounds are 2,4-dichlorophenoxyacetic acid (2,4-D) and 4-chloro-2-methylphenoxyacetic acid (MCPA). 2,4,5-Trichlorophenoxy acetic acid (2,4,5-T) has been banned because of its contamination with 2,3,7,8,-tetrachlorodibenzo-*p*-dioxin (TCDD). The aerially applied defoliant Agent Orange used during the Viet Nam war was a mixture of 2,4-D and 2,4,5-T. These compounds are effective against broadleaf plants and are used as weed killers on lawns and grain crops.

PATHOPHYSIOLOGY   The metabolic pathway or mechanism related to toxicity is unknown. Skeletal muscle toxicity can result in respiratory failure or rhabdomyolysis.[16] Toxicity results from dermal contact, inhalation, or ingestion. Local exposure results in dermal and gastrointestinal irritation.

CLINICAL FEATURES   Local exposure leads to eye and mucous membrane irritation. After ingestion, nausea, vomiting, and diarrhea occur. Tachypnea may indicate pulmonary edema. Cardiovascular findings include hypotension, tachycardia, and dysrhythmias. Muscle toxicity manifests by muscle tenderness, fasciculations, and myotonia with resulting rhabdomyolysis. The patient may become hyperthermic. Peripheral neuropathy has been described in the recovery phase and in chronic exposure.

DIAGNOSIS   Diagnosis is based on the history of exposure. Ancillary tests generally are nonspecific but may demonstrate a metabolic acidosis and evidence of hepatorenal dysfunction. Toxin levels are not immediately available. Myoglobinuria and an elevated creatine phosphate level indicate rhabdomyolysis. Differential diagnosis includes other causes of acute myopathy.

TREATMENT   Treatment is supportive, including decontamination measures and respiratory support for myopathic-related respiratory failure. Alkalinization is suggested but not proven to increase the elimination of these compounds. Rhabdomyolysis should be monitored and treated.

DISPOSITION   Severe toxicity and serious complications are not common. Since toxic effects usually appear within 4 to 6 h, patients with mild symptoms can be observed and discharged after that time. Significant toxicity warrants admission.

Bipyridyl Herbicides

These compounds, paraquat and diquat, are nonselective contact herbicides. Both are still widely used and are responsible for significant morbidity.

PARAQUAT   **Epidemiology**   Paraquat is manufactured as a liquid, granules, or an aerosol and is commonly combined with diquat and other herbicides. Most products contain an emetic. Ingestion is responsible for the majority of paraquat deaths.[17] Deaths have been reported after transdermal exposure, ingestion, and inhalation. The inhalation of sprays is unlikely to cause systemic toxicity.

Pathophysiology   There is minimal transdermal absorption of paraquat in the absence of preexisting skin lesions that increase systemic absorption. Ingested paraquat is absorbed, rapidly, particularly if the stomach is empty. Plasma concentration peaks within minutes to 2 to 4 h after ingestion. Paraquat is then distributed to most organs, with the highest concentration found in the kidneys and lungs. Acute exposure causes liver and renal necrosis that is followed within a few weeks by pulmonary fibrosis.

Paraquat actively accumulates in the alveolar cells of the lungs, where it is transformed into a reactive oxygen species, the superoxide anion. This anion is responsible for lipid peroxidation that leads to degradation of cell membranes, cell dysfunction, and death. A redox reaction results in two phases of lung injury. An initial destructive phase is characterized by loss of type I and type II alveolar cells, infiltration by inflammatory cells, and hemorrhage. These changes may be reversible initially. The later, proliferative phase is characterized by fibrosis in the interstitium and alveolar spaces. Paraquat and oxygen enhance each other's toxicity by sustaining the redox cycle. Myocardial injury and necrosis of the adrenal glands may occur.

Clinical Features   Paraquat's caustic effects produce local skin irritation and ulceration of epithelial surfaces. Severe corrosive corneal injury may result from eye exposure. Upper respiratory tract exposure may result in mucosal injury and epistaxis. Inhalation may lead to cough, dyspnea, chest pain, pulmonary edema, and hemoptysis.

Ingestion causes gastrointestinal mucosal lesions and ulcerations. An acute burning sensation of the lips or mouth may be followed by ulceration 1 to 2 days later. Buccopharyngeal, esophageal, and abdominal pain and vomiting occur. Caustic lesions of lips, oral cavity, and gastrointestinal tract can occur within a few minutes to hours. Hypovolemia occurs from gastrointestinal fluid losses and decreased oral intake. Cardiovascular collapse may occur early in intoxication. Multisystem effects then result, including gastrointestinal tract corrosion, acute tubular necrosis, and extensive pulmonary injury. Ingestion of greater than 30 mg/kg leads to pulmonary edema, congestive heart failure, and renal failure within hours. Seizures, gastrointestinal perforation and hemorrhage, and hepatic failure may occur. Massive ingestion may lead to multisystem failure with death within a few days. Clinical manifestations of renal failure and hepatocellular necrosis develop between the second and fifth days, with pulmonary fibrosis leading to refractory hypoxemia 5 days to several weeks later. Metabolic (lactic) acidosis is common as a result of pulmonary effects (hypoxemia) and multisystem failure.

Diagnosis   Early diagnosis and therapy are important. The history may be indicative of an accidental or intentional poisoning and of the route of exposure. The differential diagnosis includes exposure to other corrosive agents and herbicides. Qualitative and quantitative analyses for paraquat in urine and blood can assist in the diagnosis.[18] Nomograms have been presented for predicting survival based on plasma paraquat concentration and time of ingestion.[18,19 and 20] A 10-h level greater than 0.4 mg/L carries a high probability of death. Serial pulmonary function tests, chest radiographs, and arterial blood gas determinations, including alveolar-arterial gradient, may be used to monitor toxicity.

Chemistry abnormalities reflect multiorgan necrosis. Hypokalemia may be present. Chest radiographs may show pneumomediastinum or pneumothorax in the case of

corrosive rupture of the esophagus. Radiographic abnormalities of diffuse consolidation indicating parenchymal injury on the chest radiograph may not parallel the severity of clinical symptoms. Upper gastrointestinal endoscopy should be performed to identify the extent and severity of mucosal lesions.

Treatment   The goal of early and vigorous decontamination is to prevent pulmonary toxicity. Any exposure to paraquat is a medical emergency, with hospitalization indicated even if the patient is asymptomatic. Early treatment is mainly supportive but is an important determinant of survival. An attempt should be made to prevent superoxide radical formation by using low inspired oxygen to produce a therapeutic hypoxemia with the goal of reducing pulmonary injury. The use of low oxygen mixtures ($F_iO_2 < 21$ percent) with positive-pressure ventilation reduces pulmonary toxicity in experimental models and may be of therapeutic benefit. It is suggested that the fraction of inspired oxygen should be maintained at greater than 21 percent only when arterial oxygen pressure is less than 40 mmHg. The skin should be decontaminated with soap and water without causing abrasions that may increase absorption. Ocular irrigation with copious amounts of water or saline must take place. Fluid and electrolytic losses from gastrointestinal tract damage, vomiting, and cathartics need to be replaced. Maintaining intravascular volume and urine output is important in preventing prerenal failure. Pain associated with oropharyngeal lesions should be treated with opioids. Gastric lavage via orogastric tube is recommended despite the risk of perforation.

Immediate gut decontamination with absorbants that bind paraquat is indicated. Activated charcoal (1–2 g/kg), diatomaceous Fuller's earth (1–2 g/kg in 15% aqueous suspension), or bentonite (1–2 g/kg in a 7% aqueous slurry) may be used. Subsequent doses every 4 h may be administered. A 70% sorbitol 2 cc/kg cathartic should be administered initially. Early charcoal hemoperfusion, preferably within 12 h of ingestion, offers better clearance than hemodialysis and has been associated with some successful clinical outcomes when levels were low to moderate. Multiple other therapies have been proposed to decrease the toxic effects on the lungs, but none are of proven efficacy. Corticosteroids have been used traditionally and should be considered.

Supportive care includes airway protection, maintaining intravascular volume, monitoring of vital signs and arterial blood gases, pain relief, treatment of renal failure and complications, and treatment of infection. Maintaining renal function will assist in avoiding toxic accumulation in other tissues.

Disposition   An attempt to determine prognosis should be made. The mortality rate from ingestion is as high as 75 percent. [17] Outcome is determined by the amount ingested; therefore, intentional ingestions tend to have a worse prognosis. A poor prognosis is seen when paraquat is ingested in a highly concentrated formulation, [18] on an empty stomach thus increasing absorption, and when ingestion results in upper gastrointestinal ulcerations and renal failure. [21] Ingestion of a concentrated liquid solution is usually fatal. Dilute solid formulations rarely cause death. Three categories of toxicity have been described. [22] Ingestion of less than 20 mg/kg of paraquat ion or 28 mg/kg of paraquat dichloride produces no or only moderate gastrointestinal symptoms. Recovery is usually without sequelae. Ingestion of 20 to 40 mg/kg usually results in death 5 days to several weeks after ingestion. Early development of gastrointestinal corrosion, acute renal tubular necrosis, and symptoms of systemic toxicity predominates, with subsequent extensive pulmonary injury and pulmonary fibrosis causing death in most patients. Death may be delayed 2 to 3 weeks. Patients who ingest more than 40 mg/kg of paraquat usually die in 1 to 5 days. Mortality from multiorgan failure and corrosive gastrointestinal effects is 100 percent in this group.

If more than a mouthful (50 mg/kg) is ingested, death occurs within 72 h and is due to multiorgan failure, renal tubular necrosis, myocarditis, liver necrosis, adrenal necrosis, and corrosive lesions of the gastrointestinal tract. If less than a mouthful (20–50 mg/kg) is ingested, death may be delayed up to 70 days and usually results from pulmonary fibrosis.[23] Cardiogenic shock is the usual cause of death in patients with very high plasma concentrations. Death from lower levels is due to pulmonary fibrosis and respiratory failure.

DIQUAT   Diquat has a similar structure and mechanism as paraquat but is less toxic. For identification purposes, formulations containing diquat do not contain the dye, stenching agent, or emetic added to paraquat. The lethal dose is similar to that of paraquat, but severe poisoning and death are less common. The extent of pulmonary injury and fibrosis is less due to diquat's lower affinity for pulmonary tissue. Diquat is caustic to the skin and gastrointestinal tract, and primary effects result in renal and liver necrosis. Treatment is similar to that for paraquat poisoning. Mortality approaches 50 percent despite diquat's lower toxicity.

Urea-Substituted Herbicides

These compounds, such as chlorimuron, diuron, fluometron, and isopturon, are inhibitors of photosynthesis and have low systemic toxicity. In humans, methemoglobinuria may occur with ingestion. Treatment includes decontamination, supportive care, and treatment with methylene blue.

RODENTICIDES

Epidemiology

Several classes of compounds are used as rodenticides or rat poisons. Because these compounds are accessible in the home, young children are at risk. According to the American Association of Poison Control Centers, in 1997 there were 17,562 reported exposures to rodenticides in the United States. Of these, 16,562 were unintentional exposures, and 15,065 of the total exposures involved children under 6 years of age. Nearly 6000 patients were treated in a health care facility. There were 6 deaths, and 3 involved long-acting warfarins. About 150 exposures resulted in moderate to major morbidity. Individuals at risk are suicide victims, attempted homicide or abuse victims, exterminators, the intoxicated, the impaired elderly, and psychiatric patients. Intentional ingestions are often associated with significant morbidity and mortality. Most accidental exposures occur in children under 6 years of age and result in minimal or no toxicity. [1,24]

Most commonly used rodenticides are the anticoagulants, derivatives of fluoroacetic acid, alpha-methyl-thiourea, and various inorganic compounds (Table 176-1). The toxic mechanisms and degree of toxicity vary depending on the specific compound. Rodenticides may be classified according to the type of compound, time of onset of signs and symptoms, and degree of toxicity. Common rodenticides will be grouped and discussed by degree of toxicity. The pathophysiology, clinical features, diagnosis, and treatment will be described for each entity.

Sodium monofluoroacetate
Strychnine
Thallium
Zinc phosphide
Phosphorus
Arsenic
α-Naphthylthiourea
Cholecalciferol
Red squill
Warfarin
Superwarfarins

TABLE 176-1   Examples of Rodenticides

High Toxicity

Highly toxic compounds include *sodium monofluoroacetate* (SMFA) and its derivatives, fluoroacetamide (compound 1081) and
N-methyl-*N*-(1-naphtyl-fluoroacetamide), or MNFA. SMFA is a white crystalline, odorless, tasteless, water-soluble powder licensed only by commercial exterminators. It is toxic when absorbed through broken skin, ingested, or inhaled. The active component, fluoroacetate, is converted to fluorocitrate, which interferes with the Krebs cycle. Aerobic glycolysis is thus blocked. As a result, glucose metabolism, cellular respiration, and energy production are blocked, resulting in anaerobic metabolism and lactic acidosis. Onset of toxicity is usually delayed from 2 to 20 h after ingestion. This lag time results from the delay in conversion to fluorocitrate. Signs of toxicity are nausea, apprehension, and then lactic acidosis, seizures, coma, respiratory depression, cardiac dysrhythmias, and pulmonary edema. ECG abnormalities such as ST-T wave changes, tachycardia, premature ventricular contractions, ventricular tachycardia, and fibrillation are seen. Hyperkalemia and hypocalcemia are common.

Hypotension, an elevated serum creatinine level, and decreased blood pH are prognostic indicators of death. [25]

Treatment includes activated charcoal, sorbitol cathartic, seizure and dysrhythmia control, and supportive care. Experimental regimens include glycerol monoacetate and ethanol loading, which necessitates consultation with a toxicologist.

Strychnine is a highly toxic, naturally occurring alkaloid that comes from the seeds of the tree *Strychnis nux-vomica*. Strychnine is rarely used as a rodenticide today. It is an odorless, colorless crystal or white, bitter-tasting powder that can be absorbed through the gastrointestinal tract or nasal mucosa. Toxicity results from its competitive antagonism of the inhibitory neurotransmitter glycine at the postsynaptic spinal cord motor neuron. Signs and symptoms of CNS stimulation begin approximately 15 to 20 min after ingestion. Toxicity manifests by muscle twitching, painful extensor spasms, opisthotonos, trismus, and facial grimacing. Of diagnostic importance is that the patient remains conscious during episodes of painful muscle spasm and convulsions and that there is no postictal phase. Medullary paralysis and death can follow. Ancillary testing is not useful for diagnosis. Treatment includes aggressive airway control, a quiet environment (because any noise or manipulation may precipitate contractures), and activated charcoal. Gastric lavage may precipitate convulsions. Benzodiazepines and pain medications are administered to control painful spasms, but barbiturates and neuromuscular blocking agents may be needed. Recovery is usually complete if therapy is aggressive.

Thallium sulfate is a heavy metal with moderate to high acute toxicity that is used by industry and found in homeopathic remedies. It is a white, crystalline, odorless, and tasteless powder. It is a cumulative poison that distributes in almost every tissue of the body. Thallium combines with mitochondrial sulfhydryl groups, interfering with oxidative phosphorylation. It is readily absorbed through the skin, by inhalation, and through the gastrointestinal tract.

Gastrointestinal symptoms including hemorrhage develop acutely within 12 to 48 h. A latent period with constipation is then followed in 2 to 5 days by neurologic sequelae, painful paresthesias of the lower extremities, myalgias, headache, lethargy, tremors, ataxia, delirium, coma, and seizures. Respiratory failure and dysrhythmias may cause death in severe cases. Chronic sequelae include various neurologic syndromes, neuropathies, and alopecia. Urine sediment may be of diagnostic value, showing RBCs and protein. Liver function tests may be abnormal. Thallium can be measured in the hair, serum, and urine.

Thallium ingestion is treated by multiple doses of activated charcoal, sorbitol initially, and supportive care. Potassium chloride infusion increases renal secretion but also may facilitate entry into cells. Multiple doses of activated charcoal or Prussian blue (ferric ferrocyanide) may interrupt enterohepatic circulation and increase secretion in stool.

Zinc phosphide is a dark-gray, crystalline, water-insoluble powder that is present in multiple products (Acme Mole and Gopher Killer). It has a characteristic "phosphorus" or "rotten fish" odor. Zinc and phosphine gas are released on contact with water and acid. Toxicity is due to the phosphine formed following hydrolysis in the stomach. This gas may be inhaled and absorbed secondarily. Exposure causes cellular toxicity to the gastrointestinal tract, kidney, and liver if ingested and to the lungs if inhaled. The exact mechanism is unclear, but the toxin appears to block oxidative phosphorylation.

Onset of clinical syndromes begins within hours of ingestion but may be delayed following inhalation. Nausea, vomiting, and epigastric pain may ensue within 10 to 15 min. Signs and symptoms include a "phosphorous" or "fishy" breath, black vomitus, and signs of gastrointestinal irritation or ulceration. There is myocardial toxicity, shock, and noncardiogenic pulmonary edema with nonprominent CNS manifestations such as agitation, coma, and seizures. Hepatorenal injury is common. Metabolic acidosis and hypocalcemic tetany may occur.

Treatment includes preventing gastric conversion to toxic substances by intragastric alkalinization with sodium bicarbonate, milk, or water, activated charcoal, a cathartic, and supportive therapy. Those who survive 3 days usually recover.

Elemental or yellow phosphorus (Stearn's Electric Brand Paste) is a yellow, waxy, fat-soluble rat or roach paste that has a "garlicky" odor. It is easily mixed with molasses or peanut butter or spread on bread for rodents to eat. It ignites on contact with moisture. Skin contact causes local irritation and severe burns within minutes to hours. Toxicity is related to its ability to uncouple oxidative phosphorylation. It appears to have direct toxic effects on the myocardium and peripheral vessels. Clinically, toxicity may manifest by jaundice, cardiovascular collapse, dysrhythmias, coma, delirium, seizures, or cardiac arrest.

Three stages of clinical manifestations after ingestion consist of an initial stage of oral burns, abdominal pain, hemetemesis, "smoking" phosphorescent vomitus and stool, a garlicky odor, and possible early death from cardiovascular collapse. The second stage is relatively asymptomatic. Finally, CNS depression with multisystem toxicity including a hepatorenal syndrome may occur.

Gastric lavage with dilute potassium permanganate or hydrogen peroxide solution may convert phosphorus to harmless oxides. Activated charcoal and sorbitol catharsis, with aggressive supportive care and monitoring, are needed. Emesis should be avoided. Early cardiac and CNS toxicity are poor prognostic signs.

Arsenic is a heavy metal in the form of a white crystalline powder. It is no longer used because of its high toxicity. After ingestion, this compound combines with sulfhydryl groups and interferes with a variety of enzymatic reactions. Symptoms may occur as early as 1 h after ingestion, with death from cardiovascular collapse occurring within 24 h. Clinical presentation includes dysphagia, nausea and vomiting, bloody diarrhea, altered mental status, seizures, and late peripheral neuropathies. Treatment consists of lavage, activated charcoal, and catharsis and chelation therapy using dimercaptosuccinic acid (DMSA, succimer), dimercaprol, or penicillamine.

Moderate Toxicity

a-*Naphthyl-thiourea* (ANTU) is a moderately toxic rodenticide. It is very selective for target species, with humans being relatively resistant. This compound is a fine, blue-gray powder that is odorless, water-insoluble, and slightly bitter. The mechanism of action is unknown, but this toxin does appear to increase alveolar capillary permeability, causing pulmonary edema. Patients present clinically with dyspnea, cough, pleuritic chest pain, noncardiogenic pulmonary edema, and pleural effusion. Treatment is supportive and includes activated charcoal and catharsis.

Cholecalciferol (vitamin D_3) is used widely by professional exterminators and the general public. This compound is marketed as Quintox, Rampage, or Ortho Mouse-B-Gon. In rodents, toxic doses result in the mobilization of calcium from bones, producing hypercalcemia, osteomalacia, and systemic metastatic calcifications. No severe human toxicity or deaths have been reported. Small amounts are probably nontoxic and do not require therapy.

Signs and symptoms are those associated with vitamin D intoxication and hypercalcemia. Clinically, patients present with nausea, vomiting, abdominal pain, constipation, and CNS depression. Nerve and muscle dysfunction and dysrhythmias may be seen. Serum calcium, magnesium and electrolyte levels should be monitored. Normal levels obtained 48 h after acute ingestion probably exclude significant toxicity. Therapy after acute massive ingestion includes activated charcoal and sorbitol. Treatment of moderate to severe hypercalcemia involves intravenous infusion of normal saline, furosemide, steroids, and calcitonin (see Chap. 23).

Low Toxicity

Red squill is a botanic cardiac glycoside derived from the plant *Urginea maritima*, or sea onion. It is marketed as Deathdiet, Rat Snax, Rat Nip and has a very bitter taste. Toxicity is related to the ability to block sodium-potassium adenosine triphosphatase. Duration of onset is from 30 min to 6 h. Because of its potent emetic properties, patients present with nausea, protracted vomiting, diarrhea, and abdominal pain. Massive ingestion causes hyperkalemia, ventricular irritability with dysrhythmias, and death.

Treatment is similar to that for digoxin toxicity using antiarrhythmics and atropine as indicated. In severe poisoning, an infusion of 10 vials of digitalis-specific antibody (Fab) is recommended. Activated charcoal should be given.

Warfarin-type (*3a-acetonylbenzyl-4-hydroxy-coumarin*) *anticoagulants* (Kill-Ko, Rat Busters) were the first rodenticides. They are commonly disguised as yellow corn meal or rolled oats and are among the most commonly ingested substances in the United States. It is important to differentiate these from the more toxic superwarfarins. Most warfarin ingestions are insignificant accidental poisonings and do not cause any bleeding problems.

A single acute exposure results in virtually no bleeding in children or adults. Toxicity requires large amounts in a single exposure or a repetitive exposure over several days. Lipid solubility of the individual anticoagulant determines its elimination half-life. Warfarin's biologic half-life is approximately 42 h. These anticoagulants inhibit,

almost immediately, the synthesis of Vitamin K_1–dependent clotting factors II, VII, IX, and X. Coagulopathy develops when the level of at least one critical coagulation factor falls to 25 percent of normal.[26] This time interval is approximately 12 to 18 h.

Ingestion of a single mouthful is usually nontoxic, and therapy is not necessary. If potential toxicity is suspected, therapy consists of activated charcoal and a cathartic, with baseline prothrombin time (PT) and partial thromboplastin time (PTT) determinations to be repeated in 12 to 24 h. If the PT is greater than twice normal and the risk of bleeding exists, vitamin K_1 (phytonadione) administration is indicated. The suggested oral dose is 1 to 5 mg in children and 20 mg in adults administered two to four times daily due to its short half-life and a PT is checked every 4 h initially, then every 24 h until stable.

Second-generation superwarfarins and the indandione derivatives were introduced when rodent resistance to warfarin began to appear. They are responsible for approximately 80 percent of human rodenticide exposures reported in the United States.[1] Their mechanisms are the same as those of the warfarins, but they are more potent, have more prolonged anticoagulant activity, and therefore have the potential to be highly toxic. Poisonings involving the indandione derivatives pindone, diphacinone, and chlorophacinone have toxic and clinical characteristics similar to those of the superwarfarins.

The superwarfarins include the 4-hydroxy-coumarins brodifacoum, diphenacoum, and bromadiolone. These are readily available over the counter as grain-based bait. Since the biologic half-life of brodifacoum is approximately 120 days, a single ingestion may result in marked anticoagulation effects from weeks to months. Acute intentional or repeated ingestions can cause severe bleeding. After intentional ingestions, adults often develop a coagulopathy within 24 to 48 h. [24]

A single ingestion usually does not result in immediate toxic effects, and an ingestion may or may not be identified by history. Small children and depressed patients having an unexplained coagulopathy should elevate the index of suspicion. Clinical findings of toxicity consist of ecchymoses, hematuria, uterine or gastrointestinal bleeding, gingival hemorrhage and epistaxis, hematomas, and hemoptysis. Their onset, however, may be delayed for several days, and they may persist for several days.

An abnormal PT may identify chronic ingestions or patients who present hours or days after exposure to a long-acting warfarin. Specific serum assays for superwarfarins are available in reference laboratories. Superwarfarins are not detected by warfarin assays. Initial differential diagnosis in the patient with an elevated PT and PTT includes disseminated intravascular coagulation, liver failure, pathologic inhibitors of coagulation, acquired vitamin K deficiency, or ingestion of a vitamin K antagonist. Warfarin abuse must be suspected when no other cause of vitamin K deficiency can be found.

Resuscitation of acute hemorrhage consists of oxygen administration and repletion of volume losses with normal saline or transfusion. Fresh-frozen plasma should be used if bleeding is severe or unresponsive to vitamin therapy. Vitamin K_1 can be diluted and administered by slow intravenous infusion, less than 1 mg per minute, to minimize the risk of an anaphylactoid reaction and cardiovascular collapse. Oral absorption takes approximately 2 to 3 h. Because of the extended half-life of the anticoagulant, prolonged therapy with high doses of vitamin K_1 may be required to maintain hemostasis. Doses of vitamin K_1 should be titrated to effect. Initial doses of 1 to 5 mg in children and 20 mg in adults have been recommended, but doses up to 100 mg per day for 10 months have been reported.[27] The PT is followed every 4 h and then every 24 h.

Treatment of acute ingestion consists of gastrointestinal decontamination. Recent ingestion of amounts greater than 0.1 mg/kg necessitates activated charcoal and a cathartic. Of 110 children having ingested long-acting anticoagulants, only 8 were found to have an elevated PT, but history was not predictive. [24] Hence any patient with a superwarfarin exposure needs PT determinations at 24 and 48 h. If the PT is elevated, high-dose vitamin K_1 is initiated for at least 6 weeks. Discontinuation of vitamin K_1 therapy is followed by serial PT determinations to ensure that further therapy is not needed. After initial parenteral therapy, prolonged oral administration for several months may be required as the PT normalizes.

Clinical Approach

A number of agents with distinct toxicities are used as rodenticides. The clinical approach to rodenticide exposure is determined by whether the nature of the toxin is known or unknown or whether delayed toxicity is suspected. Identifying product name is essential for appropriate management, but actual active ingredients need to be known over the commercial name. It must be recognized that similar brand names are used for more than one agent and that some agents are no longer on the market but remain on consumers' shelves. The time of ingestion and onset of clinical symptoms should be elicited. If a specific agent is identified, evaluation and treatment are determined. It must be recognized that chemicals can be mistakenly termed rodenticides when obtaining a history and that ingestion may involve coingestants.

If a clinician only knows that a rodenticide was ingested, specific odors or CNS, cardiopulmonary, gastrointestinal, skeletal muscle, metabolic, or hemorrhagic signs and symptoms may suggest a specific toxin. A metabolic acidosis suggests sodium monofluoroacetate or its derivatives. Painful paresthesias and metallic densities on abdominal radiographs suggest thallium ingestion. Emesis and cardiac dysrythmias suggest red squill poisoning. An abnormally high PT suggests superwarfarin ingestions, but the PT may be normal initially.

Initial assessment includes immediate identification and resuscitation of any airway compromise, respiratory failure, or cardiovascular collapse. Vital signs including an accurate core temperature should be obtained immediately. Administration of diagnostic/therapeutic substrates should be considered. Orogastric lavage may be indicated if ingestion took place within 1 h, followed by activated charcoal and a cathartic. Specific antidotes are considered. Blood chemistries other than an initial PT are not particularly helpful unless the patient is clinically symptomatic.

Disposition

Disposition depends on the toxin ingested. When exposure is suspected, given the low frequency of individual physician experience with these types of exposures, poison center consultation may assist in recommending a plan for managing the patient based on the presentation and toxin. When a patient has been exposed to a rodenticide having a rapid effect, symptoms usually manifest within 4 to 6 h of ingestion. Patients who have ingested a highly toxic rodenticide and are symptomatic are admitted after initial ED therapy. Symptoms related to agents with delayed onset typically begin 12 h or more after exposure. Therefore, if there is historical evidence of an acute ingestion and there are no signs or symptoms within 4 to 6 h, rodenticides with delayed effects are then considered, the patient is discharged after initial therapy, and reevaluation with coagulation studies is done in 24 and 48 h. The threshold for hospital admission should be low for intentional ingestions. In accidental ingestions, the patient can be treated with decontamination, observed in the ED for 6 h, and, if asymptomatic, discharged with follow-up. For asymptomatic patients who have accidentally ingested a superwarfarin, baseline PT and PTT determinations are done, follow-up is ensured, and coagulation studies are repeated at 24 and 48 h. Prevention measures should be emphasized.

177 ANTICHOLINERGIC TOXICITY

Leslie R. Wolf

Because of the frequent use of tricyclic antidepressants, phenothiazines, antihistamines, and antiparkinsonian drugs, anticholinergic toxicity is commonly seen in the emergency department. Anticholinergic medications are commonly prescribed for elderly patients, often resulting in drug-induced delirium. Many drugs have anticholinergic properties (Table 177-1) that may be mild at therapeutic doses but are life-threatening in overdose. [1] The use and abuse of some plants and mushrooms also may result in anticholinergic toxicity.

TABLE 177-1   Anticholinergic Substances

PHARMACOLOGIC PROPERTIES

Drug absorption can occur after ingestion, smoking, or ocular use. The rate of absorption varies depending on the drug and the route of exposure. Because cholinergic blockade delays gastric emptying and decreases intestinal motility, absorption and peak clinical effects are often delayed. [2]

The signs and symptoms of anticholinergic toxicity are a result of both central and peripheral cholinergic blockade. Muscarinic acetylcholine receptors predominate in the brain, while nicotinic receptors predominate in the spinal cord. Depending on the drug involved, antagonism of muscarinic, nicotinic, or both receptors may occur. [2] The central effects of cholinergic blockade include agitation, amnesia, anxiety, ataxia, coma, confusion, delirium, disorientation, dysarthria, hallucinations, hyperactivity, lethargy, somnolence, seizures, circulatory collapse, mydriasis, and respiratory failure. The peripheral effects include dysrhythmias, tachycardia, decreased bronchial secretions, dysphagia, decreased gastrointestinal motility, hyperthermia, hypo- or hypertension, decreased salivation, decreased sweating, urinary retention, and vasodilation. [1,3,4]

CLINICAL PRESENTATION

The classic presentation of patients with anticholinergic toxicity can be remembered as

Hot as Hades
Blind as a Bat
Dry as a Bone
Red as a Beet
Mad as a Hatter

Clinical characteristics include unreactive mydriasis, hypo- or hypertension, absent bowel sounds, tachycardia, flushed skin, disorientation, urinary retention, hyperthermia, dry skin and mucous membranes, and auditory and visual hallucinations. Patients also can present with seizures or coma. Cardiogenic pulmonary edema may occur secondary to depression of myocardial contraction.[1,3,4]

The diagnosis of anticholinergic toxicity must be based on clinical presentation. The diagnosis may be confused with delirium tremens or an acute psychiatric disorder. Anticholinergic toxicity can be differentiated from delirium tremens and sympathomimetic toxicity by the presence of dry skin and the absence of bowel sounds. Acute psychiatric disorders may have associated tachycardia and tachypnea, but usually the physical examination is normal. Complications from anticholinergic toxicity occur secondary to hyperthermia, dysrhythmias, seizures, and circulatory collapse. [1,4]

Electrocardiographic abnormalities may include QRS prolongation, abnormal conduction, bundle branch block, AV dissociation, and atrial and ventricular tachycardias. Sinus tachycardia is the most common abnormality.[1,4] Routine laboratory evaluations, including measurement of electrolytes, glucose, and arterial blood gases, should be checked in the presence of abnormal mental status but should be normal in isolated anticholinergic toxicity. Comprehensive toxicologic screens are of little value in the acute setting, and some anticholinergic agents (e.g., scopolamine) may not be detected. The screen can be used for confirmation, but the diagnosis should be based on clinical findings.

TREATMENT

Conservative, supportive therapy is the mainstay of treatment of anticholinergic toxicity (Table 177-2). Evaluation of the airway, breathing, and circulation is a priority. An intravenous line should be established and an ECG monitor placed in any patient with significant symptoms. Gastric lavage may be useful in patients presenting within 1 h of ingestion. [5] Activated charcoal may be useful to decrease drug absorption, particularly with agents that undergo enterohepatic circulation or when the agents ingested are unknown.

TABLE 177-2   Treatment of Anticholinergic Toxicity

Hyperthermia should be controlled with conventional therapy. Seizures can be treated with benzodiazepines and barbiturates. Hypertension usually does not require treatment, but conventional therapy should be used if necessary. The treatment of dysrhythmias depends on the type and on the causative agent. Standard antiarrhythmics are usually effective, but class Ia agents should be avoided due to the quinidine-like effect of many anticholinergic drugs. Dysrhythmias, including a widened QRS, and hypotension associated with agents that cause sodium channel blockade can be treated with intravenous sodium bicarbonate (Table 177-2).[1] Agitation can be treated with benzodiazepines. Because of their anticholinergic effects, phenothiazines should be avoided.

The most controversial topic surrounding anticholinergic toxicity is the use of physostigmine. Physostigmine is a tertiary ammonium compound that is a reversible acetylcholinesterase inhibitor that crosses the blood-brain barrier and reverses both central and peripheral anticholinergic effects. [2] Physostigmine may aggravate dysrhythmias and seizures and must be used with extreme caution.[7] The indications for its use include the presence of peripheral anticholinergic signs and seizures unresponsive to conventional therapy, uncontrollable agitation, hemodynamically unstable dysrhythmias unresponsive to conventional therapy, coma with respiratory depression, malignant hypertension, or refractory hypotension. Physostigmine should be avoided in cyclic antidepressant overdose because it may potentiate toxicity and increase mortality.[7] The initial dose of physostigmine is 0.5 to 2.0 mg IV over 5 min. Improvement of central signs usually occurs within 5 to 15 min. The minimal effective dose should be used. Due to rapid elimination, repeat doses may be necessary every 30 to 60 min. Physostigmine use is contraindicated in patients with cardiovascular disease, bronchospasm, intestinal obstruction, heart block, peripheral vascular disease, and bladder obstruction. Patients receiving physostigmine should be on a cardiac monitor and observed for cholinergic symptoms (salivation, lacrimation, urination, and defecation).

Patients with mild symptoms of anticholinergic toxicity can be discharged after 6 h of observation if their symptoms are improving. Patients receiving physostigmine usually require admission for at least 24 h.

JIMSONWEED

Many plants have anticholinergic effects, including deadly nightshade, henbane, mandrake, burdock root, jimsonweed, and others. They are often used for medicinal purposes or brewed in teas. *Datura stramonium*, also known as jimsonweed, is a member of the Solanaceae family. It is a common weed that grows to be 3 to 6 ft high and can be found throughout the United States. [1,4] Its leaves are large, jagged, and have a bitter taste and foul odor. The plant has large white or purple trumpet-shaped flowers that bloom in the late spring and become thorny quadripartite capsules in the fall, filled with black seeds. The entire plant is toxic and contains atropine, hyoscyamine, and scopolamine in various amounts. In the past, jimsonweed was marked and sold in health food stores in a preparation for the treatment of asthma. Many accidental childhood poisonings from jimsonweed have been reported. Over the past 20 to 30 years, jimsonweed has been involved in inadvertent overdoses in persons experimenting with mind-altering drugs. The plant can be smoked or ingested. Fifty to one hundred seeds contain the equivalent of 3 to 6 mg atropine.[1,4]

Symptoms of anticholinergic toxicity occur within 2 to 6 hr after the ingestion of jimsonweed. As with other agents causing anticholinergic toxicity, patients present with fever, erythema, mydriasis, delirium, hallucinations, tachycardia, and amnesia. The treatment is the same as that described earlier. Because the seeds may remain in the stomach for prolonged periods, whole-bowel irrigation is recommended up to 12 to 24 h after the ingestion of seeds. The most persistent symptom of jimsonweed toxicity is blurred vision, since mydriasis can persist for up to 1 week. Mydriasis also can occur from isolated local contact of jimsonweed with the eye ("cornpicker's pupil").[8]

Marsha D. Ford

Acute metal and metalloid toxicity is an uncommon clinical entity that can be a cause of significant morbidity and mortality if unrecognized and inappropriately treated. Because of their effects on numerous enzymatic systems in the body, the metals and metalloids often present with protean manifestations primarily affecting four systems: neurologic, gastrointestinal, hematologic, and renal. Effects on the endocrine and reproductive systems are less clinically apparent. One should be familiar with the toxic manifestations of the most common metals and metalloids—lead, arsenic, and mercury—in order to appropriately diagnose poisoned patients. It is important to recognize an initial "index case" in order to prevent others from being poisoned when the metal source is environmental or industrial (Table 178-1).

TABLE 178-1   Sources of Heavy Metals

LEAD

Epidemiology

Lead is the most common cause of chronic metal poisoning and remains a major environmental contaminant. Elevated blood levels in children aged 1 to 5 years have been linked with these community characteristics: urban dwellings, dwellings built before 1974 (especially those built prior to 1946), poverty, non-Hispanic black race/ethnicity, and higher population density. [1,2] Data from phase 2 of the National Health and Nutritional Survey III (NHANS III) for children aged 1 to 5 years indicate that an estimated 890,000 children have blood lead levels of 10 µg/dL or more; this represents a substantial decline in the prevalence of elevated blood lead levels since 1976. [3] This decline is attributed to bans on lead in household paints, gasoline, plumbing systems, and food and drink cans, as well as lead abatement programs and the promulgation of standards for industrial use of lead. [1]

Elevated lead levels may have detrimental effects on intellectual development, [4] and thus lead toxicity remains a significant public health problem. Both inorganic and organic forms of lead produce clinical toxicity. Inorganic lead affects the central and peripheral nervous systems, hematopoietic system, kidney, gastrointestinal tract, liver, myocardium, and reproductive capacity. With organic lead intoxication, central nervous system (CNS) effects predominate.

Inorganic Lead

PHARMACOLOGY   Absorption is by the respiratory and gastrointestinal tracts, whereas skin absorption is negligible. Dietary deficiencies in calcium, iron, copper, and zinc may contribute to increased gastrointestinal absorption in children. Absorption also occurs when retained lead bullets or shot are in contact with body fluids such as synovial fluid. Lead can be transferred placentally to the fetus of a mother with an elevated blood lead level, which can be further exacerbated by increased bone turnover during pregnancy. In the body, lead distributes into the blood, soft tissues, and bone. Greater than 90 percent of the total-body lead is stored in bone, where it easily exchanges with the blood. Excretion of lead occurs slowly; the biologic half-life of lead in bone has been estimated to be 30 years.

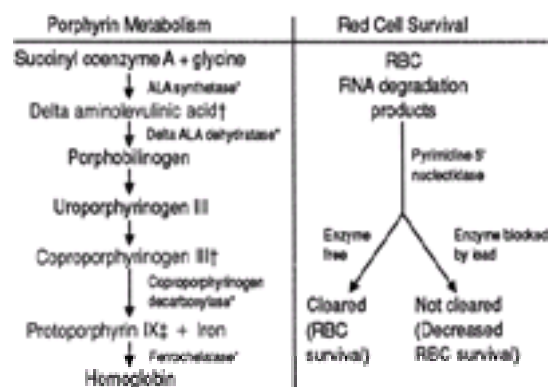
PATHOPHYSIOLOGY   In the CNS lead injures astrocytes, with secondary damage to the microvasculature and resulting disruption of the blood-brain barrier, [5] cerebral edema, and seizures; decreases cyclic adenosine monophosphate (CAMP) and protein phosphorylation, which contribute to memory and learning deficits; and alters calcium homeostasis, which leads to spontaneous neurotransmitter release. In the peripheral nervous system (PNS), nerves undergo primary segmental demyelination, followed by secondary axonal degeneration, primarily of the motor nerves. In the hematopoietic system, lead interferes with porphyrin metabolism, which may contribute to lead-induced anemia (Fig. 178-1). The two enzymes chiefly affected are D-aminolevulinic acid dehydratase and ferrochelatase, the latter being the enzyme that catalyzes the transfer of iron from ferritin to protoporphyrin to form hemoglobin. Coexisting iron deficiency may act synergistically with lead toxicity to produce a more profound anemia and, in children, may be more important than lead as the cause of a microcytic anemia. Hemolytic anemia also occurs as a result of inhibition of red blood cell (RBC) pyrimidine 5'-nucleotidase, an enzyme responsible for clearing cellular RNA degradation products. On a blood peripheral smear, these products produce the RBC basophilic stippling sometimes seen in lead-poisoned patients.


FIG. 178-1. Effects of lead on the hematopoietic system. *Enzymes affected by lead. ‡Levels elevated in urine. ‡Level elevated in RBCs.

In the kidney, acute lead toxicity affects the proximal tubule, producing a Fanconi syndrome with aminoaciduria, glycosuria, phosphaturia, and renal tubular acidosis. Chronic effects include persistence of a partial Fanconi syndrome for 13 years or longer,[6] interstitial nephritis, and increased uric acid levels due to increased tubular reabsorption of urate. Chronic lead toxicity has been linked with gout, hypertension, and chronic renal failure.

Toxic hepatitis with mildly elevated transaminases, normal bilirubin, and normal alkaline phosphatase can occur. Lead-induced adverse effects on the reproductive system include increased fetal wastage, premature membrane rupture, depressed sperm counts, abnormal/nonmotile sperm, and sterility. Chronic lead toxicity can depress free thyroxine levels without producing clinical hypothyroidism.

CLINICAL FEATURES   The common signs and symptoms of acute, chronic, and delayed toxicity are listed in Table 178-2. Young children are more susceptible than adults to the effects of lead. Encephalopathy, a major cause of morbidity and mortality, may begin dramatically with seizures and coma or develop indolently over weeks to months with decreased alertness and memory progressing to mania, delirium, and cerebral edema.[7] It has developed in infants with blood lead levels of 70 µg/dL or less. Gastrointestinal and hematologic manifestations occur more frequently with acute than with chronic poisoning, and the colicky abdominal pains may be associated with concurrent hemolysis. Patients may complain of a metallic taste and, with long-term exposure, have bluish-gray gingival lead lines. Delayed cognitive development can occur in infants and children whose cord and blood lead (PbB) levels are 10 µg/dL or more. Finally, adult and pediatric patients may be asymptomatic in the face of significantly elevated PbB levels.

TABLE 178-2   Clinical Effects of Inorganic Lead Toxicity

DIAGNOSIS   History of an exposure—occupational, hobby, environmental, or related to retained lead bullets—is the most important clue to making the diagnosis. The physician should focus on symptoms, developmental and dietary histories (in children), pica, any house or day-care remodeling, previous serum iron and blood lead levels, and possible lead toxicity in other family members. Occupational and hobby histories should be elicited, both for adults being evaluated and for children who may be exposed to lead secondarily from these adult activities.

The combination of abdominal or neurologic dysfunction with a hemolytic anemia should raise the suspicion of lead toxicity. Emergency physicians should consider the diagnosis in all children presenting with encephalopathy. Toxicity due to retained lead bullets has manifested in patients as long as several decades after being shot. Hyperthyroidism, pregnancy, fever, reinjury, or immobilization of the affected extremity can promote lead release after years of dormancy.

Laboratory studies in the emergency department (ED) should focus on evaluation for anemia and examination of bone radiographs in children for "lead bands" and abdominal radiographs for radiopaque material consistent with lead in the gastrointestinal tract. The anemia can be normocytic or microcytic, possibly with evidence of hemolysis such as an elevated reticulocyte count and increased serum free hemoglobin.

The peripheral smear may show basophilic stippling of the RBCs. Both anemia and basophilic stippling occur variably, and their absence does not rule out lead toxicity. Basophilic stippling of RBCs is nonspecific for lead toxicity, since it is also found in arsenic toxicity, sideroblastic anemia, and the thalassemias. In children, radiographs of long bones, especially of the knee, may reveal horizontal, metaphyseal lead bands, which represent failure of bone remodeling rather than deposition of lead.

The definitive diagnosis rests on finding an elevated PbB level, with or without symptoms. The PbB level is the best single test for evaluating lead toxicity, and levels of 10 µg/dL or more are considered toxic. Screening levels may be performed on fingerstick capillary blood, but because of the potential for environmental lead contamination, elevated levels always should be confirmed on a venous blood sample.[8] Previously, a calcium disodium versenate ($CaNa_2$-EDTA) provocation test was used to evaluate total-body lead stores and the need for chelation therapy when PbB levels were between 25 and 55 µg/dL. However, animal data demonstrating that one dose of $CaNa_2$-EDTA redistributes lead to the brain, the technical difficulties in performing the test, the lowering of the toxic PbB level to 10 µg/dL or more, and the advent of dimercaptosuccinic acid (DMSA) as a safe and effective oral chelator raise concerns about the utility of the provocation test. Some major lead treatment centers have abandoned its use. Also, with the lowering of the toxic PbB level to 10 µg/dL or more, the erythrocyte protoporphyrin (EP) test can no longer be used to screen for lead toxicity because of its unacceptably low sensitivity at these lower PbB levels.[9]

DIFFERENTIAL DIAGNOSIS   The differential diagnosis of lead toxicity includes causes of encephalopathy such as Wernicke's encephalopathy, withdrawal from ethanol and other sedative-hypnotic drugs, meningitis, encephalitis, human immunodeficiency virus (HIV) infection, intracerebral hemorrhage, hypoglycemia, severe fluid and electrolyte imbalances, hypoxia, arsenic, thallium, and mercury toxicity, and poisoning with cyclic antidepressants, anticholinergic drugs, ethylene glycol, or carbon monoxide. The abdominal pains can mimic sickle cell crisis or the hepatic porphyrias. Chronic lead toxicity can masquerade as depression, neurosis, hypothyroidism, polyneuritis, gout, iron deficiency anemia, and learning disability.

TREATMENT   All patients with appropriate symptoms and an elevated PbB level are classified as lead toxic and should be treated.

Severe Toxicity   Lead-induced encephalopathy rarely occurs now, but it remains a major cause of serious morbidity and mortality in lead-poisoned patients. In severely toxic patients, standard life support measures should be instituted and seizures treated with benzodiazepines, phenobarbital, phenytoin, and general anesthesia, if necessary. If abdominal films demonstrate radiopaque flecks consistent with lead, whole-bowel irrigation with a polyethylene glycol electrolyte solution should be instituted. The solution should be administered continuously at a rate of 500 to 2000 mL/h for adults and 100 to 500 mL/h for children until the abdominal radiograph is clear. It will not alter fluid or electrolyte balance in the patient. Larger lead bodies such as fishing sinkers may require surgical removal. Fluid administration should be controlled carefully to avoid worsening cerebral edema. Lumbar puncture may precipitate cerebral herniation and should be performed

carefully, if at all, with the removal of a small amount of cerebrospinal fluid (CSF) only.

Chelation therapy should be instituted immediately (i.e. in the ED) prior to obtaining laboratory verification of the diagnosis. All chelating agents supply sulfhydryl groups to which the lead attaches. Dimercaprol (British anti-Lewisite, or BAL), 75 mg/m^2, should be administered intramuscularly first, followed 4 h later by CaNa$_2$-EDTA, 1500 mg/m^2 per 24 h, in a continuous intravenous infusion. BAL administration is continued every 4 h. BAL chelates intracellular as well as extracellular lead and may be administered to patients in renal failure because it is also excreted in the bile. It is mixed in peanut oil and must be given intramuscularly. CaNa$_2$-EDTA chelates extracellular lead only and may exacerbate lead-induced CNS toxicity in patients with high PbB levels unless preceded by BAL therapy. Continuous intravenous infusion is the preferred method of delivery. CaNa$_2$-EDTA can cause renal toxicity, and patients should be adequately hydrated to promote diuresis and minimize the risk of this complication. It should not be used in patients with renal failure. Adverse effects of the chelating agents are listed in Table 178-3.

Chelating Agent	Adverse Effects
BAL (dimercaprol)	Hypertension Febrile reaction, diaphoresis Painful injection Nausea/vomiting, salivation Headache Lacrimation, rhinorrhea Hemolysis in G-6-PD deficient patients
CaNa$_2$-EDTA	Renal toxicity (especially if dehydrated) Can increase CNS levels of lead if given prior to BAL Chelates essential metals (e.g., copper, zinc, iron) Dermatitis Minor: Headache, chills, fever, myalgias, fatigue
D-Penicillamine	Nausea/vomiting Fever Rash Leukopenia, thrombocytopenia Eosinophilia Hemolytic anemia Stevens-Johnson syndrome (Probably safe in penicillin-allergic patients)
DMSA	Nausea, vomiting, diarrhea Abdominal gas, pain Transient elevated AST, alkaline phosphatase Rash, pruritus Sore throat, rhinorrhea Drowsiness, paresthesia Thrombocytosis, eosinophilia

TABLE 178-3   Adverse Effects of Chelating Agents

For symptomatic patients without encephalopathy, and for asymptomatic patients with elevated PbB levels requiring chelation, the use of BAL or DMSA (see discussion below) with or without CaNa$_2$-EDTA and the dosing schedules are determined by the PbB levels, the presence or absence of symptoms, and changing practice as more experience with DMSA is obtained. Treatment may be initiated in the ED. Children who are symptomatic but not encephalopathic can be treated as discussed earlier, except with doses of BAL, 50 mg/m^2, and CaNa$_2$-EDTA, 1000 mg/m^2 per 24 h, or with DMSA plus EDTA. A retrospective study of 45 children with lead levels of 45 μg/dL or more treated either with BAL plus EDTA or DMSA plus EDTA found comparable reductions in lead levels, with fewer side effects in the DMSA group.[10] The Centers for Disease Control and Prevention (CDC) recommend immediate chelation therapy for children with blood lead levels of 70 μg/dL or more.[8] Symptomatic, nonencephalopathic adults may be treated with BAL and CaNa$_2$-EDTA, with CaNa$_2$-EDTA alone, or with DMSA.

In asymptomatic patients, the standards for determining lead toxicity and the need for treatment differ for children and adults. In asymptomatic children, chelation therapy should be performed if the PbB level is 45 μg/dL or more. As indicated earlier, chelation therapy should begin immediately (i.e., in the ED) if the PbB lead level is 70 μg/dL or more. If the PbB level is 20 to 44 μg/dL, treatment strategies include environmental and nutritional evaluation, medical examination, and possibly chelation therapy, either with DMSA, CaNa$_2$-EDTA, or D-penicillamine. For children with PbB levels between 10 and 19 μg/dL, interventions include nutritional and medical evaluation, repeat screening PbB levels, and environmental investigation for persistently high levels. In asymptomatic adults, the guidelines are less rigorous. In asymptomatic workers, a PbB level of less than 40 μg/dL is accepted as normal, levels of 40 to 50 μg/dL require increased job surveillance, and levels greater than 50 μg/dL require temporary removal from the job until the PbB level drops below 40 μg/dL. Details on therapy for these various groups can be found in standard toxicology references.

In patients in whom the lead level is elevated on a capillary stick sample, it is best to await verification on blood, unless the clinical presentation strongly supports lead toxicity. Capillary samples may give false-positive results, as noted earlier.

Two oral chelating agents are being used in lead toxicity. DMSA, an analogue of dimercaprol, effectively chelates lead in adults and children. [11,12] Its advantages include oral administration without increasing lead absorption from the gastrointestinal tract, no serious adverse effects, and minimal chelation of essential metals. High cost is its main disadvantage. The dose is 10 mg/kg every 8 h for 5 days, followed by the same dose every 12 h for 14 days. Repeat treatment may be necessary after a 2-week drug-free period. D-Penicillamine is a less effective chelating agent but has the advantage of being inexpensive. It has been used for outpatient therapy in both asymptomatic children and adults with mild PbB elevations.

DISPOSITION   Removal of the source of lead is mandatory for all patients. Patients should not be discharged to their former environments until appropriate deleading and decontamination measures have been accomplished. Family members and coworkers should be evaluated for occult lead toxicity.

A guide for hospitalization includes

1. All children with symptoms or with a PbB level of 70 μg/dL or more
2. All adults with CNS symptoms
3. All patients with suspected toxicity when returning to the environment is considered dangerous

PROGNOSIS   Approximately 85 percent of patients who suffer encephalopathy develop permanent CNS damage, including seizures, mental retardation in children, and cognitive deficits in adults. Abdominal colic usually subsides within days after beginning chelation therapy, and other acute manifestations clear within 1 to 16 weeks with therapy. Lead-induced nephropathy may be partially reversible with chelation therapy.

Organic Lead

Exposure to tetraethyl lead (TEL), found in leaded gasoline, can occur with gasoline sniffing or in the occupational setting. TEL is metabolized to inorganic lead and triethyl lead. Triethyl lead is the primary toxic product that produces predominantly CNS toxicity. Symptoms range from behavioral changes with irritability, insomnia, restlessness, and nausea and vomiting to tremor, chorea, convulsions, and mania. Muscle, hepatic, and renal damage can occur. Anemia and elevated erythrocyte protoporphyrin levels are usually not found. PbB levels may be normal or elevated. Therapy consists of removal from the source, symptomatic treatment, and chelation only if the PbB level is elevated. Sequelae include dementia, mental status alterations, and persistent organic psychosis.

ARSENIC

Arsenic is a nearly tasteless, odorless metal; it is the most common cause of acute metal poisoning and the second leading source of chronic metal toxicity. Arsenicals are found in a variety of compounds and industries (see Table 178-1) and continue to be used as tools for homicides and suicides.

Elemental, inorganic and organic salts, and gaseous forms exist. Elemental and organic forms have little to no toxicity and will not be discussed further. Inorganic compounds include arsenite (As^{3+}) and arsenate (As^{5+}). These compounds are the most toxic forms, and the discussion below will focus on inorganic arsenic toxicity. Arsine, a gaseous form, has toxicopathologic mechanisms and treatment that differ from those of other arsenical compounds. It will be discussed under a separate heading.

Pharmacology

Arsenic is well absorbed via the gastrointestinal, respiratory, and parenteral routes and may be absorbed through damaged skin. Owing to its water solubility, pentavalent arsenic (arsenate) is more readily absorbed through mucous membranes, e.g., the gastrointestinal tract, than trivalent arsenic (arsenite). Arsenite penetrates the skin more readily due to its increased lipid solubility. After absorption, arsenic localizes in erythrocytes and leukocytes or binds to serum proteins.

Within 24 h, redistribution into the liver, kidney, spleen, lung, gastrointestinal tract, muscle, and nervous tissues occurs with subsequent integration into hair, nails, and bone. Metabolism of inorganic arsenic occurs via methylation. Elimination from the blood is rapid, and excretion is predominantly renal. [13] Toxicity of the various forms is partially determined by excretory rates, with the more toxic arsenite being excreted at a slower rate than arsenate or the organic arsenical compounds. Arsenic crosses the placenta and has produced teratogenicity in both animals and humans.

Pathophysiology

Arsenic reversibly binds with sulfhydryl groups found in many tissues and enzyme systems. The mechanisms of toxicity for inorganic arsenic are as follows:

1. For arsenite, inhibition of the pyruvate dehydrogenase complex is the primary biochemical lesion. This inhibition results in diminished adenosine triphosphate (ATP) production and, indirectly, in decreased gluconeogenesis, possibly leading to hypoglycemia. Arsenic also interferes with insulin-dependent cellular glucose uptake. [14]
2. For arsenate, uncoupling of oxidative phosphorylation and loss of ATP occur when As^{5+} substitutes for inorganic phosphate in one step of the glycolysis reaction.

Pathologically, acute exposure produces dilation and increased permeability of small blood vessels, resulting in gastrointestinal mucosal and submucosal inflammation and necrosis, cerebral edema and hemorrhage, myocardial tissue destruction, and fatty degeneration of the liver and kidneys. Subacute or chronic exposure can cause a primary peripheral axonal neuropathy with secondary demyelination.

Clinical Features

The signs and symptoms of toxicity vary with the form, amount, and concentration ingested and the rates of absorption and excretion of the various arsenical compounds. Arsenite (trivalent) is more toxic than arsenate (pentavalent). Symptoms usually occur within 30 min to several hours of ingestion. Severe gastroenteritis with nausea, vomiting, and cholera-like diarrhea is the hallmark of acute poisoning and may last several days to weeks, frequently necessitating hospitalization. Patients may complain of a metallic taste. Hypotension and tachycardia secondary to volume depletion, capillary leak, and myocardial dysfunction occur in moderate to severe cases. The electrocardiogram (ECG) may demonstrate nonspecific ST-segment and T-wave changes with a prolonged QT$_c$, although these findings are more common in chronic intoxication. Ventricular tachycardia with a torsade de pointes morphology has been reported. [15] Secondary myocardial ischemia may occur, leading to an erroneous diagnosis of primary myocardial infarction. Acute encephalopathy with delirium, seizures, and coma, pulmonary edema, acute renal failure, rhabdomyolysis, and death may ensue.

Patients with subacute or chronic toxicity typically present with complaints of peripheral neuropathy, skin rash, or a nonspecific malaise and weakness, often with a history of gastroenteritis occurring 1 to 6 weeks earlier. Survivors of acute poisonings can develop the same problems. The peripheral neuropathy develops in a stocking-glove distribution and is initially sensory, with later motor symptoms. Patients with severe poisonings can develop an ascending paralysis mimicking Guillain-Barré syndrome. The dermatologic manifestations vary. Hyperpigmentation, hyperkeratosis of the palms and soles, morbilliform rash, and epidermoid cancer have been reported. Mee lines (1- to 2-mm-wide transverse white lines in the nails) may be seen 4 to 6 weeks after an acute ingestion, whereas nasal septal perforation has been found in workers exposed occupationally to arsenic. Patients may complain of weakness, muscular aching, abdominal pain, memory loss, personality changes, periorbital and extremity edema, or decreased hearing secondary to sensorineural damage. Chronic encephalopathy with delirium, hallucinations, disorientation, agitation, and confabulation resembling Korsakoff syndrome has been reported. [16] Chronic exposure to arsenic has been linked with the development of squamous cell and basal skin carcinomas, respiratory tract cancer, hepatic angiosarcoma, and possibly with leukemia (Table 178-4).

TABLE 178-4   Signs and Symptoms of Arsenic Toxicity

Diagnosis

Without a history of known exposure to arsenic, the diagnosis must be based on the presenting signs and symptoms and a strong index of clinical suspicion. Physicians rarely encounter arsenic toxicity, and unfortunately, criminal poisonings often go undetected. The diagnosis of acute arsenic poisoning should be considered in any patient with hypotension of unknown etiology that was preceded by a severe gastroenteritis. The diagnosis of chronic arsenic toxicity should be considered in a patient with a peripheral neuropathy, typical skin manifestations, or recurrent bouts of unexplained gastroenteritis.

An abdominal radiograph may demonstrate intestinal radiopaque metallic flecks in cases of arsenic ingestions. [17] The complete blood count (CBC) may reveal either a normocytic, normochromic, or megaloblastic anemia and/or a thrombocytopenia. The white blood cell (WBC) count may be elevated in acute toxicity and decreased in chronic toxicity. A relative eosinophilia, up to 21 percent, and basophilic stippling of the RBCs have been reported. Elevated reticulocyte counts are found in cases with a component of hemolytic anemia. The ECG often reveals a prolonged QT$_c$ interval, especially in chronic poisoning.

Definitive diagnosis of acute poisoning depends on finding elevated arsenic levels in a 24-h urine collection. All urinary measurements of metals should be collected in metal-free containers. Normal urinary arsenic level is less than 0.05 mg/L, and total urinary arsenic excretion in an unexposed patient should not exceed 0.1 mg/24 h. If the baseline urinary level is within normal limits and arsenic intoxication is still suspected, hair and nail clippings should be harvested for laboratory analysis. Owing to the rapid distribution of arsenic in tissues, blood arsenic levels are unreliable. Toxicologic texts provide a detailed discussion of laboratory testing and interpretation of results in arsenic toxicity. [18]

Arsenic toxicity should be included in the differential diagnosis for septic shock, encephalopathy, peripheral neuropathy (including Guillain-Barré syndrome), Addison's disease, hypo- and hyperthyroidism, patients with the previously mentioned dermatologic manifestations, Korsakoff syndrome, persistent gastroenteritis and/or cholera-like diarrhea, porphyria, other metal toxicities such as thallium and mercury, and unexplained, prolonged malaise and weakness.

Treatment

Acute arsenical toxicity is a life-threatening illness requiring aggressive management. The first task is to ensure adequate respiratory and circulatory function. Hypotension and dysrhythmias are the chief causes of death. Hypotension, usually due to volume depletion, should be managed initially with crystalloid volume replacement. Invasive hemodynamic monitoring followed by further crystalloid and pressor therapy with dopamine or norepinephrine may be required. Overhydration should be avoided because pulmonary and cerebral edema can occur. Cardiac monitoring should be instituted. Ventricular tachycardia and fibrillation may be treated with lidocaine, bretylium, and electrical defibrillation as necessary. Isoproterenol, magnesium, and overdrive pacing therapies should be considered for torsade de pointes dysrhythmias. Drugs that prolong the QT$_c$, including classes IA (procainamide, quinidine, disopyramide), IC, and III antidysrhythmics should be avoided. Potassium, calcium, and magnesium levels should be monitored and corrected as necessary to prevent further prolongation of the QT$_c$ with possible exacerbation of torsade de pointes dysrhythmias.

Gastric lavage with a large-bore orogastric tube should be performed in all cases of acute ingestion, and activated charcoal (1 g/kg of body weight) and a cathartic should be instilled. Activated charcoal poorly adsorbs arsenic but may be effective if coingestants were taken. Whole-bowel irrigation should be considered if abdominal radiographs reveal intestinal radiopaque materials consistent with arsenic. Seizures can be treated with benzodiazepines, phenobarbital, phenytoin, and general anesthesia as necessary.

Initial management of chronic toxicity should be directed toward prevention of further arsenic absorption and gastrointestinal decontamination, if appropriate. In cases of suspected homicidal intent, patients should be advised to avoid food and drinks prepared by others, and visitor contact with hospitalized patients should be monitored carefully.

Chelation therapy with BAL should be instituted immediately in all cases of known or suspected acute arsenical poisoning. BAL doses range 3 to 5 mg/kg intramuscularly every 4 h for 2 days followed by 3 to 5 mg/kg every 6 to 12 h. In severe, life-threatening toxicity, BAL therapy should be continued until the clinical condition stabilizes and DMSA, the less toxic oral chelating agent, can be substituted. In cases of suspected chronic toxicity with stable symptoms, therapy may be withheld pending diagnosis. DMSA is the preferred chelating agent in these patients. [19] It is given according to the dosing regimen for lead, but therapy may be required beyond the initial 19-day regimen. D-Penicillamine does not effectively chelate arsenic and should no longer be used. [20] During chelation, intermittent 24-h urinary arsenic levels should be measured and therapy continued until the urine level falls below 0.05 mg/L per 24 h. Hemodialysis can remove small amounts of arsenic (2 to 4.5 mg) in patients with acute renal failure but is not indicated otherwise. [21]

Hospitalization Guidelines

1. All patients with acute or life-threatening known or suspected arsenic poisoning
2. All chronically poisoned patients requiring BAL therapy
3. All patients in whom suicidal or homicidal intent is suspected

Disposition

In acute toxicity, prognosis may be influenced favorably by the rapid institution of BAL therapy. Recovery from arsenical neuropathy appears to be related more to initial severity of symptoms than to institution of chelation therapy, although in those patients who do recover, BAL appears to significantly shorten the duration of illness. Often, neurologic recovery occurs slowly over months to years. Normalization of hematologic values can occur in the absence of any specific therapy. BAL has a variable effect on the dermatologic manifestations; hyperpigmentation is unresponsive to this therapy.

Arsine

Arsine is a colorless, nonirritating gas encountered in the semiconductor industry, ore smelting, and refining processes and is also produced when arsenic-containing insecticides are mixed with acids. Arsine attaches to sulfhydryl groups of hemoglobin, producing an acute hemolytic anemia with resulting jaundice, abdominal pain, and hemoglobinuria-induced acute renal failure. Acute poisonings are managed with blood transfusions, exchange transfusion to remove the nondialyzable arsine, and hemodialysis for the acute renal failure. BAL therapy has no role in the management of arsine toxicity.

MERCURY

Mercury occurs in both inorganic and organic forms. Inorganic compounds are divided further into elemental mercury and mercurous and mercuric salts. Organic mercurials exist as short- and long-chained alkyl and aryl compounds. The short-chained alkyls, such as methyl mercury and ethyl mercury, are more toxic to humans, with dimethylmercury being lethal in small amounts. [22] All forms of mercury are toxic but differ in the routes of absorption, constellations of clinical findings, and responses to therapy. Sources are listed in Table 178-1.

Pharmacology

Elemental mercury is primarily absorbed via inhalation of its vapor but also may be absorbed dermally. Absorption by the gastrointestinal tract is usually negligible. Intramuscular injections of mercury can induce abscess and granuloma formation; delayed systemic toxicity can occur. [23] Intravenous injections have produced mercury pulmonary and systemic emboli. Both mercuric salts and organic mercury are absorbed primarily through the gastrointestinal tract, with the short-chained alkyl organic compounds being better absorbed than the aryl organic compounds. Elemental mercury crosses the blood-brain barrier, where it is ionized and trapped in the CNS. Mercuric salts are deposited in the ionized form primarily in the kidney, as well as in the liver and spleen. The salts do not enter the CNS in consequential amounts.

With organic mercury compounds, the highly lipid-soluble short-chained alkyls easily cross membranes, accumulating in RBCs, the CNS, liver, kidney, and the fetus. Longer-chained alkyl and the aryl compounds are biotransformed into inorganic mercuric ions in the body. Therefore, toxicity with these compounds more closely resembles inorganic mercury toxicity.

Inorganic and the aryl organic mercurials are eliminated in the urine and feces. The short-chained alkyl compounds are primarily excreted in the bile, where they undergo significant enterohepatic circulation.

Pathophysiology

Mercury binds with sulfhydryl groups, affecting a diverse number of enzyme and protein systems. Methyl mercury also inhibits choline acetyl transferase, which catalyzes the final step in the production of acetylcholine, and may produce an acetylcholine deficiency. Mercuric salts produce proximal renal tubular necrosis.

Clinical Features

The clinical effects of mercury poisoning depend on the form and, in some cases, the route of administration. In general, the neurologic, gastrointestinal, and renal systems are predominantly affected. The short-chained alkyl compounds, methyl, dimethyl, and ethyl mercury, have the most devastating effects on the CNS, [24] followed by elemental mercury, whose primary toxicity is neurologic. Both forms of mercury produce erethism, a constellation of neuropsychiatric abnormalities including anxiety, depression, irritability, mania, sleep disturbances, excessive shyness, and memory loss. Tremor, either intention or nonintention, is a common physical finding. [25] The short-chained alkyls produce paresthesias (early sign), ataxia, muscular rigidity or spasticity, and visual and hearing impairment and induce CNS teratogenic effects. Gastrointestinal effects of both elemental and short-chained alkyl compounds are mild. In cases of severe, chronic poisoning with elemental mercury, stomatitis, gingivitis, and excessive salivation are seen. Chronic toxicity of elemental and organic forms may cause renal glomerular and tubular damage. Acute mercury inhalation can produce pneumonitis, adult respiratory distress syndrome, and progressive pulmonary fibrosis with death. [26]

In contrast, the mercury salts have little to no effect on the CNS but produce a severe corrosive gastroenteritis with abdominal pain that may be followed rapidly by cardiovascular collapse. Renal effects are typical, including acute tubular necrosis within 24 h. Children exposed to all forms of mercury except the short-chained alkyls can develop acrodynia, an immune-mediated condition characterized by a generalized rash, fever, irritability, splenomegaly, and generalized hypotonia with particular weakness of the pelvic and pectoral muscles. Further details of clinical findings are listed in Table 178-5.

TABLE 178-5   Clinical Effects of Mercury Toxicity

Swallowing mercury contained in a glass thermometer usually does not produce adverse effects because the mercury is not absorbed from the gastrointestinal tract unless the tract is damaged or contains fistulas.

Diagnosis

A thorough history, including occupational exposures, and typical physical findings, especially tremor or a constellation of signs and symptoms suggesting erethism or acrodynia, may alert the emergency physician to mercury toxicity. Ingestion of mercuric chloride can produce a rapidly fatal course and should be considered in any patient presenting with a corrosive gastroenteritis. Often, however, the diagnosis of mercury toxicity is subtle, arrived at only after many other diagnoses have been investigated.

For all forms of mercury except short-chained alkyls, a 24-h urinary measurement of mercury should be performed. Most unexposed individuals will have levels of 10 to 15 µg/L or less. A level of greater than 20 µg/dL either before or after therapy indicates meaningful exposure. In cases of chronic toxicity, this measurement may be falsely low. Whole-blood mercury levels are less reliable diagnostically. A seafood meal (contaminated with mercury) can temporarily elevate the blood level to the toxic range until the mercury is eliminated.

Short-chained alkyl mercury compounds are predominantly excreted via the bile, rendering urinary measurements invalid. Laboratory diagnosis rests on finding elevated whole-blood mercury levels, since these compounds concentrate in erythrocytes. Whole-blood mercury levels are normally less than 1.5 µg/dL.

Magnetic resonance imaging (MRI) findings in methyl mercury toxicity from ingestion of contaminated seafood include marked atropy of the visual cortex, cerebellar vermis and hemispheres, and the postcentral cortex.[27]

The differential diagnosis of mercury toxicity depends on the form ingested. Hypothyroidism, apathetic hyperthryroidism, metabolic encephalopathy, senile dementia, adverse effects of therapeutic drugs (such as lithium, theophylline, phenytoin), Parkinson disease, delayed neuropsychiatric sequelae of carbon monoxide poisoning, lacunar infarction, cerebellar degenerative disease or tumor, and ethanol or sedative-hypnotic drug withdrawal may produce behavioral changes or tremor similar to those caused by elemental mercury. Causes of corrosive gastroenteritis such as iron, arsenic, phosphorus, acids, or alkalis should be considered in the differential diagnosis for mercury salts. Many of the differential diagnoses for elemental mercury also apply to the organic mercury compounds. Cerebral palsy, intrauterine hypoxia, and teratogenic effects of therapeutic and illicit drugs and environmental contaminants should be considered when evaluating an infant thought to be affected in utero by the short-chained alkyl mercury compounds.

Treatment

General therapeutic measures include removal from exposure and supportive therapy. Ingestion of mercury salts should be treated with aggressive gastrointestinal decontamination, including instillation of milk or egg whites to bind the mercury, lavage, and activated charcoal. Given the profuse diarrhea that may ensue, a cathartic may not be indicated. A polythiolated resin (commercially unavailable) has been used to bind intestinal methyl mercury and interrupt the enterohepatic circulation. Neostigmine may improve motor function in methyl mercury–poisoned patients by improving acetylcholine levels.

BAL is the preferred chelator for mercury salts and is administered in a regimen of 3 to 5 mg/kg per dose intramuscularly every 4 h for 2 days and then every 6 h for 2 days, followed by every 12 h for 7 days. BAL is contraindicated in methyl mercury poisoning owing to exacerbation of CNS symptoms. The BAL-mercury complex is dialyzable, and hemodialysis may be helpful in patients receiving BAL who have diminished renal function. Plasma exchange transfusion also was beneficial in a case of mercuric chloride ingestion.[28] D-Penicillamine is used in elemental mercury and less severe cases of mercury salt toxicities. The dose is 100 mg/kg per day, to a maximum of 1 g in four divided doses for 3 to 10 days. D-Penicillamine has been used with variable results in organic mercury poisoning. DMSA has demonstrated efficacy in binding mercury, including organic forms and may become the treatment of choice for the short-chained alkyl compounds.[29]

Hospitalization Guidelines

1. All patients known or suspected of ingesting mercury salts
2. All patients known to have or suspected to have inhaled elemental mercury vapor with pulmonary injury
3. All patients requiring BAL therapy.

Disposition

Outcome depends on the form of mercury and the severity of toxicity. Mild cases of elemental and mercury salt poisoning and very mild cases of organic mercury toxicity may result in complete recovery. Death can occur in severe cases of mercuric chloride poisoning and with dimethyl mercury exposure. Most patients with organic mercury poisoning are left with residual neurologic deficits.

G. Richard Braen

Vitamins and herbal preparations, particularly those sold in health food stores, have been considered by many to be innocuous, but several have tremendous potential as toxins. This chapter covers most of the available vitamins and selected herbals. Agents compounded with vitamins, such as iron, are covered in other chapters.

VITAMIN A

Vitamin A has two primary preformed types: retinol (vitamin A_1 alcohol) and 3-dehydroretinol (vitamin A_2). Yellow carotenoid plant pigments contain a number of forms of provitamin A, but b-carotene has the highest biologic activity of these forms. There are two molecules of vitamin A per molecule of b-carotene.

The retinyl esters of dietary vitamin A are hydrolyzed into retinol in the gastrointestinal tract. Retinol is then absorbed into intestinal mucosal cells where it combines with a fatty acid to again become a retinyl ester. The retinyl ester then travels through the lymphatic system and bloodstream to storage sites in the liver. The liver contains about 95 percent of the vitamin A of the entire body.

Vitamin A forms part of the visual pigments of the retina (rhodopsin and iodopsin), is important for the formation of mucus-secreting cells of the columnar epithelium, maintains bone growth, and maintains cellular membrane stability. The daily adult recommended doses range from 4000 IU for women to 5000 IU for men.

Hypervitaminosis A generally occurs when children are given excessive amounts of a high-potency supplement and when their capacity to store vitamin A in the liver is exceeded. In the liver, retinol is bound to a liver protein (retinol-binding protein) and is stored in this bound form. As the liver binding and storing capacity is exceeded, blood levels of a retinyl ester loosely bound to low-density lipoproteins increase. This loosely bound vitamin is believed to be toxic to cell membranes. Members of Mawson's Antarctic expedition (1911–1913) are said to have died from hypervitaminosis A after eating the livers of their dogs to try to avoid starvation.

When the total dosage is similar, water-miscible preparations are more toxic than oily preparations because of better absorption. High doses of preformed vitamin A must be ingested for long periods before signs and symptoms of hypervitaminosis A develop. There is a high degree of variability among patients in the amounts necessary to develop hypervitaminosis. Dialysis patients can be at risk of developing a type of vitamin A toxicity in which resorption of bone causes hypercalcemia.

Symptoms of hypervitaminosis A include blurred vision, appetite loss, abnormal skin pigmentation, loss of hair, dry skin, pruritis, long-bone pain, and an increased incidence of bone fractures. Massive doses can additionally cause pseudotumor cerebri.

The treatment of hypervitaminosis A depends on the condition of the patient. Generally, when vitamin A is discontinued, the symptoms resolve over a period of time and no additional treatment is needed.[1] Treatment of hypercalcemia is outlined in [Chap. 23](#), "Fluid and Electrolyte Problems." b-Carotene intoxication is very rare and does not generally cause hypervitaminosis A. In diabetics and patients with hypothyroidism, however, large doses of b-carotene can cause a yellowish discoloration of the skin, which fades once b-carotene is stopped.

VITAMIN D

Vitamin D function comes from two major compounds: calciferol (vitamin D_3) and ergocalciferol (vitamin D_2). The naturally occurring provitamin forms of each of these two compounds (7-dehydrocholesterol for D_3 and ergosterol for D_2) convert to the active forms following irradiation by ultraviolet light. Most studies in humans have been made on vitamin D_3 (cholecalciferol), which is converted in the body to 1,25-dihydroxycholecalciferol, the physiologically active form of vitamin D.

Absorption of vitamin D is aided by bile and takes place in the jejunum. From there it is transported via lymph chylomicrons to the bloodstream.[1] When it reaches the liver, it is hydroxylated to 25-hydroxycholecalciferol. From the liver, it travels to the kidney, where it is again hydroxylated to 1,25-dihydroxycholecalciferol. The major function of 1,25-dihydroxyhydrocalciferol is to elevate the plasma calcium and phosphorus levels to enable normal bone mineralization.

The average daily adult requirement of vitamin D is about 400 IU, and therapeutic doses sometimes exceed 5000 IU. Infants may develop hypercalcemia from doses as low as 2000 IU, but adults require much higher doses before toxicity develops. The toxicity results from the hypercalcemia and includes anorexia, nausea, abdominal pain, lethargy, weight loss, polyuria, constipation, confusion, and coma.[1] Symptoms from massive doses (1000 to 3000 IU/kg) develop in 2 to 8 days. Persistently elevated levels of calcium can cause soft tissue calcification and renal failure.

Treatment of hypervitaminosis D includes discontinuation of vitamin D, reduction of the calcium intake, and reduction of serum calcium levels.

VITAMIN E

Vitamin E activity is not limited to one compound alone. Eight different fat-soluble, naturally occurring alcohols (called tocopherols and tocotrienols) have vitamin E activity, but a-tocopherol is the most active form. Because of its ability to be rapidly oxidized, a-tocopherol protects other foods from being oxidized, and thus is termed an *antioxidant*.[2] Foods high in vitamin E include wheat germ, corn, soybean, sunflower seed, cod liver, and others.

Vitamin E is absorbed and distributed through the body just as any fat-soluble vitamin, through the intestines and then through lymphatic chylomicrons. Between 30 and 90 percent of available vitamin E in the diet is absorbed. Normal tocopherol levels in adults range from 0.5 mg to 2.0 mg/dL. The minimum daily requirement for women is about 8 mg a-tocopherol and for men is 10 mg a-tocopherol. An IU is the activity of 1 mg of a-tocopherol. Vitamin E needs for children increase with increasing body weight and increase for pregnant or lactating women.

Vitamin E is felt to be nontoxic at daily doses of up to 600 IU. At doses higher than 600 IU/day, taken on a long-term basis, a metabolite of vitamin E acts as a competitive inhibitor of vitamin K-dependent g-carboxylation, increasing the daily vitamin K requirements. Additionally, through the production of thromboxane, high levels of vitamin E inhibit platelet aggregation. People ingesting large amounts of vitamin E who are on anticoagulants should be observed closely for bleeding tendencies, but those not on anticoagulants rarely have coagulation difficulties, except for neonates, who are more sensitive to the effects of vitamin E. Other effects in adults who take large doses for a long period of time include nausea, fatigue, headache, weakness, and blurred vision. These symptoms resolve weeks after discontinuation of the vitamin.

VITAMIN K

Vitamin K is represented by several compounds that have antihemorrhagic activity: the parent compound called menadione; vitamin K_1, which is a naturally occurring phylloquinone from plant sources; and vitamin K_2, which is a naturally occurring menaquinone from microbial sources. Vitamin K forms are generally heat resistant but are broken down by alkali, strong acids, light, and some oxidizing agents. High levels of dietary vitamin A inhibit the absorption of vitamin K. Vitamin E at high levels

acts as a vitamin K–antagonist in its liver production of clotting factors.

Vitamin K is absorbed in different sites and by different mechanisms, depending on the type of compound. Phylloquinones are absorbed from the proximal intestine through an energy-requiring process. Menadione and menaquinones are absorbed from the lower intestine and colon through a passive mechanism. Both mechanisms require the presence of bile and pancreatic juice. Between 10 and 80 percent is absorbed. Once absorbed, it is carried by the lymph chylomicrons and then transferred in the blood to b-lipoproteins. About 50 percent of the vitamin comes from the diet and 50 percent from bacterial synthesis in the intestines. The total dietary requirement of vitamin K is about 2 µg/kg body weight. Since most adults ingest a diet that contains 300 to 500 µg vitamin K, deficiency states are uncommon. In contrast to the other fat-soluble vitamins, vitamin K is not stored in the body to any significant extent. About 70 percent of menadione is excreted in the urine. Phylloquinone is excreted mainly in bile.

Vitamin K is required for the maintenance of normal prothrombin tines through its effect on factor II (prothrombin), factor VII (proconvertin), factor IX (Christmas factor), and factor X (Stuart-Prower factor). These factors are part of the extrinsic, intrinsic, and common pathways for blood clotting. Coumarin compounds work on the clotting-factor synthesis sites in the liver to stop prothrombin synthesis and to reduce the levels of all vitamin K–dependent clotting factors.

Megadoses of menadione can be toxic. Toxic effects include hemolytic anemia, kernicterus, and hemoglobinuria in premature infants and renal tubular degeneration, liver damage, hypoprothrombinemia, and petechial hemorrhages in adults. Large doses can also paradoxically inhibit the effects of oral anticoagulants. Treatment includes stopping vitamin K, monitoring prothrombin times, and monitoring liver function studies. Additionally, doses exceeding 500 µg daily have been associated with skin rashes. Fatalities from overingestion of vitamin K are rare.

VITAMIN B_1 (THIAMINE)

Vitamin B_1 is converted to thiamine pyrophosphate which acts as a cofactor for several metabolic reactions, including transketolations. Measurement of erythrocyte transketolase activity is used to reflect the availability of thiamine pyrophosphate in the tissues. Food sources of thiamine include fruits, grain, meats, fish, and milk, among others. The highest levels are found in pork products (0.63 mg/serving). The average daily adult requirement is 1.5 mg. [1]

Intestinal absorption of thiamine seems to be greatest in the jejunum. An active carrier-mediated absorption process occurs at normal levels of dietary thiamine, but passive diffusion is the major means of thiamine absorption at higher levels.

Thiamine is not stored in the body to any significant extent. At low dietary levels renal excretion decreases, whereas, at high levels of ingestion, renal excretion increases proportionately. Because of the renal excretion of thiamine, there is no toxicity to the ingestion of large doses of vitamin B_1 over prolonged periods.

VITAMIN B_2 (RIBOFLAVIN)

Vitamin B_2 (riboflavin) works as an antioxidant through its activity in the formation of glutathione reductase and glutathione. As a part of the group of enzymes called flavoproteins, it is involved in the metabolism of fats, proteins, and carbohydrates. It is not stored in appreciable quantities in the body and must be replenished daily. Vigorous exercise increases the daily requirement of riboflavin, and a deficiency results in cracked lips, reddened tongue, and eczema of the face and genitals. The average daily adult requirement is 1.7 mg.[1]

Riboflavin is excreted through the urine, and toxicity is rare regardless of the amount ingested. No adverse effects result from overdosage.

VITAMIN B_3 (NIACIN)

There are two active forms of niacin—nicotinic acid and nicotinamide—which, in conjunction with thiamine and riboflavin, have antipellagra activity. Niacin, thiamine, and riboflavin all function as a coenzyme in energy metabolism. Niacin becomes part of the coenzymes nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP). NAD is required in all major metabolic pathways in which there is oxidative breakdown of amino acids, fatty acids, and other compounds. It also acts in the oxidation of ethanol.

Niacin is found in poultry, meat, and fish, with less found in plants. Niacin deficiency causes changes first in cells of the skin, nervous system, and gastrointestinal tract. Deficiency states create symptoms such as anorexia, anxiety, depression, irritability, and weakness.

Whereas doses of nicotinic acid in the range of 100 to 200 times the recommended allowance of 20 mg daily will lower serum cholesterol and b-lipoprotein, nicotinamide does not. Large doses can also deplete cardiac muscle glycogen and can cause liver toxicity. Some patients experience a frightening "niacin flush" when taking a dose of more than 100 mg. The niacin flush, caused by histamine release and vasodilation, is characterized by face, neck, and chest burning, itching, and reddening.[1] It generally resolves within an hour. Antihistamines can provide symptomatic relief. Higher doses may additionally cause nausea, abdominal cramping, diarrhea, and headache. Even higher doses (2000 mg and above) over a prolonged period can produce abnormalities of liver function, impaired glucose tolerance, hyperuricemia, and skin changes such as dryness and discoloration. Subacute and chronic symptoms resolve within days to weeks.

VITAMIN B_6 (PYRIDOXINE)

Vitamin B_6 is a complex of three physiologically active compounds, the most active being pyridoxine. Pyridoxine is converted to pyridoxal-5-phosphate, which is a coenzyme in the transamination of amino acids that is required for the utilization of most amino acids for energy and for the synthesis of nonessential amino acids. A deficiency in vitamin B_6 in infants results in convulsive seizures (due to a reduced synthesis of g-aminobutyric acid), anemia (due to impaired synthesis of heme), xanthurenic aciduria (due to reduced formation of hydroxyanthranilic acid), cystathionuria (due to decreased cleavage of cystathionine to cysteine) and homoserine), and homocystinuria (due to impaired formation of cystathionine). Deficiency states can be induced through ingestion of antagonists to vitamin B_6, such as isoniazid, cycloserine, and penicillamine.

Vitamin B_6 deficiency in infants may lead to growth retardation, weight loss, hyperirritability, convulsions, and anemia. Vitamin B_6 deficiency in adults may result in depression, convulsions, seborrheic dermatitis, and cheilosis. The daily requirement is 2.2 mg/day for men and 2.0 mg/day for women with increased requirements during pregnancy and lactation. Many animal and vegetable sources contain vitamin B_6 (especially pork and glandular meats, legumes, potatoes, oatmeal, wheat germ, and bananas), but there is considerable loss of the vitamin during cooking.

In high doses, particularly over a long period of time, vitamin B_6 excess will cause nerve damage. Most people can tolerate 20 mg/day without difficulty, but 5 g/day or more over several weeks will produce an unstable gait and numbness of the feet. This is followed by similar symptoms in the hands and arms. There may be a marked loss of position and vibration senses. After withdrawal of the vitamin, recovery occurs within several months. Some patients, however, have residual neurologic losses.

Vitamin B_6 also can cause intestinal inactivation of levodopa in patients receiving that medication for Parkinson's disease. Patients should be instructed not to take the vitamin at the same time as the medication.

VITAMIN B_{12}

Vitamin B_{12} deficiency causes pernicious anemia identified by macrocytosis (high mean corpuscular volume) and intramedullary hemolysis (very high lactate dehydrogenase level). Associated neurologic problems include symmetric paresthesias of the hands and feet, and decreased position and vibratory senses. Vitamin B_{12} is a very potent vitamin (relatively small amounts are needed to treat patients with pernicious anemia) that takes several forms: cyanocobalamin (vitamin B_{12}), hydroxocobalamin (vitamin B_{12a}) aquocobalamin (vitamin B_{12b}), nitritocobalamin (vitamin B_{12c}), 5'-deoxyadenosylcobalamin (coenzyme B_{12}), and methylcobalamin (methyl B_{12}). All are complex nitrogenous compounds associated with cobalamin that participate in metabolic reactions necessary for the formation of amino acids,

protein, and DNA.

Partially because of the size and complexity of the vitamin B$_{12}$ molecules, deficiencies of this water-soluble vitamin result more from absorption problems than from dietary insufficiencies.[2] Absorption depends on the production of intrinsic factor (IF) by the parietal cells of the stomach. Vitamin B$_{12}$–IF complexes are formed in the stomach. The complexes pass to the ileum, where IF attaches to the intestinal epithelium, facilitating the absorption of the vitamin B$_{12}$. Once absorbed, the cobalamin portion of the molecule attaches to the protein transcobalamin II which carries the B$_{12}$ through the bloodstream to various tissues. Vitamin B$_{12}$ is stored in the liver in such quantities that it takes several years for pernicious anemia to develop in an individual who is a strict vegetarian and ingests little B$_{12}$ or in someone unable to produce IF. Meat, eggs, dairy products, and seafood contain vitamin B$_{12}$.

Health food enthusiasts believe that supplemental vitamin B$_{12}$ will energize the body, prevent mental deterioration, and protect against cancer, toxins, and infections. Because of the rate limited fashion in which vitamin B$_{12}$ is absorbed, there is no toxicity to the ingestion of large amounts of vitamin B$_{12}$. Overdosage from injection is rare and results primarily in a variety of skin changes that clear over 1 to 2 weeks.

BIOTIN

Biotin is produced in the intestines by bacterial action and is a cofactor in fatty acid synthesis. Deficiencies of biotin result in baldness and dry skin, lassitude, anorexia, depression, and hypercholesterolemia. Those taking chronic antibiotics and those on extremely low-calorie diets are at risk of developing a biotin deficiency. For such individuals, 100 to 300 µg of biotin per day are recommended. There is no known toxicity to biotin overdosage.

FOLIC ACID

Folic acid is essential for the production of DNA, RNA, and proteins. Although folic acid may reverse the megaloblastic red blood cell aspects of pernicious anemia, it will not reverse the neurologic changes associated with pernicious anemia. It is found in fresh leafy green vegetables, yeasts, and liver. Folic acid is absorbed in the small and large intestines in the form of polyglutamates. At the brush border of the intestinal cells, excess glutamates are removed from the folate molecule, making a functioning intestinal mucosa necessary for absorption.

The adult daily recommended dosage of folic acid is 400 µg/day.[2] Dietary supplementation of 100 µg/day will reverse the red cell changes of pernicious anemia but will not reverse the neurologic effects; therefore, preparations with more than 100 µg are available only through prescription. Except for the problem with masking of the hematologic changes of pernicious anemia, there are no known adverse effects to the ingestion of large doses of folic acid.

VITAMIN C

The major form of vitamin C, L-ascorbic acid, is a strong reducing agent that participates in hydroxylation reactions such as that necessary for the formation of collagen. Scurvy results from vitamin C deficiency and results in collagen, protein, and lipid metabolism abnormalities. Additionally, the presence of vitamin C in the intestines increases the absorption rate of iron. Those with a vitamin C deficiency will also be iron depleted.

Vitamin C, which is found primarily in fruits and vegetables,[2] is absorbed through the jejunum and ileum. The absorption rates decrease with increasing intraluminal quantities of vitamin C. For example, 90 percent of a 100-mg dose might be absorbed, whereas only 20 percent of a 10-g dose might be absorbed. The daily recommended dose for adults is 60 mg. Vitamin C levels, although high in fruits and vegetables, are reduced by heat, drying, and storage.

Large doses of vitamin C can produce attacks of gout and nephrolithiasis in individuals with these conditions. Others may develop diarrhea and abdominal cramps, which subside with discontinuation. Megadoses of vitamin C may result in false negative guaiac testing of feces, and may give falsely elevated glucose levels on dipstick testing.

HERBAL AGENTS

In 1997 sales of over-the-counter herbal preparations exceeded $1.5 billion in the United States. Between 1994 and 1998, the sales of herbal supplements will have increased about 105 percent. According to the New York Times, July 23, 1998, between 1995 and 1997, the sales of St. John's wort have increased by 1900 percent.[3] Many other home grown and imported herbal preparations add to the total amount of herbal agents ingested, inhaled, and rubbed on. The list is staggering and this review will encompass only some of the more common herbals used. Herbal agents can be classified as generally safe, potentially toxic, and toxic. Some generally safe herbal agents are listed in Table 179-1.

TABLE 179-1   Some Generally Safe Herbal Agents

Some of the moderately unsafe herbal preparations include absinthe (wormwood), black cohosh, comfrey, juniper, and lobelia. *Absinthe* (wormwood)—which is popular in Europe and is being produced there in clandestine laboratories—is a toxic liquor that contains volatile oils that produce psychosis, intellectual deterioration, ataxia, headache, vomiting, and diarrhea. Absinthe is used as a flavoring in alcoholic drinks.

Black (*or blue*) *cohosh* contains an estrogen-like compound and has been used to delay or treat menopause. It may cause nausea, vomiting, dizziness, and weakness.

Comfrey is used as a digestive stimulant in teas. It has, however, been linked to liver toxicity and hepatic carcinoma. The toxic action comes from the formation of pyrroles that act on DNA.

Juniper is used as a diuretic but may also be hallucinogenic. Toxicity also includes renal toxicity, nausea, and vomiting.

Lobelia is used for asthma and as an expectorant. Other uses include smoking it as a marijuana substitute for its mild euphoric effect. The active ingredients include lobeline, atropine, and scopolomine, which can produce anticholinergic symptoms.

Some herbs that are unsafe but are commonly found on store shelves include chaparral, ephedra, nutmeg, and yohimbine.

Chaparral is derived from the leaves of the creosote bush and is used for its antioxidant effects as a potential cancer preventative. It is also felt to be effective in pain

control but is felt to be hepatotoxic.

Ephedra is used in weight loss and has been implicated in multiple toxic deaths. This herbal agent is contraindicated for patients with hypertension, diabetes, or glaucoma.

Nutmeg is used for dyspepsia, muscle aches, and arthritis. It contains terpines, ethers, and myristicin. Myristicin can produce hallucinations (at about 2 to 4 teaspoonfuls of ground nutmeg). At various dosages, it can also produce gastrointestinal upset, agitation, coma, miosis, and hypertension.

Yohimbine is thought to be an aphrodisiac. Toxic effects include hallucinations, weakness, hypertension and paralysis. Yohimbine, if combined with pheopropanolamine, can lead to a stroke through marked elevation of the blood pressure.

  Antiviral and Common HIV Medications
Evaluation and Treatment of Antimicrobial Overdose
Chapter References

Antimicrobial agents are estimated to account for 15 to 30 percent of the world medical drug expenditure. [1] Most adverse reactions to antibiotics occur at therapeutic doses. The most common adverse effects of antimicrobial use include hypersensitivity reactions, alterations in body microbial flora, interactions with other drugs, and cutaneous drug reactions. Data from the American Association of Poison Control Centers (AAPCC) suggest that antimicrobial exposures are a frequent source of inquiry to poison control centers but rarely result in life-threatening outcomes. During the 5 years from 1992 through 1996, the AAPCC reported 316,653 exposures, which resulted in significant morbidity in 768 cases (0.24 percent) and 23 fatalities (less than 0.01 percent). Emergency physicians must be familiar with the common adverse effects of antimicrobial agents at therapeutic doses (Table 180-1), any significant interactions with other drugs, effects on pregnancy (Table 180-2), and the clinical presentation and management of acute antimicrobial overdose. Hypersensitivity reactions account for the highest morbidity and mortality rates related to the use of antimicrobial agents. Most patients who present after antimicrobial overdose will be asymptomatic. Observation and screening for coingestants are adequate before medical clearance in most cases. The poison control center should be contacted to assist in patient management and to aid in accurate statistical tracking of toxin exposures.

TABLE 180-1   Adverse Effects of Common Antimicrobial Agents at Therapeutic Doses

TABLE 180-2   Antimicrobials in Pregnancy

COMMON ADVERSE EFFECTS OF ANTIMICROBIAL AGENTS

Almost all antimicrobial agents have resulted in immunoglobulin E-mediated anaphylaxis in sensitized individuals. Antibiotics, led by penicillins, account for the largest number of anaphylactic deaths in the United States annually. [2] In addition to immediate hypersensitivity reactions, antibiotics may cause delayed hypersensitivity reactions (Table 180-3). A comprehensive review of the presentation and management of hypersensitivity reactions is beyond the scope of this chapter, but they are important considerations when prescribing and caring for patients on antibiotics.

TABLE 180-3   Classification of Hypersensitivity Reactions

The normal body microbial flora is altered with use of antimicrobial agents. Patients taking antimicrobial agents are at risk for infection with a number of resistant pathogens. The oral and other mucosal surfaces may become infected with *Candida albicans*. Alteration of the gastrointestinal flora may result in pseudomembranous colitis from superinfection by *Clostridium difficile*. The antibiotics most commonly associated with pseudomembranous colitis are cephalosporins, penicillins, and clindamycin.

Antibiotics account for the greatest number of adverse dermatologic drug reactions. Ampicillin and trimethoprim-sulfamethoxazole (TMP-SMX) are reported to be the most common offending agents.[3] The mechanisms of these cutaneous reactions are not well understood but appear to be mediated immunologically. Most benign skin reactions begin within 1 to 2 weeks of exposure to the drug. Rashes are often pruritic erythematous, morbilliform, or macular eruptions, which typically resolve within several days after administration of the offending drug has been stopped.

Serious drug reactions are rare. Sulfonamides were recently implicated in a large case-control study as the drugs with the highest relative rate for development of the severe drug eruptions of Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN). The sulfonamides are estimated to account for 4.5 cases of SJS and TEN per million users of the drug per week.[4] Other antibiotics significantly associated with SJS and TEN include cephalosporins, fluoroquinolones, tetracyclines, and aminopenicillins.

SPECIFIC AGENTS AND ADVERSE EFFECTS AT THERAPEUTIC DOSES

Penicillins/Cephalosporins/b Lactams

The penicillins and cephalosporins are among the most widely used antimicrobial agents. They share a common b-lactam ring and are bactericidal through inhibition of bacterial cell wall synthesis. Potential adverse effects associated with therapeutic use of penicillin and b lactams include hypersensitivity reactions, central nervous system (CNS) disturbances, impaired hemostasis, interstitial nephritis, and hepatitis.

Penicillin and b lactams have been implicated in all types of hypersensitivity reactions (types I to IV). Hypersensitivity reactions are believed to develop in 0.6 to 10 percent of patients who use these agents. Immediate hypersensitivity reactions are believed to occur less frequently and result in less morbidity with oral penicillin than with parenteral administration of penicillin. There are four reported fatalities related to oral penicillin use compared with approximately 100 to 300 deaths per year from parenteral penicillin.

The risk of hypersensitivity reactions to cephalosporins in patients with known penicillin allergies is an issue of clinical importance. The overall incidence of adverse reactions to cephalosporins is low (between 1 and 10 percent) and mostly limited to dermatologic reactions. Adverse reactions to cephalosporins occur in approximately 4 percent of non-penicillin-allergic patients and 8 percent of patients with penicillin allergies. Severe hypersensitivity reactions are reported to have an incidence of less than 0.02 percent in the general population and less than 0.04 percent in patients with penicillin allergies. A recent review concludes that cross-reactivity between penicillins and cephalosporins is low (approximately a twofold increase over the general population) and probably only significant between first-generation cephalosporins and penicillin.[5] Administration of cephalosporins to penicillin-sensitive patients is possible but should be done with caution and avoided in patients with a history of severe penicillin hypersensitivity reaction (airway compromise, bronchospasm, or hypotension).

Hoingne's syndrome, which is another "reaction" seen with use of penicillin, is believed to be related to rapid absorption of procaine. The syndrome consists of behavioral abnormalities, including headache, hallucinations, sensation of impending doom, acute psychosis and, rarely, seizure after intramuscular injection of procaine penicillin. Most symptoms are self-limited and resolve within 30 min.

Penicillins and the b-lactam agents may result in significant adverse CNS effects. Confusion, agitation, myoclonic jerking, and seizures have been reported with high-dose penicillin G (more than 20 to 30 million U/day), cephalosporins, and imipenem. Encephalopathy, agitation, and absence seizures have been reported with ceftazidime. CNS effects of penicillins and b-lactam agents are believed to result from antagonism of the g-aminobutyric acid (GABA) receptor. Patients most at risk for adverse CNS effects during b-lactam therapy are those with renal failure, with underlying CNS abnormalities, or receiving high-dose therapy.

Penicillins and b-lactam agents have the potential to impair hemostasis. Hypoprothrombinemia has been reported with several b-lactam agents (cephalothin, cephazolin, moxalactam, cefoperazone, and cefotetan).[6] These agents may decrease the production of the vitamin K-dependent coagulation factors by decreasing vitamin K absorption from the gastrointestinal tract, by interfering with vitamin K metabolism, and/or through direct enzymatic inhibition of coagulation factor activation. Qualitative and quantitative platelet disorders have also been reported with b-lactam agents. Penicillin, ampicillin, moxalactam, carbenicillin, ticarcillin, piperacillin, mezlocillin, and nafcillin have all been reported to decrease platelet aggregation and increase bleeding time in a dose-dependent manner. The absolute risk for clinically important bleeding with penicillins and b-lactam agents is not well established, but patients with renal failure and preexisting coagulopathy appear to be at greatest risk.

Dermatologic reactions are common with penicillins and include mild and severe eruptions. Cephalosporins and aminopenicillins (ampicillin and amoxicillin) are the b-lactam agents that account for most cases of the severe skin eruptions (i.e., SJS and TEN). An interesting but not well-understood erythematous, maculopapular rash is associated with ampicillin use in infectious mononucleosis. The rash has been reported in 69 to 100 percent of infectious mononucleosis cases treated with ampicillin. Typically, the rash appears 5 to 14 days into therapy and resolves with cessation of ampicillin. Recently, a similar rash has been reported with cephalexin use in a patient with mononucleosis.[7]

Aminoglycosides

Animoglycosides are bactericidal agents that bind to the 30 S bacterial ribosome and inhibit protein synthesis. Agents include gentamicin, tobramycin, amikacin, kanamycin, streptomycin, spectinomycin, and netilmicin. Aminoglycosides have a low therapeutic to toxic ratio, with ototoxicity and nephrotoxicity being common adverse effects. All aminoglycosides have the potential to damage vestibular and cochlear sensory cells, but neomycin is by far the most ototoxic. The incidence of hearing loss related to aminoglycoside has been reported to be between 2 and 25 percent. Hearing loss correlates closely with high-dose or prolonged therapy. Nephrotoxicity results from damage to the proximal renal tubules and correlates with drug dose, therapy duration, volume status, and extremes of age. Mild renal insufficiency may result in 10 to 25 percent of patients using aminoglycosides, as reflected in elevations in serum creatine. Renal damage is largely reversible with cessation of therapy, but renal function should be monitored closely during therapy.

An interesting adverse effect of aminoglycoside use is possible neuromuscular blockade. The aminoglycosides are believed to inhibit the release of acetylcholine presynaptically and block binding postsynaptically. Myasthenia gravis patients appear to be at greatest risk for weakness related to aminoglycoside usage due to a potential curare-like effect, but apnea has been reported in neurologically normal individuals after they have received intraperitoneal neomycin. Aminoglycosides may also prolong the effects of the non-depolarizing paralytic agents.

Sulfonamides/Bactrim

The sulfonamides are bactericidal agents that inhibit folic acid synthesis in bacteria. Sulfonamides are para-aminobenzoic acid (PABA) analogues and competitively inhibit the enzyme dihydropteroate synthetase in the folate synthesis pathway. Available sulfonamides include sulfisoxazole and sulfamethoxazole. Sulfonamides have a high incidence of bacterial resistance, and today the most widely used sulfonamide is sulfamethoxazole in combination with trimethoprim (Bactrim, Septra, Sulfatrim, or Cotrim). Trimethoprim also inhibits folate synthesis by inhibiting the activity of bacterial dihydrofolate reductase and produces a synergistic bactericidal effect with sulfonamides.[8] TMP-SMX has become one of the most important drugs in preventing opportunistic infections in HIV-positive individuals.

Sulfonamides have a relatively high incidence of adverse drug reactions, including immediate hypersensitivity, serum sickness, gastrointestinal irritation, dermatologic reactions, photosensitivity reactions, and hematologic abnormalities. Adverse drug reactions related to TMP-SMX are more common in HIV-positive individuals, with an incidence reported to be as high as 40 to 60 percent. Cutaneous reactions to sulfonamides and TMP-SMX are placed at approximately 3.4 percent in hospitalized patients. As previously stated, sulfonamides and TMP-SMX account for the greatest incidence of drug-related SJS and toxic epidermal necrolysis (4.5 cases per million users of the drug per week). Hematologic disorders seen with sulfonamides include aplastic anemia, agranulocytosis, hemolytic anemia, and thrombocytopenia. Patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency should not receive sulfonamides or TMP-SMX secondary to an increased risk for hemolytic anemias. TMP-SMX should be used with caution in patients with impaired renal function, because trimethoprim interferes with potassium excretion

from the kidney.

Macrolides

Macrolides are bacteriostatic agents that bind to the 50 S ribosome and inhibit bacterial protein synthesis. Available agents include erythromycin, azithromycin, clarithromycin, and dirithromycin. Macrolides rarely cause hypersensitivity reactions, but adverse effects of macrolide use include gastrointestinal irritation, reversible ototoxicities, pancreatitis, and cholestatic hepatitis.

The most important adverse reaction reported with macrolide use is cardiac dysrhythmias associated with erythromycin and possibly clarithromycin. Erythromycin-related polymorphic ventricular tachycardia (torsades de pointes) has been well documented in two clinical situations: (1) after intravenous erythromycin administration and (2) when oral erythromycin is taken with specific drugs (astemizole, terfenadine, and cisapride).

Erythromycin can prolong action potential duration and delay repolarization. Clinically, this is witnessed by prolongation of the QT interval. The mechanism of this QT prolongation is believed to be erythromycin blockade of the selective delayed rectifier potassium current in Purkinje fibers. Recently, prolongation of the QT interval and torsades de pointes was also reported with clarithromycin.[9]

Erythromycin and clarithromycin inhibit cytochrome P-450, which can lead to increased serum levels of astemizole, carbamazepine, cisapride, corticosteroids, cyclosporine, digoxin, terfenadine, theophylline, warfarin, valproate, and ergot alkaloids. Cases of torsades de pointes have occurred with coadministration of erythromycin and the antihistamines astemizole and terfenadine. It is believed that increased drug level of these antihistamines is responsible for prolongation of the QT interval. Recently, prolonged QT interval and ventricular dysrhythmias have also been reported with coadministration of clarithromycin and with cisapride. [10] Azithromycin does not inhibit the P-450 system and, to date, has not been linked to ventricular dysrhythmias.

Fluoroquinolones

The fluoroquinolones are bactericidal agents that inhibit bacterial DNA gyrases. Available agents include ciprofloxacin, enoxacin, levofloxacin, lomefloxacin, norfloxacin, ofloxacin, sparafloxacin, and trovafloxacin. Children under the age of 18 and pregnant women should not use fluoroquinolones, because of the potential for cartilage abnormalities. The fluoroquinolones are generally considered safe, with gastrointestinal irritation being the most commonly reported side effect. Fluoroquinolones are weak GABA inhibitors, and adverse CNS effects may include behavioral abnormalities, visual changes, dizziness, and seizures. [11] Photosensitivity reactions have been reported, and rarely fluoroquinolone use may result in renal insufficiency or hepatic toxicity.

Tetracyclines

Tetracyclines are bacteriostatic agents that inhibit bacterial protein synthesis through binding to the 30 S ribosome subunit in bacteria. Available agents include demeclocycline, doxycycline, minocycline, and tetracycline. Tetracycline use may result in adverse reactions that include photosensitivity reactions, discoloration of dentition in children, gastrointestinal irritation, lupus-like syndromes, renal insufficiency, and hepatic toxicity. [12] Tetracyclines are among the most frequent causes of phototoxic drug reactions. The phototoxic potential is greatest with demeclocycline and doxycycline, and least with minocycline. [13]

Tetracycline complexes with calcium and is deposited in teeth and bones. Children are at risk for permanent dental discoloration from tetracycline up to the age of 8, with the highest incidence occurring before 6 months of age. The degree of discoloration appears to be dose related. Tetracyclines should not be used in pregnancy, because they cross the placenta and permanent dental discoloration may result in children born to tetracycline-treated mothers.

Vancomycin

Vancomycin is a bactericidal agent that interferes with bacterial cell wall synthesis. In addition to hypersensitivity reactions, vancomycin use may result in an urticarial, erythematous, flushed rash termed redman syndrome. The rash is typically on the face but may also involve the trunk and extremities. Transient tachycardia and hypotension have also been noted in some cases. Red-man syndrome is most often related to rapid infusion of parenteral vancomycin, but there are case reports with oral and intraperitoneal vancomycin.[14] The reaction is believed to result from histamine release. Termination of vancomycin infusion, fluids, and H_1 antagonist may help in the acute episodes, and extending the time of vancomycin infusion or H_1 blockers can help prevent this reaction with future vancomycin doses.

Vancomycin may also result in nephrotoxicity and ototoxicity. Patients with renal insufficiency or who are using other nephrotoxic drugs (e.g., aminoglycosides or amphotericin B) are at increased risk for vancomycin-induced renal damage. Ototoxicity is rare at therapeutic doses of vancomycin, but hearing defects may result at high doses and in patients with renal insufficiency.

Chloramphenicol

Chloramphenicol is a bacteriostatic agent that binds to the 50 S ribosome of bacteria and inhibits protein synthesis. Despite broad antimicrobial activity, chloramphenicol is rarely used in the United States secondary to potential adverse effects at therapeutic doses. Chloramphenicol may result in hypersensitivity reactions, neurologic abnormalities, and hematologic toxicity. The most notorious is a symptom complex of vomiting, poor sucking, cyanosis, and diarrhea in neonates and children. The syndrome (gray baby syndrome) is seen after several days of high-dose chloramphenicol administration and often progresses to obtundation, palor, hypotension, hypothermia, and death. The toxicity of chloramphenicol in neonates is believed to result from inability to metabolize the drug.

Chloramphenicol is responsible for two types of hematologic toxicity: the most common is reversible myelosuppression, and the second is aplastic anemia. Reversible bone marrow suppression appears to be related to mitochondria injury in bone marrow. This inhibition is reversed with cessation of use of the drug. Aplastic anemia is a rare complication, occurring in from 1:24,000 to 1:40,500 recipients of the drug. The mechanism of toxicity is hypothesized to be a toxic metabolite resulting in stem cell damage.[15] Aplastic anemia with chloramphenicol is not dose related and does not typically resolve with cessation of the drug.

Antimycobacterial Drugs

Infection with *Mycobacterium tuberculosis* (tuberculosis or TB) is common in developing countries, and during 1990s there was an increased incidence of TB in the United States. Patients being treated for active TB as well as patients taking chemoprophylaxis for positive purified protein derivative (PPD) skin tests are now commonplace in many urban emergency departments. First-line therapy for TB includes isoniazid (isonicotinylhydrazide or INH), rifampin, pyrazinamide, ethambutol, and streptomycin.

Antimycobacterials may have adverse effects at therapeutic doses. Rifampin may result in gastrointestinal distress, flulike symptoms, hepatic toxicity, renal toxicity, and various dermatologic reactions. Rifampin is also noted for a nontoxic orange-red discoloration of skin, mucous membranes, urine, semen, and tears. Pyrazinamide is the most hepatotoxic of the first-line TB medications and also inhibits the excretion of urate, with acute episodes of gout possible secondary to therapy. Adverse effects of ethambutol include gastrointestinal irritation, optic neuritis, headache, behavioral changes, pruritis, and joint pain. Optic neuritis is manifested by the loss of green-red differentiation and is usually reversible with termination of therapy.

INH   In addition to treating active TB, INH is also used for chemoprophylaxis in patients with positive PPD tests. INH has important adverse effects, including hepatic toxicity and neurotoxicity, at therapeutic doses. Approximately 10 to 20 percent of patients who use INH for chemoprophylaxis will have elevation in serum transaminases and 1 percent will develop overt hepatitis. [16] Patients should have the serum transaminase level evaluated frequently, and therapy should be terminated if the level is elevated two to three times above normal.

Neurotoxicity includes paresthesias, ataxia, obtundation, optic neuritis, behavioral abnormalities, peripheral neuropathies, and seizures. INH inhibits production of the neurotransmitter GABA. Seizures related to INH are believed to result from decreased levels of GABA and are most commonly seen after acute overdoses or in patients who have underlying seizure disorders. INH forms hydrazones with pyridoxine (vitamin B_6), which causes pyridoxine deficiencies. Peripheral neuropathies are believed to result from pyridoxine deficiencies, and supplementation with pyridoxine may relieve symptoms.

Acute INH ingestion of more than 20 to 30 mg/kg may cause seizures that are refractory to standard anticonvulsive therapy (benzodiazepines, barbiturates, etc.). Most INH-induced seizures occur within 2 h of overdose, and patients who remain asymptomatic for 6 h are safe for medical clearance. INH ingestion should be entertained in any patient presenting with refractory seizures. INH seizures are treated with pyridoxine (vitamin B_6). The dose is a gram-for-gram equivalent to the amount of INH ingested. For patients who ingest an unknown quantity of INH, the recommended dose of pyridoxine is 5 g intravenously over 3 to 5 min.

Antimalarial Drugs

Antimalarials are not used in the United States as frequently as other antimicrobials; however, they are among the agents with the greatest potential for toxic effects. Common agents include quinine, chloroquine, mefloquine, and primaquine. Adverse effects associated with quinine at therapeutic doses include *cinchonism,* which is the symptom complex of ringing in ears, headache, visual disturbance, and nausea. Chloroquine, quinine and, to lesser extent, primaquine may be associated with ventricular dysrhythmias. Primaquine and chloroquine have been associated with methemoglobinemia. Hemolytic anemia is also reported with quinine, primaquine, and chloroquine in patients with G6PD deficiency. CNS effects associated with the antimalarials include headache, visual disturbances, dizziness, seizures, and behavioral changes. Mefloquine use results in greater neuropsychiatric reactions than the other antimalarials and has been associated with acute psychotic reactions.

Quinine and chloroquine may both result in severe CNS and cardiac abnormalities in acute overdose. CNS manifestation of toxicity includes obtundation, headache, and seizures. Quinine also has significant ocular toxicity in acute overdose, and blindness may result with serum levels of greater than 10 to 15 μg/mL. Possible electrolyte abnormalities include hypoglycemia with quinine and hypokalemia with chloroquine. Both drugs have cardiac effects and may lead to PR, QT, or QRS prolongation. Patients may be hypotensive, with early cardiovascular collapse. Aggressive supportive care is used for overdose. [17] A decreased mortality rate has been demonstrated in chloroquine overdose treated with early intubation, gastric lavage, deep sedation with benzodiazepines, and vasoactive pressor support with epinephrine to maintain a systolic blood pressure of 100 mmHg. [18] Sodium bicarbonate (to adjust serum pH of 7.45 to 7.50) may be helpful in treating dysrhythmias related to the sodium-channel blockade from quinine and chloroquine, although good data do not exist to support its use.

Metronidazole

Metronidazole is effective for treating anaerobic bacteria, *Trichomonas,* and anaerobic protozoal parasites. Adverse effects of metronidazole use include gastrointestinal distress, CNS toxicities, stomatitis, and disulfiram-like reactions. CNS toxicities include headache, paresthesias, behavioral changes, vertigo, and seizures. Disulfiram-like reactions are common with metronidazole, and all patients should be warned not to drink alcohol.

Antiviral and Common HIV Medications

Current treatment for human immunodeficiency virus (HIV) and the resulting acquired immune deficiency syndrome (AIDS) requires patients to take multidrug regimens to prevent progression of their disease and to treat opportunistic infections. HIV therapy has grown complex over the past several years with the introduction of new therapeutic agents and evolving recommendations for prophylaxis against opportunistic infections. Drugs used to decrease the HIV load in the body include nucleoside analogues (zidovudine, lamivudine, etc.), nonnucleoside reverse transcriptase inhibitors (nevirapine and delaviridine), and protease inhibitors (indinavir, ritonavir, etc.). Adverse effects seen with the antivirals include nausea, malaise, gastrointestinal irritation, myalgias, neurologic abnormalities, and bone marrow suppression. Neurologic abnormalities include headache, peripheral neuropathy, and seizure. In acute overdose, there is little experience with many of the new antiviral agents. Zidovudine (AZT) overdose has resulted in seizure, but major morbidity or deaths have not been reported.

Antimicrobial agents used against opportunistic infections are numerous and a comprehensive review is beyond the scope of this chapter; however, several agents warrant mention. TMP-SMX to treat and prevent *Pneumocystis carinii* pneumonia (PCP) has a 40 to 60 percent incidence of cutaneous reactions in HIV-positive patients. Parenteral pentamidine also used against PCP may result in nephrotoxicity, hepatic toxicity, hypoglycemia secondary to pancreatic necrosis, hypotension, and ventricular tachycardia at therapeutic doses. [19] Dapsone, a second-line agent for PCP and toxoplasmosis, may have significant adverse effects at therapeutic doses and in overdose: its use may result in headache, nausea, rash, neuropathy, and seizures. The two most important adverse effects of dapsone use are methemoglobinemia and hemolysis. Hemolysis is most common with patients who have G6PD deficiency.[20]

EVALUATION AND TREATMENT OF ANTIMICROBIAL OVERDOSE

Most antimicrobial overdoses will be asymptomatic; however, significant ingestions of agents such as INH, chloroquine, and quinine can result in severe toxicities. Patients who present with symptomatic ingestions (altered mental status, seizure, electrolyte disturbances, anion-gap acidosis, or renal failure) should be treated with supportive care using emergency medicine principles. The history should include the amount and type of antimicrobial ingested. Patients should also be asked about possible coingestants. Suicide potential should be assessed.

Asymptomatic antimicrobial ingestions require minimal laboratory evaluation. As is common in all cases of possible overdose, patients should have acetaminophen levels determined and an electrocardiogram performed to screen for coingestants. Emergency medicine and critical care principles should guide laboratory evaluation in symptomatic overdoses. The electrolyte level should be determined to evaluate potential anion-gap acidosis in cases of suspected INH overdose. Methemoglobin levels should be determined in dapsone, chloroquine, and primaquine overdoses. Drug levels are not helpful in the management in the acute antimicrobial overdose but may be confirmatory and are available for several antibiotics (INH, quinine, and chloroquine).

Gastric decontamination should be initiated in all patients with suspected antimicrobial overdoses. Activated charcoal with the cathartic sorbitol should be given orally or through a nasogastric tube. Repeat-dose activated charcoal without sorbitol is indicated in symptomatic patients. Dialysis and charcoal hemoperfusion are effective at eliminating aminoglycosides and possibly pentamidine but are not highly effective at removing other antimicrobial agents.

181 HAZARDOUS MATERIALS EXPOSURE

Suzanne R. White
Col. Edward M. Eitzen, Jr.

A *hazardous material* can be defined as any substance (chemical, nuclear, or biologic) that may pose a risk to health, safety, property, or the environment. There are currently over 500,000 potentially toxic chemicals and compounds listed in the most commonly used poisoning database, Poisindex, and it is estimated that 600 new chemicals are introduced yearly into the workplace. Given the quantity (1.5 billion tons per year) and frequency of transport (500,000 shipments per day) of hazardous substances throughout the United States, it seems inevitable that the practicing emergency physician will be faced with the management of a chemically exposed or contaminated patient.[1]

The Hazardous Substances Emergency Events Surveillance (HSEES) database registered 5531 hazardous chemical accidents during 1997.[2] Petroleum products, which account for approximately 50 percent of hazardous materials spills, were not included, and this reporting included only 13 states. Similar registries such as Chemtrec and the National Response Center logged over 13,000 and 25,000 hazardous oil and chemical incidents, respectively, during that same time period.[3] Eighty percent of events occur at fixed facilities, while 20 percent are transportation-related, and over 10 percent occur within hospitals and schools. Seventy percent of hazardous materials accidents occur Monday through Friday 6 A.M. to 6 P.M.[4] Incidents typically result in one or two victims, usually employees and less frequently the general public and first responders. Of the 10 to 30 percent of incidents that involve victims, traumatic injury is common.[5,6] Nontraumatic injuries most commonly include respiratory and eye irritation, nausea, vomiting, headache, dizziness, or other neurologic effects. Sixty-five percent of fatalities following a hazardous materials incident result from trauma, 22 percent from burns, and 10 percent are attributed to respiratory compromise. Most injuries and deaths are associated with exposure to chlorine, ammonia, nitrogen fertilizer, or hydrochloric acid. Other commonly involved chemicals include petroleum products, pesticides, corrosives, metals, and volatile organics. Unknown or unclassified chemicals constitute a full 25 percent of events.[7]

As indicated by the recent World Trade Center, Oklahoma City, 1996 Summer Olympics site, and abortion clinic bombings, along with the use of *Salmonella, Shigella,* and cyanide to taint food and pharmaceuticals in this country, state-sponsored or terrorist use of readily available hazardous substances has become a reality. Materials used in a terrorist event may be nuclear, biologic, or chemical and are referred to as *NBC agents* or *weapons of mass destruction* (WMD). During the 1995 release of sarin in the Tokyo subway system, 5510 people sought medical attention. Six hundred and forty chemically contaminated patients arrived by private conveyance within the first few hours of the incident to a single health care facility. Twenty-three percent of emergency department (ED) staff at that hospital became secondarily poisoned as the nerve agent was transported via contaminated victims from the scene.[8,9]

Chemical disasters, whether they be at industrial fixed-facility sites, transportation-related, or terrorist-mediated, share many features. They may involve mass casualties with serious concomitant injuries, such as trauma, burns, or smoke inhalation, that outstrip medical resources. Communication breakdown is prevalent, as is chaos among medical personnel who are unfamiliar with the agents involved, unaware of available resources, or have become secondarily contaminated. The need for emergency community and medical preparedness to mitigate the adverse consequences of such hazardous materials accidents cannot be overly stressed.

PLANNING

The hospital and ED have the following responsibilities when planning for hazardous materials exposure: (1) identify any potential local hazards, (2) recognize that a hazardous material is involved, (3) identify the agent involved, (4) obtain information about the toxicity and secondary contamination potential of the agent, (5) protect hospital personnel, other patients, and the facility itself from secondary contamination and loss of serviceability to other patients, (6) triage and decontaminate victims, (7) stabilize and treat the injured, and (8) protect the community from secondary contamination. One excellent resource for designing such procedures is the ATSDR *Medical Management Guidelines for Acute Chemical Exposures.*[10] Chapter 5, Disaster Medical Services, covers planning in detail.

ADVANCE INFORMATION RETRIEVAL

Detailed information about the involved chemical(s) is most helpful if received prior to patient arrival. Regional poison control centers (PCCs) are already integrated into the emergency medical, HazMat, and Metropolitan Medical Response Systems (MMRS).[11,12] Another information resource is the Material Safety Data Sheet (MSDS), a document that identifies health and safety information for any product containing hazardous chemicals. MSDSs may be obtained by facsimile from the work-site employer or safety officer, regional PCCs, Chemtrec, NRC, the Internet, and computer databases such as Safetydex™. Included are chemical and physical hazard data as well as information regarding safe use, handling, and storage. Basic first aid procedures are outlined, but advanced medical information usually is not included. While the merit of MSDSs has been questioned,[13] at the least they will assist with correct identification and spelling of the chemical agent(s) involved. Limitations of MSDSs use are that they may not exist for all toxic substances, they are not always comprehensive with regard to ingredient listing or toxicity data, they may not be up to date, ingredients listed as "inert" may be toxic, and "trade secret" ingredients may be deleted (although trade secret toxicity data must be listed, and the treating physician is entitled to immediate identity on request). Other resources that may assist with hazard identification determination of toxicity are listed in Table 181-1.

TABLE 181-1   Aids in Chemical Identification and Hazard Determination

DECONTAMINATION ZONES

Patient decontamination should occur outside the hospital. Hot, warm, and cold zones should be established and cordoned off with brightly colored tape. The hot zone is the area of the spill or chemical release (at the scene) or the hospital area where arriving patients with no prior decontamination are held. Therefore, only those trained and properly attired may enter. Only the most immediate life threats are addressed in the hot zone (opening of the airway, cervical spine immobilization, brushing off of gross contaminants, and applying pressure to stop arterial bleeding). The warm zone is an area where thorough decontamination and further medical stabilization occur. Theoretically, this area poses no risk of primary contamination (direct exposure to the toxin), but secondary contamination (transfer of the toxic material from the victim to personnel or equipment) may still occur. Access, therefore, is also restricted, and the use of protective clothing is required. The cold zone is the area to which fully decontaminated patients are transferred. There is no personnel flow between hot/warm or warm/cold areas.

Personal Protection

The various levels of personal protection are levels A through D. Level A attire [fully encapsulating chemical-resistant suit and self-contained breathing apparatus (SCBA)] is recommended when the highest level of eye, mucous membrane, skin, and respiratory protection is needed. Lower levels of protection include level B (splash protection with chemical-resistant clothing and a SCBA) and level C (splash protection with chemical-resistant clothing and a full-faced air-purifying respirator). Level D protection is a standard work uniform and includes firefighter bunker gear. Military mission-oriented protective posture (MOPP) level IV gear, comprised of an air-purifying respirator, protective mask, hood, charcoal-impregnated suit, and butyl rubber gloves and boots, affords effective protection against the biochemical weapons of mass destruction.

While level A protection is recommended by National Institute of Occupational Safety and Health (NIOSH) and the Environmental Protection Agency (EPA) in situations where the concentration or identity of toxins involved is unknown (i.e., most hazardous materials incidents), there is no consensus regarding the level of protection needed for the hospital decontamination of patients. This is particularly controversial with regard to nontraditional hazardous threats such as WMD. Only limited patient care can be rendered while wearing level A gear, and air availability restricts its use to only short periods of time. Furthermore, specialized protective gear is only recommended for those with prior training and fitting, given the added level of physical and heat stress and false sense of security that its use may render. Despite these limitations, if level A protection is to be used by the emergency staff, it is recommended that the hospital coordinate equipment acquisition with the local fire departments or HazMat team so that regulator fittings (replacement air bottles) are interchangeable. Practically speaking, most hospitals have only level C protection available to employees. Ideally, persons responsible for selecting the personal protective equipment and decontamination process should be trained to the first responder operations level under OSHA 29 CFR 1910.120.

TRIAGE

The first wave of minimally exposed victims arrives within 30 min of the incident, overwhelming the ED and impeding the care of patients who will arrive later. [14] ED triage must be efficient and should occur outdoors. *First and foremost, the patient should not be allowed to enter the ED.* Second, those personnel who are not in an appropriate level of protective gear should not be allowed in the triage/decontamination area. The incoming ambulance or ambulatory patients should be met by a triage officer, an individual in appropriate level of personal protective gear, to determine whether decontamination has been performed and, if so, its adequacy. The most difficult situations involve those victims who are seriously injured and who have bypassed the field decontamination procedure. A management dilemma is created between immediate medical treatment and decontamination. While the appropriate response varies depending on the chemical(s) involved, many situations involve unknown chemicals and therefore unknown risk to personnel. It is always prudent to err on the side of decontamination before treatment in unknown situations. Examples of those substances with little or no risk of secondary contamination include gases, vapors, and substances with no serious toxicity or skin absorption. Patients exposed to gases or vapors only, with no symptoms other than respiratory irritation and no signs of condensation of vapor on the clothing, do not require decontamination beyond clothing removal. This may not hold true, however, for large numbers of victims exposed to nerve agent vapor or for those in confined spaces. Substances with high risk of secondary contamination include highly toxic substances that are readily absorbed dermally, radioactive agents, and certain biologic agents.

DECONTAMINATION

Outside portable decontamination systems include portable showers, large inflatable heated tents, or a series of kiddy pools with privacy screens. Effluent must be contained, and disposable equipment should be used wherever feasible. Suggested equipment for outdoor hospital decontamination is listed in Table 181-2. Decontamination inside the hospital should only be done in a designated room with a separate entrance, separate ventilation, and separate water drainage systems.

TABLE 181-2   Suggested Equipment for Outdoor Hospital Decontamination

The goal of decontamination is to decrease the absorbed dose for the victim and prevent secondary contamination of health care providers. Clothing should be removed quickly because this is thought to accomplish 80 percent of the decontamination. Those covered with particulate or radioactive matter should remove clothing very carefully by the roll-down method. Further particulate matter should be brushed away prior to showering, since interaction of some dry chemicals with water may produce heat. All clothing should be double bagged and treated as toxic waste. All patients' belongings and waste must be accounted for by a tracking log. Jewelry and valuables should be bagged separately from clothing, which may require disposal.

While undergoing decontamination, the nonambulatory patient should have a patent airway ensured, the cervical spine immobilized, oxygen administered, ventilation assisted, and pressure maintained on arterial bleeding. Further medical care, such as intubation or intravenous line insertion, is delayed until gross decontamination

has been completed and the patient has been transferred to the cold zone. Ocular exposures take precedence and should be treated first with immediate eye irrigation. Ideally, this should have begun in the prehospital phase. Wounds are the next decontamination priority and should be irrigated, debrided of gross contaminants, and then covered with a water-occlusive dressing to prevent recontamination during subsequent showering. Whole-body decontamination should begin with the head and proceed downward. Along with the hands, the face and head generally are the most heavily contaminated areas and should be washed or shampooed in the head-back position to avoid runoff onto other body parts and incorporation of toxic material. This may best be accomplished initially in the sitting position, prior to showering. Most agents are readily removed with copious amounts of water and a mild soap, shampoo, or detergent. Tincture of green soap has been recommended by some based on its small concentration of ethanol that enhances dissolution of certain agents such as hydrocarbons. Typically, 3 to 5 min of showering is recommended, although 15 min may be required for concentrated, strongly alkaline materials or oily, adherent substances. The use of abrasives, such as corn meal or scrub brushes, is generally not advised, since abrading the skin may increase toxin absorption. New amphoteric decontamination solutions, such as Diphoterine, for specific acid, base, solvent, oxidizer, and reducing agent exposures are under investigation. Water temperature should be tepid, since heat potentially will increase dermal absorption of some toxins.

Certain agents may be removed more effectively with the use of specific decontamination solutions. Dilute household bleach solutions (9 parts water to 1 part bleach) will inactivate nerve agents and most biologic agents. The use of neutralizing solutions for acid or alkaline corrosives is controversial. Other agents requiring targeted decontamination solutions include phenol and hydrofluoric acid and are discussed below. One should not delay decontamination if such solutions are not readily available but rather begin washing with deluge volumes of water in an attempt to prevent toxin absorption through massive dilution.

Certain metals such as sodium, lithium, and potassium react violently with water, releasing heat, hydroxide ion, and hydrogen gas and potentially causing thermal burns. Proper treatment of alkali metal burns involves clothing removal, covering the affected area with mineral or cooking oil, followed by removal of any remaining metal with dry forceps. Only then can wounds be copiously irrigated with water. Burning fragments should be extinguished by smothering or with a class D fire extinguisher. Again, in the absence of proper solutions, decontamination with deluge volumes of water may be considered. Other water-reactive chemicals are listed in Table 181-3. In contrast to water-reactive chemicals, white phosphorus ignites spontaneously on exposure to air. Burns from this agent must be kept continuously moist with water or saline dressings until adequate debridement is accomplished. Each phosphorus particle must be removed. The application of copper sulfate solution blackens the phosphorus, aids in visualization, and provides neutralization. Alternatively, a Wood's lamp may be used. Some adherent toxins are extremely difficult to remove from the skin. Epoxy resins and cyanoacrylates (glues) may be removed by swabbing with acetone. Use of vegetable or mineral oil or saline-soaked gauze pads for the eyes and mucous membranes is safe. Hot tar, typically inflicting burns to the face and upper extremities, should be allowed to cool prior to removal. Effective tar removal has then been reported using Neosporin cream, Tween 80, plain Vaseline, Shur Clens, Desolv-It, or mayonnaise. No attempt should be made to remove tar by mechanical means, since this may increase tissue destruction and result in hair follicle loss.

Acetic anhydride, acetyl chloride
Alkali metals: lithium, sodium, potassium (also form caustic sodium and potassium hydroxides)
Calcium
Chlorosulfonic acid
Concentrated sulfuric acid (oleum), concentrated muriatic acid
Dry lime (calcium oxide), calcium carbide
Hydrides: boranes, silanes
Inorganic chlorides (some): titanium tetrachloride peroxides
Organometallics: alkylaluminums
Zinc phosphide

TABLE 181-3 Water-Reactive Substances

Nausea and vomiting are common following chemical exposures. These symptoms may indicate toxin ingestion with gastrointestinal irritation or, more commonly, systemic toxin effect or hysteria. Regardless of the cause, secondary contamination by toxic vomitus may occur, and the need for its containment should be anticipated. Furthermore, some materials may react with stomach acid to produce secondary poisoning through toxic gas formation (sodium azide®hydrazoic acid, cyanide salts®hydrogen cyanide gas). Suction with outdoor venting should be available. If spontaneous emesis has not occurred already, gastric emptying or the administration of charcoal may be considered for large ingestions. Induction of vomiting is not recommended. Following the accidental ingestion of a corrosive material, 4 to 8 oz of water may be administered, if the patient is conscious. Decisions regarding gastrointestinal tract decontamination may be guided by the regional PCC.

Following decontamination, zipping patients into body bags or placing them into hooded Tyvek suits prior to transport to the support zone is no longer recommended. This technique is not effective in minimizing the transfer of toxin to hospital staff and poses the risk of increased toxin absorption by the patient. The patient simply should be wrapped in clean blankets or sheets prior to transfer to the cold zone. [10]

Complete medical assessment and specific medical treatment can be carried out in the support zone (cold zone). ED personnel in this area should maintain protective gear (chemical-resistant gowns, latex gloves, eye protection) until the chemical has been definitively identified and the risk of secondary contamination is known.

SPECIFIC MEDICAL MANAGEMENT

Inhaled Toxins

Gases, mists, aerosols, fumes, or dusts may be inhaled. Determinants of airborne agent toxicity include many factors such as concentration of the inhaled toxin, duration of exposure, and whether the exposure occurred in an enclosed space. Other influencing factors include vapor density, allergic or nonallergic bronchospastic response, exertional state or metabolic rate of the victim, and unique host susceptibility such as the underlying reactive airways disease, history of smoking, or extreme age. Aspiration of gastric contents may cause further pulmonary insult.

Other primary determinants of injury pattern include toxin particle size and solubility in water. Those agents with particles diameters greater than 10 μm or that are highly water soluble are deposited primarily in the upper airways. Examples of water-soluble chemicals include ammonia, sulfur dioxide, and acid gases such as hydrochloric acid and sulfuric acid. Following exposure, signs of upper airway irritation develop rapidly and are accompanied by eye and mucous membrane irritation. Coughing, wheezing, or stridor may progress to upper airway obstruction in severe exposures. Those inhaled toxins of smaller particle size or lower water solubility such as phosgene, ozone, or nitrogen oxides will reach the lower respiratory tract and may result in delayed symptom onset. Gases with intermediate water solubility, such as chlorine, may cause early irritative symptoms following mild exposure or delayed pulmonary edema after massive exposure.

The presence of fire or explosion complicates the ability to predict patterns of illness following toxin inhalation. Because it is particulate, smoke carries adherent products of combustion such as acrolein, ammonia, acids, and diisocyanates deeper into the lungs than normally would be expected. Thermal physical damage to respiratory tract also may occur, particularly in the presence of steam. General management of the patient with toxic inhalation injury involves removal from the source, application of 100% oxygen, humidification if irritative symptoms are present, and inhaled bronchodilators for bronchospasm. A detailed examination should include inspection of the upper airway for evidence of singed nasal hair, soot in the oropharynx, facial or oropharyngeal burns, erythema or parching of the mucous membranes, stridor, hoarseness, dysphagia, cough, carbonaceous sputum, tachypnea, retractions, accessory muscle use, wheezing, rales, diaphoresis, or cyanosis. Early intubation should be considered for patients with upper airway edema. Pertinent laboratory studies include arterial blood gas analysis with carboxyhemoglobin, methemoglobin, and lactate levels; red blood cell (RBC) cyanide levels for persistent acidosis; electrocardiographic (ECG) monitoring; and chest x-ray. The role for diagnostic or therapeutic bronchoscopy in inhaled toxin exposure is controversial. Administration of sodium thiosulfate to victims of smoke inhalation with persistent acidosis who are suspected to have cyanide toxicity is indicated. Management of noncardiogenic pulmonary edema may involve the use of positive end-expiratory pressure or BiPAP, but diuretics generally are not indicated. The use of prophylactic steroids with antibiotics is reserved for nitrogen oxide exposures. Systemic toxicity from products of combustion such as cyanide or carbon monoxide is common and is reviewed in Chap. 182 and Chap. 198.

Many highly toxic gases produced in large quantities in the industrial sector are potential agents for malicious use. Those with a history of previous battlefield use or

stockpiling, such as phosgene, chlorine, or ammonia, are of particular concern. Their toxicology has been reviewed extensively elsewhere [15] and is summarized below.

Phosgene (CG, carbonyl chloride, D-Stoff, or green cross) is a gas with a density four times that of air. Once released, it forms a white cloud with a characteristic odor of newly mown hay. It is relatively water insoluble and therefore reaches the alveoli, where hydrolysis forms carbon dioxide and hydrochloric acid. Acylation of alveolar capillary membranes results in diffuse capillary leak and noncardiogenic pulmonary edema, which is delayed for up to 24 h. If the exposure is massive, immediate dyspnea and mucous membrane and eye irritation may occur. The onset of dyspnea or pulmonary edema within 4 h of exposure suggests a very poor prognosis. Those who become symptomatic greater than 6 h after exposure generally survive if intensive medical care is available. Recovery occurs in 3 to 4 days with respiratory supportive care and management of noncardiogenic pulmonary edema. Since exertion is known to increase pulmonary edema from phosgene, rest is mandatory for those exposed. Furthermore, a 24-h observation period with frequent reassessments is indicated, even if the patient is asymptomatic.

Chlorine is also widely available in the industrial sector, in the setting of paper manufacture, swimming pool chemical distribution, and municipal water treatment. This dense green-yellow gas has an acrid, pungent odor and is of intermediate water solubility. The formation of acids and oxidants on contact with moist membranes causes inflammation. Immediate ocular and upper airway irritation along with nausea and vomiting are seen following mild exposures. More significant exposure results in coughing, hoarseness, and pulmonary edema, usually within 12 to 24 h. Permanent reactive airways disease has been described following significant chlorine gas inhalation. Care is primarily supportive with the use of humidified oxygen and bronchodilators as needed. The role of nebulized sodium bicarbonate as a neutralizing therapy is controversial.

Nitrogen oxides are encountered in the form of silo gas, as products of fire combustion, in industrial processes, or as military smokes and obscurants. These oxides have limited water solubility and generally result in lower airway toxicity. Slow conversion of nitrogen oxide to nitric acid in the alveoli results in delayed alveolar injury and pulmonary edema. A triphasic illness typically is seen with initial dyspnea and flulike symptoms, transient improvement, and then worsening dyspnea, which heralds the onset of pulmonary edema 24 to 72 h after exposure. Methemoglobinemia also may occur. Bronchiolitis obliterans, a potential late complication, may be prevented by the use of steroids.

Ammonia is a highly water-soluble alkaline corrosive gas that rapidly reacts with wet surfaces to form ammonium hydroxide. The presence of ammonia is usually obvious based on its characteristic pungent odor and immediate induction of symptoms of mucous membrane, eye, and throat irritation. Bronchospasm, pulmonary edema, and residual reactive airways disease have all been described following massive exposures. Treatment is supportive with humidified oxygen and bronchodilators. Anhydrous ammonia is extremely hazardous to the eyes and can penetrate the anterior chamber within 1 min of exposure. Prolonged irrigation and a careful ophthalmologic examination are warranted, as outlined below under "Ocular Toxins."

Riot control agents (CS, CN or "mace," capsaicin or "pepper spray") are a group of compounds that cause transient noxious effects on exposure. Although generally considered to be only briefly incapacitating, fatalities from pulmonary edema have occurred following large exposures in confined spaces. Typically, symptoms include immediate irritation of the eyes and respiratory tract, blepharospasm, lacrimation, coughing, sneezing, and rhinorrhea, followed by a burning sensation of exposed skin and mucous membranes. Nausea, vomiting, headache, and photophobia may be seen. These symptoms usually disappear within a few hours after cessation of the exposure. Burns and sensitization of the skin have been described, especially if contact with the agent is prolonged. Long-term corneal damage is more likely to occur with CN than CS. Management includes removal of the patient from the area, copious irrigation of the eyes with normal saline, and skin decontamination with soap and water as indicated. Contact with water can briefly exacerbate skin symptoms from CS. The use of bleach solutions to decontaminate the skin may increase irritation or trigger blister formation from some agents. Patients with preexisting lung disease should be observed carefully for bronchospasm. [16]

NEUROTOXINS

Hydrocarbon inhalation results in early stimulatory effect followed by headache, dizziness, confusion, lethargy, stupor, or coma. Central nervous system (CNS) stimulants such as organophosphates or nitrophenols may cause seizures, agitation, excessive muscular activity, and hyperthermia. Simple asphyxiants such as nitrogen, carbon dioxide, natural gas, and argon also may produce dramatic CNS effect, especially if encountered in confined-space situations. High concentrations of these gases may displace oxygen and result in symptoms of hypoxia such as headache, dizziness, giddiness, nausea, confusion, collapse, hyperventilation, seizures, or even death. Treatment consists of the administration of 100% oxygen and removal from the environment. Large acute exposures to some substances may harbor long-term neurotoxicity. Examples include metals, carbon monoxide, hydrogen sulfide, methanol, ethylene glycol, and pesticides. Patients exposed to these agents will require close follow-up.

The most likely neurotoxins to be used maliciously are the nerve agents. Their toxicologic profiles have been reviewed extensively by Sidell [17] and are summarized below. Currently the most toxic chemical threats known, nerve agents were developed by the Germans around the time of World War II, placed in munitions, yet never employed on the battlefield. Despite the cessation of chemical synthesis for military use, precursors are commonly found in industry. Five organophosphorus compounds are recognized as nerve agents: tabun (GA), sarin (GB), soman (GD), GF, VX. GF is believed to be obsolete. Properties of these liquids vary in terms of vapor pressure, persistence in the environment, and potency, with VX being the most potent and persistent and sarin (GB) the most volatile. A potentially fatal exposure to VX involves a skin area of only 2 to 3 mm in diameter. The agents are mildly irritating with odors variably described as fruity (tabun), odorless (sarin, VX), or fruity/camphorous (soman).

The nerve agents are powerful inhibitors of acetylcholinesterase (AChE), found in nerve, skeletal muscle, and other tissues innervated by cholinergic neurons. Likewise, RBC cholinesterase and plasma pseudocholinesterase, found in RBCs and plasma, are inhibited and serve as laboratory markers of toxicity. The ability of nerve agents to interfere with normal acetylcholine hydrolysis at cholinergic synapses causes accumulation of this neurotransmitter and greatly enhanced neurotransmission. Excess acetylcholine at brain synapses, for example, results in seizures, coma and respiratory depression, and apnea. Acetylcholine accumulation at the motor endplate causes initial fasciculations with progression to weakness and paralysis. Overstimulation of sympathetic and parasympathetic ganglia of the peripheral nervous system results in tachycardia, hypertension, diaphoresis, miosis, lacrimation, salivation, bronchorrhea, bronchospasm, bradycardia, vomiting, diarrhea, and urination. Extremely high risk of secondary contamination is posed to physicians caring for exposed patients because these agents are readily absorbed by all routes.

The onset and type of symptoms are determined by both concentration and route of exposure to nerve agents. Following sarin vapor inhalation, death may occur within minutes. Likewise VX dermal exposure may cause death within minutes if the exposure is massive, but symptoms may be delayed for up to 18 h following milder dermal exposures. Vital sign abnormalities may result from stimulation of both the sympathetic and parasympathetic ganglia. While bradycardia is expected from stimulation of the parasympathetic nervous system, 90 percent of patients exposed to nerve agents have normal heart rates or are tachycardic. Vapor exposure typically creates a triad of ocular, nasal, and respiratory symptoms. The eyes and nose are most sensitive, with miosis, conjunctival injection, pain, and rhinorrhea developing at low doses. Respiratory effects such as chest tightness, dyspnea, and copious secretions are seen at higher concentrations. Neurologic findings such as giddiness, collapse, convulsions, fasciculations, and flaccid paralysis develop with severe exposures. Apnea resulting from central respiratory depression is a predominant cause of death. In contrast to vapor exposure, dermal exposure results in a unique pattern of early symptoms. Miosis may not be seen initially, but localized sweating and fasciculations will be noted surrounding the exposed area. Nausea, vomiting, diarrhea, and fatigue manifest with increasing dose. As with vapor exposure, respiratory and neurologic symptoms indicate severe toxicity.

Once a nerve agent release has been recognized, self-protection and patient decontamination take precedence over other medical treatment. The use of self-contained breathing apparatus is suggested, since neither surgical nor HEPA masks render protection from these agents. Even double latex gloves will be ineffective in preventing dermal exposure, and butyl rubber gloves are preferred. As stressed earlier, removal of patient clothing alone may provide significant decontamination. In addition, a 0.5% sodium hypochlorite solution (9:1 household bleach to water) will effectively inactivate these agents and should be followed with copious water irrigation. A considerable amount of VX may remain on the skin even after decontamination, and precautions should be taken to avoid secondary contamination.

Following decontamination, restoring oxygenation is the single most critical step in medical management. Succinylcholine, if used to facilitate intubation, may have prolonged effect because the plasma cholinesterase level is inhibited. Cardiac monitoring for dysrhythmias should be instituted. Specific antidote therapy with atropine and pralidoxime should be anticipated. Atropine blocks muscarinic receptors and reverses the parasympathetic findings of lacrimation, bronchorrhea, bronchoconstriction, salivation, and gastrointestinal spasm, along with some CNS manifestations. It does not affect the motor endplate or symptoms of fasciculations or weakness. The dose is best determined by signs, symptoms, and route of exposure (Table 181-4). The endpoint for dosing of atropine is drying of pulmonary secretions. Miosis is not a useful therapeutic endpoint, and tachycardia is not a contraindication to use of atropine. In contrast to organophosphate poisoning, continued atropine therapy generally is not necessary beyond 2 to 3 h following nerve agent exposure. Pralidoxime (2-PAMCl) also has antidotal efficacy against certain nerve agents via nucleophilic attack on those molecules phosphorylated to AChE. Subsequent liberation of the enzyme occurs along with detoxification of the

nerve agent. This ameliorates nicotinic, muscarinic, and CNS effects. Whereas atropine is not effective in treating neuromuscular findings such as weakness or fasciculations, 2-PAMCl will reverse these symptoms so long as "aging" of the enzyme has not occurred. Aging is the process whereby permanent inhibition of AChE activity occurs due to nerve agent alkyl group hydrolysis and covalent binding. This reaction, which occurs within 2 min of soman exposure and within 5 h of sarin exposure, provides a rationale for early 2-PAMCl therapy. Like atropine, PAMCl dosing in adults is determined by route of exposure and signs and symptoms (see Table 181-4). Unlike pesticide exposures, long-term or continuous infusions of 2-PAMCl have not been required. Seizures generally do not continue after ventilatory support, atropine, and 2-PAMCl therapy are instituted. If present, they should be treated aggressively with benzodiazepines, which have been shown to decrease neuropathologic lesions in animals exposed to nerve agents. Military Mark I autoinjector kits contain 2 mg atropine and 600 mg 2-PAMCl for immediate intramuscular administration in the field. The emergency physician should be familiar with this form of these antidotes, since these kits may be stockpiled for civilian use by MMRS throughout the United States. Symptomatic patients or those with dermal exposures should be kept under close observation for 24 h.

TABLE 181-4   Nerve Agent Symptoms, Severity, and Treatment Summary

TABLE 181-5   Dermally Adsorbed Agents Through Intact Skin Resulting in Systemic Toxicity

Acrylamide
Acrylonitrile, acetonitrile, propionitrile
Aniline
Chlordane
Dinitrophenol
Hydrocarbons: benzene, gasoline, toluene, toluene diisocyanate, xylene (all slowly absorbed)
Hydrogen cyanide, cyanide salts
Hydrogen fluoride (hydrofluoric acid)
Metals (organic mercury, thallium)
Methyl bromide
Methylene chloride (also)
Nerve agents
Nitrates
Nitrobenzene
Pesticides
Phenol
T3 toxin
Others: may be absorbed through abraded skin

Dermal Toxins

Factors that enhance the dermal absorption of toxins include the presence of wounds, defatting properties of the chemical (solvents), temperature (heat increases absorption), and high lipid solubility of the agent (organophosphate or organochlorine pesticides). Commonly encountered agents that may cause systemic toxicity via dermal absorption are listed in Table 181-5.

CORROSIVES   Local dermal injury from corrosive agents may be obvious immediately after exposure to mineral acids or may be delayed following exposure to alkaline corrosives or hydrofluoric acid. Alkaline burns (sodium hydroxide, cement) are most common. These agents tend to penetrate tissues and cause liquefaction necrosis. In general, injury to the skin is more extensive than that from acids, which coagulate proteins and do not penetrate tissues deeply. Acids may cause desiccation of the skin and form darkened areas or eschars. Treatment may involve prolonged irrigation or hydrotherapy of the area. The use of nitrazine paper to monitor pH may guide therapy. Contact with other substances may cause frostbite or freezing injuries to the skin, including liquid forms of phosphine, phosgene, ammonia, chlorine, ethylene oxide, hydrogen sulfide, and propane. Hydrocarbons such as gasoline may cause dermal burns or a defatting dermatitis.

PHENOL   Phenol and its derivatives, creosol, carboxylic acid, and the polycyclic phenols, cause intense cutaneous destruction. They are then rapidly absorbed through the skin and may produce CNS depression, hypotension, intravascular hemolysis, pulmonary edema, and hepatic and renal dysfunction. Theoretically, phenol absorption may be enhanced by small volumes of water. Deluge volumes of water, however, should remove the toxin safely. The burn area may then be lavaged or soaked for 5 to 10 min with gauze impregnated with polyethylene glycol (PEG 300 or 400). Glycerol or isopropanol may be substituted if PEG solutions are not available. Because phenol acts as a local anesthetic, pain may not be an appropriate indicator of ongoing tissue destruction.

HYDROFLUORIC ACID   Hydrofluoric acid is an aggressive substance commonly used in the semiconductor or glass-etching industry and also marketed for household use as a metal or brick cleaner, wheel brightener, and rust remover. Dermal contact with concentrations greater than 50% cause immediate throbbing pain, blanching, and blistering. Contact with lower concentrations causes no immediate symptoms but results in delayed pain, swelling, and potentially serious injury 8 to 24 h later. Accidents involving only 2.5 percent surface area exposure to concentrated forms may be fatal. Systemic absorption may result in malignant cardiac dysrhythmias, seizures, local tissue destruction, bone demineralization, hypocalcemia, hyperkalemia, and hypomagnesemia. Inhalation of hydrofluoric acid vapor is rare but may result in delayed fatal pulmonary edema. Overall management involves cardiac monitoring, intravenous calcium or magnesium administration as indicated, skin decontamination, topical application of calcium gluconate gel to the affected area, and narcotics for pain. Injection of calcium gluconate (never calcium chloride) into the affected area at a maximum of 0.5 mL/cm^2 of tissue may be considered for intractable pain to neutralize the fluoride ion. Since such infiltration may cause fingertip ischemia, intraarterial calcium through a radial arterial line has been recommended for digital burns (10 mL 10% calcium gluconate in 50 mL D$_5$W infused over 4 h). Hydrofluoric acid burns are often much more painful than the appearance of the wound would indicate, and persistent pain represents continuous injury. Newer decontamination solutions such as Hexafluorine are currently under evaluation. There is little data to support the instillation of calcium or magnesium solutions into the eyes.

Vesicants

The terrorist use of vesicants, or agents that produce blisters, would overwhelm the ED with patients presenting with severe dermal complaints. The toxicology of these agents has been reviewed extensively elsewhere and is summarized below.[18] Mustards are the most likely threat among this group, since over a dozen countries have mustard in their arsenals and they are the easiest of the chemical agents to synthesize. Mustards caused more casualties than all other chemical agents combined during World War I and were used again during the recent Iran-Iraq war. Sulfur mustard (H, HS, HD) is an oily liquid with an odor of garlic or mustard. The LD$_{50}$ is approximately 1.5 teaspoons, which can result in a 20 percent body surface area (BSA) burn. Mustards are alkylating agents that are highly reactive and electrophilic. They induce toxicity through immediate combination with peptides, proteins, RNA, DNA, and cell membranes. At low doses vesication occurs, whereas at higher doses systemic cytotoxicity is seen. Clinical effects are delayed for 4 to 8 h. Skin erythema progresses to blister formation over the next day. Warm, moist areas are affected most. Ocular findings are similarly delayed and include edema of the lid, conjunctival injection, and corneal ulceration in the most severe exposures. Respiratory involvement is delayed for 4 to 6 h and manifests as a dry, barking cough and hoarseness. Tachypnea or dyspnea indicates exposure to a lethal amount of mustard. In such cases, bronchospasm, bronchiolar obstruction by sloughed pseudomembranous bronchial epithelium, and hemorrhagic pulmonary edema ensue over 1 to 2 days. Systemic absorption is seen with massive exposures and results in hematopoietic, gastrointestinal tract, and CNS involvement. Mortality is approximately 3 percent in those reaching medical facilities.

Lewisite (L) is an oily colorless liquid with the odor of geraniums. It has a potency similar to that of mustard. Known stockpiles of a Lewisite-mustard mixture are possessed by Russia. While its active ingredient, trivalent arsenic, inhibits various enzymes throughout the body and interferes with glycolysis, the mechanism for vesication is not clear. Unlike mustard, skin irritation from Lewisite exposure occurs within 15 to 30 min. Blister formation also occurs more quickly (within 2 h) and is followed by cessation of pain. Resulting lesions heal more quickly and have less secondary infection and scarring than those caused by mustard. Ocular pain and irritation also occur within minutes, and in most cases, reflex blepharospasm seems to prevent the severe injury seen with mustard exposure. Immediate upper airway irritation progresses to pulmonary edema only in the most severe cases. Hypotension and hemolytic anemia are seen rarely and result from systemic arsenic toxicity.

Phosgene oxime (CX), an agent that causes extensive tissue damage, is considered here even though it is not a true vesicant. Its mechanism of action is unknown. Following exposure, instantaneous irritation of skin, eyes, and airways occurs, after which the affected skin blanches, turns grayish, and becomes urticarial, erythematous, and edematous. Necrosis of the area may penetrate to the muscle layers and results in eschar formation. Prolonged hospitalization is usually needed.

Immediate skin and eye decontamination, ideally within 1 to 2 min of exposure, is the only effective way of preventing tissue damage from the vesicants. Late decontamination is recommended, however, because spread to uninvolved areas of the skin or to other personnel may be prevented. A dilute hypochlorite solution is recommended for skin decontamination of mustards and Lewisite, which are relatively water insoluble. Water alone is the preferred decontamination solution for phosgene oxime. BAL (British anti-Lewisite, or dimercaprol) is an arsenic chelator that will prevent or greatly decrease the severity of skin and eye lesions if applied topically within minutes of Lewisite exposure, but the topical form is not widely available. Given intramuscularly, BAL reduces the mortality from systemic effects of Lewisite. There are no antidotes for mustard poisoning, although mustard scavengers, antioxidants, nicotinamide-adenine dinucleotide (NAD) precursors, polymerase inhibitor, and corticosteroids are investigational.

As with thermal burns, aggressive airway, fluid, electrolyte, and pain management, along with prevention of secondary infection with topical antibiotics and sterile dressing changes, is the mainstay of therapy for chemical burns. All burns resulting from caustic chemical agents are classified as "major" by the American Burn Association and require referral to a burn surgeon.

Ocular Toxins

Symptoms following ocular chemical burns include blepharospasm, clouding of the cornea, and conjunctival injection. In severe exposures, corneal ulceration or globe perforation may be evident. Cessation of pain may not necessarily be an indicator of cessation of ocular damage, particularly with penetrating toxins such as alkaline corrosives or hydrofluoric acid. Three grades of corneal involvement are described. Grade I involves irritation only; grade II includes corneal erosion, congestion, or chemosis; and grade III includes corneal stromal damage or conjunctival and scleral necrosis or both. [19] In pure ocular exposures, prehospital irrigation of the eyes for 15 to 20 min at the scene prior to transport is recommended. Contact lenses should be removed. Eye hydrotherapy can continue during transport with the use of a large water-filled container in which the patient intermittently submerges the face and blinks the eyes open and closed. In the ED, irrigation should continue until the pH of the conjunctival sac returns to 7.4. Visual acuity, fluorescein staining, and slit-lamp evaluation are indicated. Consultation with an ophthalmologist is warranted in all but the most trivial of exposures, especially for chemically induced disruption of the cornea, anterior chamber reaction, hyphema, or obvious globe perforation.

Metabolic Toxins

Hydrogen sulfide is a colorless flammable gas that may be encountered in industry or as a natural product of organic decomposition, such as sewer or manure gas. The ability to detect its characteristic rotten egg odor is lost at high concentrations or with lengthy exposures to low concentrations. Its mechanism of toxicity is similar to that of cyanide, with disruption of oxidative phosphorylation through inhibition of cytochrome oxidase aa3. Cellular asphyxia and impaired ATP production promote anaerobic metabolism with lactate accumulation and metabolic acidosis. It is one of the few chemical asphyxiants that also possesses irritative properties, and respiratory and ocular irritation occur following exposure. In high concentrations, rapid loss of consciousness, seizures, and death may occur after only a few breaths. Delayed pulmonary edema and corneal destruction should be anticipated with massive exposures. Treatment involves decontamination of the skin and eyes as appropriate. Administration of the nitrite component of the cyanide antidote kit to promote low-level methemoglobin formation may result in conversion of sulfide to less toxic sulfmethemoglobin. Other treatments include 100% oxygen and possibly hyperbaric oxygen therapy. Other metabolic poisons such as carbon monoxide and cyanide are discussed in depth in Chap. 182 and Chap. 198.

Myocardial Toxins

Certain solvents such as halogenated hydrocarbons, Freons, and aromatic hydrocarbons may sensitize the myocardium to the dysrhythmic effect of catecholamines. Myocardial irritability may persist for several hours following exposure. Avoidance of physical activity or sympathomimetic drugs, other than selective b_2 agonists, for the treatment of bronchospasm is warranted. Furthermore, dc countershock cannot be administered to patients soaked with flammable chemicals until decontamination has been carried out due to fire and explosion risk. Hydrofluoric acid exposures may result in cardiac dysrhythmias as a result of hypocalcemia, hypomagnesemia, or hyperkalemia. In this setting, the administration of intravenous calcium may be lifesaving.

Hematologic Toxins

Hematologic toxicity may be caused by many chemical exposures. Both hemolysis and methemoglobinemia (oxidation of the iron of heme) may result from exposure to chemical oxidants or drugs. Derivatives of aniline or nitrites are the industrial chemicals most frequently associated with RBC oxidant stress. Other workplace agents include chlorates, benzene, acetanilid, nitrogen oxides, nitrophenols, *para*-toluidine, phenols, and sulfonamides.

Pediatric Exposures

Children are uniquely sensitive to chemical exposures. The child's thinner stratum corneum results in increased skin permeability. A relatively greater surface area (approximately 2.5 times larger than that of adults on a pound-per-pound basis), greater fluid intake per body weight, and increased minute volume provide greater dermal, oral, and respiratory uptake of chemicals. Children are at greater risk than adults to develop methemoglobinemia when exposed to oxidant stresses based on low NADH methemoglobin reductase activity. Other factors rendering them more susceptible to toxins include lower oxygen-carrying capacity, owing to lower baseline hematocrits, and greater susceptibility to bronchospasm following exposure to inhaled toxins. [20] When wet, infants develop rapid hypothermia; therefore, special consideration for decontamination will need to be made with use of warm liquids and control of ambient temperature. Finally, ocular irrigation is difficult in children. One method involves the use of a "papoose" followed by flooding the bridge of the nose with normal saline rather than the eyes directly.

BIOLOGIC HAZARDS

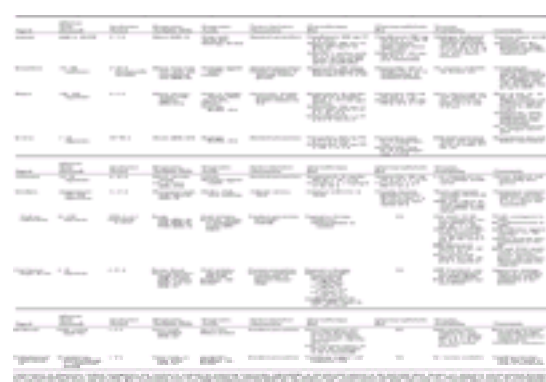
Biologic weapons (BWs) are microorganisms or biologic toxins that are used to produce death or disease in humans, animals, or plants (Table 181-6). Some are more deadly per weight than chemical agents, including nerve agents and cyanide. Recent awareness of proliferating offensive programs, stockpiles of munitions containing botulinum toxin and anthrax by countries like Iraq hostile to the United States, and terrorist threats surrounding their use suggest that a large-scale incident involving bioagents is now more likely than at any point in history. Aspects of a biologic release have been completely reviewed by military experts, [21,22] as summarized below.


TABLE 181-6 Summary of Biological Warfare Agents*

Desirable BW agents must be stable, deliverable as an aerosol with particle diameter size of 1 to 5 μm, and highly infectious, without an effective vaccine to counter the threat. These agents could be disseminated by missile warheads loaded with bomblets, by aerosol generators either through line sources (airplanes, boats) or point sources (fixed aerosol device), through contamination of food or water, or less likely, percutaneously. The covertness of these agents comes from their variable incubation period and the fact that they are essentially undetectable at the time of exposure. The most likely route of transmission is respiratory. Those agents felt to be significant threats are discussed below.

Anthrax

In 1979, an accident involving aerosolized anthrax spores at a Soviet bioweapons military compound resulted in fever, respiratory difficulty, and over 60 fatalities in civilians living downwind from the facility. Anthrax has been weaponized by other countries as well. A recent hoax involving the delivery of a leaking package to the B'nai B'rith Center in Washington, D.C., labeled "Anthrachs" resulted in temporary yet serious disruption of that city's activities. This incident has been followed by numerous similar threats in many areas of the United States such that anthrax threats have become the "bomb scares" of the late 1990s. The problem is that such threats must be taken seriously, at least initially, since this organism is potentially so deadly. Early expert consultation is critical in such situations to assess whether a legitimate threat to health exists (i.e., biologic agents are nonvolatile and generally not dermally active, so if there is no aerosol generated, then there usually is no credible threat). Soap and water decontamination generally is adequate in this type of scenario, and postexposure antibiotic therapy usually can be delayed for up to 24 h to allow time for determining whether a lethal agent is indeed present.

Anthrax spores are stable and relatively easy to cultivate. Dispersion by a line source of 50 kg of spores over a population of 500,000 has been estimated to result in up to 220,000 people killed or seriously incapacitated. Infectious spores germinate and elaborate toxins that result in tissue edema and necrosis. Various forms of this zoonosis exist in nature. Most commonly, human illness is acquired by handling animal fluids or pelts. Following skin inoculation, the developing "malignant pustule" has an untreated mortality of 25 percent and a treated mortality of less than 1 percent. Gastrointestinal and inhalational forms of illness, as in an aerosol attack, have nearly 100 percent mortality if not treated within 24 to 48 h.

A WMD attack would likely result from inhalation of anthrax spores or "Woolsorter's disease." An incubation period of 1 to 6 days is seen, followed by fever, myalgia, cough, chest pain, and fatigue. Transient improvement may be noted after 1 to 2 days of symptoms but is followed by abrupt onset of sepsis, hypotension, and death in 24 to 36 h. Hemorrhagic meningitis occurs in 50 percent of patients. The disease does not involve the lung parenchyma but instead causes a necrotizing hemorrhagic mediastinitis. The chest x-ray in late stages is characteristic, with significant mediastinal widening, pleural effusion, but no infiltrates. The diagnosis in most laboratories rests on Gram stain and blood cultures for the bacillus (not spores) late in the illness. Other methods of confirmation are available in some laboratories. Treatment involves ciprofloxacin 400 mg IV every 8 to 12 h or doxycycline 100 mg IV every 12 h. Others exposed, even if asymptomatic, should be started on either of the preceding antibiotics orally for 4 weeks while being immunized with three doses of vaccine after exposure. A licensed vaccine exists and is currently administered to U.S. soldiers. It is safe (side effects are local and self-limited) and is extremely effective in animal studies, providing protection against high-dose aerosol exposures to virulent strains. Standard precautions in caring for a patient with anthrax are recommended. There are no known cases of human-to-human transmission of inhalation anthrax. Iodine or hypochlorite at disinfectant strengths is required to destroy spores on equipment, although a dilute (1:9) household bleach solution is recommended to decontaminate victims immediately after exposure. Soap and water are probably adequate decontamination for human skin as well.

Plague

Plague, transmitted by *Yersinia pestis,* is a rodent zoonosis passed in nature from fleas to humans. In nature, the illness occurs following skin inoculation, transport of the organism to regional lymph nodes, and subsequent dissemination through blood. This bubonic form, characterized by one or more tender lymph nodes, hepatosplenomegaly, skin lesions, and septicemia, has a 50 percent mortality. A WMD attack likely would involve inhalation of the aerosolized organisms. The resulting illness, pneumonic plague, has an untreated mortality of 80 to 100 percent. Two to three days following inhalation, a fulminant illness involving malaise, fever, headache, cough, bloody sputum, shock, and a bleeding diathesis develops. Cardiopulmonary collapse ensues. Laboratory features include patchy infiltrates on chest x-ray, leukocytosis with a left shift, disseminated intravascular coagulation (DIC), and elevated transaminases. The diagnosis is confirmed by Gram stain and culture of lymph node aspirate, blood, sputum, or cerebrospinal fluid (CSF). ELISA or serology is confirmatory. Treatment must be started within 24 h of symptom onset to affect survival. Streptomycin 30 mg/kg per day IM bid for 10 days (or gentamicin if streptomycin is unavailable) or doxycycline 100 mg IV bid for 10 to 14 days is recommended. Chloramphenicol is the antibiotic of choice for patients with meningitis. Prophylaxis of those exposed includes oral ciprofloxacin or doxycycline for 7 days. Secondary transmission is possible for pneumonic plague. Respiratory isolation and droplet precautions are necessary for at least 48 h until sputum cultures are documented as negative.

Tularemia

Tularemia is a zoonosis that most commonly causes an ulceroglandular disease in humans exposed to diseased animal fluids or bites from infected deerflies, mosquitoes, or ticks. Typhoidal or septicemic forms can occur following inhalation of the inciting organism, *Francisella tularensis.* While not highly fatal, both its extremely high infectivity and ability to escape laboratory detection make this a likely terrorist agent. Infectivity by the inhalation route approaches 100 percent, with an untreated mortality of 35 percent. Only 10 to 50 organisms are required for an infection. Following a 2- to 10-day incubation period, fever, prostration, chest pain, and dry cough develop. Patchy infiltrates and hilar adenopathy may be seen on chest x-ray. The diagnosis is confirmed by serology. Antibiotic treatment includes streptomycin 1 g IM every 12 h for 14 days (30 mg/kg per day) or gentamicin 3 to 5 mg/kg per day. Prophylaxis with oral tetracycline or doxycycline for 14 days is recommended for those exposed. Immunity following tularemia is permanent. Person-to-person transmission does not occur, and respiratory isolation is not required. Standard precautions should be sufficient in protecting health care professionals.

Q Fever

Q fever is a zoonotic illness spread in nature by contact with animal secretions. Its extremely high infectivity by the aerosol route and persistence in the environment make it a biologic threat. Following inhalation, a long incubation period of 10 to 20 days is seen. Subsequently, a self-limiting febrile illness characterized by chills, sweats, severe headache, cough, and myalgias develops. Patchy infiltrates are seen on chest x-ray, along with leukocytosis, and elevated transaminases. The illness is generally incapacitating but self-limited. Laboratory culture of the agent should not be attempted because only one organism is needed to cause infection. Specimens should be sent to U.S. Army Medical Research Institute of Infectious Diseases (USAMRIID) or the Centers for Disease Control and Prevention (CDC) for serologic testing (see Table 181-1). The antibiotic of choice is tetracycline or doxycycline for 5 to 7 days. Prophylactic antibiotic therapy should not be initiated until 8 to 12 days after exposure and should be given for 5 days. Tetracycline or doxycycline is currently recommended. Secondary transmission does not occur.

Smallpox

The last documented case of endemic smallpox occurred in Somalia in 1977. While repositories of the virus currently are held by the United States and Russia, it is possible that others exist. An outbreak of smallpox would be an international emergency, given the high rate of person-to-person transmission and the termination of public vaccination programs that has rendered civilian and military populations now susceptible. Desirable properties of this virus in terms of weaponization are its relative ease of cultivation and stability on freeze-drying. Mortality of variola major is 3 to 30 percent depending on immune status. Following an incubation period averaging 12 days, abrupt onset of fever, rigors, vomiting, headache, backache, and in severe cases, delirium occurs. Two to three days later, an enanthem appears, along with a centrifugal rash on the face, hands, and forearms. The lower extremities and trunk become involved over the next week as lesions progress from macules to papules to pustules and then scab over. All lesions are in the same stage of eruption, unlike chickenpox. The diagnosis is clinical and may be confirmed by polymerase chain reaction or electron microscopy. Treatment is primarily supportive, although there are antiviral drugs that are investigational. Strict quarantine of the patient until all lesions scab over or for 17 days for all those in contact with the index case is recommended. Vaccination of all exposed within 5 days and administration of vaccinia-immune globulin (VIG), if available, should be carried out as well. Supplies of vaccine and VIG are unfortunately limited.

Viral Encephalitis

Viral encephalitides such as Eastern equine encephalitis (EEE), Western equine encephalitis (WEE), and Venezuelan equine encephalitis (VEE) caused by the alphaviruses are naturally transmitted by mosquitoes. These agents, stable for delivery by aerosol, are highly infectious, with nearly 100 percent of persons exposed to such aerosols developing illness. Children are affected most severely. Neurologic symptoms suggestive of viral encephalitis include headache, confusion, obtundation, dysphasia, seizures, paresis, ataxia, myoclonus, and cranial nerve palsies. Fever, photophobia, sore throat, myalgia, and vomiting are common prodromal symptoms. EEE is most severe, with a 75 percent case fatality and a 35 percent incidence of neurologic sequelae. Other forms are milder, resulting in neurologic symptoms in 0.5 to 4 percent and complete recovery in survivors; however, inhaled VEE may be much more severe clinically than what is seen with natural vector-borne disease. Laboratory studies may show leukopenia, elevated transaminases, and CSF lymphocytic pleocytosis. The diagnosis is made through viral isolation or serology. Magnetic resonance imaging (MRI) is a sensitive technique in identifying early, characteristic findings. Treatment is supportive, and respiratory isolation may be recommended, since person-to-person transmission may occur, although it has not been seen clinically. Patients' rooms should be treated with a residual insecticide to prevent mosquito-borne transmission.

Hemorrhagic Fever

Viruses causing viral hemorrhagic fever (VHF) are highly infectious by the aerosol route, cause high morbidity, and are easily grown in cell culture. RNA viruses causing Ebola and Marburg (filoviruses), Lassa, Argentine, Bolivian, Venezuelan, Brazilian, Rift Valley, and Congo-Crimean hemmorhagic fevers are felt to be possible threats. Common to all these illnesses is an acute febrile illness, characterized by malaise, prostration, and signs of vascular permeability. Findings of conjunctival injection, hypotension, flushing, petechial hemorrhages, and mucous membrane, neurologic, pulmonary, and hematopoietic involvement are seen. Some unique differences among these agents exist. Lassa fever, for example, is characterized by fewer hemorrhagic and neurologic complications. RVF classically presents with retinitis and hepatitis. Congo-Crimean hemorrhagic fever and Marburg/Ebola may cause profound DIC and hemorrhage. The diagnosis is made at a diagnostic laboratory with highest level (BL-4) containment possible (USAMRIID or CDC) using ELISA, reverse transcriptase polymerase chain reaction, cell culture, or the characteristic "shepherd's crook" appearance of the filoviruses on electron microscopy. Treatment involves supportive care, blood product replacement, and convalescent plasma for AHF. Ribavirin may be considered if within 7 days of symptom onset but is not effective against the filoviruses.

Botulism

Botulism, the most potent toxin known, has been weaponized by several countries. In 1995, an Iraqi defector revealed Iraqi research into and deployment of over 100 munitions containing the toxin. Both aerosol delivery and food supply contamination are possible methods of attack. The toxin exerts its effect through entering presynaptic cholinergic neurons and blocking acetylcholine release. Failed acetylcholine transmission results throughout the nervous system. This causes a clinical picture that is physiologically the opposite of nerve agent intoxication (too much acetylcholine in synapses). Following an incubation period of 3 to 8 days (ingestion) or 24 to 36 h (inhalation), bulbar palsies, diplopia, ptosis, mydriasis, dysarthria, dysphonia, and dysphagia develop. A classic descending, symmetric skeletal muscle paralysis ensues. Death is usually related to respiratory failure. The diagnosis is clinical and is confirmed by cultures of food, stool, and gastric contents. ELISA nasal mucosa swabs may be helpful within 24 h of inhaled botulinum toxin exposure. Treatment is directed primarily at providing respiratory support. Antitoxin is available through the CDC or USAMRIID (see Table 181-1). The CDC-licensed antitoxin is trivalent (effective against three toxin types) and is a horse IgG product, with attendant risks of anaphylaxis and serum sickness. The USAMRIID product is heptavalent (effective against toxin types A through G), and although also equine derived, it is a FAB-fragment product with a theoretically lower risk of anaphylaxis and serum sickness. It is only available for use under an IND protocol. An investigational pentavalent vaccine also exists for high-risk groups.

Staphylococcus

Staphylococcal enterotoxin B (SEB) is a heat-stable toxin, commonly associated with food poisoning. Less well recognized is the ability of this bacterial superantigen to incapacitate those who inhale it through stimulation of cytokine production and other mechanisms. The toxin therefore could be delivered either by aerosols or in sabotaged food or water supplies. It is expected that patients would present in large numbers over a very short period of time. Early symptoms include fever, headache, chills, myalgia, cough, and chest pain, beginning 3 to 12 h following inhalation. Nausea, vomiting, or diarrhea may be seen if the toxin is ingested. Massive exposures may cause pulmonary edema. Victims of inhalation exposure may develop an incapacitating fever and cough that may last for up to 4 weeks. The physical examination is generally unremarkable, except for mild conjunctival injection immediately following exposure to the aerosolized form. The diagnosis is made clinically or possibly by nasal swabs or urine samples for SEB metabolites during the first 24 h. Treatment is supportive.

Ricin

Ricin is a potent cytotoxin derived from castor bean mash. Over a million tons of mash are processed each year into industrial fluids. Traditionally, toxicity occurs following the ingestion of masticated castor beans. Hemorrhagic gastroenteritis, vascular collapse, and multisystem organ failure result from inhibition of protein synthesis. Following exposure to aerosolized ricin, airway necrosis is seen. Fever, chest tightness, cough, dyspnea, arthralgias, and profuse sweating begin within 4 to 8 h. Over the next 2 to 3 days, severe lung inflammation manifests as a progressive cough and hemorrhagic pulmonary edema. The diagnosis is difficult but may be confirmed by ELISA testing of serum or tissue. Treatment is supportive. If ricin is ingested, aggressive gut decontamination including the administration of activated charcoal may be considered.

Trichothecene

Trichothecene (T2) mycotoxins are nonvolatile fungal products that are extremely stable agents. Their use is suspected to have caused widespread toxicity in Laos, Kampuchea, and Afghanistan in the late 1970s and early 1980s, although this is still an issue of much debate. Russia realized these mycotoxins' potential as BW agents following the accidental contamination of flour resulting in a severe illness known as *alimentary toxic aleukia* (ATA) in civilians. These potent toxins exert their effects through bone marrow suppression and protein synthesis inhibition. Unique among biologic toxins are the mycotoxins' strong irritant effect and capacity for dermal absorption. These agents also may be inhaled or swallowed following an aerosol release. Symptoms include intense burning of the skin, eye pain, and tearing within minutes of exposure. Progression to skin blistering, necrosis, epistaxis, rhinorrhea, cough, wheezing, nausea and vomiting, bloody diarrhea, and death may occur over minutes to days depending on dose. Blood and environmental samples may be analyzed by gas chromatography–mass spectroscopy to confirm or support the diagnosis.

Detectors for biowarfare agents are being fielded in the military, but realistically, the first indication of a terrorist-mediated biologic agent release will be ill patients. Critical management points for all biologic agents include mandatory standard precautions for all health care providers and containment of all bodily fluids. Additionally, airborne precautions are necessary for smallpox, droplet precautions for plague, and contact precautions for VHFs. A dilute household bleach solution will effectively neutralize most biohazardous materials and should be used for patient decontamination. Full-strength bleach solution should be used to clean up body fluids and blood. Respiratory isolation should be maintained for those agents known or suspected of causing secondary transmission (smallpox, pneumonic plague, and possibly viral hemorrhagic fevers). Initiation of antibiotic therapy for treatable agents should be expedient and not delayed for definitive diagnosis. Persons exposed to anthrax but not yet ill should be immunized with three doses of anthrax vaccine over 30 days in addition to receiving antibiotics. Persons exposed to smallpox patients should be immunized within 3 to 5 days to prevent secondary cases. Personnel familiar with infection control and biologic waste disposal should be contacted to provide cleanup services.

POSTINCIDENT RESPONSE

Prolonged observation should be considered following significant exposures to those agents listed in Table 181-7.

Acrylonitrile, acetonitrile, propionitrile	Cyanide toxicity
Aniline	Methemoglobinemia
Arsine	Hemolysis
Benzene	Bone marrow suppression and leukemia
Chlorine	Pulmonary edema (high doses)
Ethylene oxide	Pulmonary edema and mutagenicity
Halogenated solvents	Hepatorenal toxicity
Hydrofluoric acid	Pulmonary edema, burns, electrolyte changes
Hydrogen sulfide	Pulmonary edema
Metals	Hepatorenal, neurotoxicity
Methanol	Neurologic, acid-base disturbance
Methyl bromide	Pulmonary edema
Methylene chloride	Carbon monoxide toxicity, dysrhythmias
Organophosphates (highly lipid soluble, or derived exposure to nerve agents)	Cholinergic toxicity
Nitrogen oxides	Pulmonary edema, methemoglobinemia
Ozone (rare)	Pulmonary edema
Paraquat	Pulmonary edema/fibrosis
Phosgene	Pulmonary edema
Phosphine	Pulmonary edema
Zinc phosphide	Pulmonary edema

TABLE 181-7   Toxins with Delayed Onset of Symptoms or Requiring Prolonged Monitoring

Patients with chemical contamination may require special medical follow-up, depending on the nature of the contaminant. About 30 percent of those who were symptomatic will have persistent symptoms at 2 weeks after exposure.[23] Medical resources such as the company's occupational physician or medical toxicologist should be involved. This allows for continuity of care and provides the patient with a common medical provider knowledgeable in the area of toxic exposures. Counseling may be needed in the areas of carcinogenesis or reproductive or developmental effects. Follow-up liver and renal function tests several days to 1 week after exposure may be warranted.

Psychological factors affect health after toxicologic disasters. Victims of a hazardous materials incident may experience a post-traumatic stress disorder consisting of anxiety, depression, insomnia, amplification of symptoms, and somatization. This is estimated to occur in 25 percent of victims, as evidenced by abnormal psychological test scores.[24] Early psychological debriefing and interviews with patients and personnel can help prevent postexposure stress syndrome.

All medical equipment used during outdoor or indoor decontamination remains in the area used until it can be decontaminated adequately. An industrial hygienist or environmental cleanup company must be involved to determine the extent of cleanup that is needed. It should be determined in advance what agencies will be involved in the decontamination of facility and ALS vehicles. Contaminated departments or vehicles will be taken out of service until decontaminated. Contaminated clothing or other items should not be released to the patient. Contact the ATSDR/CDC emergency response 24-h hotline or EPA environmental response for advice on the disposal of contaminated equipment and clothing.

The requirements for reporting of work-related hazardous materials accidents vary by state. Advance determination of regional requirements can be made by contacting local or state health departments and governmental agencies. Patients should be advised to contact regional Occupational Health and Safety Administration (OSHA) offices to report a suspected violation of safe work practices. Reporting of a suspected terrorist event should begin with local government and health departments. Ultimately, the FBI has jurisdiction over such situations in terms of crisis management, with jurisdiction being passed to Federal Emergency Management Administration (FEMA) under the federal response plan for consequence management. Local public health officials should be involved as early as possible in a biologic incident.

182 CYANIDE

Kathleen A. Delaney

Cyanide is a potent cellular toxin with an infamous history. The ability of extracts of bitter almonds and cherry laurel leaves to cause rapid death has been known for centuries, although the causative agent was not identified as cyanide until the end of the eighteenth century. Cyanide was used in state executions by the ancient Greeks and Romans and, until recently, by the state of California. The first chemist to synthesize hydrogen cyanide gas succumbed dramatically in 1786 when a vial of the gas broke on his laboratory floor. In 1978, hundreds of people died in Jonestown, British Guiana, following a mass suicidal cyanide ingestion.

Cyanide is a simple, highly reactive compound of carbon and nitrogen that has many uses in industry and the chemical laboratory. Its wide availability was emphasized by the experience of investigators who found 65 legitimate sources of cyanide in the Chicago area during attempts to trace the source of cyanide used in the infamous Tylenol-substitution poisonings. [1] In nature it is found in large amounts in certain nuts, plants, and fruit pits in the form of cyanogenic glycosides. [2] Tobacco smoke has been estimated to contain from 100 to 1600 parts per million (ppm) of cyanide, and smokers have been shown to have higher levels of cyanide and thiocyanate, a "detoxified" form of cyanide. [3] The antihypertensive agent, sodium nitroprusside contains cyanide.

Since it is so ubiquitous in nature, animals have evolved biochemical means of detoxifying cyanide. In humans and many other mammals, the enzyme rhodanese detoxifies cyanide by converting it to thiocyanate, a less toxic form that is excreted by the kidneys. [4,5]

SOURCES OF EXPOSURE

Acute cyanide poisoning occurs in a number of settings: (1) inadvertent occupational poisonings, (2) inadvertent, suicidal, or homicidal ingestions of cyanide or chemicals metabolized to cyanide, (3) iatrogenic toxicity due to infusion of sodium nitroprusside, [6] (4) ingestion of plant products containing naturally occurring cyanogenic glycosides,[2] and (5) inhalation of smoke from burning plastics in closed-space fires. [7,8]

Industrial Exposure

Cyanide compounds are both precursors and incidental by-products in the production of plastics, solvents, enamels, high-strength paper, paints, glues, wrinkle-resistant fabrics, herbicides, pesticides, and fertilizers. [9] The affinity of cyanide for metals makes it useful in the extraction of ores, in metal polishing, and in electroplating.[9] It is also used to strip hair from hides in the leather industry. The once widespread use of cyanide as a fumigant resulted in many poisonings. [5] Cyanide is produced in industry by combining ammonia (NH_3) and methane (CH_4) to form hydrogen cyanide gas (HCN). Commercial quantities of water-soluble salts such as sodium cyanide (NaCN) and potassium cyanide (KCN) are synthesized from hydrogen cyanide gas. [9] HCN is readily liberated when cyanide salts are exposed to acid. Industrial exposures occur most commonly through inhalation; however, skin exposure to solutions of cyanide salts also has resulted in poisoning. Inadvertent ingestion of cyanide salts while eating in a contaminated work setting also has been proposed as a cause of accidental subacute poisoning in the workplace. [10]

Smoke Inhalation

Large amounts of hydrogen cyanide may be released when natural and synthetic nitrogen-containing polymers such as wool, silk, polyurethane, or vinyl are burned. Elevated cyanide levels have been reported frequently in victims of smoke inhalation, most often in association with elevated carbon monoxide levels, and have been implicated in fire-related fatalities. [7,8]

Chronic Exposure

Adverse physiologic effects due to chronic subacute cyanide exposure have been proposed but are poorly defined. Studies of workers chronically exposed to cyanide have demonstrated a higher incidence of thyroid disease and vitamin B_{12} deficiency.[10] Linamarin is a cyanogenic glycoside found in the cassava plant, a significant source of carbohydrate in many developing countries. In areas of the world where cassava ingestion is high, goiter and tropical ataxic neuropathy are endemic, and plasma and urinary levels of cyanide are elevated. A recent epidemiologic survey in Cuba of patients with optic neuropathy showed that poorly nourished smokers were at greatest risk and implicated an etiologic association between elevated levels of cyanide found in cigarette smokers and dietary deficiency of the natural cyanide scavengers vitamin B_{12} and b carotene.[4]

BIOCHEMICAL TOXICOLOGY

The avidity with which cyanide binds to metals accounts for its serious physiologic effects in poisoning. Cyanide disrupts metabolism by inhibiting the function of a number of important metal-containing enzymes. Its most dramatic physiologic effects are produced by the disruption of mitochondrial oxidative phosphorylation through the inhibition of cytochrome A_3.[4,11] Cytochrome A_3 uses trivalent ferric (Fe^{3+}) to catalyse the reduction of molecular oxygen to water, which is the final step in electron transport. Inhibition at this step blocks the ability of body tissues to use oxygen so that only anaerobic metabolism occurs. This inhibitory binding of cyanide to the cytochrome ferric ion is labile and readily reversible. [4]

CLINICAL TIME COURSE OF POISONING: ROUTES OF EXPOSURE

The time course and severity of the clinical effects of cyanide are a function of the nature of the cyanide-containing compound, the route of exposure, and the concentration of cyanide to which the patient is exposed. The onset of symptoms of poisoning following inhalational exposure to hydrogen cyanide gas is virtually immediate. Symptoms depend on the concentration of inspired gas. Several hours of exposure to low concentrations of gas (<50 ppm) cause restlessness, anxiety, palpitations, dyspnea, and headache. [12] Death may occur following prolonged exposure at these levels. Inhalational exposure to higher levels of hydrogen cyanide gas leads to severe dyspnea, loss of consciousness, seizures, and cardiac dysrhythmias. Coma, cardiovascular collapse, and death may occur immediately on exposure to very high levels. The LD_{50} for humans has been estimated at 200 ppm for a 30-min exposure and 680 ppm for a 5-min exposure.[12]

Although in most industrial accidents it has been difficult to separate the effects of inhalational absorption from percutaneous absorption, animal studies and studies of human skin have shown clearly that absorption of both cyanide ion (CN^-) and HCN vapor occur through intact skin. [10]

The onset of symptoms following ingestion of a cyanide salt may occur within minutes, depending on the amount of cyanide ingested and the rate of absorption.

Deaths have occurred in adults following the ingestion of as little as 50 mg of cyanide salt, and survival has been reported in much larger ingestions with aggressive resuscitation and use of antidotes. The median lethal dose of the potassium or sodium salt of cyanide in an untreated adult is 140 to 250 mg. [12]

Symptoms of poisoning are delayed following the ingestion of compounds that require metabolic activation to release free cyanide. Acetonitrile, a solvent sold commercially as a cosmetic nail remover, undergoes hepatic oxidative metabolism that results in the release of hydrogen cyanide. Severe poisonings and deaths attributed to cyanide poisoning have been reported following latency periods as long as 24 h after ingestion. [13] Amygdalin is a cyanogenic glycoside that is found in particularly high concentrations in apricot pits and bitter almonds. It is the principal constituent of Laetrile, a compound popular for nontraditional cancer therapies in the late 1970s. Because the release of cyanide requires hydrolysis of the glycoside by enzymes in the small intestine, the progression of symptoms following these ingestions is characteristically slow, with a latency of onset of several hours. Amygdalin does not produce cyanide poisoning when given intravenously. [2]

CLINICAL FEATURES

Symptoms of Poisoning

The symptoms are somewhat dose-dependent (Table 182-1). At the onset of poisoning, there is an inspiratory gasp followed by hyperventilation. Patients complain of breathlessness and feel anxious. Symptoms related to anxiety about the exposure also may mimic these initial symptoms of toxicity. During inhalational exposure, these symptoms will resolve following removal from the toxic exposure. In significant exposures, cerebral function is affected rapidly. Loss of consciousness occurs, often associated with seizures.[14]

TABLE 182-1   Signs and Symptoms of Acute Cyanide Toxicity

Early cardiac effects include sinus tachycardia, atrial dysrhythmias, and premature ventricular contractions. This progresses to bradycardia and asystolic arrest. As with hypoxia, ventricular tachycardia and fibrillation are uncommon.

Pathophysiology

The clinical signs and symptoms of cyanide poisoning mimic those of hypoxia, with one exception: Unless respiratory arrest has occurred, patients are not cyanotic. Although small amounts of cyanide bind to the ferrous (Fe^{2+}) form of hemoglobin, there is no significant interference with the ability of hemoglobin to bind oxygen. [15] The clinical manifestations of cyanide poisoning are readily understood based on the effect of cyanide on cytochrome oxidase activity. Blockade of the ability of mitochondria to use oxygen produces a state of severe hypoxia despite the presence of oxygen. The resulting anaerobic metabolism generates large amounts of lactic acid.[4,11] Unexplained lactic acidosis is an important, albeit nonspecific clinical clue to the timely diagnosis of cyanide poisoning in case of an "unknown" exposure.

The inability to use oxygen leads to decreased oxygen extraction by tissues with a concomitant increase in the oxygen content of venous blood. This results in a decrease in the normal arteriolar-venous oxygen [(A-v) O_2] difference, a measure of the amount of oxygen extracted by the tissues.[6] Although discussion of these concepts facilitates understanding of the cellular effects of cyanide, it is difficult to detect this underutilization of oxygen in an emergency setting. A reliable estimation of the (A-v) O_2 difference requires that the venous sample be taken from the pulmonary artery. This is most practical in the invasively monitored intensive care unit patient who has suspected cyanide toxicity due to a nitroprusside infusion. [6,16] Anticipated laboratory abnormalities are shown in Table 182-2.

TABLE 182-2   Anticipated Laboratory Abnormalities in Cyanide

Some authors suggest measurement of the oxygen saturation of venous blood drawn from the femoral vein, which is about 40 mmHg in normal patients on room air.[12] The oxygen saturation from an antecubital vein reported in one cyanide poisoned patient on 100% O_2 was 95 percent.[16] Unfortunately, the range of normal values for peripheral venous oxygen saturation and the effects of oxygen administration on these values have not been well studied. Thus, little useful information is likely to be gained.[17] An indirect but potentially useful finding related to this phenomenon is due to increased "arteriolization" of veins on funduscopic examination due to increased Po_2.[16]

The Unknown Exposure

A brief occupational history may provide a clue to the diagnosis of cyanide poisoning in an acutely ill adult. In patients with work-related industrial poisoning, the diagnosis is suggested by the patient's occupation and circumstances. Often, multiple exposures result from the same incident. Suicidal ingestions of cyanide often occur in patients whose occupations provide access to cyanide salts. These include industrial and research chemists, laboratory technicians, science students, and jewelers. A history of use of nontraditional cancer therapies would provide a clue to the ingestion of Laetrile or other cyanogen-containing preparations. Victims of homicide do not provide a history of exposure. Accidental or suicidal ingestions of cyanide-containing commercial products, such as metal polishes or acetonitrile-containing solvents, have been associated with severe cyanide toxicity. [13] Careful identification of ingestants in asymptomatic patients will prevent the mistaken discharge of a patient who has ingested a compound with delayed toxicity. [13]

Cyanide-poisoned patients frequently present to emergency departments without any history of exposure. Although isolated individual poisonings with cyanide are relatively rare, it is important that emergency physicians recognize signs of serious poisoning because specific antidotal treatment is available and effective. Rapid

onset of symptoms is an important clue. Cyanide salts are caustic and may cause oral burns when concentrated solutions or undiluted salts are ingested. A deeply comatose, acidotic patient without evidence of cyanosis or hypoxia on arterial blood gas examination should cause the clinician to think of cyanide. The finding of bright red retinal vessels, an elevated venous oxygen saturation, oral burns, or the smell of bitter almonds supports the diagnosis, although clues of this nature are elusive. It is estimated that only 20 to 40 percent of the population can detect the characteristic almond odor of cyanide.

Nitroprusside Therapy

Sodium nitroprusside contains 40 percent cyanide by weight. Cyanide is released by the deterioration of sodium nitroprusside in aqueous solutions, especially when exposed to bright sunlight. The rate of rise of cyanide levels in patients on a nitroprusside infusion is proportional to the infusion rate and increases at infusion rates greater than 1 to 2 μg/kg/min.[6] The onset of poisoning occurs after several days of therapy, so the emergency physician will see this problem only if called to the intensive care unit to evaluate a deteriorating patient. Cyanide poisoning should be suspected in patients receiving nitroprusside infusions who develop mental state disturbances or unexplained metabolic acidosis. In patients in whom a Swan-Ganz catheter is used for monitoring, a narrow (A-v) O_2 difference, especially in the setting of an unchanged or declining cardiac output, suggests cyanide toxicity. [6]

DIFFERENTIAL DIAGNOSIS

Cyanide poisoning always should be considered in the poisoned patient with metabolic acidosis. The differential diagnosis of acidosis in the setting of inhalational exposure includes other cellular toxins such as hydrogen sulfide and carbon monoxide and simple asphyxiants. Hydrogen sulfide is a product of organic decomposition encountered in septic tanks and sewers, petroleum production, and a number of other occupational settings. The characteristic odor of "rotten eggs" is frequently detectable. Carbon monoxide poisoning is readily confirmed by measurement of a carboxyhemoglobin level. The differential diagnosis of (increased anion-gap type metabolic) acidosis in patients with suspected ingestions includes methanol, ethylene glycol, metformin, salicylates, and iron. The slower time course of deterioration and the variable depth of mental status depression frequently help to distinguish the effects of these agents from those of cyanide. Severe isoniazid and cocaine poisoning are also associated with significant acidosis that occurs in the setting of seizures. The initial manifestations of severe intoxication with these agents may be indistinguishable clinically from cyanide intoxication.

The diagnosis of thiocyanate toxicity should be considered in the patient receiving a sodium nitroprusside infusion who becomes encephalopathic. Thiocyanate, the product of metabolic detoxification of cyanide, accumulates in patients with renal insufficiency and results in encephalopathy without the development of lactic acidosis or impaired oxygen utilization.[6] Levels of thiocyanate greater than 100 mg/L support the diagnosis of toxicity.[6]

PHARMACOLOGIC PRINCIPLES OF TREATMENT

Standard accepted therapy for cyanide poisoning in the United States is based on experimental and chemical principles developed in 1933. [5] The antidotes are contained in a kit now provided by Taylor Pharmaceuticals. The kit contains nitrites in two forms, an ampule of amyl nitrite for inhalation and 10 cc of a 3% solution of sodium nitrite for intravenous infusion. It also contains 50 cc of a 25% solution of sodium thiosulfate. The usual adult dose of sodium nitrite is 300 mg (10 mL of the 3% solution), followed by 12.5 g (50 mL of the 25% solution) of sodium thiosulfate. The pediatric dose is 0.33 mL/kg of 10% sodium nitrite and 1.65 mL/kg of 25% sodium thiosulfate.[18] A case report of the death of a child who succumbed to methemoglobinemia following aggressive treatment of a nonlethal ingestion of cyanide has led to the standard practice of adjusting the pediatric dose of sodium nitrite according to the patient's hemoglobin level, as illustrated in   Table 182-3.[19] Inhaled amyl nitrite is used to temporize in the prehospital setting or until intravenous access can be obtained and does not need to be administered when sodium nitrite is readily available.

Adults
1. 100% oxygen.
2. Amyl nitrite inhaler; crack vial and inhale 30 s.*
3. Sodium nitrite: 10 mL IV (10-mL ampule 3% $NaNO_2$ = 300 mg).†
4. Sodium thiosulfate: 50 mL IV (50-mL ampule 25% $Na_2S_2O_3$ = 12.5 g).
5. Repeat at half dose if symptoms persist.

Children (adapted from recommendations by Berlin[5] and Isom and Johnson[4])
1. 100% oxygen.
2. IV sodium nitrite and sodium thiosulfate:

Hb (g/100 mL)	3% $NaNO_2$* (mL/kg)	2.5% $Na_2S_2O_3$ (mL/kg)
7	0.19	1.65
8	0.22	1.65
9	0.25	1.65
10	0.27	1.65
11	0.30	1.65
12	0.33	1.65
13	0.36	1.65
14	0.39	1.65

3. Repeat once at half dose if symptoms persist.
4. Monitor methemoglobin to keep level less than 30 percent.

*Not necessary if IV is in place.
†Avoid nitrites in the presence of severe hypotension if diagnosis is unclear.

TABLE 182-3   Treatment of Cyanide Poisoning

The initial rationale for using nitrites was based on their capacity to form methemoglobin. Methemoglobin binds avidly to cyanide and prevents its binding to cytochrome oxidase. Although the antidotal efficacy of nitrites is not disputed, their actual mechanism of action has been questioned recently. [4] The formation of methemoglobin is a slow process relative to the rapidity of the therapeutic response to nitrites. In addition, the reversal of cyanide toxicity in animals by nitrites has been demonstrated to occur in the presence of methylene blue, which prevents the formation of methemoglobin.[4] Rapid methemoglobin formers, such as dimethyl-4-aminophenol, which is now used in Germany to treat cyanide poisoning, do not appear to have a more rapid effect than sodium nitrite. [4] Many papers imply that a level of methemoglobin of at least 25 percent should be a goal of therapy. This is based on work in dogs, who are much more sensitive to the methemoglobin-forming effects of nitrites than humans.[5] It has been demonstrated repeatedly that the rapid clinical reversal of cyanide toxicity occurs despite the demonstration of only very small amounts of methemoglobin.[20]

It should be noted that nitrites have a potential to cause serious side effects. Their vasodilatory properties can exacerbate hypotension. Death has been reported secondary to massive methemoglobinemia in an asymptomatic child with an inconsequential cyanide ingestion. [19]

Following the administration of sodium nitrite, sodium thiosulfate is given. Studies of the cyanide LD$_{50}$ in animals demonstrate that the therapeutic effect of the combination of sodium nitrite and sodium thiosulfate is greater than the additive effects of both agents alone. [4,5] Sodium thiosulfate enhances the activity of the body's own detoxification enzyme, rhodanese, by acting as a sulfur donor. Rhodanese catalyzes the transfer of a sulfur molecule from thiosulfate to cyanide, forming thiocyanate, which is excreted by the kidneys. The rate of this detoxification reaction in humans is limited by the availability of sulfur. [4] There are limited data on the efficacy of sodium thiosulfate as sole therapy for cyanide poisoning in humans, although anecdotal reports suggest that it may be very effective as sole therapy. [21] This may be an important finding because sodium thiosulfate has very limited toxicity in comparison with nitrites and is a safer empirical therapy when the diagnosis is not clear.[8,18]

If the only mechanism of toxicity of cyanide were binding to cytochrome A$_3$, then oxygen would not be expected to have any therapeutic effect. However, administration of 100% oxygen has been shown in animal studies clearly to enhance the therapeutic efficacy of antidotal therapy of cyanide poisoning. [4] It has been proposed that oxygen may affect the binding of cyanide to cytochrome oxidase or the ability to form methemoglobin. Hyperbaric oxygen has not been shown to offer any benefit over 100% oxygen in animal studies of cyanide poisoning. [4] Hyperbaric oxygen is very useful in the management of patients with suspected cyanide poisoning who have concomitant carbon monoxide poisoning. [8]

Because of the potential side effects of the nitrites, a great deal of effort has been made to develop equally efficacious but less toxic therapies. Many agents bind cyanide and render it nontoxic. Cobalt compounds have a high affinity for cyanide and are less toxic than cobalt salts, which injure the myocardium. [4] Hydroxocobalamin (vitamin B$_{12a}$) has been shown to reverse cyanide toxicity but can cause anaphylactoid reactions. In addition, the large amounts (in the range of 5 g) of the agent needed to neutralize cyanide require large-volume infusions in the concentrations (1 mg/μL) currently available in the United States. [4,8,12] Hydroxocobalamin in combination with sodium thiosulfate is used widely in France to treat cyanide poisoning. The concurrent use of sodium thiosulfate is thought to "recycle" the hydroxocobalamin binding sites, allowing administration of a smaller dose of hydroxocobalamin. When only hydroxocobalamin is administered, cyanide

is held in the form of cyanocobalamin. When sodium thiosulfate is added, cyanide appears in the form of thiocyanate. This effect has been termed *antidotal synergy.*[12]

Dicobalt edetate (Kelocyanor) is the therapeutic agent used as first-line treatment of cyanide poisoning in the United Kingdom. It is highly effective as a cyanide antidote but is not devoid of toxicity. Metabolic acidosis and hypotension have occurred in animals, and massive edema and ventricular tachycardia have been attributed to its administration to humans. The toxicity of dicobalt edetate is greater when cyanide is not present, limiting its use as an empirical therapy. [4]

4-Dimethylaminophenol (DMAP) is an agent developed in Germany for the treatment of cyanide poisoning. It rapidly produces methemoglobinemia but has not been demonstrated to be more clinically efficacious than sodium nitrite. It does not cause the same degree of hypotension but has been associated with renal failure in experimental animals. Unlike dicobalt edetate, it does not have greater side effects in the absence of cyanide. [4] In practice, most of these agents are used in combination with sodium thiosulfate.

MANAGEMENT DECISIONS: USE OF SPECIFIC ANTIDOTES

Severely poisoned patients have survived with supportive care, although survival in cases of massive exposure undoubtedly has been facilitated by antidotal therapy. The largest reported ingestion where survival occurred with supportive care alone was 600 mg. Patients have survived following much larger ingestions with use of specific antidotes. All patients with known or suspected cyanide poisoning should receive 100% oxygen by mask, be put on a cardiac monitor, and have an intravenous line in place. Patients with a history of ingestion should have careful gastric lavage, followed by endoscopic inspection of the esophagus to exclude caustic injury once the danger of death from the toxin is past. Ipecac is absolutely contraindicated because of the expected rapid onset of symptoms. Gastric decontamination should never take priority over resuscitation of the symptomatic patient. Superactivated charcoal has been shown to bind small amounts of cyanide and may be useful in decreasing the significance of an ingestion. Patients with inhalational exposures do not require gastric decontamination. Extensive decontamination of the skin with water should be accomplished in patients with cutaneous exposure, with adequate precautions to protect the staff from skin contamination. Patients with inhalational exposures often recover following their rescue from the toxic exposure. They do not require antidotal treatment if significant recovery has occurred prior to reaching medical attention. [14]

The decision to administer the sodium nitrite–thiosulfate antidote is straightforward when faced with a comatose, bradycardic patient with a clear history of cyanide exposure. Hypotension is not a contraindication to sodium nitrite therapy in this setting. Due to the potential toxicity of the nitrites, it is never appropriate to treat an asymptomatic patient. A patient with mild to moderate symptoms may be observed closely for more serious signs prior to the initiation of treatment. More difficult management decisions arise in (1) patients with smoke inhalation who have or may have carbon monoxide exposure as well as suspected cyanide exposure and (2) patients who are critically ill and acidotic without any history of cyanide exposure. In these patients, an antidote that is effective and has no toxicity obviously would be useful as empirical therapy for cyanide poisoning. The empirical administration of nitrites is problematic for two reasons. First, it may induce significant hypotension, and second, it may induce methemoglobinemia. Empirical administration of nitrites to patients who have or may have elevated carboxyhemoglobin levels has been considered to be contraindicated by some authors because of the decreased oxygen-carrying capacity caused by simultaneous induction of methemoglobinemia. [7,8] A limited study of seven patients with smoke inhalation and elevated cyanide and carboxyhemoglobin who were treated empirically with both sodium nitrite and sodium thiosulfate demonstrated that the measured decrease in oxygen-carrying capacity accounted for by combined carboxyhemoglobin and methemoglobin ranged from 10 to 21 percent and was not clinically significant. The maximum elevation of the methemoglobin level was 13 percent 1 h after treatment with sodium nitrite. None of these patients had initial carbon monoxide levels greater than 38 percent. [7] Due to limitations of this study, the safety of administering both agents in this setting remains unclear. The clinical detection of cyanide poisoning in victims of smoke inhalation also has been problematic because lactic acidosis may be the result of cyanide, carbon monoxide, hypoxia, severe burns, shock, or any state that induces anaerobic metabolism. A recent study of smoke inhalation victims showed a significant correlation between toxic cyanide levels and plasma lactate levels greater than 10 mM/L. This association was independent of the carbon monoxide concentration. [8] For the critically ill victim of smoke inhalation with significant lactic acidosis, the safest immediate empirical therapy that avoids the hypotensive effects of nitrites and the concerns about decreased oxygen-carrying capacity due to methemoglobin formation is the administration of sodium thiosulfate in addition to 100% oxygen.[8] The institution of hyperbaric oxygen therapy for patients with carbon monoxide poisoning obviates concern about induction of methemoglobinemia in the smoke inhalation victim with carbon monoxide poisoning.

The differential diagnosis of the comatose patient with metabolic acidosis is extensive. Empirical therapy in the unknown patient with suspected poisoning who is critically ill should include 100% oxygen, 50% dextrose, and naloxone, in addition to aggressive supportive care. When cyanide poisoning is considered, anecdotal reports support the utility of the empirical administration of sodium thiosulfate. [21] Significant hypotension is a contraindication to the empirical administration of sodium nitrite. Following the demonstration of adequate oxygenation and the absence of an elevated carboxyhemoglobin level, sodium nitrite may be administered after the sodium thiosulfate if the diagnosis is strongly entertained. A summary of nitrite and thiosulfate therapy is given in Table 182-3.

LABORATORY EVALUATION

In order to be effective, treatment of cyanide poisoning must be instituted long before confirmatory laboratory studies can be accomplished. Cyanide levels are useful to confirm a clinical diagnosis in retrospect or for forensic purposes. They cannot be obtained in time to make the diagnosis at the bedside. Because cyanide is sequestered in erythrocytes, erythrocyte and plasma cyanide levels should be obtained. Whole-blood cyanide levels are not useful. Cyanide levels do not correlate well with toxicity but will support a diagnosis. Normal erythrocyte cyanide levels are less than 1.9 μ M/L (50 μg/L), while death from cyanide is associated with erythrocyte levels greater than 40 μM/L (1 mg/L). Toxicity is seen with serum cyanide levels ranging from 0.5 mg/L (anxiety, confusion, tachypnea) to more than 3 mg/L (apnea, cardiovascular collaspse). [6] The arterial blood gas is a rapid and useful test, as noted earlier. The absence of a metabolic acidosis is inconsistent with the diagnosis of acute cyanide poisoning (Table 182-2). Recently, the demonstration of a serum lactate level greater than 10 mM/L was shown to have a significant correlation with toxic cyanide levels in victims of smoke inhalation. [8] The measurement of carboxyhemoglobin levels by use of a cooximeter is important in the assessment of smoke inhalation victims. Table 182-2 summarizes laboratory findings anticipated in cyanide poisoning.

DISPOSITION

Full recovery is anticipated in many cases of severe poisoning where treatment is initiated rapidly and cardiac arrest has not yet occurred. Recovery despite cardiac arrest also has been reported. Most patients who survive do not suffer neurologic injury, although anoxic encephalopathy may ensue.

183 DYSHEMOGLOBINEMIAS

Sean M. Rees
Lewis S. Nelson

The dyshemoglobinemias are a constellation of disorders in which the hemoglobin molecule is structurally altered and prevented from carrying oxygen. The most clinically relevant dyshemoglobinemias are carboxyhemoglobin, methemoglobin, and sulfhemoglobin. Carboxyhemoglobin develops following carbon monoxide exposure and due to its unique importance and prevalence is discussed in Chap. 198. This section of the text reviews methemoglobinemia and sulfhemoglobinemia. Although the exact prevalence of these disorders remains undefined, the American Association of Poison Control Centers database reports thousands of exposures to drugs and chemicals capable of producing methemoglobinemia, but unfortunately, cases in which methemoglobinemia actually occurred are not tallied. [1]

METHEMOGLOBINEMIA

Pathophysiology

Under normal circumstances, the iron moiety within deoxyhemoglobin exists in the ferrous (Fe^{2+}) form. Iron in this oxidation state avidly interacts with compounds seeking electrons, such as oxygen, and in the process is oxidized to the ferric (Fe^{3+}) state. On exposure to a nonoxygen oxidizing agent, iron donates an electron and transforms oxidation states from Fe^{2+} to Fe^{3+}. The ferric iron that remains is unreactive, and the hemoglobin that contains the ferric iron is termed *methemoglobin.* Methemoglobin, therefore, is unable to bind oxygen. Under normal circumstances, a small amount of methemoglobin exists in the blood (<1 percent). An elevated level of methemoglobin defines methemoglobinemia, although this is somewhat of a misnomer as the hemoglobin is contained within the erythrocyte and not free within the blood. The accumulation of methemoglobin is normally limited by enzymatic reduction of the ferric iron back to the ferrous form as rapidly as it forms. The enzyme NADH-methemoglobin reductase (also referred to as NADH cytochrome-b_5 reductase) is primarily responsible for this reduction, in which NADH (reduced nicotine adenine dinucleotide) donates its electrons to cytochrome-b_5, which subsequently reduces methemoglobin to hemoglobin.[2] In this process, NAD+ (oxidized NAD) is regenerated (Fig. 183-1). This pathway is responsible for reducing nearly 95 percent of the methemoglobin. A second enzymatic pathway utilizes NADPH and NADPH-methemoglobin reductase to effect methemoglobin reduction analogous to the NADH-linked enzyme system. This enzyme is of limited importance normally (<5 percent total reduction) due to the lack of a suitable molecule to shuttle electrons in a manner similar to cytochrome-b_5. However, this enzyme is crucial for the antidotal effect of methylene blue, which performs this function when administered exogenously (Fig. 183-1). To a very limited extent, nonenzymatic reduction systems, such as vitamin C and glutathione, may participate in the reduction of methemoglobin to hemoglobin. This limited effect of glutathione explains why patients with glucose-6-phosphate dehydrogenase deficiency, who are deficient in reduced glutathione, are not at increased risk of developing methemoglobinemia.

FIG. 183-1. Pathophysiology of methemoglobin formation and mechanism of action of methylene blue.

The primary clinical effect of methemoglobin is to reduce the oxygen content of the blood. Because the hemoglobin-bound oxygen accounts for the vast majority of an individual's oxygen-carrying capacity, as the methemoglobin level rises, oxygen delivery to the tissues fall. However, patients with methemoglobinemia are more symptomatic than patients who suffer from a simple anemia that produces an equivalent reduction in their oxygen-carrying capacity. This is due to a leftward shift in the oxyhemoglobin dissociation curve, the consequence of which is a reduced release of oxygen from the erythrocyte to the tissue at a given partial pressure of oxygen (Fig. 183-2).

FIG. 183-2. The oxyhemoglobin dissociation curve describes the change in oxygen binding to hemoglobin as the dissolved oxygen (pO_2) varies. The oxyhemoglobin dissociation curve of blood with a 50 percent reduction in erythrocytes (anemia) follows a curve similar to that of nonanemic blood, although the oxygen content is lower to start; i.e., unbinding of half of the oxygen occurs at the same pO_2. The oxygen dissociation curve of blood with 50 percent methemoglobin is shifted to the left so that it is less willing to give up its oxygen despite a similar reduction in oxygen binding sites as the anemic blood.

Acquired Methemoglobinemia

Methemoglobinemia is acquired when the normal mechanisms responsible for the elimination of methemoglobin are overwhelmed by an exogenous oxidant stress, such as a drug or chemical agent (Table 183-1). Drugs rarely produce clinically significant methemoglobinemia in conventional doses, although subclinical methemoglobinemia may go unrecognized. Currently, most cases of methemoglobinemia are due to phenazopyridine (a commonly used agent for the symptomatic

treatment of urinary tract infections), benzocaine (a topical anesthetic), and dapsone (an antibiotic often used in HIV-related therapy) (Table 183-1). Many of these compounds require metabolism to the "active" oxidant, and a substantial time delay until toxicity may occur. Methemoglobinemia can affect any age group and, due to undeveloped methemoglobin reduction mechanisms, the perinatal and infant age groups are more susceptible than older age groups. This explains the relatively common development of methemoglobinemia in infants given certain nitrogenous vegetables (e.g., spinach) or well-water that contains high nitrate levels. Bacteria within the gastrointestinal flora are capable of converting nitrates to the nitrite form, accounting for the toxicity of nitrates in well water and vegetables. Another common cause of acquired infantile methemoglobinemia is gastroenteritis, although the exact cause remains undefined. [3]

Nitrates/nitrites	Dapsone
Amyl nitrite	Phenazopyridine
Isobutyl nitrite	Local anesthetics
Sodium nitrite	Benzocaine
Ammonium nitrate	Lidocaine
Silver nitrate	Prilocaine
Well water	Dibucaine
Nitroglycerin	

TABLE 183-1 Agents Commonly Implicated in Patients with Methemoglobin

Epidemics of methemoglobinemia continue to occur and most commonly are related to nitrogenous chemicals that inadvertently admix with water or food. [4] Methemoglobin induction with sodium nitrite is a therapeutic goal in the management of patients suffering from cyanide poisoning.

Hereditary Methemoglobinemia

Although not usually diagnosed in the emergency department, patients may present with profound cyanosis that is related to a genetic abnormality. Hereditary methemoglobinemia results from either an enzymatic deficiency (i.e., NADH cytochrome- b_5 reductase) or from the presence of an amino acid substitution within the hemoglobin molecule itself (i.e., Hb M). Patients with NADH cytochrome- b_5 reductase deficiency develop methemoglobin levels of 20 to 40 percent, but these are easily reduced by the administration of daily oral doses of methylene blue or vitamin C. [4] Cyanosis in these individuals begins at birth, but they remain asymptomatic and develop normally. Hemoglobin M is an abnormal form of hemoglobin in which it's tertiary structure is altered and the heme iron exists in an environment favoring the ferric form. This disease only occurs in the heterozygous form, as the homozygous form is incompatible with life. Currently there is no treatment for this form of methemoglobin. As with NADH cytochrome- b_5 reductase deficiency, patients develop profound cyanosis, but tolerate the elevated methemoglobin concentrations extremely well.

Clinical Features

Patients with normal hemoglobin concentrations do not develop clinically significant effects until the methemoglobin levels rise above 15 percent of the total hemoglobin. However, patients may seek evaluation for the profound cyanosis that occurs when the methemoglobin concentration reaches about 1.5 g/dL, which is about 10 percent of the total hemoglobin in normal individuals. At levels between 15 and 30 percent, symptoms, including anxiety, headache, weakness, and lightheadedness develop, and patients may exhibit tachypnea and sinus tachycardia. Methemoglobin levels of 50 to 60 percent impair oxygen delivery to vital tissues, resulting in myocardial ischemia, dysrhythmias, depressed mental status (including coma), seizures, and lactate-associated metabolic acidosis. Levels above 70 percent are largely incompatible with life. Anemic patients may not exhibit cyanosis until the methemoglobin level rises dramatically above 10 percent, because it is the absolute concentration (i.e., 1.5 g/dL), not the percentage of methemoglobin that determines cyanosis. Anemic patients may likewise suffer significant symptoms at lower methemoglobin concentrations because the relative percentage of hemoglobin in the oxidized form is greater. Patients with preexisting diseases that impair oxygen delivery to the red blood cells (e.g., COPD, CHF) will also manifest symptoms with less significant elevations in their methemoglobin levels.

On the other hand, conditions that shift the oxyhemoglobin dissociation curve to the right such as acidosis or elevated 2,3-DPG, may result in somewhat better toleration of methemoglobin.

Diagnosis

The diagnosis of methemoglobinemia should be considered in all patients who present with cyanosis, and is particularly suspect in those whose cyanosis does not improve with supplemental oxygen. The blood of these patients has a characteristic "chocolate brown" color, analogous to that seen in the chocolate agar used to plate gonococcus (which contains methemoglobin). The ability to detect this discoloration is improved when compared directly to normal blood. [5] Pulse oximetry should be used cautiously in patients with methemoglobinemia. Because the pulse oximeter cannot properly differentiate oxyhemoglobin from methemoglobin, it may read an inappropriately normal value in patients with moderate methemoglobinemia, and it trends toward 85 percent in patients with severe methemoglobinemia. [6] Definitive identification of this abnormal hemoglobin species relies on co-oximetry, which is an in vitro spectrophotometric method that is capable of differentiating among oxy-, deoxy-, met- and carboxyhemoglobin species. This widely available test requires only a venous specimen, although arterial blood may be used if arterial puncture is indicated for another reason. The oxygen saturation obtained from a conventional arterial blood gas analyzer will also be falsely normal, because it is calculated from the dissolved oxygen tension, which is appropriately normal.

Treatment

Patients with methemoglobinemia require optimal supportive measures to ensure oxygen delivery and the administration of appropriate antidotal therapy if indicated. In general, gastric decontamination is limited, because there often is a substantial time interval between exposure to the toxic agent and the development of methemoglobin. If a source of continuing exposure exists, decontamination is indicated, and in most stable patients a single dose of activated charcoal is likely sufficient. Antidotal therapy with methylene blue is reserved for patients with documented methemoglobinemia or a high clinical likelihood of the disease. Highly unstable patients should receive methylene blue, but may require transfusion or exchange transfusion to produce an immediate enhancement of oxygen delivery.

Methylene blue serves to indirectly accelerate the enzymatic reduction of methemoglobin by NADPH-methemoglobin reductase, a normally minor enzymatic pathway. In this capacity, methylene blue is reduced to leucomethylene blue, which itself is capable of directly reducing the oxidized iron back to its oxygen carrying form (Fig. 183-1). The initial dose of methylene blue is 1 to 2 mg/kg intravenously (0.1 mL/kg of the 1% solution, about 7 mL in an adult) and its effect should be seen with 20 min. As the methemoglobin concentration falls, the most severe signs and symptoms will resolve first. Resolution of the cyanosis is a late finding, occurring only after the concentration of methemoglobin falls below 1.5 g/dL. Repeat dosing of methylene blue may be acceptable if needed, but high doses of methylene blue (<7 mg/kg) may actually induce methemoglobin formation. Treatment failures may result if the patient is deficient in glucose-6-phosphate dehydrogenase (G6PD), because this enzyme is critical in the production of NADPH within the hexose monophosphate shunt (see Fig. 183-1).[7] Because this group of patients does not lack NADH cytochrome- b_5 reductase, they are not at increased risk of developing methemoglobinemia, and they only lack the ability to respond to methylene blue. The concomitant occurrence of methemoglobinemia and hemolysis is not unexpected because both occur through similar oxidative mechanisms, and it is the rule for some agents such as chlorates. However, hemolysis may impede a response to methylene blue, which requires an intact erythrocyte to be effective. Oxidant drugs with long serum half-lives, such as dapsone ($T\frac{1}{2}$ ~50 h) produce prolonged oxidant stress to the red blood cell. Although not a true treatment failure, exposed patients may require repetitive dosing of methylene blue. In rare instances, patients may be deficient in NADPH-methemoglobin reductase, the required enzyme for methylene blue activation. Lastly, treatment failure may occur in patients with sulfhemoglobinemia, which is clinically indistinguishable from methemoglobinemia, but which is not responsive to methylene blue (see below). Patients that do not respond to methylene blue should be treated supportively. If clinically unstable, the use of blood transfusions or exchange transfusions is indicated. In the event that the newly administered red blood cell hemoglobin undergoes oxidation, it will likely respond appropriately to methylene blue.

SULFHEMOGLOBINEMIA

Sulfhemoglobinemia is less common than methemoglobinemia. Although patients with sulfhemoglobinemia have a clinical presentation similar to those with methemoglobinemia, the disease process itself is substantially less concerning.[8] Although the reduction in the patients oxygen carrying capacity is quantitatively similar, the patient's oxygen dissociation curve is shifted rightward, not leftward as in methemoglobinemia, favoring the release of hemoglobin-bound oxygen to the tissue. Because the pigmentation of the blood by sulfhemoglobin is substantially more intense than other colored hemoglobin species, only 0.5 g/dL of sulfhemoglobin is needed to produce a cyanosis equivalent to that produced by 1.5 g/dL of methemoglobin. At the level of the hemoglobin molecule, sulfhemoglobin occurs by oxidation of the porphyrin ring. Many of the responsible agents are identical to those that induce methemoglobin, and the agents do not need to contain sulfur. The diagnosis is difficult to confirm, because standard co-oximetry does not differentiate sulfhemoglobin from methemoglobin because of similar spectral absorbances. The addition of cyanide to the laboratory sample differentiates the two hemoglobin species, because cyanide binds to methemoglobin and changes its spectrophotometric pattern. Thus, if the addition of cyanide to this sample fails to eliminate the methemoglobin peak, the diagnosis of sulfhemoglobinemia is confirmed. Sulfhemoglobin is not reduced by treatment with methylene blue, and generally patients require only supportive care, although transfusions may be necessary for severe toxicity.

184 HYPOGLYCEMIC AGENTS

Joseph G. Rella
Lewis S. Nelson

Diabetes mellitus is the most common endocrine disorder in the United States, and the mainstay of pharmacotherapy includes the hypoglycemic agents. Poisoning by hypoglycemic agents may be the result of unintentional therapeutic misadventures, intentional self-poisoning, or homicidal intent. Many factors contribute to unintentional poisoning, including prescription errors, dosing errors, and the onset of complicating metabolic factors.

It is difficult to ascertain an accurate rate of overdose among diabetics. Generally, up to 20 percent of patients with diabetes using insulin or oral hypoglycemic agents experience hypoglycemic symptoms sufficient to visit an emergency department sometime during their lives. The 1997 annual report of the American Association of Poison Control Centers recorded 3846 exposures to oral hypoglycemics, 1619 of them in children under 6 years of age. There were 4 reported deaths. [1] Among oral hypoglycemic agents, severe hypoglycemia occurs in 1 percent of the populations using tolbutamide and tolazamide, 2 to 4 percent of glipizide users, and 4 to 6 percent of chlorpropamide users.[2]

Hypoglycemia, the failure to maintain a blood glucose above 60 mg/dL, is perhaps the most common endocrine emergency. However, the presenting clinical findings in patients with hypoglycemia may be quite varied (Table 184-1).[3] Neuroglycopenia, or insufficient glucose supply to the brain, can be manifested as dizziness, confusion, dysarthria, decreased concentrating ability, headache, diplopia, lethargy, coma, focal or generalized seizures, and status epilepticus. Hypoglycemia typically precipitates a physiologic attempt to try to correct the deficiency in blood glucose. This response includes an autonomic-nervous-system–mediated release of catecholamines, which produces the most common symptoms in hypoglycemic patients, including diaphoresis, anxiety, nausea, tremor, and palpitations. [4]

Signs of Neuroglycopenia	Signs of Autonomic Response to Hypoglycemia
Dizziness	Diaphoresis
Confusion	Anxiety
Dysarthria	Nausea
Decreased ability to concentrate	Tremor
Headache	Palpitations
Diplopia	Tachycardia
Lethargy, coma	Dry mouth
Focal or generalized seizures	Pallor

TABLE 184-1   Manifestations of Hypoglycemia

In healthy persons, complex regulatory systems maintain a constant level of glucose in the blood. Unfortunately, certain medical conditions may impair the ability of the body to maintain glucose levels, and hypoglycemia results. Chronic ethanol users are at increased risk for hypoglycemia due to diminished glycogen supply and impaired gluconeogenesis. Persons at extremes of age are also potentially at increased risk for hypoglycemia. Young children have a disproportionately higher brain requirement for glucose as well as smaller glycogen reserves. The elderly may have health problems that alter the normal counterregulatory response to hypoglycemia as well as contribute to hypoglycemia (e.g., hepatic or renal disease). Older patients are also more likely to be taking medications that may exacerbate hypoglycemia or blunt the normal response to hypoglycemia (e.g., b-adrenergic antagonists).

INSULIN

Insulin is the agent most commonly associated with severe hypoglycemia in patients evaluated in the emergency department. The hypoglycemic effects of excessive use of insulin may exceed the patient's caloric intake and precipitate hypoglycemia. The Diabetic Control and Complications Trial research group demonstrated that, although tighter glycemic control delayed the onset and progression of microvascular and neurologic complications in patients with type 1 diabetes, there were at least 120 episodes of treatment-requiring hypoglycemia per 100 patient years. [5,6] Therefore, intensive therapy directed at maintaining euglycemia increases the risk of hypoglycemia.

The pharmacokinetics of the various forms of insulin weigh heavily in management decisions. The rapidly acting but short-lived regular insulin produces relatively predictable hypoglycemia, whereas the long-acting insulins, such as NPH, have less predictable kinetic characteristics. Following large parenteral overdose, regular insulin manifests the unpredictable kinetics characteristic of the long-acting forms of insulin (Table 184-2).

Class and Name	Duration of Action, h	Metabolism
INSULIN		
Ultra–short acting		
Lispro	<5	Hepatic
Short acting		
Regular	6–8	Hepatic
Semilente	12–16	Hepatic
Intermediate acting		
Lente	24	Hepatic
NPH	24	Hepatic
Mixtard	24	Hepatic
Long acting		
PZI	24–36	Hepatic
Ultralente	>36	Hepatic
SULFONYLUREAS		
First generation		
Acetohexamide	12–24	Renal
Chlorpropamide	24–72	Renal
Tolazamide	12–24	Renal
Tolbutamide	6–12	Renal
Second generation		
Glipizide	10–16	Renal
Glyburide	24	Renal, hepatic

TABLE 184-2   Characteristics of Hypoglycemia Agents

SULFONYLUREAS

Sulfonylureas stimulate the b-islet cells of the pancreas to release insulin through inhibition of potassium channels and changes in membrane potential. [7] First-generation sulfonylureas, such as chlorpropamide, reduce hepatic clearance of insulin and have active metabolites. These agents are renally excreted, complicating glycemic control in diabetics with intrinsic renal disease. Second-generation sulfonylureas, such as glyburide and glipizide, have half-lives that exceed 24 h and are therefore associated with frequent episodes of hypoglycemia. Sulfonylureas represent about 1 percent of all prescriptions in the United States and are

therefore a prevalent cause of hypoglycemia.[2] In addition, the onset of hypoglycemia is unpredictable and commonly does not occur for 12 to16 h following ingestion.

BIGUANIDES

The biguanides include metformin and phenformin, both of which are derivatives of guanidine. Metformin acts to increase the peripheral sensitivity to insulin and to suppress endogenous glucose output. Metformin also inhibits gluconeogenesis, which reduces glucose production, and while it stimulates glucose uptake by cells, it does not stimulate insulin secretion.[8] Metformin lowers blood glucose levels only in diabetic patients and is more appropriately termed an antihyperglycemic than a hypoglycemic agent.

Phenformin was withdrawn from the US marketplace in 1976 due to its association with fatal lactic acidosis. Although not completely clear, the mechanism appears to be an enhanced production and inhibited metabolism of lactic acid, with a resultant fall in serum pH and cardiovascular collapse. Although metformin has not been demonstrated to alter lactate metabolism, lactic acidosis occurs in about 3 cases per 100,000 patient-years of therapy.[9] The risk of adverse reactions from metformin also rises with coexisting medical conditions, such as liver disease, congestive heart failure, and renal insufficiency. Phenformin toxicity is occasionally seen in the United States, since it is still available in other countries.

a-GLUCOSIDASE INHIBITORS

Acarbose acts to decrease postprandial glucose concentrations by decreasing gastrointestinal absorption of carbohydrates. Acarbose inhibits the brush-border enzyme a-glucosidase, thereby preventing the metabolism of polysaccharides into smaller units for absorption. By itself, acarbose does not cause hypoglycemia. To date, experience with acarbose overdose is limited. However, flatulence, bloating, and malabsorption can complicate use of this medication and should be expected in overdose.

THIAZOLIDINEDIONES

Troglitazone, a thiazolidinedione, offers the theoretical advantage of reducing hyperglycemia without increasing insulin secretion. Troglitazone effectively reduces plasma glucose concentrations both when given alone and in combination with either a sulfonylurea or insulin.[10] Troglitazone reduces insulin resistance as well as decreasing endogenous glucose production, and its effects are evident in both the liver and the skeletal muscle. Troglitazone exerts its antihyperglycemic effect only in the presence of insulin and does not cause hypoglycemia in nondiabetics. Troglitazone has been demonstrated to improve glycemic control in patients with type 2 diabetes mellitus.[11]

To date, the package insert of troglitazone has been altered three times since its release. Each version suggests closer monitoring of hepatic function due to the risk of potential hepatic failure.

MISCELLANEOUS SOURCES OF HYPOGLYCEMIA

The ackee tree is native to Jamaica, where it produces a fruit that is commonly eaten. The unripened fruit contains hypoglycins, a group of toxins that produce vomiting (Jamaican vomiting sickness), central nervous system sedation, and seizures. In addition, hypoglycins inhibit hepatic gluconeogenesis and may contribute to hypoglycemia. Epidemics of hypoglycin-mediated hypoglycemia have occurred only during times of famine, when poor nutrition and the increased eating of unripened fruit are perhaps more commonplace. Ackee is available in the United States in canned form, but only the unripe, fresh fruit is associated with hypoglycemia.

The sympathetic nervous system mediates glucose autoregulation partly through the release of epinephrine, which prevents the release of insulin and elevates blood glucose levels. This mechanism explains the role of epinephrine in the counterregulatory response to hypoglycemia. b-adrenergic antagonists interfere with both of these effects, potentially resulting in hypoglycemia through excessive insulin release while preventing the development of the typical autonomic response to hypoglycemia.[12,13 and 14] In addition, caffeine has been demonstrated to enhance patients' awareness of hypoglycemic events, theoretically because of its ability to induce neuroglycopenia.[15]

An increased incidence of neonatal hypoglycemia during the first day of life has been reported many times in those whose mothers had received b-adrenergic antagonists.[16] Neonates may also demonstrate characteristic radiographic findings on computed tomography resulting from hypoglycemia (Table 184-3).[17]

Angiotensin-converting enzyme inhibitors	Pentamidine
Acetaminophen	Phenylbutazone
Ackee	Propoxyphene
β-adrenergic antagonists	Quinine
Chloramphenicol	Salicylates
Disopyramide	Streptozocin
Ethanol	Sulfonamide
Haloperidol	Trimethoprim-sulfamethoxazole
Monoamine oxidase inhibitors	Pyriminil
Para-aminobenzoic acid	

TABLE 184-3   Drugs or Toxins Associated with Hypoglycemia

TREATMENT

Hypoglycemia should be considered part of the differential diagnosis for all patients with either gross or subtle alterations in mental status. Initial management includes rapid blood glucose determination with a reagent strip or glucometer, followed by administration of 1 g/kg body weight dextrose using 50% dextrose in water in adults. Since approximately 3 percent of hypoglycemic patients present with a new focal neurologic deficit as the chief complaint,[3] rapid glucose assessment prior to further care, such as computed tomography scan or thrombolytic therapy, is critical in patients with presumed cerebrovascular accidents. For children, 25% or 10% dextrose in water is used, since the hypertonicity of the dextrose preparation may damage their smaller blood vessels.

It is critical that, after the initial serum glucose correction has been made, therapy continues to prevent recurrence. Although the pharmacokinetics of intravenous dextrose is not completely defined, it has been demonstrated that the duration of hyperglycemia following its administration is transient and lasts only about 30 min. In normal subjects, intravenous glucose induces a rebound hypoglycemia 1 to 2 h following the bolus, presumably due to pancreatic insulin release.

Once the patient is awake and alert, 10% dextrose should be infused at a rate sufficient to maintain euglycemia (100 to 250 mg/dL). The blood glucose level should be closely monitored during the initial stages of therapy. In addition to a continuous infusion, repeat boluses of dextrose may be necessary initially to maintain euglycemia. Iatrogenic hypokalemia may result from repetitive boluses of dextrose, as may dilutional hyponatremia following exceedingly large infusions of dextrose-containing solutions.

Food is the best medicine for awake hypoglycemic patients. At least 300 g of carbohydrates should be provided to replete stores of glycogen and maintain euglycemia. This goal may be achieved by a variety of food sources, such as soda, chocolate, orange juice, or apple juice. More substantial food may also be available in the emergency department, such as sandwiches or snacks, as additional sources of carbohydrates. A single bolus of 50 mL of 50% dextrose in water contains only 100 calories, none of which may persist to be stored as glycogen, whereas a sandwich may contain significantly more calories and produce more favorable glucose pharmacokinetics.

Glucagon should not be used as empiric therapy for hypoglycemia except in specific cases. Since the action of glucagon is to mobilize glycogen stores, those patients who are glycogen-depleted (e.g., alcoholics, children, the malnourished, or the elderly) may not improve with glucagon. This may mislead the caretaker from establishing the diagnosis of hypoglycemia. For this reason, glucagon is better utilized in patients known to be diabetic or for whom intravenous access is not easily obtained. In such patients, glucagon 1 mg intramuscularly or intravenously in adults and children over 10 kg body weight may be administered. In children who weigh less than 10 kg, 0.1 mg/kg up to a maximum dose of 1 mg may be given. Glucagon requires several minutes for effect, and intravenous administration of hypertonic dextrose should never be delayed while waiting for glucagon to work. Glucagon is available as a 1-mg unit dose in lyophilized powder, accompanied by 10 mL of diluent that contains 2 mg/mL of phenol. As a precaution against systemic phenol toxicity, it is recommended that sterile water, rather than the accompanying diluent, be used for injection. Since emesis is common following glucagon administration, precautions should be taken to assure airway patency.

Diazoxide, formerly used as an antihypertensive agent, directly inhibits insulin secretion by opening potassium channels in b-islet cells. Hypoglycemia secondary to insulin-secreting tumors or refractory to oral hypoglycemic agents may require diazoxide, but diazoxide does not improve hypoglycemkia from insulin overdose. [18] Oral and intravenous preparations of diazoxide are available. Diazoxide 300 mg is administered intravenously over 30 min, and dosing may be repeated every 4 h. Diazoxide may cause hypotension and sodium retention. Oral diazoxide may be given at a dose of 200 to 300 mg every 4 h but is rarely needed.

Octreotide, a somatostatin analogue, has been demonstrated to inhibit glucose-stimulated insulin release through a mechanism utilizing a G protein within the pancreatic b-islet cells. [19] In healthy subjects, octreotide has a half-life of 72 h following intravenous administration, which directly contributes to its success in treating hypoglycemia from oral hypoglycemic agents, insulinomas, and quinine-induced hypoglycemia. Octreotide may be given in a dose of 50 μg subcutaneously every 12 h and is not expected to be useful in cases of insulin overdose.

The cornerstone of management of most poisoned patients is gastrointestinal decontamination to prevent absorption into the body, and this is equally true of patients who have overdosed with oral hypoglycemic agents. Several oral hypoglycemic agents have been demonstrated to adsorb well to activated charcoal in vitro, and there is no reason to suspect that the rest are not adsorbed as well. [20] A single dose, and perhaps several doses, of activated charcoal may be beneficial for such patients.

Emesis has not been demonstrated to produce consistent evacuation of the stomach contents and may be complicated should altered consciousness or seizure activity develop abruptly from the hypoglycemia. Gastric lavage with a large-bore tube may evacuate pill fragments and allow administration of activated charcoal but is associated with aspiration, esophageal injury, and vagal complications. Whole-bowel irrigation with a polyethylene glycol-based electrolyte solution may specifically benefit patients who have ingested sustained-release preparations. Since large pills may not be evacuated by a lavage tube and supplying adequate doses of activated charcoal may be difficult, whole-bowel irrigation may be the only effective means of preventing profound and prolonged hypoglycemia.

Following large subcutaneous deposition of insulin, toxicity may be reduced by removal of the reservoir. Percutaneous aspiration or excision may reduce the extent and duration of hypoglycemia, although this therapy is not commonly recommended. [21]

The half-life of chlorpropamide may be reduced from 49 to 13 h by alkalinization of the urine through ion trapping, in a fashion analogous to treatment of salicylate toxicity.[22] However, this effect may be limited to this agent. Alkalinization may be accomplished by adding three ampules (135 to 150 meq) of hypertonic sodium bicarbonate (7.5 to 8.4%) to a liter of 5% D/W for intravenous administration and infusing this solution, which is near isotonic, at a rate of twice maintenance. The ideal urine pH is 7.5 to 8 for maximal excretion, and difficulty in obtaining this pH is often related to inadequate serum potassium levels. Potential complications include excessive alkalinization and fluid overload.

The management of metformin-associated lactic acidosis must be aggressive to reduce the 50 percent mortality rate. [23] In addition to discontinuation of the drug, supportive care is critical. Hemodialysis appears to be the most beneficial therapy and should be instituted early. [24]

DISPOSITION

Patients with hypoglycemia resulting from nonintentional overdose of a short- or intermediate-acting insulin may not require admission if their condition is corrected and a normal blood glucose level is maintained prior to discharge. Those with hypoglycemia resulting from long-acting insulin should be admitted, as should those with underlying diseases, such as liver or renal insufficiency or starvation. Patients with serious complications of hypoglycemia, such as seizures, and those with refractory hypoglycemia should be closely monitored. Patients who are hypoglycemic due to attempted suicide, attempted homicide, or abuse should be admitted.

Hypoglycemia may occur in a delayed fashion after the ingestion of an oral hypoglycemic agent, particularly in children. Therefore, adults who have deliberately overdosed with oral hypoglycemics and children who have ingested even a single pill should be admitted for 24 h of observation, even though they may demonstrate euglycemia for many hours. Investigations of child abuse may arise from the unindicated administration of insulin to children.

185 FROSTBITE AND OTHER LOCALIZED COLD-RELATED INJURIES

Mark B. Rabold

Throughout history the most celebrated and extreme reports of cold-related injuries have been in the field of military endeavor. From Hannibal's losing half his 46,000-man army crossing the Pyrenean Alps to frostbite and hypothermia, to the tens of thousands of cases of trench foot during World War I, we have learned much. Perhaps the most famous cold-injury mass-casualty incident was Napoleon's retreat from Moscow during the dreadful winter of 1812–1813. This first authoritative account, as described by Napoleon's surgeon-in-chief, Baron de Larrey, described how each evening thousands of French soldiers thawed, and often inadvertently burned, their frozen extremities over campfires, only to refreeze them again on the next day's march. Combined heat and cold injury coupled with refreezing and forced ambulation resulted in abysmal outcomes. In addition, thousands died from the tetanus sustained from their frostbite wounds. It was from this experience that Larrey recommended rubbing frostbitten extremities with snow. This destructive therapy was the standard of care until the 1950s and is still used occasionally by the lay public. It was not until 1956 that rapid rewarming of frozen extremities was studied by a Public Health Service medical officer in Tanana, Alaska, which laid the foundation of modern therapy.[1]

PATHOPHYSIOLOGY

It is the inability to physiologically compensate for cold that produces injury. However, cold itself is not the only factor in determining whether injury will occur. Duration of contact, humidity, wind, altitude, clothing, medical conditions, behavior, and individual variability all contribute to the picture.

Cold-induced injury may be instantaneous, as with contact frostbite after touching a cold metal bottle of fuel, or more chronic, as in chilblains. Humidity is also important because it contributes to evaporative heat loss. Wet skin is more conducive to both subcutaneous ice crystal formation and trench foot. Wind velocity and cold, the wind-chill factor, have a synergistic effect on heat loss. For example, an ambient temperature of –7°C (19.4°F), when combined with a wind of 72.5 kph (45 mph), will feel equivalent to –40°C (–40°F) on a windless day. The rigors of travel at high altitude may also predispose to cold injury. Although the lower barometric pressure has not been shown to directly influence susceptibility to cold injury, a variety of factors associated with high altitude travel have. The fatigue, dehydration, and hypoxia often seen in climbers or trekkers, coupled with the sometimes extreme weather conditions and remote locations, all contribute to the incidence and severity of cold-related injuries at high altitude. [1]

Inadequate clothing is probably the most avoidable cause of cold-related injuries. Constrictive clothing and boots can reduce circulation to extremities and predispose to frostbite. An exposed head and neck can account for 80 percent of body heat loss. Natural-fiber clothing, such as wool and cotton, when compared to modern synthetics, such as polypropylene, have poorer wicking ability and greater thermal conductance and moisture retention. [1] Simply changing out of cold, wet clothes into dry ones can also be preventive. During World War I, the British decreased the number of trench foot cases from 29,172 in 1915 to a total of only 443 in 1916–1918 by frequent foot drying and sock changing. [2,3]

Certain disease states, such as atherosclerosis, arteritis, hypovolemia, diabetes, vascular injury secondary to trauma or infection, and previous cold-related injuries, may predispose to cold-related injury.

Individual behavior is extremely important as well. In fact, alcohol- or drug-intoxicated persons, combined with psychiatric patients, account for the majority of frostbite cases in the United States. Impaired judgment and lack of self-preservation instincts prevent these populations from dressing adequately and making rational decisions about exposure to the cold. Alcohol consumption also increases peripheral vasodilatation and heat loss, which increases the risk for hypothermia. In addition, many of these patients smoke, which results in peripheral vasoconstriction and increases the risk of frostbite. [1] Other examples of the precipitation of cold injury by individual behavior can be seen in recent case reports of significant facial frostbite by inhalation abuse of fluorinated hydrocarbons (e.g., Freon) and nitrous oxide.[4,5] There have also been case reports of full-thickness frostbite resulting from inappropiate use of dry ice as a first-aid cold pack. [6]

Military studies suggest that dark-skinned soldiers and those from warmer climatic regions are more susceptible to frostbite. Conversely, peoples indigenous to frigid climates, such as Eskimos, Tibetans, and Laplanders, are often "acclimated" to the cold and are less prone to injury. [1]

Local cold-related injuries are classified into nonfreezing and freezing injuries.

NONFREEZING COLD INJURIES: CHILBLAINS AND TRENCH FOOT

Clinical Features

Chilblains, or pernio, is characterized by usually mild but uncomfortable inflammatory lesions of the skin of bared extremities caused by chronic intermittent exposure to damp, nonfreezing ambient temperatures. It is precipitated by acute exposure to cold. The hands, ears, lower legs, and feet are most commonly involved. The cutaneous manifestations, which appear up to 12 h after acute exposure, include localized edema, erythema, cyanosis, plaques, nodules, and, in rare cases, ulcerations, vesicles, and bullae. Patients may complain of pruritus and burning paresthesias. Rewarming may result in the formation of tender blue nodules, which may persist for several days. This is primarily a disease of women and children, and, although rare in the United States, chilblains is common in the United Kingdom and other countries with a cold or temperate, damp climate. Also, it appears that young females with Raynaud phenomenon are at greatest risk, as well as those in households with inadequate heating and lack of warm clothing. [7]

Trench foot was given its current name after it was frequently found among World War I troops who had been confined for long periods in trenches filled with standing cold water. Significant numbers of cases were also seen in the Falkland and Vietnam wars. Immersion foot describes a more severe variant of trench foot seen in downed pilots and shipwrecked sailors exposed for extended periods in life rafts in the North Atlantic Ocean. Although they are a significant problem in military operations, trench foot and immersion foot are rarely seen in the civilian population.

The pathophysiology is multifactorial but involves direct injury to soft tissue sustained from prolonged cooling, and it is accelerated by wet conditions. The peripheral nerves seem to be the most sensitive to this form of injury. Trench foot develops slowly over hours to days and is initially reversible but if allowed to progress will become irreversible. Early symptoms progress from tingling to numbness of the affected tissues. On initial examination, the foot is pale, mottled, anesthetic, pulseless, and immobile, which initially does not change after rewarming. A hyperemic phase begins within hours and is associated with severe burning pain and reappearance of proximal sensation. As perfusion returns to the foot over 2 to 3 days, edema and bullae form, and the hyperemia may worsen. Anesthesia frequently persists for weeks but may be permanent. In more severe cases, tissue sloughing and gangrene may develop. Hyperhidrosis and cold sensitivity are common late features and may persist for months to years. Severe cases may be associated with prolonged convalescence and permanent disability.

Treatment

Management of chilblains is supportive. The affected skin should be rewarmed, gently bandaged, and elevated. Some European studies support the use of nifedipine

(Procardia), at a dose of 20 mg tid, as both prophylactic and therapeutic. Topical corticosteroids (.025% fluocinolone cream) or even a brief burst of oral corticosteroids, such as prednisone, have been shown to be useful. Affected areas are more prone to reinjury.

Effective prophylaxis for trench foot includes keeping warm, ensuring good boot fit, changing out of wet socks several times a day, never sleeping in wet socks and boots, and, once early symptoms are identified, maximizing efforts to warm, dry, and elevate the feet. Once injury has occurred, treatment is supportive. Currently there is no specific therapy. Feet should be kept clean, warm, dryly bandaged, and elevated. Signs of early infection should be monitored. [1,2 and 3]

FREEZING COLD INJURIES: FROSTNIP AND FROSTBITE

Pathophysiology

Cutaneous vascular tone can be altered by direct heating (e.g., warming hands over a fire) and indirect heating (e.g., putting on a hat to increase core temperature), and is modulated by sympathetic adrenergic vasoconstrictive fibers. In a euthermic 70-kg male, the total basal cutaneous blood flow is 200 to 500 mL/min. However, as the skin temperature drops to 14°C (57.2°F), the flow falls to 20 to 50 mL/min. As cooling continues to 10°C (50°F), cutaneous blood flow becomes negligible, and 5- to 10-min cycles of vasodilatation and vasoconstriction, known as the hunter's response, or cold-induced vasoconstriction, occur. For individuals who are well acclimated to the cold, such as Eskimos, the intervals between cycles are often much shorter. As the vasodilatory phases carry cooled blood back from the extremities, the core temperature begins to fall. These cycles continue until the core temperature is threatened. The body attempts to maintain thermal integrity by completely shutting down flow to the coldest extremities. This begins phase I of frostbite, and irreversible tissue damage commences. As skin temperatures fall well below 0°C (32°F), ice crystals form in the extracellular space. Crystals exert an osmotic force and pull fluid from the intracellular space, resulting in cellular dehydration and hyperosmolarity. The intracellular NaCl concentration may rise ten fold. As the damage continues, proteins are denatured, enzymes are destroyed, and the cellular membranes are altered. Theoretically, intracellular ice crystals then form, especially in rapid freeze and refreeze injuries, and may be even more lethal to the cell. Actual structural damage from the ice crystals may result.

Phase II is characterized by reperfusion injury as the involved extremity is rewarmed and some initial blood flow returns. Over a period of several hours to days, the damaged endothelium-lined capillaries allow leakage of fluid into the interstitium, intracellular swelling occurs, and oxygen free radicals are generated, which furthers endothelial damage. An arachidonic acid cascade forms, which liberates prostaglandin and thromboxane. This cascade promotes vasoconstriction, platelet aggregation, and leukocyte sludging, which results in venule and arterial thrombosis and subsequent ischemia, necrosis, and dry gangrene. Profound vasoconstriction and arteriovenous shunting occur at the margin between injured and noninjured tissue. Phase II is remarkably similar to the dynamics of a burn injury.[8]

Frostbite injury can be divided into three zones. The zone of coagulation is the most severe, distal region of damage and is irreversible. The zone of hyperemia is the more superficial, proximal region with the least cellular damage and generally recovers without treatment in less than 10 days. The zone of stasis is the middle ground and is characterized by severe, but possibly reversible, cell damage. It is here that treatment is directed. [9]

Table 185-1 summarizes the pathophysiology of frostbite.

PREFREEZE STATE
Tissue cooling
Increased viscosity
Capillary constriction-dilatation cycle

FROZEN STATE
Extracellular ice crystal formation
Intracellular dehydration and hyperosmolarity
Fluid crossing cell membrane

ISCHEMIC AND VASCULAR COMPLICATIONS
Reperfusion injury
Endothelium leaky
Coagulation from stasis
Leakage of destructive prostaglandins and oxygen free radicals
Vasoconstriction and arteriovenous shunting
Necrosis demarcation and gangrene

TABLE 185-1   Frostbite Pathophysiology Summary

Clinical Features

Frostbite can occur on any skin surface but is generally limited to the nose, ears, face, hands, and feet. Frostbite has been reported in the penis and scrotum of joggers and in burn patients after prolonged treatment with ice. Also, a freezing keratitis of the cornea has been reported in snowmobilers and skiers who did not wear protective goggles.

Frostnip is on a continuum with frostbite and is a superficial freeze injury characterized by lack of extracellular ice crystal formation and absence of progressive tissue loss. The involved extremity appears pale from intense vasoconstriction and is associated with some discomfort. Symptoms resolve on rewarming, and tissue loss does not occur.

There has been much debate over the proper classification of the severity of frostbite. [10] One may classify frostbite into degrees of injury or into superficial and deep groups (Table 185-2). First- and second-degree injuries are classified as superficial, whereas third- and fourth-degree injuries are classified as deep. The initial clinical appearance is often deceiving, especially if some warming has not occurred. Most patients present after some warming has occurred and are in phase II of the injury. Frostbite classification is based on the time of presentation.

Classification	Symptoms
SUPERFICIAL	
First degree: partial skin freezing; Erythema, edema, hyperemia; No blisters or necrosis; Occasional skin desquamation (5–10 d later)	Transient stinging and burning; Throbbing and aching possible; May have hyperhidrosis
Second degree: full-thickness injury; Erythema, substantial edema, vesicles with clear fluid; Blisters that desquamate and form blackened eschar	Numbness; Vasomotor disturbances in severe cases
DEEP	
Third degree: full-thickness skin and subcutaneous freezing; Violaceous or hemorrhagic blisters; Skin necrosis; Blue-gray discoloration	Initially, no sensation; Tissue feels like "block of wood"; Later, shooting pains, burning, throbbing, aching
Fourth degree: full-thickness skin, subcutaneous tissue, muscle, tendon, and bone freezing; Little edema; Initially mottled, deep red, or cyanotic; Eventually dry, black, mummified	Possible joint discomfort

TABLE 185-2   Classification of Cold Injury According to Severity

First-degree injury is characterized by partial skin freezing, erythema, mild edema, lack of blisters, and occasional skin desquamation several days later. The patient may complain of transient stinging and burning, followed by throbbing. Prognosis is excellent.

Second-degree injury is characterized by full-thickness skin freezing, formation of substantial edema over 3 to 4 h, erythema, and formation of clear blisters rich in thromboxane and prostaglandins. The blisters form within 6 to 24 h, extend to the end of the digit, and usually desquamate and form black, hard eschars over several

days. The patient complains of numbness, followed later by aching and throbbing. Prognosis is good.

Third-degree injury is characterized by damage that extends into the subdermal plexus. Hemorrhagic blisters form and are associated with skin necrosis and a blue-gray discoloration of the skin. The patient may complain that the involved extremity feels like a "block of wood," followed later by burning, throbbing, and shooting pains. Prognosis is often poor.

Fourth-degree injury is characterized by extension into subcutaneous tissues, muscle, bone, and tendon. There is little edema. The skin is mottled, with nonblanching cyanosis, and eventually forms a deep, dry, black, mummified eschar. Vesicles often present late, if at all, and may be small, bloody blebs that do not extend to the digit tips. The patient may complain of a deep, aching joint pain. Prognosis is extremely poor. [1,10,11,12,13 and 14]

Treatment

FIELD MANAGEMENT   Field management of frostbite by emergency medical service personnel is simple. The hypothermia and dehydration associated with frostbite should be addressed. Wet and constrictive clothing should be removed. The involved extremities should be elevated and carefully wrapped in dry sterile gauze, with affected fingers and toes separated. Further cold injury should be avoided. In most cases, more aggressive wound management should be avoided and the patient transported to the emergency department. However, in some cases the patient may be several days away from evacuation and medical services and more complex management might be indicated before arrival to the hospital (Table 185-3).

THAW
Give thermometer bath at 40–42°C (104–107.6°F) for 10–30 min with active motion.
Give parenteral analgesics (morphine 0.1 mg/kg, meperidine 1–1.5 mg/kg) as needed.
POSTTHAW
Débride clear blisters.
Leave hemorrhagic vesicles intact.
Dress all with aloe vera (Dermaide Aloe Cream).
Give tetanus prophylaxis as needed.
Give ibuprofen 400 mg orally q12h.
Consider penicillin G 500,000 U q6h for 48–72 h.
Begin daily hydrotherapy.

TABLE 185-3   Frostbite Treatment Summary

There is a correlation between the length of time tissue is frozen and the degree of cellular damage. Rapid rewarming is the single most effective therapy for frostbite. However, rewarming in the field is often impractical and is sometimes dangerous. In fact, in some unusual circumstances, it is best to endeavor to keep the affected part frozen until definitive care can be administered. For instance, if the victim has frozen feet and the only avenue to evacuation is prolonged ambulation, then rewarming can significantly complicate matters. The risk of refreezing the feet and causing even more severe damage is a real concern. Also, if adequate analgesia is not available, the rewarming process itself can be excessively painful. Ambulation on edematous and blistered feet may not be possible because of pain. In extreme situations such as this, it may be wise to keep the feet frozen and ambulate the patient to a location where more advanced evacuation can occur. If rewarming is attempted in the field, only clean water warmed to 40° to 42°C (104° to 107.6°F), as measured by thermometer, should be used. The use of hot, untested tap water should be avoided because the 50° to 60°C (122° to 140°F) temperatures will cause a destructive thermal injury and worsen the prognosis. Attempts to directly warm with dry air, such as campfires and heaters, should be avoided. Dry heat tends to desiccate damaged tissue, and temperature cannot be adequately measured. Adding a thermal injury to frostbite will worsen the outcome. Rubbing snow on frostbitten tissue to stimulate circulation is ineffective, destructive, and absolutely contraindicated.

Controversy surrounds management of the blisters associated with frostbite. Clear blisters are rich in tissue-injurious thromboxane and prostaglandins. Common sense suggests that blister débridement or aspiration would limit contact with these chemicals and allow direct contract with aloe vera (Dermaide Aloe Cream) to counteract their injurious effects. Also, tense blisters, which tend to only worsen when immobilization is not possible, are painful. Débridement or aspiration can bring some pain relief. When the patient is ambulating on rewarmed, frostbitten feet, the associated blisters often rupture anyway. Field débridement of clear blisters is controversial, but adequate research is lacking to support or condemn this practice. Hemorrhagic blisters should not be drained in the field.

One possible complication of field aspiration or débridement is the theoretical increased risk of infection. Prophylactic use of penicillin might be wise in the field setting to combat any potential wound infection. Wounds should be cleansed daily, and, if feet are involved, socks should be clean and changed at least once or twice per day. Affected digits should be covered with aloe vera and separated by dry, sterile cotton and dressings should be changed daily. Pain management should begin with nonsteroidal anti-inflammatory drugs, such as ibuprofen 12 mg/kg/day in divided doses, to counteract the arachidonic acid cascade and should be continued even if opioids analgesics are required as well. The victim should be discouraged from smoking because it exacerbates vasoconstriction and tissue damage. [1,10,11,12,13 and 14]

EMERGENCY DEPARTMENT MANAGEMENT   In taking the patient's history, it is important to determine as many prognostic factors as possible. What was the temperature and wind velocity? How long was the extremity frozen, and, if it was thawed, did any refreezing occur? Was there any self-treatment, such as rubbing with snow or use of aloe vera or ibuprofen? Were recreational drugs, alcohol, or tobacco involved? Are there any predisposing medical conditions?

Frostbite is often associated with systemic hypothermia and dehydration, both of which can have a negative impact on the prognosis for tissue salvage. Rehydration and general warming are important adjuncts to therapy when indicated.

Frostbitten patients often present to the emergency department subacutely (>24 h after injury) and with the involved extremity in a partially thawed state. This more prolonged injury and slow, partial thawing usually translates to significantly longer hospital stays and greater tissue loss. However, this should not mean the patient is treated any less aggressively than the acute patient. The target of treatment remains minimizing tissue loss by focusing on the zone of stasis, where damaged but potentially salvageable tissue exists.

Rapid rewarming is the core of frostbite therapy and should be initiated as soon as possible. The injured extremity should be placed in gently circulating water at a temperature of 40° to 42°C (104° to 107.6°F) for approximately 10 to 30 min, until the distal extremity is pliable and erythematous. Frostbitten faces can be thawed using moistened compresses soaked in warm water. Some patients may tolerate immersion of their ears in a bowl or pool of warmed water. Anticipate severe pain during rewarming and titrate with parenteral narcotics. The patient will probably require daily hydrotherapy and physical therapy during the inpatient phase.

Blister management is somewhat controversial, as is the use of prophylactic antibiotics. The current consensus is that clear blisters should be débrided or at least aspirated. The blister fluid is rich in destructive thromboxane and prostaglandins. Removal limits damage from these chemicals and enables access to the underlying tissue for topical therapy. Hemorrhagic blisters should not be débrided because this often results in tissue desiccation and worsened outcome. However, there is some controversy as to whether aspiration is helpful. Both blister types should be treated with topical aloe vera (Dermaide Aloe Cream) q6h, which helps to combat the arachidonic acid cascade. Affected digits should be separated with cotton and wrapped with sterile, dry gauze. Elevation of the involved extremities helps decrease edema and pain.

The role of prophylactic antibiotics is unclear. The edema associated with the first several days after injury does appear to predispose to infection.   *Staphylococcus aureus, Staphylococcus epidermidis,* and b-hemolytic streptococci account for nearly half of infections, but anaerobes, *Pseudomonas,* and *Enterococcus* are important pathogens as well. Therapy with penicillin G 500,000 U intravenously q6h, for 48 to 72 h, is recommended in several successful protocols and seems to be beneficial. One study, however, demonstrated better infection prophylaxis using topical bacitracin. Silver sulfadiazine (Silvadene) cream has also been advocated by some, but it has not been shown to be consistently beneficial. One disadvantage of using topical antibiotics is that it complicates the concurrent use of aloe vera (Dermaide Aloe Cream). It is important to address tetanus status and administer appropriate vaccination, if needed, because frostbite is a tetanus-prone wound.

Several agents besides aloe vera (Dermaide Aloe Cream) have been advocated to battle the arachidonic acid cascade and thereby limit tissue damage. The most commonly advocated oral medication is ibuprofen at a daily dose of 12 mg/kg. Animal studies suggest possible future roles for oral methimazole, a thromboxane synthetase inhibitor, and topical 1% methylprednisolone acetate, which acts as a phospholipase A_2 inhibitor, preventing the formation of arachidonic acid.

Another controversial area is the use of sympathectomy to relieve vasospasm and edema. The treatment may be medical, as in the use of intraarterial reserpine, or surgical. There is no role for early sympathectomy, and the controversy is beyond the scope of emergency department management.

Heparin, and hyperbaric oxygen therapy have been studied and appear to be of little value. To date; frostbite treatment with intravenous low-molecular-weight dextran has not been studied clinically in human, but anecdotal reports have been encouraging. Some preliminary data from a study using intraarterial recombinant tissue plasminogen activator in patients with third-degree frostbite suggest that it may hold some promise in decreasing the rate of amputation. [15] A recent limited study suggests that the prostaglandin E_1 analogue limaprost may be an effective prophylactic and therapeutic vasodilator for local cold injuries at high altitudes. [16]

Early surgical intervention is not indicated in the management of frostbite. Premature surgery has been an important contributor to necessary tissue loss and poor results in the past. This is primarily due to the inability to assess the depth of frostbite at early stages and the fact that the blackened, mummified carapace is protective of the underlying regenerating tissue. Limited, early escharotomy may be indicated if the eschar is preventing adequate range of motion or circulation. Fasciotomy is rarely, if ever, indicated. Amputation may be unavoidable, however, if wet gangrene or infection complicates recovery. It usually takes at least 3 to 4 weeks for full demarcation to occur. Most amputations and grafts occur during the third week. The mean length of hospital stay for all degrees of frostbite is reported to be 8.5 days to 33.2 days. To minimize extended hospital stays, some have advocated the early use of radionuclide angiography with bone scan at 7 to 14 days to assess tissue viability and possible early surgical débridement. [17,18] However, a recent case report suggests that the use of magnetic resonance imaging with magnetic resonance angiography may prove to be more helpful in the early determination of the degree of tissue damage and the eventual prognosis. [19]

Disposition

Since it is difficult to determine the extent of frostbite on initial examination, it is best to be conservative when contemplating admission. It has been the standard of care in the past to admit all but the most isolated and superficial frostbite cases. It is important to consider the associated social factors as well. The homeless or elderly, especially when unable to care for themselves adequately, should never be discharged into subfreezing temperatures. If the frostbite is extensive and the hospital and staff are not equipped to treat the degree of severity, transfer to a tertiary hospital should be considered after initial rewarming and treatment. Patients who are discharged from the emergency department should be treated with topical aloe vera (Dermaide Aloe Cream) and oral ibuprofen and encouraged not to smoke. Close surgical follow-up should be arranged.

Sequelae

The sequelae of frostbite can be significant and prolonged. Permanent cold sensitivity, pain, tingling, and hyperhidrosis are common. Skin color changes may occur. When deep frostbite involves bones or joints, arthritis may result. In pediatric patients, growth plate damage may result in digit shortening and radial deviation. Infection is a possible complication and often results in a poor outcome. Deep frostbite often results in amputation.

186 HYPOTHERMIA

Howard A. Bessen

EPIDEMIOLOGY

Hypothermia is defined as a core temperature less than 35°C (95°F). While most commonly seen in cold climates, it may develop without exposure to extreme environmental conditions. Hypothermia is not uncommon in temperate regions and may even develop indoors during the summer. In the United States, more than 700 people die from hypothermia each year. Half of those who die from hypothermia are older than 65 years. [1]

Individuals at the extremes of age and those with an altered sensorium for any reason are particularly susceptible to developing hypothermia. The elderly may lose their ability to sense cold; neonates easily become hypothermic because of their large surface area to volume ratio. Both groups have a limited ability to increase heat production and to conserve body heat. Individuals with an altered sensorium, if unable to carry out the appropriate behavioral responses to cold stress, may develop hypothermia despite otherwise intact thermoregulatory mechanisms.

PHYSIOLOGY OF TEMPERATURE HOMEOSTASIS

Body temperature may fall as a result of heat loss by conduction, convection, radiation, or evaporation. *Conduction* is the transfer of heat by direct contact, down a temperature gradient, e.g., from a warm body to the cold environment. Since the thermal conductivity of water is approximately 30 times that of air, the body loses heat rapidly when immersed in water, producing a rapid decline in body temperature.

Convection is the transfer of heat by the actual movement of heated material, e.g., wind disrupting the layer of warm air surrounding the body. Convective heat loss increases in windy conditions, a particular hazard for outdoors enthusiasts.

Heat also may be lost by *radiation* to the environment (primarily from noninsulated body areas) and by *evaporation of water*. Evaporation of the water contained in exhaled, water-saturated air occurs over a wide range of ambient temperatures and may be prevented by inhalation of warmed, humidified air.

Opposing the loss of body heat are the mechanisms of heat conservation and gain. In general, these are controlled by the hypothalamus; thus hypothalamic dysfunction may cause an impairment in temperature homeostasis. Heat is conserved by peripheral vasoconstriction and, importantly, by behavioral responses. If behavioral responses such as putting on clothing or coming indoors from a cold environment are impaired for any reason (e.g., drug intoxication or trauma), the risk of hypothermia is increased.

Heat gain is effected by shivering and by "nonshivering thermogenesis." The nonshivering component of heat production consists of an increase in metabolic rate brought about by increased output from the thyroid and adrenal glands.

ETIOLOGY

Although there are other, more unusual etiologies of hypothermia, nearly all patients seen in the emergency department will have hypothermia due to one or more of the causes noted in Table 186-1.

"Accidental" (environmental)

Metabolic

Hypothalamic and CNS dysfunction

Drug-induced

Sepsis

Dermal disease

Acute incapacitating illness

Iatrogenic (fluid resuscitation)

TABLE 186-1   Causes of Hypothermia: Clinical Settings

"Accidental" hypothermia may be divided into immersion and nonimmersion cold exposure. Exposure to cold environmental conditions may lead to hypothermia even in healthy subjects, especially in wind and rain. Inadequate clothing and physical exhaustion contribute to the loss of body heat. The high thermal conductivity of water leads to the rapid development of immersion hypothermia. Though the rate of heat loss is determined by water temperature, immersion in any water less than 16 to 21°C (60.8–69.8°F) may lead to hypothermia.

Metabolic causes of hypothermia include various hypoendocrine states (hypothyroidism, hypoadrenalism, hypopituitarism), which lead to a decrease in metabolic rate. Hypoglycemia also may lead to hypothermia; the probable mechanism is hypothalamic dysfunction secondary to glucopenia.

Other causes of hypothalamic and CNS dysfunction (e.g., head trauma, tumor, stroke) may interfere with mechanisms of temperature regulation. Wernicke's disease may involve the hypothalamus; this is a rare but important cause of hypothermia, since it is potentially reversible with parenteral thiamine.

In the United States, the majority of hypothermic patients are intoxicated with ethanol or other drugs. Ethanol is a vasodilator, and because of its anesthetic and CNS depressant effects, intoxicated subjects neither feel the cold nor respond to it appropriately. Other drugs commonly implicated in the development of hypothermia include sedative-hypnotics, phenothiazines, and occasionally insulin.

Sepsis may alter the hypothalamic temperature set point and is a well-known cause of hypothermia. Subnormal body temperature is a poor prognostic factor in patients with bacteremia. [2]

Severe dermal disease may impair the skin's thermoregulatory functions. Significant burns or severe exfoliative dermatitis may prevent cutaneous vasoconstriction

and increase transcutaneous water loss, predisposing to the development of hypothermia.

Hypothermia may develop in anyone with an acute incapacitating illness. Thus patients with severe infections, diabetic ketoacidosis, immobilizing injuries, and various other conditions may have impaired thermoregulatory function, including altered behavioral responses.

Hypothermia also may be induced by resuscitation with room-temperature fluid or cold blood. This is a particular risk in patients undergoing massive volume replacement, such as trauma patients.

PATHOPHYSIOLOGY AND CLINICAL FEATURES

The response of various organ systems to lowered temperature varies widely among individuals. [3,4 and 5] In general, however, body temperatures from 32 to 35°C (89.6–95°F) constitute "mild" hypothermia. In this temperature range, the patient is in an excitation (responsive) stage, in which physiologic adjustments attempt to retain and generate heat.

When temperature drops below 32°C (89.6°F), general excitation gives way to the slowing (adynamic) stage, in which there is a progressive slowdown of bodily functions. Metabolism slows, causing a decrease in both oxygen utilization and CO_2 production. Shivering ceases when body temperature falls below 30 to 32°C (86–89.6°F).

In the initial excitation phase, heart rate, cardiac output, and blood pressure all rise. With decreasing temperature, these all decline. Cardiac output and blood pressure may be markedly depressed by the negative inotropic and chronotropic effects of hypothermia and further depressed by concomitant hypovolemia.

Hypothermia causes characteristic ECG changes and may induce life-threatening dysrhythmias (Table 186-2). The Osborn (J) wave, a slow, positive deflection at the end of the QRS complex (Fig. 186-1), is characteristic, though not pathognomic, of hypothermia.

T-wave inversions

PR, QRS, QT prolongation

Muscle tremor artifact

Osborn (J) wave

Dysrhythmias:
  Sinus bradycardia
  Atrial fibrillation or flutter
  Nodal rhythms
  AV block
  PVCs
  Ventricular fibrillation
  Asystole

TABLE 186-2   ECG Changes in Hypothermia
FIG. 186-1. Rhythm strip from patient with temperature of 25°C (77°F) showing atrial fibrillation with a slow ventricular response, muscle tremor artifact, and Osborn (J) wave (*arrow*).

Patients are at risk for dysrhythmias at body temperatures below 30°C (86°F); the risk increases as body temperature decreases. Although various dysrhythmias may occur at any time, the typical sequence is a progression from sinus bradycardia to atrial fibrillation with a slow ventricular response, to ventricular fibrillation, and ultimately, to asystole. The hypothermic myocardium is extremely irritable, and ventricular fibrillation may be induced by a variety of manipulations and interventions that stimulate the heart, including rough handling of the patient. [4,6]

Pulmonary effects include initial tachypnea, followed by a progressive decrease in respiratory rate and tidal volume. Cold-induced bronchorrhea, along with a depression of cough and gag reflexes, makes aspiration pneumonia a common complication.

Much attention has been paid to the temperature correction of arterial blood gases in the hypothermic patient. Since the blood gas analyzer warms the blood to 37°C (98.6°F), thus increasing the partial pressure of dissolved gases, the machine will report a higher P_{O_2} and P_{CO_2} and lower pH than the actual values at the patient's body temperature. Correction factors and nomograms are available to determine the actual values in the patient's body; however, the optimal or "normal" values in hypothermia are not known. The simplest solution is to use the uncorrected values as if the patient were normothermic; studies suggest that this approach is the most physiologically sound. [7,8] P_{CO_2} is often quite low secondary to depressed metabolism and decreased CO_2 production, and iatrogenic hyperventilation may lead to marked respiratory alkalosis.

Hypothermia causes a leftward shift of the oxyhemoglobin dissociation curve, potentially impairing oxygen release to tissues. Patients may have minimal oxygen reserves despite diminished oxygen requirements, warranting the administration of supplemental oxygen.

The CNS is affected by hypothermia, with a progressive depression of consciousness with decreasing temperature. Mild incoordination is followed by confusion, lethargy, and coma; pupils may be dilated and unreactive. These changes are associated with a decrease in cerebral blood flow. An even greater decrease in cerebral oxygen requirements may protect the brain against anoxic or ischemic damage.

Hypothermia impairs renal concentrating abilities and induces a "cold diuresis," leading to significant volume losses. Because of this concentrating defect, urine flow and specific gravity are unreliable indicators of intravascular volume and circulatory status. The immobile hypothermic patient is prone to rhabdomyolysis, and acute tubular necrosis may occur because of myoglobinuria and renal hypoperfusion.

Intravascular volume is also lost due to a plasma shift to the extravascular space. The combination of hemoconcentration, cold-induced increase in blood viscosity, and poor circulation may lead to intravascular thrombosis and subsequent embolic complications. Disseminated intravascular coagulation may occur because of release of tissue thromboplastins into the bloodstream, especially when circulation is restored during rewarming.

Because cold inhibits both platelet function and the enzymatic reactions of the coagulation cascade, hypothermic patients are prone to bleeding. The coagulopathy

may be evident clinically but not detected with routine coagulation tests, which are performed at 37°C (98.6°F).

Endocrine function is fairly well preserved at low body temperatures. Plasma cortisol and thyroid hormone levels are usually normal or elevated unless the patient has a preexisting deficiency. Glucose levels may be normal, low, or elevated. Though hyperglycemia is common due to decreased insulin release as well as decreased glucose utilization, hypoglycemia may occur in up to 40 percent of patients.[9]

Acid-base disturbances are common in hypothermia but follow no uniform pattern. Acidosis may occur due to severe respiratory depression and CO_2 retention and to lactic acid production from shivering and poor tissue perfusion. Alkalosis may result from diminished CO_2 production with low metabolic rates or from iatrogenic hyperventilation or sodium bicarbonate administration.

Pancreatitis (not only hyperamylasemia but true pancreatic necrosis) may occur in hypothermia. Hepatic function is depressed by cold, so drugs normally metabolized, conjugated, or detoxified by the liver (e.g., lidocaine) may rapidly accumulate to toxic levels.

Finally, local cold injury and frostbite may occur in the hypothermic patient.

DIAGNOSIS

The diagnosis of hypothermia is often not obvious; exposure to profound cold is *not* necessary to produce hypothermia. Since many standard clinical thermometers record only to 34.4°C (94°F), low-reading glass or electronic thermometers are required to accurately measure the temperature of hypothermic patients. Electronic thermometers with flexible probes can be used to continuously monitor rectal or esophageal temperatures.

TREATMENT

Treatment includes both general supportive measures and specific rewarming techniques.[3,4,5 and 6] Therapy begins with careful, gentle handling, since manipulation can precipitate ventricular fibrillation in the irritable hypothermic myocardium.

Controversy has arisen regarding the performance of CPR on an unmonitored patient who appears to be profoundly hypothermic and in cardiopulmonary arrest. Opponents of CPR argue that pulses may be difficult to detect in this setting and that chest compressions may precipitate ventricular fibrillation. They recommend withholding CPR until the presence of an arrested rhythm (ventricular fibrillation or asystole) is confirmed. Alternatively, withholding CPR in the patient who is truly in cardiac arrest may unnecessarily subject the brain and other organs to prolonged ischemia. This CPR controversy applies only to patients with severe hypothermia, with core temperatures less than 28°C (82.4°F); practically, it may be difficult to confirm this diagnosis in the field. To avoid inappropriate chest compressions, prehospital care personnel should examine the patient for 30 to 60 s before diagnosing pulselessness. If no pulses are detected, most physicians recommend initiating CPR. The optimal rate of chest compressions and ventilations has not been determined.

Similar considerations apply to monitored patients. Some authors recommend avoiding chest compressions in severely hypothermic patients with "nonarrested rhythms" (sinus bradycardia, artrial fibrillation with slow ventricular response, junctional rhythms), even without a palpable pulse. Most, however, recommend full CPR in patients with pulseless electrical activity, even with profound hypothermia.

Oxygen and intravenous fluids should be warmed, and patients should have constant monitoring of their core temperature, cardiac rhythm, and oxygen saturation. Pulse oximetry is usually accurate in hypothermic patients,[10] although unreliable data may be obtained with profound vasoconstriction or a very low cardiac output. If central venous lines are placed, care should be taken to avoid entering and irritating the heart. In general, indications for endotracheal intubation are the same as in the normothermic patient. Concern has been raised regarding induction of dysrhythmias during intubation; however, there is a very low complication rate with careful intubation after oxygenation.[11]

Although dysrhythmias in the hypothermic patient may represent an immediate threat to life, most rhythm disturbances (e.g., sinus bradycardia, atrial fibrillation or flutter) require no therapy and revert spontaneously with rewarming. In addition, the activity of antiarrhythmic and cardioactive drugs is unpredictable in hypothermia, and the hypothermic heart is relatively resistant to atropine, pacing, and countershock.

Ventricular fibrillation may be refractory to therapy until the patient is rewarmed. The American Heart Association's 1992 guidelines suggest initial defibrillation attempts with up to three shocks. If this is unsuccessful, CPR should be instituted and rapid rewarming begun. Defibrillation should be reattempted as the core temperature rises. Bretylium has been suggested as the drug of choice for the prophylaxis or treatment of ventricular fibrillation in hypothermic patients, although data concerning its efficacy are conflicting.[12,13]

Drug Therapy

Because many hypothermic patients are thiamine-depleted alcoholics (and because Wernicke's disease may cause hypothermia), patients should be given intravenous thiamine. Fifty to 100 mL of 50% dextrose should be administered if a dipstick serum glucose measurement is low or if a rapid test is unavailable.

Administration of antibiotics, steroids, and thyroid hormone must be individualized. Serious, often occult, infections may either precipitate or complicate hypothermia, and a thorough search for infection is indicated. Routine steroid therapy is generally not indicated, but hydrocortisone (100 mg) should be given to the patient with a history of adrenal suppression or insufficiency preceding the hypothermic episode, as well as to the patient with myxedema coma.

Hypothermia and hypothyroidism share many clinical features. While the majority of patients with myxedema coma are hypothermic, only a small minority of hypothermic patients are hypothyroid; thyroid hormone levels are most often normal or elevated. Thyroxine in large doses is necessary for the patient in myxedema coma but could potentially cause dysrhythmias or cardiac ischemia in other hypothermic patients. Therefore, thyroid hormone replacement is indicated only in patients with a known history of hypothyroidism, a thyroidectomy scar, or other strong clinical evidence of myxedema coma.

Rewarming Techniques

Modalities available for rewarming are listed in Table 186-3. The choice of method is a matter of controversy. There are no prospective, controlled studies comparing rewarming methods in humans, and each method has advantages and disadvantages.

Passive rewarming:
  Removal from cold environment
  Insulation
Active external rewarming:
  Warm water immersion
  Heating blankets
  Heated objects (water bottles, etc.)
  Radiant heat
  Forced air
Active core rewarming:
  Inhalation rewarming
  Heated IV fluids
  GI tract lavage
  Bladder lavage
  Peritoneal lavage
  Pleural lavage
  Extracorporeal rewarming
  Mediastinal lavage via thoracotomy

TABLE 186-3   Rewarming Techniques

Passive rewarming allows patients to rewarm on their own, using endogenous heat produced by metabolism. Since patients often become hypothermic over a period of hours to days, slow, passive rewarming is physiologically sound, avoiding rapid changes in cardiovascular status and the complications associated with active rewarming methods.

Patients must have intact thermoregulatory mechanisms and be capable of metabolic heat production for successful passive rewarming. With severe hypothermia or hypothermia secondary to an underlying illness (see Table 186-1), patients may fail to rewarm passively; active rewarming is then indicated. In addition, since temperature rises slowly with passive rewarming, it is inappropriate for patients with cardiovascular compromise.

Active external rewarming (application of exogenous heat to the body) is often very effective in raising body temperature. Most of the methods listed in Table 186-3 are easily instituted, although some, especially warm water immersion, make resuscitation and monitoring difficult. Rewarming with heated air forced through slits in commercially available plastic or paper blankets appears very promising; this method has been used successfully in moderately to severely hypothermic patients. [14],[15]

External rewarming does have disadvantages. It may be ineffective with poor perfusion of the periphery, especially in patients in cardiac arrest. Application of external heat may cause peripheral vasodilation and venous pooling, leading to relative hypovolemia and hypotension (rewarming shock). Washout of lactic acid from the peripheral tissues may lead to "rewarming acidosis," and an increase in metabolic demands of the periphery before the hypothermic heart can provide adequate tissue perfusion may lead to further tissue hypoxia and acidosis.

The core temperature may continue to decline after rewarming has begun. This "core temperature afterdrop" was previously ascribed to the return of cold blood to the core induced by external warming and peripheral vasodilation. This mechanism is unlikely; afterdrop can be explained by the continued conduction of heat from the relatively warmer core to the colder peripheral tissues. The incidence and magnitude of afterdrop are unclear, and it is probably of little clinical significance. [6]

Active core rewarming has several theoretical advantages. Internal organs including the heart are preferentially rewarmed, decreasing myocardial irritability and returning cardiac function. Peripheral vasodilation is avoided, decreasing the incidence and magnitude of rewarming shock and acidosis. However, some internal rewarming techniques are invasive and may be difficult to institute.

Inhalation rewarming—administration of warmed, humidified oxygen via mask or endotracheal tube—provides a fairly small heat gain and is not effective for rapid rewarming. This is an important modality, however, because it minimizes heat loss from the lungs, a potential loss of up to 30 percent of the total metabolic heat production. Similarly, intravenous fluids should be warmed to avoid further cooling by the administration of fluids at room temperature. Heat gain is usually fairly small, although warming of infused fluid and blood can contribute significant amounts of heat to patients receiving massive fluid resuscitation. Commercial fluid warmers allow the temperature of infused fluids to be precisely controlled. Inhalation rewarming and warm intravenous fluids should be used in all but mild cases of hypothermia, since these are simple, noninvasive techniques with minimal risk of complications.

Gastrointestinal tract (gastric or colonic) lavage with warmed saline is technically simple, and patients can be lavaged with large volumes of fluid in a short time period. The obtunded hypothermic patient may develop pulmonary aspiration if lavaged with an unprotected airway. In a manner similar to gastrointestinal tract lavage, the bladder can be lavaged with warm saline solution using a Foley catheter.

Peritoneal lavage affords relatively rapid rewarming. [16] It is widely available, may be instituted rapidly and with little technical difficulty, and has been shown to be effective in both animal studies and human applications. Potassium-free dialysis solution is warmed to 40 to 45°C (104–113°F), instilled, and then removed; the use of two catheters (one for fluid instillation and one for removal) may increase the rewarming rate.

Pleural lavage using thoracostomy tubes has provided effective rewarming in animal studies and a few human cases. [17] Lavaging the left thoracic cavity delivers heated fluid in close proximity to the heart, potentially allowing rapid cardiac warming. Two thoracostomy tubes (for fluid inflow and outflow) have generally been employed. If this technique is chosen, care must be taken to monitor the net fluid infusion, as increased intrathoracic pressure and tension hydrothorax may complicate the procedure. The risk of precipitating dysrhythmias during chest tube insertion is unknown.

Rapid internal rewarming also can be accomplished through an extracorporeal circuit. [18],[19] This consists of an arteriovenous shunt in which blood is routed to a warming device and then returned to the patient. Pump-assisted cardiopulmonary bypass using the femoral vessels for access is the most commonly used extracorporeal technique; right atrial-aortic bypass using a median sternotomy and heated hemodialysis also have been employed. Continuous arteriovenous rewarming using a countercurrent heat exchanger (a modified commercial fluid warmer) interposed between catheters placed in the femoral vessels, with flow driven by the patient's blood pressure, also has been reported. [20] This technique obviates the need for pump support and systemic heparinization but is ineffective in hypotensive patients.

Profoundly hypothermic patients may be rewarmed in a very short time period with these methods. [18],[19] In addition to allowing rapid rewarming, pump-driven partial (femoral-femoral) or complete cardiopulmonary bypass provides circulatory support and oxygenation of blood, a great advantage in the management of patients in cardiac arrest or with severe cardiovascular compromise. Specialized equipment and personnel are required, however, and lack of immediate availability often precludes the use of this technique. In addition, the heparinization required for some extracorporeal techniques may cause complications in hypothermic trauma patients.

Various diathermy and radiowave techniques, although promising, have had limited use in hypothermic humans.

Finally, mediastinal irrigation using open thoracotomy has been used successfully as a rewarming technique in a few patients. It is possible that these patients could have been resuscitated using less invasive modalities. Thoracotomy has many potential complications and should only be considered in arrested patients. Even then, indications for this procedure are unclear.

Approach to Rewarming

No prospective, controlled studies comparing the various rewarming modalities have been done in humans. Therefore, firm guidelines for therapy cannot be given.

Patients with mild hypothermia, who are still in the "excitation" stage, generally improve spontaneously, as long as endogenous heat production mechanisms are functional. In addition, at temperatures above 30°C (86°F), the incidence of dysrhythmias is low, and rapid rewarming is rarely necessary.

By far the most important consideration is the patient's cardiovascular status; a secondary consideration is the presenting temperature. Some feel that patients with a stable cardiac rhythm (including sinus bradycardia and atrial fibrillation) and stable vital signs do not need rapid rewarming, even if the temperature is very low. They recommend passive rewarming and noninvasive internal modalities (e.g., warm moist oxygen and warm intravenous fluids) in this setting. Others argue that profoundly hypothermic patients, even if currently "stable," are at risk of developing life-threatening dysrhythmias. They recommend rapid rewarming until the temperature has reached 30 to 32°C (86–89.6°F) to minimize the time period during which dysrhythmias may develop. The relative merits of each approach have not been studied.

Patients with cardiovascular insufficiency or instability, including persistent hypotension and life-threatening dysrhythmias, need to be rewarmed rapidly. The best method remains to be definitively determined. Extracorporeal techniques offer many advantages but are often unavailable. If extracorporeal rewarming is not available, multiple other rewarming modalities can be used simultaneously.

PROGNOSIS

Many hypothermic patients have severe infections or other life-threatening illnesses. Patients with "uncomplicated" hypothermia (often purely due to cold exposure) have a fairly low mortality rate; patients with significant associated diseases have a much worse prognosis. [21] In terms of ultimate outcome, the underlying disease process is far more important than the initial temperature or the rewarming method chosen. Therefore, evaluation and treatment of these patients must include a

search for associated diseases as well as treatment of the hypothermia itself.

The protective effect of hypothermia may have an important influence on prognosis; decreased oxygen requirements can protect the brain and other organs against anoxic and ischemic damage. This means that the usual criteria indicating death or irreversibility of disease are not valid in the hypothermic patient, who may even survive prolonged cardiac arrest without neurologic sequelae.

Hypothermic patients may recover completely after presenting in a rigid, apneic state with fixed and dilated pupils. Recovery has been documented with core temperatures as low as 14.2°C (57.6°F),[22] and with cardiac arrest for 6.5 h.[23] Death in hypothermia must be defined as a failure to revive with rewarming; unless there is strong evidence that the patient is not viable, resuscitative efforts should be continued until core temperature is at least 30 to 32°C (86–89.6°F).

DISPOSITION

Patients with mild accidental hypothermia caused purely by environmental exposure may be discharged after rewarming in the emergency department, provided that they are asymptomatic and can return to a warm environment. Most other hypothermic patients require hospital admission, both for the management of hypothermia and for the evaluation and management of underlying diseases.

187 **HEAT EMERGENCIES**

James S. Walker
S. Brent Barnes

Humankind has developed an amazing ability to acclimatize and adapt to environmental heat. Despite these adaptations, history is filled with the accounts of the devastating effects of heat on humans. Heat-related illnesses are not simply an interesting historical footnote but are still commonly seen today.

EPIDEMIOLOGY

Between 1979 and 1995, a total of 6615 deaths (about 390 per year) in the United States were considered to be caused by the effects of heat and excessive heat exposure.[1] Because many of those who died were elderly, with underlying cardiopulmonary illnesses, there is a general acknowledgment that deaths caused by heat are underreported.[2] Estimations of the number of heat-related deaths per year have been as high as 4000 in the United States. The annual rate of heat-related deaths is highest among the elderly: fewer than 1 per million in the 5- to 44-year age group and increasing to about 5 per million in the over-85-year age group. [1] The young are also at increased risk, with attack rates of 0.3 per million among those younger than age 4 versus 0.05 among those older than age 4. [1] Heat-related illness is the second leading cause of death among young athletes. For patients with heatstroke, the most severe heat-related illness syndrome, mortality rates range from 10 to 75 percent. Heat-related illness and deaths are clearly related to high environmental temperature, and increased numbers have been seen in urban heat waves in the United States and elsewhere.[3,4] Although heat-related illness occurs in healthy individuals exposed to extremes of heat and humidity, it is especially dangerous for those impaired by chronic illness, drugs, and age.

PATHOPHYSIOLOGY

Body temperature is dependent on the balance between heat production from metabolism and heat loss (or gain) to the environment. The heat-balance equation is

$$
\begin{aligned}
\text{Body heat} &= \text{metabolism} \\
&\quad + [+ \text{ conduction} + \text{radiation} \\
&\quad + \text{convection} - \text{evaporation}] \\
\text{Body heat} &= M + [+ K + R + C - E]
\end{aligned}
$$

Through the four mechanisms of radiation, convection, conduction, and evaporation, the body is able to maintain core temperature within a very narrow range. Radiation, conduction, and convection are considered sensible or "dry" heat-exchange mechanisms. Heat can be transferred in either direction by these three methods: heat can be gained or lost, depending on the environment and the body. Radiation, which is heat transferred by electromagnetic waves, is the primary mechanism of heat loss when the air temperature is lower than body temperature, accounting for 65 percent of cooling in such an environment. Convection is heat exchange between a surface and a medium, usually the air water molecules circulating around the body, and is usually a minor mechanism of heat loss, accounting for only 10 to 15 percent. Once environmental air temperature exceeds body temperature, however, convection can be a source of heat gain. Convection is greatly affected by winds: as wind speed increases, the amount of heat loss through convection also increases. Conduction, which is heat exchange between two surfaces in direct contact with each other, accounts for only 2 percent of heat loss under normal circumstances. However, the conductivity of water is 25 percent times greater than air; thus, heat can be lost very quickly with immersion in cool water.

Evaporation is considered insensible or "wet" heat exchange. Unlike the "dry" or sensible heat exchanges in which heat can be gained or lost, evaporation can only result in heat loss. Evaporation is the conversion of liquid to a gaseous phase at the expense of energy. Humans primarily disperse heat by evaporation through the mechanism of sweating; the respiratory component of evaporation does not contribute significantly to heat loss. Sweating can dissipate a tremendous amount of heat, and in an environment in which the air temperature is greater than the body temperature, sensible exchange mechanisms cease to become a source of heat gain, and evaporation becomes the only means of heat dispersal. Sweat that drips to the ground or is wiped off does not result in significant heat loss. Actual evaporation must take place for heat loss to occur. Conditions of high humidity block evaporation, and conditions of both high humidity and high ambient temperatures are particularly hazardous.

PHYSIOLOGIC RESPONSE TO HEAT

The body shows a rapid and remarkable response to heat stress. As the core temperature rises, afferent receptors stimulate the anterior hypothalamus, causing multiple physiologic responses that result in heat loss. The hypothalamus stimulates the autonomic nervous system, resulting in a decrease in vasomotor tone and increased blood flow to the skin. This can cause a marked increase in cutaneous blood flow, from 0.2 to 0.5 L/min in cool temperature to 7 to 8 L/min in hot temperature. Sweating is stimulated by parasympathetic fibers, with the recruitment of more sweat glands followed by an increase in sweating rate of each gland. Sweating can increase dramatically, from less than 0.5 L/day in a temperate environment to 10 to 15 L/day in a trained individual exercising in a warm environment. Sweating is an efficient means of cooling. Evaporation of 1 L of sweat consumes 600 kcal of heat. For this reason, dehydration can predispose individuals to heat illness by inhibiting their sweating.[5] The tremendous peripheral vasodilation results in significant stress on the heart; cardiac output rises approximately 3 L/min for each 1°C (1.8°F) rise in core body temperature.[6] Since stroke volume is reduced by peripheral vasodilation, a compensatory rise in heart rate is required in order to maintain cardiac output. Patients with preexisting cardiac disease or on medications that blunt an increased heart rate are at significant risk for heat injury.

Acclimatization

Through acclimatization, the body adapts to a more efficient response to intense heat exposure. Acclimatization results from repeated bouts of moderate exercise in a hot environment. During acclimatization, physiologic changes occur that result in sweating at lower temperatures, a higher sweat rate, an increase in peripheral blood flow, and a decreased sodium chloride concentration in sweat and urine, due to increased aldosterone secretion. The end result of these physiologic changes includes a decreased heart rate, a decreased core body temperature, increased plasma volume, increased exercise tolerance time, and decreased perceived exertion.[7,8] Acclimatization requires repeated exposures to heat: usually 1 to 4 h/day for 14 days. The results of acclimatization are transient and are lost if heat

exposure does not continue.

Factors Predisposing to Heat Injury

Serious heat injury does not occur at random: heat-injury victims almost always have one or more identifiable risk factors. The three factors that influence the temperature regulation of the body are (1) increased internal heat production, (2) increased external heat gain, and (3) decreased ability to disperse heat. Conditions that produce increased heat gain or decreased heat dispersal can quickly overwhelm the body's physiologic adaptive systems and lead to serious heat injury.

INCREASED INTERNAL HEAT PRODUCTION   The three most common causes of increased heat production are physical activity, febrile illnesses, and pharmacologic agents. Any form of vigorous physical activity can quickly produce temperature elevation through internal heat production. Exercise is the most common cause of internal heat production from physical activity. Highly trained athletes have been shown to generate heat in excess of 1033 kcal/h, which can lead to an increase in body temperature of 0.3°C/min (0.54°F/min).[9] Other forms of activity that involve skeletal muscle contraction, such as seizures, neuroleptic malignant syndrome, combative behavior, and drug-withdrawal states, can also markedly increase internal heat production.

A febrile illness is the most common cause of an increased core body temperature. Hyperthermia due to fever has a completely different pathophysiologic cause than does environmental hyperthermia. Fever results from pyrogens derived from activated immune system cells that "reset" the thermoregulatory center in the hypothalamus. The body will actually utilize heat-producing mechanisms, such as shivering, to maintain this new set point. Treatment of simple fever differs drastically from treatment of environmental hyperthermia. Attempts at cooling the body of a patient with fever will result in shivering and an attempt to maintain the increased set-point temperature. Fever is treated with antipyretics, which block the molecular interaction that leads to fever. Antipyretics are not useful in environmental hyperthermia. A febrile illness is a risk factor for heat injury, because the body will use autonomic mechanisms to increase body temperature. Hyperthyroidism and pheochromocytoma also lead to increased endogenous heat production.

Many pharmacologic agents can increase internal heat production through various mechanisms. Amphetamines and cocaine cause increased muscle activity and lead to heat production. Lysergic acid diethylamide (LSD) and phencyclidine (PCP) act on the central nervous system (CNS) to induce a hypermetabolic state. Salicylates uncouple oxidative phosphorylation, causing cellular energy generated by the oxidation of facts and glucose to be released as heat rather than stored as ATP.

INCREASED EXTERNAL HEAT GAIN   Exposures to high ambient temperatures and high humidity can lead to rapid exogenous heat gain. During heat waves, direct exposure to sunlight, living on higher floors of multistory buildings, and lack of air conditioners have been shown to increase the risk of heatstroke markedly.[3,4,10] Interestingly, the use of fans has not been shown to decrease the risk of heatstroke.[11] During the heat wave of 1980, the risk of heatstroke was 49 times greater for people without home air-conditioning than for those with continuous home air-conditioning, making the lower socioeconomic class with poorer living conditions at increased risk. It has also been reported than simply spending 2 h/day in an air-conditioned environment such as a shopping mall significantly decreases the risk of heat injury for those not living in an air-conditioned environment.

Several measurements of environmental heat stress have been developed to help assess the risk of heat injury. Simple temperature measurement alone is not adequate in predicting risk of heat injury, because humidity and direct radiation must also be considered. The wet-bulb globe temperature (WBGT) index was developed to provide an indication of thermal load on military troops training in the field. The WBGT measures air temperature through a dry-bulb thermometer, humidity through a wet-bulb thermometer, and the radiant heat with a black-globe thermometer. Many agencies, including the military, use the WBGT as a guide for recommended outdoor activity levels:

$$WBGT = 0.7\ T_{wb} + 0.2\ T_{bg} + 0.1\ T_{db}$$

where T_{wb} is the wet-bulb temperature of ambient air measured in the shade, T_{bg} is black-globe temperature, and T_{db} is dry-bulb temperature. A WBGT greater than 33°C (91.4°F) has been shown to increase the incidence of heat injury and heatstroke significantly. The wet-bulb temperature is the most significant variable in the WBGT equation, emphasizing the importance of humidity in heat injury.

Another measurement of heat stress that is commonly reported in the weather segment of television newscasts is the heat index, which is determined by a complicated formula developed by the National Weather Service using the air temperature and relative humidity (Table 187-1). The heat index, often referred to as "apparent temperature," is a measurement of how hot it actually feels when relative humidity is combined with the effects of air temperature. The heat index is calculated for shady, light-wind conditions. If there is exposure to direct sunlight, the heat index should be adjusted by adding 15°F.[6] The National Weather Service has reported that increasingly severe heat illnesses are seen with prolonged exposure or activity when the heat index is 105°F or greater. For this reason, the National Weather Service has identified specific procedures that will be followed when the heat index is expected to exceed 105° to 110°F for at least 2 consecutive days in a geographic region:

TABLE 187-1   Heat-Index Chart

1. Heat index values will be included in zone and city weather forecasts
2. Special weather statements and public information statements will be released with a detailed discussion of the extent of the hazard including heat-index values, who will be most at risk for heat injury, and safety rules for reducing the risk of heat injury
3. Assistance will be given to state and local health officials in preparing Civil Emergency Messages in severe heat waves which will include detailed medical information and names and telephone numbers of health officials
4. All of the above information will be released to the media and over the National Oceanic and Atmospheric Administration's Weather Radio.

FACTORS THAT DECREASE ABILITY TO DISPERSE HEAT   Several factors can lead to a decreased ability to disperse heat (Table 187-2). One of the most important of these is dehydration, which can develop quickly under intense heat stress. Even mild dehydration (as little as 1 percent) can impair physiologic and performance responses.[12] It is estimated that every 1 percent decrease in body weight from dehydration results in a body temperature increase of 0.1 to 0.3°C (0.18° to 0.54°F). Dehydration impairs cardiovascular and thermoregulatory function by decreasing skin blood flow and sweating rate, leading to a decreased ability to disperse heat. Even when fluid is available, the human body is not able to assess fluid losses accurately and compensate by oral rehydration. Even when fluid is readily available to athletes during exercise, they will voluntarily ingest only 50 percent of their sweat loss and can rapidly become dehydrated.[5]

TABLE 187-2   Risk Factors for Serious Heat Injury/Heatstroke

Extremes of age are risk factors for heat illness. Infants and children are at increased risk of heat illness due to a greater surface area-mass ratio, the production of more metabolic heat per mass unit, and a decreased sweating capacity as compared with adults. The elderly are generally unable to disperse heat as well as younger people due to the frequent presence of neurovascular and cardiovascular disease, the use of multiple drugs that affect heat dispersal, increased obesity, decreased cutaneous blood supply, poorer physical conditioning, and reduced sweat production.

Cardiovascular disease is also a risk factor for heat illness, because the cardiovascular system is one of the primary systems that disperse heat. Patients with chronic cardiovascular diseases such as cardiomyopathies, congestive heart failure, valvular disease, and coronary artery disease may be unable to compensate for the increased stress that heat exposure causes on the cardiovascular system. This increased stress can lead to arrhythmias, myocardial infarction, congestive heart failure exacerbation, or heatstroke.

Obese people are at increased risk for heat illness. Adipose tissue has decreased vascularity and inhibits heat dispersal by decreasing blood flow to the skin. Obesity makes less area available for heat exchange, and the lower water content of adipose tissue leads to a higher elevation of body temperatures with exertion. In essence, adipose insulates the body.

By diminishing sweating ability, many skin diseases can decrease the ability to disperse heat. Scleroderma, cystic fibrosis, eczema, psoriasis, and burns decrease sweating ability. Congenital diseases, such as ectodermal dysplasia, involving the sweat glands increase risk of heat injury. Interestingly, even the presence of simple heat rash has been shown to decrease sweating. Histologic studies of skin with heat rash have demonstrated obstruction of sweat gland ducts by keratin debris, resulting in significantly lower sweating rates and decreased tolerance time in a hot environment. [13]

Clothing can act as a major deterrent to heat dispersal. Thick clothing has less thermal conductance, a lower evaporative capability, and less wind resistance and thus can significantly impair heat loss. The evaporative rate of water loss from wet skin depends on skin-clothing–ambient air vapor pressure gradient. [14] Clothing that interferes with evaporation of sweat from skin causes an increase in skin temperature and lower cooling efficiency.

Many medications decrease the body's ability to disperse heat. The most notable agents include the anticholinergic agents, diuretics, phenothiazines, cardiovascular drugs, and sympathomimetic agents (this can be remembered by the mnemonic All Desert People Capitulate Sweat). All anticholinergic agents impair the sweating response. Diuretics lead to volume depletion and a decreased cardiac output, resulting in diminished sweating. Phenothiazines deplete the central stores of dopamine and interfere with the thermoregulatory center of the hypothalamus. They also have anticholinergic properties. Cardiovascular medications such as b blockers, calcium-channel blockers, or a agonists decrease the cardiovascular response to heat and reduce peripheral blood flow and the ability to sweat. Sympathomimetics lead to cutaneous vasoconstriction, which decreases sweating.

Alcohol and drug abuse can lead to decreased heat dispersal. Alcohol inhibits antidiuretic hormone and leads to a relative dehydration that can contribute to heat illness. The influence of alcohol can also blunt the stimulation to leave a hot area and seek a cooler environment. Other drugs such as heroin and cocaine can predispose individuals to heat injury. Endogenous endorphins and adrenocorticotropic hormone are likely involved in the body's adaptation to heat. Chronic abusers of heroin, cocaine, or alcohol have disruption of the endorphin response to thermal stress, predisposing them to heat injury. [15]

CLINICAL FEATURES

Heat-related illnesses are usually divided into minor syndromes (e.g., heat edema, prickly heat, heat syncope, heat cramps, and heat exhaustion) and major syndromes (e.g., heatstroke).

Heat Edema

This is a self-limited process manifested by mild swelling and tightening of the hands and feet that appears within the first few days of exposure to a hot environment. Heat edema is due to cutaneous vasodilatation and orthostatic pooling of interstitial fluid in the extremities. Some authorities feel increased secretion of aldosterone and antidiuretic hormone also plays a role. It is found most commonly in elderly nonacclimatized individuals who are physically active after a prolonged period of sitting in a car, bus, or plane. To a lesser extent, it is seen in healthy travelers just arriving from a colder climate. Edema is usually mild and does not restrict normal activities. Rarely, pitting edema of the ankles may develop, but heat edema does not progress to the pretibial region. A typical history and thorough physical examination are sufficient to exclude systemic causes of edema. Heat edema usually resolves spontaneously in a few days but may take up to 6 weeks. No special treatment is necessary. If a patient is insistent on treatment, elevation of the legs and the use of support hose will facilitate the removal of the interstitial fluid. Diuretics are not effective and can predispose patients to electrolyte abnormalities, volume depletion, or a more serious heat illness.

Prickly Heat

This is a pruritic, maculopapular, erythematous rash over clothed areas of the body. Also known as lichen tropicus, miliaria rubra, or heat rash, it is an acute inflammation of the sweat ducts caused by blockage of the sweat pores by macerated stratum corneum. The ducts become dilated under pressure and ultimately rupture, producing superficial vesicles in the malpighian layer of the skin on a red base. Itching is the predominant clinical feature during this phase and is treated successfully with antihistamines. Prickly heat can be prevented by wearing clean, light, and loose-fitting clothing and avoiding sweat-generating situations. The use of talc or baby power is of no benefit. Sometimes, ducts become secondarily infected with *Staphylococcus aureus*. Chlorhexidine in a light cream or lotion is the treatment of choice in the acute phase.

With prolonged heat exposure, a keratin plug fills the duct, causing obstruction in the stratum malpighian layer. When the duct ruptures a second time, the resultant vesicle will be driven deeper into the dermis. This rash simulates the white papules of piloerection and is not pruritic. This is known as the profunda stage of prickly heat and can readily advance into a chronic dermatitis. Infection with *S. aureus* is a common complication and requires the use of dicloxacillin or erythromycin. The skin can be desquamated by applying 1% salicylic acid to the affected area three times a day. Caution should be used to avoid salicylate toxicity.

Heat Syncope

This is a variant of postural hypotension resulting from the cumulative effect of peripheral vasodilation, decreased vasomotor tone, and relative volume depletion. It occurs most commonly in nonacclimatized individuals during the early stages of heat exposure. It does not necessarily represent a state of significant volume depletion.

Evaluation of patients with heat syncope requires the usual exclusion of neurologic, metabolic, and cardiovascular disorders. Patients should also be examined for any injuries acquired as a result of the syncopal episode and subsequent fall. Treatment consists of removal from the heat source, oral or intravenous rehydration,

and rest. Hospitalization is usually not necessary. Most patients with heat syncope recover promptly with fluids.

Heat Cramps

These are painful, involuntary, spasmodic contractions of skeletal muscles, usually those of the calves, although they may involve the thighs and shoulders. Heat cramps usually occur in individuals who are sweating liberally and replace fluid loss with water or other hypotonic solutions. Cramps may occur during exercise or after a latent period of several hours. Unconditioned or nonacclimatized individuals who are just starting manual labor in a hot environment are at high risk for developing heat cramps. Although heat cramps usually do not cause significant morbidity and are considered to be self-limiting, the pain associated with them can readily result in an emergency department visit. In fact, the pain is commonly recalcitrant to the effects of narcotics alone.

The exact pathogenesis of heat cramps is not known but is generally accepted to be a relative deficiency of sodium, potassium, and fluid at the cellular level. The production of large amounts of sweat, which has a high sodium content, coupled with inadequate sodium replacement results in hyponatremia. This in turn produces muscle cramps by interfering with calcium-dependent muscle relaxation. Hypokalemia from hyperventilation and dehydration may also play a contributing role.

Treatment consists of rest in a cool environment and fluid and salt replacement, either orally or intravenously. For mild cases, or if an overwhelming number of patients require treatment, a 0.1% to 0.2% saline solution can be given orally. Many electrolyte drinks are commercially available. More severe cases of heat cramps will respond to intravenous rehydration with normal saline. Rarely, rhabdomyolysis occurs secondary to protracted and diffuse muscle spasm.

Heat cramps can be prevented by maintaining adequate dietary salt intake or by drinking commercial electrolyte beverages. Salt tablets by themselves should not be used because (1) the tablets are a gastric irritant and often result in nausea and vomiting and (2) they do not replace volume.

Heat Tetany

This is characterized by hyperventilation resulting in respiratory alkalosis, paresthesia, and carpopedal spasm, and is usually associated with short periods of intense heat stress. Treatment consists of removal from heat and decreasing the respiratory rate. Generally, concomitant heat cramps are not present.

Heat Exhaustion

This is an obscure syndrome characterized by nonspecific symptoms such as dizziness, weakness, malaise, light-headedness, fatigue, nausea, vomiting, headache, and myalgias. Clinical manifestations include syncope, orthostatic hypotension, sinus tachycardia, tachypnea, diaphoresis, and hyperthermia. The core temperature is variable, however, and can range from normal to 40°C (104°F). Mental status remains normal. Because of the ill-defined and nonspecific symptoms, heat exhaustion is a diagnosis of exclusion. Physiologically, heat exhaustion is characterized by a combination of salt depletion and water depletion. Heat cramps may also be present on rare occasions.

Laboratory studies will almost universally demonstrate hemoconcentration, although specific electrolyte abnormalities depend on the ratio of fluid and electrolyte losses to intake. Patients who have virtually no fluid intake of any kind will usually develop hypernatremia, whereas those who partially rehydrate with salt-containing fluids may develop isotonic dehydration with normal sodium and chloride levels. Serum potassium and magnesium levels are variable.

Heat exhaustion is treated by rest and volume and electrolyte replacement. Rapid administration of moderate amounts of intravenous fluids (1 to 2 L of saline solution) may be necessary in some patients who demonstrate significant tissue hypoperfusion. The choice of solution is guided by laboratory determinations, but balanced salt solutions may be used until specific electrolyte abnormalities are determined to be present. Generally, these patients do not require hospitalization.

The signs and symptoms of early heatstroke may be difficult to differentiate from heat exhaustion. Patients with heat exhaustion will have normal findings on neurologic examination and normal mental status, although they may complain of headache, dizziness, weakness, or blurring of vision. Any patient with altered mental status in this situation has heatstroke.

Heatstroke

Classically, heatstroke is defined as the triad of a core temperature greater than 40.5°C (104.9°F), CNS dysfunction, and anhidrosis. However, anhidrosis, or a lack of sweating may not be present for a variety of reasons and is not considered to be an absolute diagnostic criterion. Subsequently, anyone with hyperpyrexia and CNS dysfunction should be considered to have a heatstroke, which is a medical emergency with multiple organ system involvement and a high mortality rate and requires immediate intervention.

The CNS is particularly vulnerable in heatstroke, manifesting with such symptoms as irritability, bizarre behavior, combativeness, hallucinations, seizures, or coma. The cerebellum is highly sensitive to heat, and ataxia can be an early finding. Virtually any neurologic abnormality may be present in heatstroke, including plantar responses, decorticate and decerebrate posturing, hemiplegia, status epilepticus, and coma. Cerebral edema is a common finding. CNS dysfunction is universal at core temperatures higher than 42°C (107.6°F). However, there is no arbitrary core temperature threshold for heatstroke. Cellular injury is a function of both the maximum temperature reached and the time of exposure. Patients with lower temperatures for longer periods may do worse than patients with higher temperatures for shorter periods.

The presence or absence of sweating has traditionally been one of the important distinctions between true heatstroke and other heat emergencies. The presence of sweating does not exclude the diagnosis of heatstroke. Patients with early heatstroke typically demonstrate marked sweating but eventually develop anhidrosis due to profound volume depletion or sweat gland dysfunction.

Heatstroke is a total breakdown of thermoregulation. Traditionally, two forms of heatstroke have been described: nonexertional and exertional. Nonexertional or "classic" heatstroke usually occurs during summer heat waves. Since physical exertion is not a major component of heat production in classic heatstroke, it tends to be more insidious in onset. Because of this slow evolution, there is sufficient time for fluid and electrolyte abnormalities to develop. The poor, the elderly, infants, and the chronically ill are at greatest risk. The pathophysiology is increased exogenous heat gain and diminished heat dispersion. The specific stressors are lack of air-conditioning, presence of cardiovascular disease, older age, and use of cardiovascular or anticholinergic drugs. Small children are at risk because of the immaturity of their thermoregulatory systems, as well as their dependence on others for fluids.

Exertional heatstroke usually strikes a younger segment of the population as a consequence of vigorous physical activity. The primary cause is increased endogenous heat production. Individuals who perform physical labor or exercise in a hot, humid climate are especially prone to develop exertional heatstroke. The distinction between exertional and nonexertional heatstroke is moot, because signs, symptoms, and management are the same. The primary factor that contributes to the morbidity and mortality of heat illness is the severity of underlying disease and not the absolute height of the core temperature.

The definitive diagnosis of environmental heatstroke is a diagnosis of exclusion. The differential diagnosis for fever and altered mental status is varied and lengthy (Table 187-3). However, once heatstroke is suspected, efforts to lower the body temperature must be initiated immediately by whatever means available, whether in the prehospital or emergency department setting. A delay in cooling represents a primary reason for the high potential mortality rate associated with heatstroke.

Alcohol withdrawal syndrome	Meningitis
Neuroleptic malignant syndrome	Brain abscess
Malignant hyperthermia	Malaria (cerebral falciparum)
Anticholinergic toxicity	Typhoid fever
Salicylate toxicity	Status epilepticus
PCP, cocaine, or amphetamine toxicity	Cerebral hemorrhage
Tetanus	Diabetic ketoacidosis
Sepsis	Thyroid storm
Encephalitis	

TABLE 187-3   Differential Diagnosis of Heatstroke

TREATMENT OF HEATSTROKE

Initial Resuscitation

Initial attention must be paid to the ABCs, with the initiation of high-flow supplemental oxygen, continuous pulse oximetry and cardiac monitoring, and intravenous access (we recommend the initial infusion of normal saline or lactated Ringer's solution at 250 mL/h). If a patient is elderly or has cardiovascular disease, it is wise to monitor cardiac filling pressures (central venous pressure or pulmonary artery occlusion pressure) to guide fluid therapy. A Foley catheter should be inserted. Of paramount importance is the serial monitoring of the patient's core temperature. This is best accomplished by inserting an electronic rectal thermistor probe or a temperature probe equipped Foley catheter. Another option, especially in intubated patients, is the use of an esophageal thermometer.

Diagnostic studies necessary to detect the end-organ sequelae of heatstroke include a complete blood cell count, comprehensive metabolic profile, hepatic panel, coagulation profile (prothrombin time, partial thromboplastin time, and international normalized ratio), creatine kinase, urinalysis, toxicology screen, ECG, and chest radiograph. Computed tomography of the head and lumbar puncture may also be indicated as part of the evaluation of altered mental status.

Cooling Techniques

Rapid reduction of core temperature to 40°C (104°F) is the primary goal of treatment and is accomplished by physical cooling techniques. Antipyretics are not effective. The fastest cooling techniques reported in the literature are usually implemented in a structured research laboratory environment, using animal models and equipment and techniques that are not universally available. In clinical practice, a technique that allows easy patient access and is readily available is preferable to a technique that may be faster but is difficult to perform or does not permit easy access to the patient (Table 187-4). Many of the techniques may be used in combination. Although effective and reported to be widely used, immersion cooling is relatively contraindicated if the patient may require cardiac monitoring and defibrillation. Also, the efficiency of immersion has been primarily documented in young, healthy patients without comorbid diseases. The safety and efficacy of immersion in classic heatstroke victims has not been established. Special considerations should be taken for invasive cooling techniques. Iced gastric lavage should not be used unless the airway is protected. Iced peritoneal lavage is relatively contraindicated if the patient is pregnant or has had previous abdominal surgery.

TABLE 187-4   Comparison of Cooling Techniques

We favor evaporative cooling as the technique of choice: it is simple and the fastest noninvasive cooling technique in humans. Other simple measures include ice packs placed at the groin and axillae to cool blood in the axillary and femoral vessels. Gastric lavage is safe if a patient is intubated. Cooling with peritoneal lavage is an effective and rapid central cooling technique. Immersion cooling should be limited to situations where evaporative cooling is not possible.

Evaporative cooling is performed by positioning fan(s) close to the completely undressed patient and then sponging the skin or spraying tepid water on the patient. Inexpensive plastic spray bottles work the best. We avoid covering the patient with sheets and then wetting the sheets, because this impairs evaporation of heat from the skin. Only one person is needed to monitor and continue cooling the patient.

An extremely effective means of evaporative cooling reported in the literature is the Makkah body cooling unit (BCU). [16] Patients are placed undressed on a modified hammock or litter, sprayed with lukewarm water, and room temperature air is blown over them with powerful fans. This is the method of field treatment for pilgrims traveling to Mecca who succumb to heatstroke. The BCU is very effective in treating patients who are vasodilated and in a dry environment. This mode of therapy would not be ideal for patients in shock or in a humid environment. Also, it may be difficult to reproduce these physical conditions in conventional clinical practice.

Two problems associated with complications of evaporative cooling are shivering and inability of cardiac electrodes to adhere to the skin. Shivering is treated primarily with intravenous benzodiazepines and secondarily with phenothiazines. Phenothiazines, however, lower the seizure threshold. Cardiac electrodes can be applied to a patient's back.

Immersion cooling is performed by placing an undressed patient into a tub of water deep enough to cover the trunk and extremities. The head must be kept out of the water. Cardiac monitoring electrodes and rectal temperature probes must be secured to the patient. Problems associated with immersion cooling include shivering, displacement of monitoring leads, and inability to perform defibrillation or resuscitative procedures.

The most rapid method of cooling a heatstroke victim is cardiopulmonary bypass. Although the logistics and availability are major drawbacks, it may be required if a patient's condition is recalcitrant to all other measures.

Regardless of the cooling technique chosen, cooling efforts should be discontinued when the rectal temperature reaches 40°C (104°F). Continued cooling below this temperature will lead to "overshoot hypothermia."

Treatment of Complications

Some of the complications associated with heatstroke occur early as opposed to late (Table 187-5). In patients with a relatively intact cardiovascular system, heat stress causes an increase in heart rate and cardiac index. Most heatstroke victims have a high cardiac index, elevated central venous pressure, and a low peripheral resistance. However, heart failure, pulmonary edema, and cardiovascular collapse can occur even in young healthy individuals. In any age group, the presence of hypotension, decreased cardiac output, and a falling cardiac index indicates a particularly poor prognosis. A pulmonary artery catheter may be necessary in the assessment of appropriate volume replacement.

Initial	Delayed
Hypotension	Hyperkalemia
Shivering	Hypocalcemia
Seizures	Hyperuricemia
Coma	Renal failure
Hypothermia, overshoot	Cerebral edema
Hyperthermic rebound	Hyperosmolar coma
Electrocardiographic changes	Persistent neurologic deficit
Pulmonary edema (cardiogenic)	Thrombocytopenia
Congestive heart failure	Disseminated intravascular coagulation
Hypokalemia	Hepatic failure
Hyponatremia	Adult respiratory distress syndrome
Rhabdomyolysis	Gastrointestinal hemorrhage
Diarrhea	

Source: Adapted from Tek and Olshaker, with permission.

TABLE 187-5 Complications of Heatstroke

Centrilobular necrosis due to direct thermal injury results in abnormal liver functions, although jaundice is unusual. Recovery is to be expected. Renal injury is manifested by microscopic hematuria, proteinuria, and hyaline and granular casts. Patients with hypovolemic complications and decreased renal blood flow may develop acute tubular necrosis. Exercise-induced heatstroke is often complicated by rhabdomyolysis, sometimes with massive myoglobinuria and renal failure. This complication may not develop until several days after the initial injury, so that careful monitoring of creatine kinase levels and renal function is necessary. Occasionally, a patient may present to the emergency department with the dark urine of myoglobinuria and should be questioned about recent heat exposure or heavy exertion.

Widespread hematologic disorders may be apparent both clinically and on laboratory evaluation. Purpura, conjunctival hemorrhages, petechiae, pulmonary, gastrointestinal, and renal hemorrhages may be present. Coagulation studies may show thrombocytopenia, hypoprothrombinemia, and hypofibrinogenemia. Thermal injury to the vascular endothelium causes increased platelet aggregation, changes in capillary permeability, thermal deactivation of plasma proteins resulting in a decreased level of clotting factors, and, rarely, disseminated intravascular coagulation or fibrinolysis.

As expected, the fluid and electrolyte abnormalities vary with the onset and duration of the disorder, underlying disease (especially cardiovascular disease), and prior use of medications such as diuretics. The most important consideration with respect to fluid and electrolyte abnormalities in heatstroke is that dehydration and volume depletion may not occur in classic heatstroke, whereas they are common signs in heat exhaustion. Vigorous fluid administration may produce pulmonary edema, especially in the elderly. A myriad of blood-gas abnormalities may be encountered, from respiratory alkalosis to severe metabolic acidosis.

Disposition

All of the minor heat illnesses except for heat exhaustion can be managed totally in the emergency department, and then patients can be safely discharged to home care and for outpatient follow-up. Patients with heat exhaustion who are at the extremes of age and have substantial volume depletion, comorbid diseases, or heat-induced end-organ damage should be admitted to the hospital.

Heatstroke is a true medical emergency, and all patients with this diagnosis should be admitted. The issue of whether to admit to the floor as opposed to the intensive care unit depends on the level of service that will be required as an inpatient. Patients who are hemodynamically labile, those who need continued cooling, or those who require invasive hemodynamic monitoring should be admitted to the intensive care unit. If the original health care facility is unable to provide the services needed for quality care, then the patient should be referred to a higher-level facility.

Prevention

Serious heat-related illness is predictable and preventable. The incidence of heatstroke can be reduced by (1) attention to environmental conditions, (2) social service care for the chronically ill and the elderly, (3) access to air-conditioning for individuals at risk, (4) acclimatization for workers, athletes, and the military, (5) paced work schedules for those who need to work under adverse conditions, and (6) adequate hydration. 188 ARTHROPOD BITES AND STINGS

Richard F. Clark

The phylum Arthropoda is the largest division of the animal kingdom. The American Association of Poison Control Centers reported 79,378 cases of exposures to arthropods in 1997.[1] Just over 100 of these were listed as resulting in major or severe reactions, including severe pain, neurotoxicity, or other signs and symptoms. Only two fatalities were listed from contact with arthropods—both from Hymenoptera stings. Clearly, these number are the tip of the iceberg. Toxic reactions to multiple stings by members of the order of Hymenoptera and severe systemic allergic reactions to one or more stings or bites of other insects such as deerflies, blackflies, horseflies, and kissing bugs can all present as emergency, life-threatening situations (Table 188-1). Other arthropod envenomations merit review either for causing various organ system toxicities or as infectious disease vectors. This chapter will review the most common arthropod envenomations encountered by emergency physicians in the United States.

TABLE 188-1   Harmful Arthropods of the United States

HYMENOPTERA (WASPS, BEES, AND ANTS)

The Hymenoptera are the most important venomous insects known to humans, and more fatalities result from stings by these insects than any other arthropod. There are three major subgroups or superfamilies of medical importance: (1) Apidae, including the honeybee and bumblebee, (2) Vespidae, including the yellow jackets, hornets, and wasps, and (3) Formicidae, or ants (Fig. 188-1).
FIG. 188-1. Representative venomous hymenoptera. **A.** Hornet (*Vespula maculata*). **B.** Wasp (*Chlorion ichneumerea*). **C.** Yellow jacket (*Vespula maculiforma*). **D.** Honey bee (*Apis mellifera*). **E.** Fire ant (*Solenopsis invicta*). Bees and Wasps (Apidae and Vespidae)

Apids, such as honeybees and bumblebees, are docile and tend to sting only when provoked. Bees are capable of stinging only once since its stinger has multiple barbs that cause the sting apparatus to detach from its body. Africanized honeybees, or so-called killer bees, are now found in Texas, Arizona, California, and some other southeastern states. These bees are hybrids of African bees that escaped from laboratories in Brazil during the 1950s and have spread successfully northward along the coasts and temperate regions of the continent.[2] Their venom is no more toxic than that of the American counterpart, but African honeybees are very aggressive and a hive can respond to a perceived threat with 10 or more times the number of bees as a typical North American bee response. An attack from Africanized bees can lead to massive stinging resulting in multisystem damage and death from severe venom toxicity. [3] With no natural predators, it is predicted that Africanized bees eventually will inhabit much of the Southeast and Southwest of the United States.

Most of the allergic reactions reported each year from Hymenoptera occur from vespid (wasp, hornet, and yellow jacket) stings. These arthropods nest in the ground or in walls, have volatile tempers, and may be disturbed by work around the yard, including mowing, gardening, and outdoor sports. As with bees, only the females have stingers, adapted from the ovipositor on the posterior aspect of the abdomen. Although some vespids possess barbed stingers, all have adapted the ability to

withdraw their stingers from the victim, enabling multiple stings.

VENOM   Hymenoptera venom contains several components. Although histamine is one of those components and was once thought to be responsible for most of the reactions observed following envenomation, other substances have now been recognized as more important. Mellitin, a known membrane-active polypeptide, constitutes over 50 percent of the dry weight of bee venom. Since all Hymenoptera share many of these components, cross-sensitization may occur in individuals allergic to one species. Yellow jacket venom is perhaps the most potent sensitizer.

CLINICAL FEATURES   The most common response to Hymenoptera venom consists of pain, slight erythema, edema, and pruritus at the sting site. In addition to this response, more significant reactions may occur.[4,5]

Local Reaction   A local reaction consists of marked and prolonged edema contiguous with the sting site (Fig. 188-2). Although there are no systemic signs or symptoms, a severe local reaction may involve one or more neighboring joints. A local reaction occurring in the mouth or throat can produce airway obstruction. Stings around the eye or on the lid may result in the development of an anterior capsule cataract, atrophy of the iris, lens abscess, perforation of the globe, glaucoma, or refractive changes. When local reactions become increasingly severe, the likelihood of future systemic reactions appears to increase and, if skin tests are positive, may warrant immunotherapy.
FIG. 188-2. Inflamed nodular reaction to insect bites. (From Moschella SL, Hurley HJ, eds: Dermatology, 2d ed. Philadelphia: Saunders, 1985, with permission.)

Toxic Reaction   When there is a history of multiple stings, such as in an Africanized bee attack, a systemic toxic reaction from venom may occur. Symptoms of a toxic reaction may resemble anaphylaxis, but there is generally a greater frequency of nausea, vomiting, and diarrhea. Light-headedness and syncope are common signs. There also may be headache, fever, drowsiness, involuntary muscle spasms, edema without urticaria, and occasionally seizures. Urticaria and bronchospasm are not present, although respiratory insufficiency and arrest may occur. Renal and hepatic failure also has been reported, as well as disseminated intravascular coagulation (DIC). Symptoms usually subside within 48 h, but may last for several days in severe cases. Toxic reactions are believed to occur from a direct multisystem effect of the venom.

Anaphylactic Reaction   A generalized systemic allergic or anaphylactic reaction, whether in response to a single sting or multiple stings, may range from mild to fatal, and death can occur within minutes. The majority of such reactions occur within the first 15 min, and nearly all occur within 6 h. There is no correlation between systemic reactions and the number of stings. In general, the shorter the interval between the sting and the onset of symptoms, the more severe is the reaction. Fatalities that occur within the first hour of the sting usually result from airway obstruction or hypotension. Initial symptoms usually consist of itching eyes, facial flushing, generalized urticaria, and dry cough. Symptoms may intensify rapidly with chest or throat constriction, wheezing, dyspnea, cyanosis, abdominal cramps, diarrhea, nausea, vomiting, vertigo, chills and fever, laryngeal stridor, shock, syncope, involuntary bowel or bladder action, and bloody, frothy sputum. Initial mild symptoms may progress swiftly to anaphylactic shock.

Generalized systemic allergic reactions to Hymenoptera venom are thought to be immunoglobulin E (IgE)-mediated. When an individual predisposed to allergy to bees is stung, there is usually an increase in the production of IgE antibodies, which become attached to the mast cells and basophils. This sensitizes the individual so that a subsequent sting may result in an antigen-antibody interaction releasing pharmacologically active mediators such as histamine, the slow-reacting substance of anaphylaxis (SRS-A) and eosinophil chemotactic factors of anaphylaxis (ECF-A). It is these mediators that actually cause tissue damage and systemic symptoms.

Delayed Reaction   A delayed reaction, appearing 10 to 14 days after a sting, consists of serum sickness-like signs and symptoms of fever, malaise, headache, urticaria, lymphadenopathy, and polyarthritis. Frequently, the patient has forgotten about the encounter and is puzzled by the sudden appearance of symptoms. This reaction is likely immune complex–mediated.

Unusual Reactions   Infrequently, a reaction to Hymenoptera venom produces neurologic, cardiovascular, and urologic symptoms, with signs of encephalopathy, neuritis, vasculitis, and nephrosis. A case of Guillain-Barré syndrome has been reported as a possible consequence of a Hymenoptera sting.

DIAGNOSIS   Identification of the offending insect can be difficult, except for the honeybee, which almost invariably leaves its stinger with venom sac attached in the lesion. In general, definitive identification is unnecessary because signs and symptoms of envenomation are similar among all Hymenoptera. A careful history is often necessary to distinguish members of Vespidae from each other, and slides or pictures of the various species can aid the patient in recall. Skin tests are of little value in the identification process.

If edema persists at the sting site, secondary infection, such as cellulitis, must be considered. Severe local reactions on the foot or ankle can be misdiagnosed as gout if the insect sting is not visible.

TREATMENT   If the bee stinger is present in the wound, try to remove it. Although conventional teaching suggested scraping the stinger out to avoid squeezing remaining venom from the retained venom gland into the victim, involuntary muscle contraction of the gland continues after evisceration and the venom contents are quickly exhausted. Immediate removal is the important principle and the method of removal is irrelevant.[6] As a general rule, the sting site should be washed thoroughly with soap and water to minimize the possibility of infection. For local reactions, ice packs at the site will diminish swelling and delay the absorption of venom while limiting edema. Oral antihistamines and analgesics may limit discomfort and pruritus. Nonsteroidal anti-inflammatory drugs (NSAIDs) can be effective in relieving pain. Standard doses of opioid analgesics also can be administered. If edema is significant, elevation and rest of the affected limb should limit swelling unless secondary infection develops, in which case antibiotics will be necessary. In local tissue reactions, there is often significant inflammatory erythema and swelling, making it difficult to distinguish from infection; as a general rule, infection is only present in a minority of cases.

While the initial signs and symptoms of a systemic reaction may be mild, victims can deteriorate rapidly in a matter of minutes. Treatment regimen is that for anaphylaxis and the most important agent to administer is epinephrine hydrochloride 0.3 to 0.5 mg (0.3–0.5 mL of 1:1000) in adults and 0.01 mg/kg in children (never more than 0.3 mg). It should be injected subcutaneously and the injection site massaged to hasten absorption of the drug. The patient should then be observed for several hours to ensure that symptoms do not intensify or relapse. Parenteral administration of standard antihistamines (diphenhydramine 25–50 mg) and H $_2$ receptor antagonists (ranitidine 50 mg) is recommended. While steroids (methylprednisolone 125 mg) are of little help in combating the immediate effects, their administration tends to limit urticaria and edema and may potentiate the effects of other measures. Bronchospasm is treated with b-agonist nebulization. Hypotension may require massive crystalloid infusion, and central venous pressure monitoring may be helpful in some patients. Persistent hypotension after massive volume replacement may require dopamine. If dopamine is ineffective, an intravenous infusion of epinephrine can be used. The patient who suffers a severe systemic reaction should be admitted and monitored for potential cardiac, bleeding, renal, or neurologic complications.

LONG-TERM MANAGEMENT AND PREVENTIVE CARE   Skin tests and radioallergosorbent tests (RAST) are not fully reliable in determining which patients are at risk for systemic reaction during future encounters with Hymenoptera (Table 188-2). Patients with negative results may have been sensitized by the skin tests themselves. Every patient who has had a systemic reaction should be provided with an insect sting kit containing premeasured epinephrine and be carefully instructed in its use. The Ana-Kit (Hollister-Stier, Spokane, WA) contains a sterile syringe preloaded with two doses of epinephrine (1:1000, 0.5 mL in each dose with a stop

between) and several antihistamine tablets. The Epi-Pen (Dey Laboratories, Napa, CA) contains a single self-injecting, spring-loaded syringe of epinephrine 1:1000. Its advantage is the ease of injection; its disadvantages are that to be on the safe side, the patient should carry two kits, and there is no way to measure proper dosage for children. The physician should stress that the patient must inject the epinephrine subcutaneously at the first sign of a systemic reaction.

TABLE 188-2   Long-Term Management for Patients with Reactions to Hymenoptera Stings

Physicians should, as a matter of course, advise their patients who are allergic to insects to wear Medic Alert tags, and they should provide such patients with a list of avoidance measures to prevent being stung (see Table 188-3).

TABLE 188-3   Prevention of Insect Stings

Ants (Formicidae)

There are five known species of fire ants (*Solenopsis*) in the United States: *S. aurea, S. geminata, S. xyloni,* and the two imported species, *S. invicta* and *S. richteri.* The two imported species entered the United States through Mobile, Alabama, in the 1930s and have now spread throughout the Gulf Coast states and are pushing westward.[7] The fire ant inhabits a loose amount of dirt and breeds 9 to 10 months of the year. One mature nest can produce 200,000 ants during a 3-year period, which accounts for the rapid spread of this arthropod. The venom of the fire ant is almost entirely an insoluble alkaloid. There is potential cross-reactivity between the venoms of fire ants and other Hymenoptera, and individual stings may produce systemic toxicity in sensitized individuals.

Fire ants are characterized by their tendency to swarm when provoked and they may attack in great numbers. Most often fire ants in a swarm position themselves on their victim and sting simultaneously in response to an alarm pheromone released by one or several individuals. Each sting usually results in a papule, which becomes a sterile pustule in 6 to 24 h. Localized necrosis, scarring, and secondary infection can result. [8] There may be a systemic reaction manifested by urticaria and angioedema.

One study has estimated a hypersensitivity rate to the fire ant of 16 percent in the general population. [8] Treatment of fire ant stings consists of local wound care. If there is evidence of systemic reaction, give the usual treatment for anaphylaxis. Desensitization should be directed to any person exhibiting a potentially life-threatening reaction to these arthropods.

ARACHNIDA

Spiders (Araneae)

There are over 30,000 species of spiders worldwide, of which approximately 50 species in the United States have been implicated in medically significant envenomations. All spiders are carnivores utilizing venom to paralyze their prey prior to ingestion (Fig. 188-3).

FIG. 188-3. External anatomy of a spider. **A.** Dorsal. **B.** Ventral. **C.** Frontal. (Reproduced with permission from Management of Wilderness and Environmental Emergencies. St. Louis: Mosby, 1989.)

Loxosceles and Necrotic Arachnidism

Loxosceles spiders have a worldwide distribution. There are 18 species in the genus *Loxosceles* in North America, with 13 of these found in the United States. Five of these, *L. reclusa, L. laeta, L. refuscens, L. arizona,* and *L. unicolor,* have been associated with ulcers and necrotic skin lesions. *L. reclusa* (the brown recluse spider) is one of the most common species found in the United States and has been reported in over 20 states, particularly those in the region of the Missouri, Ohio, and Mississippi river basins, but also in several southwestern, southern, and midwestern states. *L. reclusa* prefers warm dry areas such as abandoned buildings, wood piles, and cellars and is generally nocturnal in activity. It is difficult to find the exact incidence of severe bites from these spiders, although one U.S. study of 460

deaths from venomous bites attributed 63 (14 percent) to *L. reclusa.* Loxoscelism is the reaction to the envenomation by species of the brown spider.

CLINICAL FEATURES   Bites by *Loxosceles* spiders are initially painless, prohibiting definitive identification of the spider. The most common manifestation of a *Loxosceles* bite consists of a mild erythematous lesion that may become firm and heal with little or no scar over several days to weeks. [9] Occasionally, a more severe reaction occurs, with mild to severe pain several hours after the bite. There may be erythema and blister formation and bluish discoloration within the first 24 h (Fig. 188-4). This lesion may become necrotic over the next 3 to 4 days (Fig. 188-5), with eschar formation by the end of the first week. These lesions may vary in size from 1 to 30 cm.

FIG. 188-4. Brown recluse spider bite approximately 12 h old. Note central hemorrhagic vesicle with surrounding spread of toxin. (Reproduced by permission from Management of Wilderness and Environmental Emergencies. St. Louis: Mosby, 1989.)

FIG. 188-5. Brown spider bite 4 days after injury. (Reproduced with permission from Emergency Medicine, June 1988.)

The necrosis is caused by aggregation of leukocytes and platelets forming a hemostatic plug in venules and arterioles. The bite of the brown recluse spider also may cause systemic involvement, which generally occurs within 48 h of the bite. The patient may experience fever, chills, nausea, vomiting, myalgias, arthralgias, petechiae, and hemolysis. Hemolysis is apparently mediated by direct effect of the spider venom on red blood cell membranes and may be severe, causing hemoglobinuria, renal failure, DIC, and rarely, death. Systemic reaction is more common in children and almost all deaths are reported in children under 7 years of age. There may be little correlation between systemic symptoms of *Loxosceles* envenomation and the severity of the skin lesions.

The venom of *Loxosceles* consists of multiple proteases, alkaline phosphatase, lipase, anaronidase, and other substances that involve the complement system. It is still unclear which of these substances is the major factor related to the necrosis-producing activity of the spider.

DIAGNOSIS   In the United States, *L. argiope, L. atrax, L. chiracanthium, L. lycosa, Tegenaria agrestis* and numerous other varieties can all cause bites similar to that of *L. reclusa.*[10] Although the brown recluse spider is the most renowned biting spider to produce necrotic lesions in humans, the most common biting spider in the United States is the so-called jumping spider, one of the *Phidippus* species. These small, furry, and relatively aggressive spiders are sometimes confused with the black widow spider because of their black and red markings. Although jumping spiders bite and tend to hang onto the victim and can lead to a necrotic lesion, they generally only produce a local reaction, which may take hours to days to subside.

In patients suspected of having a bite from *L. reclusa* and exhibiting signs and symptoms of envenomation, a complete blood count (CBC), creatinine, blood urea nitrogen (BUN), and coagulation profile should be ordered, as well as an urinalysis for hemoglobinuria. No laboratory tests yet exist to confirm bites of *Loxosceles.*

TREATMENT   Treatment of a brown recluse or any necrotic spider bite should include the usual supportive measures. No antivenom is available commercially. For those bites with cytotoxic reactions and necrosis, tetanus prophylaxis and daily wound care should be given. Antibiotics should be used if evidence of infection exists. In some cases, analgesic therapy will be required. In general, surgery should not be done until the necrotic ulcers are greater than 2 cm in diameter and the borders of the ulcers are well established, usually 2 to 3 weeks after the bite.

Dapsone has been suggested by some clinicians to prevent ongoing necrosis from *L. reclusa* bites by inhibiting local infiltration by polymorphonuclear leukocytes, although there are no controlled data to substantiate this claim. More recently, hyperbaric oxygen has been proposed as treatment for severely necrotic *Loxosceles* bites based on case reports. However, controlled trials in animals failed to demonstrate superiority of this treatment over simple supportive wound management. [11]

Adults and children with evidence of a significant systemic reaction to a brown recluse spider bite warrant hospitalization and close observation. If hemolysis occurs, appropriate hydration, red blood cell transfusion, and monitoring of renal function are important to avoid complications such as acute renal failure.

Hobo Spider (*Tegenaria agrestis*)

The hobo spider is a venomous spider found in the Pacific Northwest and its bite is often misattributed to the brown recluse spider, which is not found in that region. [10] Originally native to Europe, the hobo spider entered the Pacific Northwest and has spread as far as central Utah and southern Alaksa. Hobo spiders are brown with gray markings and 7 to 14 mm in body size with 27- to 45-mm leg span. These spiders live in dark areas close to the ground in wood piles or basements.

CLINICAL FEATURES, DIAGNOSIS, AND TREATMENT   Local reaction to *T. agrestis* bite is similar to that of the brown recluse spider. The bite is initially painless, followed by induration and expanding erythma. Blisters eventually develop that rupture, leaving an encrusted, cratered wound. Healing occurs gradually over 45 days, often with a permanent scar. Severe headache is the most common systemic symptom, followed by nausea, vomiting, diarrhea, and lethargy. Aplastic anemia has been reported rarely as a severe complication.

The hobo spider is rarely seen by the victim because the bite is painless, the bite occurs in dark areas where the spider lives, and the spider moves quickly away (up to 1 m/s) after the bite. No diagnostic test exists for hobo spider envenomation.

No proven treatment exists for *T. agrestis* local or systemic reactions.[10] Surgical excision and grafting eventually may be required for severe wounds. Corticosteroids may be of some benefit for aplastic anemia.

Black Widow (*Latrodectus*)

Latrodectus or "widow" spiders are found throughout the United States. Of the estimated 30,000 species of spiders, the black widow is probably the most well known, although of the five species found commonly in the United States, only three (*L. mactans, L. variolus,* and *L. hesperus*) are actually black. Other varieties may be predominantly brown or red (*L. geometricus,* or brown widow, and *L. bishopi,* or red widow). The classic orange-red hourglass-shaped marking is noted only in *L. mactans.* Female spiders are relatively large, with a body size ranging up to 1.5 cm in length and leg spans of 4 to 5 cm. The male spider is approximately one-third the size of the female, lighter in color, and his bite can not penetrate human skin. Black widow spiders are found most often in wood piles, basements, garages, or sheds. *Latrodectus* will aggressively defend her web, particularly when guarding her eggs. Most black widow bites occur between April and October and usually are seen on the hands and forearms.

The black widow spider injures its victim by secretion of one of the most potent neurotoxic venoms produced by any animal, producing release of acetylcholine, norepinephrine, and other neurotransmitters at the neurosynaptic junction.

CLINICAL FEATURES   Most *Latrodectus* bites are almost immediately mild to moderately painful. The pain often begins as a pinprick sensation at the bite site but may spread quickly to include the entire bitten extremity. [12] Erythema appears approximately 20 to 60 min after the bite. In over 50 percent of cases, the initial erythema evolves into a lesion resembling a "target," with a diameter of about 1 to 2 cm (Fig. 188-6). Victims frequently complain of muscle cramp-like spasms in large muscle groups, although physical examination of the "cramping" extremity rarely exhibits rigidity, and serum creatine kinase concentrations do not appear to be significantly elevated. The pain often increases progressively, becomes generalized, and can involve the trunk, back, and abdomen. Involvement of the abdominal wall musculature with severe pain and cramping has been mistaken for peritonitis.

FIG. 188-6. Classic "target lesion" from patient bitten by a black widow spider.

Latrodectus bite victims may experience severe pain for 24 h or more that can be intermittent in course. Rarely, pain may persist for several days, whereas muscle weakness may continue for weeks to months. The most serious complications include hypertension, which is reported in 10 to 30 percent of envenomations and is likely the result of catecholamine release. In addition, severe envenomation also may cause shock, coma, and respiratory failure secondary to muscle paralysis.

DIAGNOSIS AND TREATMENT   Since an immediate pinprick sensation is almost always reported with *Latrodectus* bites, it is rare for victims not to see the offending spider. There are no confirmatory laboratory tests, but the presence of the typical target lesion along with pain, muscle spasms, and toxic appearance is virtually pathognomonic of the diagnosis.

The initial therapy is supportive care of the airway, breathing, and circulation. Wound care should consist of routine cleansing of the bite site and tetanus prophylaxis, if indicated.

Patients should be given appropriate opioid analgesics and benzodiazepines for pain relief and muscle relaxation. Intravenous calcium gluconate has been advocated to relieve pain and muscle spasms from the black widow bite, although controlled data are lacking, and a review of 163 patients with *Latrodectus* envenomation found ineffective relief of muscle spasm and pain with calcium treatment. [12] Most severe bites will require parenteral opioids for extended periods, necessitating admission for observation. Antivenom is reserved only for severe envenomation refractory to the measures indicated earlier. [12] The usual dose is one to two vials infused over 20 to 30 min. Since antivenom is a horse-serum preparation, anaphylaxis can occur, particularly in patients with a history of allergy to horse-serum products or those who have been sensitized by prior antivenom treatment. [12] Skin testing should be performed before antivenom administration. Serum sickness, while a theoretical possibility, was not observed in 58 patients treated with 1 or 2 vials of antivenom. [12]

Tarantula

The term *tarantula* is used for several species of large spiders such as the desert tarantula, which is found in the southwest region of the United States and is a member of the family Theraphosidae. Despite their large size (up to 7 cm), their venom is very mild and usually does not produce systemic reactions. The typical tarantula bite causes local swelling and pain at the bite site often resembling a Hymenoptera sting that may last for a few hours and is treated successfully with local wound care.[13]

Perhaps the most common problem with tarantulas involves the hairs on their abdomen. When threatened, these spiders can use their hind legs to flick these hairs a distance of 1 to 2 m. The body of their hair follicle is studded with what appears to be spurs when viewed with a dissecting microscope and can become imbedded in skin. The hairs are quite irritating and can lead to a significant contact dermatitis. Cases have been reported of these hairs being impaled in the cornea of a victim, necessitating surgical removal.

The South American tarantula, also known as the *banana spider,* is aggressive and frequently bites when threatened. This spider also has a potent venom and its bite may cause both necrotic and systemic reactions. An antitoxin is available.

Scabies (*Sarcoptes scabiei*)

Scabies infestation resembles that of lice but is generally concentrated around the hands and feet, especially in the web spaces between the fingers and toes. In children, the face and scalp may be infested as well. In adults, scabies frequently affect the nipples in females and the penis in males.

The scabies mite is a universal pest that appears to follow a 30-year cycle of proliferation. During the past several years, there has been an epidemic of scabies infestation in the United States. Scabies infestation is more likely to occur by direct contact between the infested individual and the non-infested individual than by indirect contact with clothing and personal articles.

Diagnostically, pruritus is the dominant symptom, although it takes up to a month for sensitization to develop and itching to begin. In patients who become infested and are already sensitized, inflammation and pruritus may develop within a few hours of contact.

The distinctive feature of scabies infestation is the burrow that the female mite digs into the skin to lay her eggs. Vesicles and papules form at the surface of these zigzag, whitish, threadlike channels that may contain small gray spots at the closed ends where the parasite rests. Burrows tend to enlarge and be more visible in children. The burrows can be traced with a hand lens and the female mite scraped out with a needle or razor blade. A thin shaving of skin containing both burrow and mite can be examined under a microscope to formally establish the diagnosis. Unfortunately, burrows are often disguised by excoriations, crusting, eczematization, and secondary infection.

Treatment for scabies infestation consists of a thorough application of a scabicide. Although lindane is usually effective, scabies mites have developed immunity to the compound in many areas, and less toxic alternatives are available. Permethrins (Nix, Warmer-Lambert; Elimite, Allergan, Inc.) and pyrethrins (RID, Pfizer) are effective scabicides with little human toxicity, some of which are available in pharmacies over the counter. These agents are usually applied from the neck down, following a warm bath with liberal use of soap. The patient should be cautioned to keep the substance from the eyes and mucous membranes and to avoid inhaling the vapors. The scabicide is left on for 8 to 12 h and then is washed off.

Even after the scabies mites have been destroyed, lesions and pruritus can persist. No further use of scabicide is needed, but calamine lotion, oral antipruritic agents, and analgesics will help alleviate discomfort. Antibiotics are only necessary where secondary infection occurs.

Ticks (*Ixodes, Dermacentor,* and Others)

Ticks are found throughout the world, mostly in rural areas. Their bodies consist of a fused abdomen and thorax in an oval shape and vary from a millimeter or less in length to over a centimeter when engorged with blood. Ticks attach to humans painlessly with strong jaws and cement-like adhesive. Granulomas may develop at the site of a tick bite and require several months to heal.

The main concern with ticks is that they are disease vectors. Typhus, tularemia, Colorado tick fever, Rocky Mountain spotted fever, viral encephalitis, and Lyme disease (*Borrelia burgdorferi*) all can be transmitted through tick bites. Tick paralysis, a symmetric ascending paralysis, occurs from the secretion of a neurotoxin by some species and may lead to respiratory failure in humans. It is treated by removing the tick.

Insect repellants and tight-fitting clothing can be helpful in preventing tick bites in infested areas. Although organic solvents, heat, and other methods have been advocated to aid in dislodging a tick so as not to leave its mouth parts beneath the skin surface and to prevent further toxin release, no technique has definitively proven superior.[14] The often insidious presentation of tick-borne illnesses such as Lyme disease has prompted some physicians to prophylactically administer antibiotics following tick bites. However, less than 5 percent of tick bites in highly endemic areas result in *B. burgdorferi* infection. In addition, most people remove the tick before it has been attached for the 36 to 48 h required to transmit an infectious dose of *B. burgdorferi.* For these reasons, routine prophylaxis of tick bites to prevent Lyme disease is neither cost effective nor recommended.[15]

Chiggers (Trombiculidae)

Chigger infestations are caused by mite larvae that feed on host skin cells. European varieties of these arachnids are called *harvest mites.* The combination of the effect of digestive enzymes secreted by the mite and an immune response of the host produces the typical pruritic lesions. Although the usual response is intense pruritus at the bite site, more severe systemic reactions and chigger-borne diseases also may occur. Mites live comfortably in warm and cold climates. There are approximately 2500 species of chigger mites, with *Trombicula alfreddugèsi* the most common. Mites are quite small, 0.3 to 1.0 mm in length, and attach themselves to the host skin with their mandibular structures, known as *chelicerae.* Once attached they release digestive enzymes to liquefy epidermal cells, leading to an immune response in the victim and subsequent symptomotology.

Itching usually begins a few hours after the chigger bite, with a papule developing initially that ultimately enlarges over 24 to 48 h to form a nodule. Pruritus usually peaks on the second day, and the nodules can persist for up to 14 days. Children who play or sit on the grass are prone to chigger bites in the genital area. Bites can manifest in some patients as impressive soft tissue edema (Fig. 188-7). Mite infestations may be associated with fever and an erythema multiforme–like rash. The diagnosis of chigger infestation usually can be made on the basis of known outdoor exposure and typical skin lesions.

FIG. 188-7. Chigger bites. Edema of the foreskin, scrotum, and penis is dramatic. There is no meatal obstruction.

The treatment of chigger bites consists largely of symptomatic measures to control the itching. Chiggers may be killed with lindane 1% topical lotion or crotamiton 10% topical lotion (Eurax, Westwood-Squibb Pharmaceuticals). For moderate to severe cases, topical steroid creams and oral antihistamines may provide some relief. There have been reports of systemic steroids providing relief for severe pruritus. If secondary infection occurs, antibiotic therapy is indicated. Clothes fitting snugly at the neck, wrists, and ankles, supplemented with insect repellent, can help prevent chigger infestation.

Scorpions (Scorpionidae)

Several species of scorpions are found in the warmer parts of the southern United States. All are generally nocturnal and capable of stinging humans. Most species found in this country cause little more than localized pain similar to that following Hymenoptera stings. Cytotoxicity or inflammation does not occur from North American scorpion venom, and the exact site of the sting may not be readily apparent. Only *Centruroides exilicauda,* or the bark scorpion, found throughout Arizona, New Mexico, and parts of Texas and California, possesses venom potent enough to cause systemic toxicity.

C. exilicauda venom can open sodium channels on neurons, causing prolonged and excessive firing of axons, and may lead to abnormal activity along motor, sensory, and autonomic fibers. Systemic symptoms following envenomation by this scorpion can be pronounced and variable. Immediate onset of pain and paresthesias in the stung extremity is usually noted and may become generalized. In severe cases, cranial nerve and somatic motor dysfunction can develop, resulting in abnormal roving eye movements, blurred vision, pharyngeal muscle incoordination, and drooling, occasionally leading to respiratory compromise. Excessive motor activity may present as restlessness or uncontrollable jerking of the extremities, appearing to be seizure-like activity. Nausea, vomiting, and tachycardia can be present in significant envenomations. Symptoms usually last 24 to 48 h. Cardiac dysfunction, pulmonary edema, pancreatitis, bleeding disorders, skin necrosis, and occasionally death can be seen with stings from Asian and African scorpions such as *Buthus, Tityus,* and *Androctonus* but are not found following envenomation by scorpions native to the United States.[16]

Diagnosis of a scorpion sting is clinical. Stings can be confused initially with anything that causes local pain, especially in children. As the syndrome progresses in moderate to severe cases to include autonomic and motor findings, the diagnosis becomes more apparent. Treatment is supportive and should include liberal use of analgesics and sedatives. A *Centruroides*-specific antivenom is available only in the state of Arizona and is produced from goat serum. Like all partially purified animal-derived serum products, both immediate and delayed allergic reactions and serum sickness occur with administration of *Centruroides* antivenom, and it therefore should be used only in severe cases.[17] One to two vials are generally enough to provide a resolution of symptoms. The patient should be skin tested prior to administration of the antivenom.

MOSQUITOS, FLIES, FLEAS, AND LICE (DIPTERA)

Mosquitoes

Mosquitoes are aquatic breeding arthropods found in all parts of the world. Like other members of this group, they possess one pair of wings, the second pair having evolved into smaller structures used as stabilizers.

Mosquitoes penetrate skin with a piercing motion of a bayonet-like proboscis. The actual puncturing of the skin surface causes minimal trauma and is frequently not felt by the host. A type of local anesthetic is injected into the wound that causes local tissue damage and local hypersensitivity. Bites can lead to both immediate and delayed reactions. An immediate skin reaction includes redness, a wheal, and itching. A delayed reaction usually consists of edema and a burning pruritus. The immediate reaction tends to be of short duration, whereas a delayed reaction may persist for hours, days, and even weeks. Severe local reactions with skin necrosis occur occasionally. The history of an allergy to mosquito saliva constituents consists of an increasing reaction to seasonal exposures with more and more pronounced edematous and pruritic lesions, accompanied sometimes by complications such as fever, malaise, generalized edema, severe nausea and vomiting, and necrosis with resulting scarring. Treatment is symptomatic, with antihistamines and NSAIDs.

The greatest dangers from mosquitos in other countries is their function as disease vectors. Even with extensive pest control programs, arboviruses and malaria are epidemic in some parts of the world. Japanese B encephalitis, yellow fever, dengue hemorrhagic fever, and various types of equine encephalitis are among the many viruses transmitted by mosquitos. Malaria is encountered frequently in patients in the United States after travel and in immigrant populations from areas where malaria is endemic.

Flies

Bloodsucking flies range in size from the tiny sand fly, about 1 to 3 mm in length, to horse flies that can be over 2 cm. All members stab and pierce the skin, causing some degree of pain and, commonly, subsequent pruritus. Several species, such as deerflies, blackflies, horseflies, and sand flies, can produce allergic reactions, although rarely as severe as those produced by Hymenoptera venom. There is also the possibility of myiasis with fly bites, but this, too, is rare in the United States.

The diagnosis of fly bites depends chiefly on the patient's history and a knowledge of the arthropods that frequent the area of encounter. Treatment for most local reactions to Diptera bites is symptomatic, whereas treatment of systemic reactions is the same as it is for Hymenoptera venom. Cold compresses may alleviate localized edema. Secondary infection from Diptera bites can occur, and antibiotics may be necessary in some cases. Oral antihistamines such as diphenhydramine and hydroxyzine may be helpful in relieving pruritus in these cases, but, topical steroids can be used when local reactions are severe, and oral steroids are indicated when systemic hypersensitivity symptoms are present.

Fleas (Siphonaptera)

Bites of fleas, lice, and scabies produce lesions so similar that diagnosis is often difficult. Flea bites are frequently found in zigzag lines, especially on the legs and in the waist area. The lesions have hemorrhagic puncta surrounded by erythematous and urticarial patches. Pruritus is intense, and often, even after the lesions clear, dull red spots persist.

The main concern in the treatment of flea bites is the possibility of secondary infection. Children may develop impetigo as a complication. The lesions should be washed thoroughly with soap and water. Children with flea bites should have their fingernails cut short to prevent scratching. To relieve discomfort and itching, starch baths at bedtime (about 1 kg starch to a tubful of water), local application of calamine, cool soaks, and oral antihistamines may be helpful. For severe discomfort, application of a topical steroid cream or spray may be necessary. If secondary infection develops, topical or oral antibiotics may be needed.

Lice (Anoplura)

Body lice concentrate about the waist, shoulders, axillae, and neck. The lice and their eggs often can be found in the seams of clothing. The lesions produced from bites of these arthropods begin as small, noninflammatory red spots that quickly become papular wheals. They are so intensely pruritic that their linear scratch marks are diagnostically suggestive of infestation. The white ova of head lice can be mistaken for dandruff, but unlike dandruff, they cannot be brushed out because they are glued to the hair itself ("nits").

Pubic lice leave bluish spots in the abdomen and thighs, and ova are evident on the shafts of pubic hairs. If sensitization to lice saliva and feces components occurs, delayed allergic reactions may develop, leading to fever and malaise. Secondary infection may produce enlarged lymph glands or cellulitis. Long periods of infestation may bring a decrease in pruritus and often impart a thick, dry, scaly appearance to the skin.

Treatment for body lice infestation is similar to that for scabies. Permethrin or pyrethrin shampoos and creams are usually effective in eliminating body and hair infestations, but sterilization of clothing, bedding, and personal articles also must occur. Lice and eggs are destroyed by temperatures in excess of 52°C, necessitating hot water washing. Storage of articles in plastic bags for 2 weeks also can eliminate infestations.

KISSING BUGS AND BED BUGS (HEMIPTERA)

Triatoma species, commonly known as *conenose, reduviid,* or *kissing bugs,* are found mainly in the southeastern and Pacific Coast regions of the United States. They feed on the blood of vertebrate animals, including humans. Their common name derives from their habit of feeding at night on any exposed surface of a sleeping victim, which is commonly the face. Since their bite is relatively painless, the victim is rarely aware of the attack. Bed bugs (*Cimex lectularis*) cause a similar pattern of envenomation in humans at night, and can be found throughout the United States. These arthropods are adapted to domestic environments, living in baseboards, between cracks in walls and floors, and in furniture.

Bites are usually multiple and consist of hemorrhagic papules or bullae if they occur on the hands or feet and large wheals if they are on the trunk. Diagnostically, kissing bug bites can be differentiated from bedbug bites in that they often do not appear in a linear formation and usually are not accompanied by telltale brown or black patterns of excrement on the bed linen characteristic of bed bugs.

Treatment of Hemiptera bites is symptomatic, with cool compress applications and antihistamines to relieve pruritus. Some individuals become highly sensitive to kissing bugs and react with systemic allergic symptoms following a bite. These individuals should be treated as previously outlined for Hymenoptera envenomation.

CATERPILLARS AND MOTHS (LEPIDOPTERA)

There are at least 10 families of venomous caterpillars and moths. Stinging moths are found in the southern United States that can cause an illness termed *lepidoterism.* Some caterpillars possess hollow spines among their hairs that contain urticating poisons that can cause symptoms ranging from local dermatitis to generalized systemic reactions. The puss caterpillar or woolly slug, larval stage of the moth *Megalopyge opercularis,* is perhaps the most toxic variety in the United States and is especially hazardous for children who tend to find it intriguing and thus handle it. [18] Puss caterpillars are found primarily in the southeastern states and especially in Texas and Florida. The venom of the puss caterpillar can induce hemolysis and increase vascular permeability. The venom of the flannel moth caterpillar (*L. crispata*), saddleback caterpillar (*Sibine stimulae*), range caterpillar (*A. ic*), and oak slug (*E. delphini*) is not as toxic, tending to produce only urticaria. The gypsy moth caterpillar (*Porthetria dispas*) may produce a delayed hypersensitivity type of dermatitis in some individuals.

Stings from the hairs of the puss caterpillar most often cause skin irritation with a pruritic erythematous lesion at the site on contact. In severe cases, the victim may complain of immediate intense pain, often rhythmic or cyclic. The characteristic lesions consist of white or red papules and vesicles, frequently forming a gridlike pattern where the caterpillar made contact. Systemic symptoms occur commonly, with fever and muscle cramps. Shocklike symptoms also have been reported. Within several hours or days, local desquamation may develop. Lymphadenopathy has been described.

Treatment should begin with thorough washing of the affected area. Broken-off spines can be removed by placing cellophane tape over the sting site. Calcium gluconate, 10 mL of a 10% solution intravenously, has been reported to provide analgesia in some severe cases of caterpillar stings, whereas oral antihistamines usually bring relief in milder cases. Generalized symptoms are treated supportively.

BLISTER BEETLES (COLEOPTERA)

Although there are more members of the Coleoptera or beetle family than any other arthropod, the only ones with clinical significance for envenomation in humans are blister beetles. Blister beetles (families Staphylindae and Meloidae) are found throughout the United States, and include beetles known as Spanish fly (*Lytta vesicatoria*).[19] When disturbed or crushed on the skin, they exude a vesicating agent called *cantharidin* from the joints of their legs or from their bodies that can penetrate the epidermis to produce irritation and blistering within a few hours of contact. If ingested, cantharidin can produce intense gastrointestinal disturbances with symptoms of nausea, vomiting, diarrhea, and abdominal cramps.[20] Initial contact with the beetle produces a burning, tingling sensation and a mild rash. Within a few hours, flaccid, elongated vesicles and bullae develop from a few millimeters to several centimeters in diameter. Blebs erupt 2 to 5 h after contact and can be hemorrhagic and painful. A severe chemical conjunctivitis can occur if cantharidin contacts the eyes from contaminated hands.

Treatment consists of protecting the bullae from secondary infection with an occlusive dressing. Large bullae should be drained and an antibiotic ointment applied. Bullae occurring on the feet should be managed with wet dressings applied for 24 to 48 h. Application of steroid creams to blebs may be helpful. Lesions usually resolve in 2 to 3 days.

189 REPTILE BITES

Richard C. Dart
Hernan F. Gomez
Frank F. S. Daly

RATTLESNAKE BITES

Approximately 19 of the 115 snake species in the United States are venomous. Snakes inflict about 45,000 bites each year in the United States, of which 8000 are inflicted by venomous snakes. Most bites occur in the warm summer months, when snakes and victims are most active. In the past, it was estimated that mortality from venomous snakebite approached 25 percent. Because of the availability of antivenom and advances in emergency and critical care, mortality rates today are below 0.5 percent. Approximately 5 to 10 deaths occur per year. [1]

Except for bites by imported species, North American venomous snakebite involves the pit vipers (Crotalidae family) or coral snakes (Elapidae family). The crotalids are represented by the rattlesnakes (*Crotalus* species), pygmy rattlesnakes and massasauga (*Sistrurus* species), and the copperheads and water moccasins (*Agkistrodon* species).

Poisonous snakebites from imported exotic species are infrequent but may occur in zoo personnel as well as in amateur herpetologists. A regional poison center can provide information on snake identification, expected toxicity, and location of antivenom.

The crotalid snakes are called pit vipers because of bilateral depressions or pits located midway between and below the level of the eye and the nostril (Fig. 189-1). The pit is a heat receptor that guides strikes against warm-blooded prey or predators. Crotalid snakes are also distinguished by two fangs that can be folded against the roof of the mouth, in contrast to the coral snakes, which have shorter, fixed, and erect fangs. Within the pit vipers, the rattle distinguishes the rattlesnake from other crotalids. The mistaken belief that rattlesnakes always rattle before striking has persisted for centuries. In truth, many strikes occur without a warning rattle. [2]
FIG. 189-1. Rattlesnake surface anatomy. (Reprinted with permission from Robert E. Hill.)

Pathophysiology

Crotalid venom is a complex enzyme mixture that causes local tissue injury, systemic vascular damage, hemolysis, fibrinolysis, and neuromuscular dysfunction, resulting in a combination of local and systemic effects. Crotalid venom quickly alters blood vessel permeability, leading to loss of plasma and blood into the surrounding tissue and causing hypovolemia. It also consumes fibrinogen and platelets, causing a coagulopathy. In some species, specific venom fractions block neuromuscular transmission, leading to ptosis, respiratory failure, and other neurologic effects.

Clinical Features

Up to 25 percent of crotalid snakebites are termed dry: venom effects do not develop. The manifestations of crotalid venom poisoning involve a complex interaction of the venom and the victim. The species and size of the snake, the age and size of the victim, the time elapsed since the bite, and characteristics of the bite (location, depth, and number, the amount of venom injected) all affect the clinical appearance. The severity of poisoning following a crotalid bite is therefore variable. Crotalid bites are generally classified as *minimal, moderate,* or *severe,* depending on the degree of local and systemic injury (Table 189-1). An initially minimal bite may evolve into a moderate or severe bite and require large amounts of antivenom.

TABLE 189-1   Grading of Envenomation by Crotalid Snakes

The cardinal manifestations of crotalid venom poisoning are the presence of one or more fang marks, localized pain, and progressive edema extending from the bite site.[3] Other early symptoms and signs of rattlesnake venom poisoning are nausea and vomiting, weakness, oral numbness or tingling of tongue and mouth, tachycardia, dizziness, hematemesis, hematuria, thrombocytopenia, and fasciculations. In general, swelling becomes apparent within 15 to 30 min, but in some cases it may not start for several hours. In severe cases, edema may progress to involve an entire limb within an hour. In less severe cases, edema may progress over a 1- to 2-day period. Edema near an airway or in a muscle compartment may threaten life or limb without the presence of systemic effects.

Progressive ecchymosis may also occur because of leakage of blood into subcutaneous tissue. Ecchymoses may appear within minutes or hours in the area of the snakebite. Hemorrhagic blebs may occur within several hours for similar reasons. Hemoconcentration often develops as a result of fluid loss into subcutaneous tissue, followed by a decrease in hemoglobin over several days from blood loss secondary to coagulopathy.

Diagnosis

The diagnosis of snakebite is based on the presence of fang marks and a history consistent with exposure to a snake (walking through a field, etc.). Snake envenomation involves the presence of a snake bite plus evidence of tissue injury. Clinically, the injury may be manifest in three ways: local injury (swelling, pain, ecchymosis), coagulopathy (thrombocytopenia, elevated prothrombin time, hypofibrinoginemia), or systemic effects (oral swelling or paresthesias, metallic or rubbery taste in the mouth, hypotension, tachycardia, etc.). Abnormalities in any one of these areas indicate that venom effect is developing. The absence of all three manifestations for a period of 8 to 12 h following the bite indicates that no venom was injected.

Treatment

FIRST AID   First aid measures should never substitute for definitive medical care or delay the administration of antivenom. All patients bitten by a pit viper should be taken to a health care facility. Table 189-2 lists one prudent approach to first aid. Several first aid products are marketed. The Coghlan's Snake Bite Kit (Coghlan's Ltd.) or similar products should not be used because it contains cups that produce little suction and seal poorly on digits. The blade in the kit or any method of incision can injure digital nerves, arteries, and tendons; incision is not recommended. The Sawyer Extractor (Sawyer Products) suction pump removes venom without incision, producing up to 750 mmHg of suction over a puncture site. The usefulness of this device is unknown, although it has been shown to remove some venom in one animal study. Other useless or dangerous techniques are electric shock and ice. Electric shock treatment of the bite site is mentioned only to be condemned. This dangerous procedure is not effective and has resulted in electrical injuries. Ice-water immersion worsens the injury.

Retreat well beyond striking range. Many victims are bitten again while trying to capture the snake.

Remain calm. Movement will increase venom absorption.

Immobilize the extremity in a neutral position below the level of the heart.

Keep physical activity minimal.

Promptly transport the victim to a medical facility regardless of whether overt signs of envenomation are quickly apparent. Signs and symptoms of snakebite may be delayed.

TABLE 189-2   Recommended First Aid Measures

Tourniquets are contraindicated because they obstruct arterial flow and cause ischemia. Constriction bands may be of some use, especially when immediate medical care is not available. A constriction band is an elastic bandage or Penrose drain, rope, or piece of clothing wrapped circumferentially above the bite, applied with tension that restricts superficial venous and lymphatic flow while maintaining distal pulses and capillary fill. The band should be snug but loose enough to easily slide a finger underneath. In theory, a constriction band retards venom absorption. This should increase local tissue injury but reduce the severity of systemic effects. Anecdotal human reports and animal studies suggest that constriction band use delays venom absorption without causing increased swelling. [4] Additional controlled studies are needed to better define the clinical indications for constriction band use.

Emergency Management

In the prehospital phase, personnel should be directed to immobilize the limb, establish intravenous access in another limb, administer oxygen, and transport the victim to a medical facility. Previously placed tourniquets and constriction bands should not be removed until intravenous access is established.

As in any emergency, initial snakebite management should include advanced life support. If the patient is hypotensive, initial treatment should include rapid intravenous isotonic fluid infusion. Other supportive care measures should include limb immobilization to reduce further venom absorption. Consultation with a physician or poison center familiar with the management of snake envenomation is recommended for all but the simplest of cases.

Antivenin (Crotalidae) polyvalent is the mainstay of therapy for poisonous snakebite. [4] It is the name for a refined and concentrated preparation of polyclonal equine immunoglobulins capable of neutralizing the venoms (an "antivenom") of North, Central, and South American pit vipers. All crotalid bites that show evidence of progressive signs and symptoms should immediately receive the antivenom. Progression is defined as worsening of local injury (e.g., pain, ecchymosis, or swelling), laboratory abnormalities (e.g., worsening platelet count, prolonged coagulation times, decreased fibrinogen), or systemic manifestations (e.g., unstable vital signs or abnormal mental status).

Because Antivenin (Crotalidae) polyvalent is derived from horse serum, it is common for patients to develop an allergic reaction during infusion. An intradermal skin test should be applied before antivenom is given, but only when a definite decision to administer the antivenom has been made. This is to prevent unnecessary sensitization. A positive test (wheal >10 mm in diameter) indicates that the patient may develop an allergic reaction, whereas a negative result usually indicates that the patient will tolerate the infusion. Some patients with negative skin tests will develop acute allergic reactions; likewise, some patients with positive skin tests tolerate antivenom infusion without difficulty. The skin test is a guide and antivenom decisions should be based on a risk-benefit analysis of the patient's condition. To prevent a delay while waiting for the skin test results, the antivenom should be mixed simultaneously with placement of the skin test. Because the antivenom takes 15 to 45 min to enter solution, it will be ready when the skin test is interpreted.

The recommended dose of antivenom has increased over the years. The use of at least 10 vials is recommended as the initial dose in rattlesnake bites. In rapidly progressive envenomations or hemodynamically unstable cases, an initial dose of at least 20 vials of antivenom is recommended in addition to aggressive supportive care. Poisoning by water moccasins usually requires lesser doses, whereas in copperhead bites, antivenom may not be required except for severe cases, children, and the elderly. Under no circumstances should antivenom be injected directly into finger or toes. Intramuscular injection is also not recommended because venom-induced hypovolemia may retard absorption of antivenom. Hospital pharmacies in those regions of the United States where poisonous snakes are prevalent should maintain adequate stocks of antivenom. Unfortunately, many hospitals stock insufficient amounts of antivenom, even in endemic areas. [5]

The package insert may be used as a guide for antivenom preparation. Antivenom should be administered only in a critical care facility such as an emergency department or intensive care unit. After reconstitution, the antivenom should be diluted in 250 to 500 mL of crystalloid and infused slowly, until it is evident that anaphylaxis will not occur. If a reaction does not develop, the rate should be increased in a stepwise manner until the infusion is complete, usually in 1 h. Infusion of antivenom should be done under the direct supervision of a physician. If an acute allergic reaction occurs, the infusion should be stopped immediately and antihistamines administered (both H_1- and H_2-receptor blockers). Epinephrine should be added depending on the severity of the reaction.

The end point of antivenom therapy is arrest of progression or improvement of clinical findings. One infusion of 10 to 20 vials is often sufficient. It is extremely

important, however, that observation for progression of edema and systemic signs of envenomation be continued even after antivenom infusion. Limb circumference should be measured at several sites above and below the bite, and the advancing border of edema should be outlined with a pen every 30 to 60 min. This serves as an index of the progression as well as a guide for antivenom administration. Laboratory determinations are repeated q4h or after each course of antivenom therapy, whichever is more frequent. Additional antivenom therapy may be warranted if the patient's condition worsens.

The value of aggressive supportive care cannot be overemphasized. Isotonic fluid resuscitation followed by pressor agents is appropriate for hypotension. Antivenom is the best treatment for coagulopathy, but if active bleeding occurs, blood component replacement may be necessary. Another complication of snakebite is compartment syndrome. Increased compartment pressure may occur when venom is injected into a compartment during a bite. This is usually manifest by severe pain, localized to a compartment, that is resistant to narcotic analgesia. The use of fasciotomy is controversial. Recommended management is shown in Table 189-3.

1. Determine intracompartmental pressure.

2. If not elevated, continue standard management.

3. If signs of compartment syndrome are present and compartment pressure is >30 mmHg:
   Elevate limb.
   Administer mannitol 1–2 g/kg IV over 30 min.
   Simultaneously administer additional Antivenin (Crotalidae) polyvalent, 10 to 15 vials IV over 60 min.
   If elevated compartment pressure persists another 60 min, consider fasciotomy.

*Elevated compartment pressure is caused by the action of the venom on the tissues; thus, the most effective treatment is to neutralize the venom, which may reduce the compartment pressure.
†This protocol delivers a high osmotic load and should not be used when contraindicated. The protocol must be completed promptly so that, if ever needed, fasciotomy may be performed as early as possible.

TABLE 189-3   Management of Compartment Syndrome*†

The wound area should be cleaned and the need for tetanus booster determined. Cultures and antibiotic therapy should be initiated only if signs of infection are present. Although recommended by some authors, no objective evidence supports the use of prophylactic antibiotics. [6] The use of steroids is also controversial. Several studies suggest lack of efficacy or even deleterious effects. Without evidence of efficacy, steroids should be reserved for the treatment of allergic reactions or the treatment of serum sickness.

Disposition

Patients are ready for discharge when swelling begins to resolve, the coagulopathy has been reversed, and the patient is ambulatory. During recovery, the bitten part (particularly the hand) should be regularly exercised to preserve as much function and strength as possible. Outpatient follow-up is necessary to monitor for infection and serum sickness.

It cannot be overemphasized that one can easily be deceived by a bite that initially appears innocuous. An unremarkable physical and laboratory examination at presentation does not reliably indicate an insignificant envenomation. We recommended that physicians observe patients for at least 8 h. Patients with severe or life-threatening bites and patients receiving antivenom should be admitted to an intensive care unit. The general ward is appropriate for patients with mild or moderate envenomations who have completed or do not require further antivenom therapy.

Patients with dry bites who have been observed for at least 8 h may be discharged. They should return if pain, swelling, or bleeding develops.

CORAL SNAKE BITE

North American coral snakes include the eastern coral snake (*Micrurus fulvius fulvius*), the Texas coral snake (*Micrurus fulvius tenere*), and the Arizona (Sonoran) coral snake (*Micruroides euryxanthus*). The eastern coral snake is found primarily in the southeast United States. The Texas and Arizona coral snakes are found primarily in the states that bear their names. Coral snakes account for 20 to 25 bites a year.

All coral snakes are brightly colored with black, red, and yellow rings. The red and yellow rings touch in coral snakes, but they are separated by black rings in nonpoisonous snakes, creating the well known rhyme: "Red on yellow, kill a fellow; red on black, venom lack." This rule is *not* true outside of the United States.

Coral snake venom is primarily composed of neurotoxic components that do not cause marked local injury. Elapid bites produce primarily neurologic effects: tremors, salivation, dysarthria, diplopia, bulbar paralysis with ptosis, fixed and contracted pupils, dysphagia, dyspnea, and seizures. The immediate cause of death is paralysis of respiratory muscles. Signs and symptoms may be delayed up to 12 h.

The potential coral snake victim should be admitted to the hospital for 24 to 48 h of observation. Coral snake venom effects may develop hours after a bite and are not easily reversed. It is suggested that 3 vials of the Antivenin (*Micrurus fulvius*) be administered to patients who have definitely been bitten because it may not be possible to prevent further effects or reverse effects that have already developed. [7] Additional coral snake antivenom is reserved for the appearance of symptoms or signs of coral snake envenomation. However, because respiratory failure may result from clinical effects of the neurotoxin, baseline and serial pulmonary function parameters (such as inspiratory pressure and vital capacity) in addition to intensive care observation may be useful. Prolonged ventilatory support may be required in severe cases. The patient must be observed closely for signs of respiratory muscle weakness and hypoventilation. Bites by the Sonoran coral snake are mild. Medical care is not usually needed.

GILA MONSTER BITE

Gila monsters are slow-moving lizards that inhabit the desert in the southwestern United States. They possess a venom as potent as rattlesnake venom but lack the apparatus to effectively inject it. Instead of fangs, they simply have short, grooved teeth down which their venom flows. Therefore, envenomation requires a prolonged bite. Gila monsters bite tenaciously and may be difficult to remove from the bitten extremity.

Most bites result in local pain and swelling only, which worsens over several hours and then subsides over several more hours. Dislodged teeth often contaminate the wound. Occasionally, a more severe syndrome of systemic toxicity develops, including weakness, light-headedness, paresthesia, and diaphoresis. Severe hypertension may occur, which also resolves over several hours. There are few if any documented deaths from gila monster bite.

First aid involves removal of the reptile from the bite site without sustaining another bite. This may require force. It helps to place the animal on a solid surface; like other animals, it will often loosen its grip when it is no longer suspended in midair. Otherwise, standard local wound care is sufficient, taking care to remove any teeth in the wound. The usefulness of prophylactic antibiotics is unknown and tetanus status should be determined.

AUSTRALIAN ELAPIDS

About 3000 people are bitten by snakes each year in Australia, of whom at least 200 receive antivenom. [8] In the decade up to 1992, there was an average fatality rate of 1.8 per year, but in the years 1992–1994, the rate was 3.7 deaths per year (the Australian population is approximately 18.5 million). Half of all Australian snakebite deaths are caused by the brown snake (genus *Pseudonaja*).[9]

Biology

The venomous snakes of Australia are members of the family Elapidae, of which the cobras are also members. In contrast to North American Crotalidae, the Elapidae

possess a relatively unsophisticated venom delivery apparatus with nonretractile small- to medium-sized paired fangs that have grooved venom channels rather than hollow venom ducts. It is thought that the Elapidae exert voluntary control over the injection of venom, hence the occurrence of the "dry bite," without envenomation. [9]

The venom of the Australian elapids contains several important components. [9] Neurotoxins (tiger snake, taipan, and death adder) act at the neuromuscular junction and cause paralysis. Signs may become apparent 2 to 4 h after the bite and may include ptosis, partial ophthalmoplegia (diplopia), dysarthria, loss of facial expression, and loss of airway control as well as respiratory paralysis in severe cases. Myolysins are structurally related to the neurotoxins but instead produce rhabdomyolysis, which may result in muscle pain, weakness, myoglobinuria, renal failure, and hyperkalemia. The procoagulant toxins (brown snake, tiger snake, taipan) act as prothrombin converters, leading to fibrinogen consumption and resulting in a coagulopathy. Intracranial hemorrhage is a recognized complication. Renal impairment or failure may also result from snakebite. The mechanisms are poorly understood and may include hypotension, myoglobinuria, coagulopathy, and direct renal toxicity (the brown snake). [10] Local tissue destruction is uncommon with any Australian species, although mild to moderate ecchymosis and swelling may occur.

The brown snakes are capable of inflicting bites that cause rapid collapse and death. [4] Brown snake venom has been found to cause severe cardiovascular depression in anesthetized dogs, and these effects may account for the sudden deaths described.

Clinical Presentation

Patients typically present with a myriad of symptoms including nausea, vomiting, headache, diplopia, dysphonia, progressive muscle weakness, neck stiffness, discoloration of urine, collapse, and seizures. Young children may not provide a history of snakebite; therefore a high index of suspicion is required in this group. The absence of signs or symptoms at presentation does not exclude significant systemic envenomation.

First Aid

The aim of first aid is to delay absorption of venom from the bite site until the patient is in a facility that can administer antivenom if required. [8] The pressure-immobilization method described below is used for elapid bites because they do not manifest much local soft tissue swelling. This technique is not recommended for crotalid bites because the immobilization dressing causes severe pain when swelling develops. [12,13] All patients should immediately have the bitten extremity wrapped in a snug elastic bandage from either the ankle to the hip or the wrist to shoulder. The bandage should be applied as if to a sprained joint; if it is too loose or too tight, it will be ineffective. [13] The idea is to contain the venom and prevent systemic absorption. The limb is splinted to prevent motion. The patient should rest until help arrives. Examination of lymphatic flow rates with simulated venom has demonstrated that even if the upper or lower limb is appropriately bandaged and immobilized, walking will hasten systemic envenomation. [13] Tourniquets are an outmoded therapy and are contraindicated because they obstruct arterial flow and add ischemia injury to venom injury. In the rare circumstance that a bite is inflicted on the trunk, firm pressure should be applied without restricting breathing.

Management

Any history suggestive of snakebite should prompt the initiation of first aid, investigation, and observation, as detailed below. The pressure bandage should remain in place until the patient can receive antivenom. Once in a suitable facility, bandages and splints should not be left on for prolonged periods, as venom is then not available for interaction with circulating antivenom. In addition, there is no evidence that venom is inactivated by being trapped at the bite site. [8] If the patient's condition deteriorates immediately after bandage removal, the bandages may be reapplied while antivenom is given. Snakebite cases often present a number of complex clinical problems; therefore early consultation with an expert is recommended.

The Commonwealth Serum Laboratory (CSL) Snake Venom Detection Kit (SVDK) detects snake venom in the urine or at the bite site, identifies the type of snake involved, and provides guidance in antivenom selection if antivenom is needed. Positive SVDK identification of venom at the bite site or in the urine is not an indication for antivenom therapy without other evidence of systemic venom effect. False-positive and false-negative results have been described for blood testing by the SDVK and so should not be used.[8]

Antivenom should be given only in cases when there is clear clinical or laboratory evidence of systemic venom effect. Clinical indications for immediate antivenom therapy include vomiting and severe headache; neurotoxic effects such as ptosis, cranial nerve involvement, progressive muscle weakness, or diaphragmatic involvement; or evidence of coagulopathy. Pertinent investigations include full blood count, serum electrolytes, renal function, creatine kinase levels, and urine testing for hematuria or myoglobinuria.[9] Abnormal renal or coagulation studies may provide laboratory evidence of systemic venom effect before neurotoxic effects are apparent. If prothrombin time or activated partial thromboplastin time are prolonged, then levels of fibrinogen and fibrin degradation products should be obtained.

In the absence of clinical or laboratory evidence of venom effect, the elastic bandage should be removed and the patient observed for 12 h. Delayed envenomation after benign presentation has been documented. If significant envenomation has occurred, most patients will develop clinical or laboratory evidence of envenomation within 2 h of removing a bandage.[8] Therefore, coagulation studies should be repeated 2 h after bandage removal and at intervals thereafter, depending on the patient's condition.

Five antivenom products, derived from equine IgG, are produced by the CSL to treat envenomation by certain groups of Australian snakes. These are termed *monovalent antivenoms.* A polyvalent antivenom, also equine IgG, neutralizes the venom of all five major groups of dangerous Australian snakes. The reader is directed to more detailed sources or CSL product information for the species covered by each antivenom product. [2]

If indicated, antivenom should be given immediately in sufficient doses to improve coagulation studies. A child should receive the same dose as an adult. [8] Pregnancy is not a contraindication to antivenom therapy. Skin testing before antivenom administration is not routinely recommended. [8] If the type of snake cannot be identified, one or two appropriate monovalent antivenoms, specific for a known group of snakes, may be selected using knowledge of snakes found in the geographic area. Polyvalent antivenom is used in the following circumstances: (1) monovalent antivenom is not available; (2) the SVDK is not available or has failed to identify the type of snake and the range of possible snakes would require the mixing of three or more monovalent antivenoms; (3) the patient is severely envenomated, there is insufficient time to wait for SVDK results, and the range of possible snakes would require the mixing of three or more monovalent antivenoms; or (4) stocks of appropriate monovalent antivenom have been exhausted and the patient requires further antivenom treatment. [9]

In contrast to experience around the world, anaphylaxis appears to be a rare complication of antivenom therapy in Australia. [8,14] Nevertheless, patients should be treated in a setting where anaphylaxis can be managed. Premedication with a subcutaneous dose of 0.3 mL of 1:1000 epinephrine (adrenaline) in an adult or 0.1 mL in a child along with a parenteral antihistamine is recommended by some authors. [8,15] Although prospective data are lacking, corticosteroids may have a role in premedication and prevention of serum sickness. Most treatment protocols dictate that patients with a history of allergy to equine proteins should receive corticosteroids. In addition, a 5-day course of prednisolone may be prescribed in an attempt to reduce the incidence of serum sickness in those patients who receive large doses of monovalent antivenom or polyvalent antivenom. Paul S. Auerbach

Although encounters with noxious marine organisms occur predominantly in warm temperatures and tropical seas, dangerous marine animals are found to a significant degree as far north as 50° N latitude. Because of increasing numbers of recreational divers and private salt-water aquariums, as well as the ease of international travel, emergency physicians everywhere should be familiar with treatment for injuries and illnesses associated with the marine environment. Included among these dangers are injuries from traumatizing and envenoming animals. Exposure to these creatures may occur while walking on the beach, wading in tidal pools, deep-water diving, or simply changing the water in a home aquarium. The infections that may occur after marine trauma are sometimes unique and can be debilitating.

MARINE TRAUMA

The notoriety of shark attacks seems undeserved when the statistics are examined.[1] Fewer than 100 attacks are reported annually worldwide, with 10 or fewer fatalities. Of approximately 370 shark species, only 32 have been definitely implicated in human attacks, the majority by the tiger, great white, blue, mako, hammerhead, bull, and grey reef sharks.

Two general attack behaviors have been described: feeding and agonistic. Feeding attacks appear to be the result of mistaking a human for a pinniped or other common shark prey. Such attacks often terminate as soon as the shark realizes the mistake. Agonistic attacks seem to be defensive or territorial-protective.

Shark attack wounds range from severe dermal abrasions (due to sharkskin denticles) following a "bumping" to massive tissue loss with fractures and hemorrhage. Such injuries occur from razor-sharp teeth on jaws brought together with an estimated force approaching 18 tons/in[2] tooth to tooth. "Hit-and-run" attacks occur in the majority of instances, and 70 percent of victims are bitten only once or twice. The lower extremity is most frequently injured, followed by the upper extremity. Death is usually the result of hemorrhagic shock or drowning.

As with other resuscitative endeavors, the ABCs are fundamental, with special attention to hemorrhage control, volume resuscitation, and rewarming as needed. Tetanus toxoid and tetanus immunoglobulin should be administered as indicated. Prophylactic intravenous antibiotics are empirically recommended to counter a potential *Vibric* species infection. Third-generation cephalosporins, trimethoprim-sulfamethoxazole, chloramphenicol, ciprofloxacin, norfloxacin, or an aminoglycoside may be given. Meticulous wound care is most appropriately performed in the operating room for adequate surgical exploration, irrigation, and débridement of wounds. To minimize tissue destruction associated with an infection, wounds may be packed open for delayed primary closure or closed around drainage systems.

It has been suggested that most shark attacks could be prevented if a few precautionary measures were taken: (1) avoid swimming in river mouths, low-visibility waters, or shark-infested waters; (2) avoid wearing bright or shiny clothing, jewelry, or equipment; (3) avoid swimming with an open (bleeding) wound; and (4) obey beach authorities and posted warnings.

The great barracuda (*Sphyraena barracuda*) is the only barracuda species implicated in human attacks. Attacks are generally by solitary fish and occur only in tropical climes. Moray eels, found in tropical-to-temperate waters, can inflict severe puncture wounds or lacerations, commonly to the hands of inquisitive divers. Other marine vertebrates known to cause traumatic injuries to humans include giant groupers, sea lions, seals, crocodiles, alligators, needlefish, wahoos, piranas, and triggerfish. Wounds resulting from interactions with such creatures are a combination of crush injury, abrasion, puncture, and laceration. Treatment of such injuries is analogous to that of shark bites, with an emphasis on irrigation, removal of foreign bodies (e.g., teeth), and allowing adequate wound drainage (e.g., leaving puncture wounds open).

Coral cuts are probably the most common injuries sustained underwater. The initial reactions to a coral cut are stinging pain, erythema, and pruritus, most commonly on the hands, forearms, elbows, and knees. Within minutes, a break in the skin may be surrounded by an erythematous wheal, which fades over 1 to 2 h.

With or without treatment, the local reaction of red, raised welts and local pruritus may progress to cellulitis with ulceration and tissue sloughing. The wounds heal slowly over 3 to 6 weeks. In extreme cases, the victim develops cellulitis with lymphangitis, reactive bursitis, local ulceration, and wound necrosis. *Coral poisoning* usually refers to systemic malaise, fever, diarrhea, and general inanition associated with a wound from coral.

Coral cuts should be promptly and vigorously irrigated to remove all foreign matter. Any fragments that remain can become embedded and increase the risk of infection or foreign-body granuloma. If stinging is a major symptom, there may be envenomation by nematocysts. A brief rinse with dilute acetic acid (vinegar) or papain solution may diminish the discomfort. If a coral-induced laceration is severe, it should be closed with adhesive strips, rather than sutures, if possible. Sharp débridement each day for 3 to 4 days is preferable if the wound is deep. For superficial (no fat showing) wounds, utilize daily saline solution or dilute povidone-iodine wet-to-dry dressing changes, or apply a topical antiseptic under a nonadherent dressing.

Bacteriology of the Marine Environment and Antibiotic Therapy

Ocean water provides a rich saline milieu for microbes.[2] Although the greatest number and variety of bacteria are found near the ocean surface, diverse bacteria and fungi are found in marine silts, sediments, and sand. Microbes, including bacteria, microalgae, protozoa, yeasts, and viruses, are most abundant in areas with the greatest number of life forms. Marine bacteria are generally gram-negative rods. Bacteria isolated from the marine environment or from marine-acquired wounds of greatest concern to humans include *Aeromonas hydrophila, Bacteroides fragilis, Chromobacterium violaceum, Clostridium perfringens, Erysipelothrix rhusopathiae, Escherichia coli, Mycobacterium marinum, Pseudomonas aeruginosa, Salmonella enteritidis, Staphylococcus aureus, Streptococcus* species, and *Vibric* species.

There is no substitute for meticulous wound care, including irrigation and débridement of devitalized tissue, with particular attention to retained foreign bodies, such as teeth, vegetable matter, and spines. Quantitative wound culture prior to the appearance of clinically evident wound infection has not been shown to be useful. The issue of prophylactic antibiotics in the treatment of marine wounds has not been well studied. Pending a prospective study of prophylactic antibiotics in this setting, the following recommendations are generally advised, based on the morbidity of soft-tissue infections caused by *Vibric* species:[3]

- Minor abrasions and lacerations of the normal, immunocompetent patient do not require prophylactic antibiotics.
- Minor abrasions and lacerations of immunocompromised or chronically ill patients require initiation of therapy with trimethoprim-sulfamethoxazole, tetracycline, cefuroxime axetil, norfloxacin, or ciprofloxacin.
- High-risk wounds (e.g., extensive lacerations or burns; deep puncture wounds, particularly involving the joint space; or grossly contaminated wounds) require initiation of parenteral trimethoprim-sulfamethoxazole, a third-generation cephalosporin, an aminoglycoside, chloramphenicol, or one of the oral agents mentioned above.

The objectives for the management of infections from marine microorganisms are to recognize the clinical condition, culture the organism, and provide antimicrobial therapy. The appearance of an infection indicates the need for prompt débridement and search for a retained foreign body. Infected wounds should be cultured for aerobes and anaerobes. Since special media may be necessary for culture and sensitivity testing, the clinician should alert the microbiology laboratory that a marine-acquired organism might be present. Empirical antibiotic therapy should be initiated based on the clinical condition.

Management of marine-acquired infections must include coverage against *Vibric* species with a third-generation cephalosporin, trimethoprim-sulfamethoxazole,

tetracycline, norfloxacin, ciprofloxacin, or cefuroxime. Freshwater infections may be treated with the abovementioned agents, imipenem, or an aminoglycoside, to cover *Aeromonas* species. Appropriate antibiotic coverage against staphylococcal and streptococcal species is mandatory, since they remain the most common infecting organisms. Imipenem-cilastatin is reserved for established wound infections and/or sepsis.

Several special clinical conditions are of note. A patient with rapidly progressive cellulitis, myositis, or necrotizing fasciitis warrants consideration of *Vibrio parahaemolyticus* or *Vibrio vulnificus* infection. *Vibrio vulnificus* can also cause primary septicemia in chronically ill individuals, particularly those with hepatic disease. Mortality rates for such patients approach 60 percent. *Erysipelothrix rhusopathiae* is the infectious agent in "fish-handler's disease" and causes sharply marginated, painful, expanding plaques on the fingers or hands following cutaneous inoculation. It responds to penicillin, ampicillin, cephalexin, b-lactam antimicrobials, ciprofloxacin, and clindamycin. Resistance has been noted to vancomycin, the aminoglycosides, trimethoprim-sulfamethoxazole, tetracycline, and erythromycin. *M. marinum* is an acid-fast bacillus that causes "swimming-pool granuloma" or "aquarium granuloma." Some 3 to 4 weeks following an abrasion or puncture wound, the patient develops a red papule, which progresses to a cutaneous granuloma. Excision or antibiotics (minocycline, trimethoprim-sulfamethoxazole, rifampin, or ethambutol) are the treatments of choice, although spontaneous resolution typically occurs over 2 to 3 years. *Aeromonas hydrophila* is a gram-negative bacterium found in marine and freshwater environments; it causes wound infections that can rapidly become cellulitic and progress to necrotizing myositis.

MARINE ENVENOMATIONS

Marine venoms are large-molecular-weight compounds of vasoactive and proteolytic enzymes with diffuse effects on the circulatory, neurologic, immunologic, and respiratory systems.[4,5,6 and 7] They require a specialized delivery system, are commonly heat and gastric-acid labile, show nonseasonal toxicity, and can be released in varying amounts. Conversely, poisons are usually metabolic byproducts of lower molecular weight. They are ingested (thereby requiring no delivery system), are usually heat and gastric-acid stable, and carry some seasonal toxicity.

Venoms are produced in specialized glands and are broadly classified as parenteral toxins, which are injected mechanically, or crinotoxins, which are delivered topically as slimes (mucous or gastric secretions). Practically, venoms are used offensively or defensively. An offensive venom is employed to kill prey and is typically located near the mouth or on the tentacles. Defensive venoms are used to protect the animal and are usually located near the tail. A human's reaction to an envenomation can be allergic or toxic.

Invertebrate Envenomations

Envenoming invertebrates are found in five phyla: Cnidaria (Coelenterates), Porifera, Echinodermata, Mollusca, and Annelida. [4]

CNIDARIA (COELENTERATES)   The phylum Cnidaria is an enormous group of approximately 9000 species, at least 100 of which are dangerous to humans. The phylum contains three classes: Hydrozoa, Scyphozoa, and Anthozoa. Cnidariae, from *cnid,* the stem of the Greek word "nettle," are known for their specialized venom-containing stinging cells, called cnidocytes. The cnidocytes are located near the mouth or on the outer surfaces of tentacles. A physical or chemical stimulus causes the release of a hollow, sharply pointed threadlike tube from the contained nematocyst. [8] This tube penetrates the victim's skin, allowing injection of the venom, with diffusion into the general circulation. [8,9] Detached, moistened tentacles carry live nematocysts capable of discharging for months. Air-dried nematocysts may retain considerable potency for weeks.

The class Hydrozoa includes the hydroids, milleporina (fire corals), and siphonophores (Portuguese man-of-war and bluebottle jellyfish). Hydroids are the most numerous of the hydrozoans. The feather hydroids are plumelike animals that sting the victim who brushes against or handles them. [10] Coastal storms can break off feather hydroid branches and infest a local swimming area.

Contact with the nematocysts of a feather hydroid induces a mild reaction, which consists of instantaneous burning, itching, and urticaria. If the exposure is brief, the skin rash may not be noticeable or may consist of a faintly erythematous morbilliform eruption. A second variety of envenomation consists of a delayed papular, hemorrhagic, or zosteriform reaction occurring 4 to 12 h after contact. Rarely, erythema multiforme or a desquamative eruption may develop. Systemic manifestations are rarely reported.

The *Millepora* species, or fire corals, are not true corals. The fire coral *Millepora alcicornis* probably accounts for the majority of coelenterate envenomations. Fire corals are widely distributed in shallow tropical waters and often mistaken for seaweed. Tiny nematocyst-bearing tentacles protrude from numerous minute surface gastropores. Immediately following contact with fire coral, the victim notices burning or stinging pain, with rare proximal radiation. Over the course of 5 to 30 min, pruritic urticarial lesions develop. The pain generally resolves without treatment in 30 to 90 min. In the case of multiple stings, regional lymph nodes may become inflamed. Skin lesions resolve over 3 to 7 days, occasionally resulting in postinflammatory hyperpigmentation, which may take months to disappear.

The Atlantic Portuguese man-of-war (*Physalia physalis*) inhabits the surface of the ocean.[10] It is constructed of a floating sail (pneumatophore) from which are suspended multiple nematocyst-bearing tentacles measuring up to 30 m in length. The smaller Pacific bluebottle (*Physalia utriculus*) usually has a single fishing tentacle that attains lengths of up to 15 m. Each tentacle in a larger specimen may carry more than 750,000 nematocysts. Nematocysts from fractured tentacles may remain active for months. The most common reaction from contact is an immediate, toxic dermal reaction with linearly arranged urticarial lesions. [11] Respiratory distress and death have been reported following *P. physalis* envenomation.

The class Scyphozoa, or jellyfish, includes the Indo-Pacific box jellyfish (*Chironex fleckeri*), the sea nettle (*Chrysaora quinquecirrha*), and the thimble jellyfish (*Linuche unguiculata*).[11] The Indo-Pacific chirodropids are armed with some of the most potent venoms in existence. An extreme example of envenomation occurs with the Indo-Pacific box jellyfish. Found along the northern coast of Australia, *C. fleckeri* has killed at least 65 people in the past century. Death is attributed to hypotension, profound muscle spasm, muscular and respiratory paralysis, and subsequent cardiac arrest. The overall mortality rate following box jellyfish stings approaches 15 to 20 percent. Most stings are minor, but severe reactions or death can follow skin contact with tentacles in excess of 6 to 7 m. The sting is instantly and intensely painful, and the victim may struggle purposefully for only a minute or two prior to collapse. The toxic skin reaction may be quite intense, with rapid formation of wheals, vesicles, and a darkened reddish-brown or purple whiplike flare pattern with stripes of 8 to 10 mm in width. Major stings show skin blistering within 6 h, with superficial necrosis in 12 to 18 h. On occasion, a pathognomonic "frosted" appearance with a transverse crosshatched pattern may be present.

Sea nettles (*Chrysaora* and *Cyanea* species) are found in tropical and temperate waters, particularly the Chesapeake Bay, and are far less dangerous. Sea nettle envenomation presents similarly to that from *Physalia* species.

Seabather's eruption, commonly referred to by the misnomer "sea lice," is a vesicular or morbilliform pruritic dermatitis. [12] It occurs a few minutes to 12 h after saltwater exposure. The eruption primarily involves skin surfaces covered by bathing suits, swim caps, or fins. Divers may be afflicted on the neck when floating in water churned by boat propellers that have ground floating jellyfish into fragments. Dermatitis persists for 2 to 14 days and resolves spontaneously. Other symptoms include headache, chills, pronounced nocturnal pruritus, malaise, conjunctivitis, and urethritis. The 0.5-mm larval form of the thimble jellyfish *Linuche unguiculata* has been recently identified as the cause of outbreaks in southern Florida and the Caribbean. The planula form of the sea anemone *Edwardsiella lineata* has been implicated in outbreaks off the coast of Long Island, New York.

The class Anthozoa includes the sea anemones, stony (true) corals, and the soft corals. Anemones are attractive creatures often found in tidal pools, where the unwary may brush up against them or inquisitively touch them. Like other coelenterates, they possess tentacles loaded with nematocysts. The dermatitis resulting from contact is identical to that produced by fire coral. If the envenomation is severe, hemorrhagic bullae with necrosis and ulceration may occur.

Due to considerable phylogenetic resemblance among *Cnidaria* species, the clinical features of *Cnidaria* envenomation are similar across a wide spectrum of severity. The toxicity of envenomation depends on the venom dose, the marine species, and the victim. Mild envenomation results in bothersome dermatitides that resolve spontaneously over 1 to 2 weeks, with occasional postinflammatory hyperpigmentation. Anemones, *Physalia* species, and scyphozoans may cause moderate-to-severe envenomations compounded by systemic symptoms. These symptoms may appear immediately or within several hours.

Therapy is directed at the ABCs, detoxifying the venom, and providing symptomatic and pain relief. Nematocysts still attached to the patient need to be deactivated and removed to prevent continued envenomation. All victims with systemic signs or symptoms should be observed for at least 8 h, since rebound of symptoms can occur. *Chironex fleckeri* produces the only venom for which there is a specific topical antidote, 5% acetic acid (vinegar). While the venoms are heat labile, this fact

does not appear to be of clinical significance, and hot water immersion is not recommended.

Deactivation of attached nematocysts is important but controversial, due to locale-dependent variations in therapy. [13] A generally accepted method is to immediately apply a topical decontaminant (see below), if available, to putatively inactivate undischarged nematocysts. Freshwater rinsing is not recommended because the hypotonic solution is felt to stimulate nematocyst discharge. However, some lifeguards in Florida report that a victim of a *Physalia* sting may find relief from being showered with a forceful stream of water, which implies that the mechanical removal of nematocysts supercedes the deleterious effect of hypotonicity. Gentle application of fresh water is prohibited. After decontamination, visible tentacles can be removed with forceps or a double-gloved hand.

As a decontaminant, 5% acetic acid (vinegar) is the treatment of choice to inactivate most venoms. It is absolutely indicated in the event of a sting from *Chironex.* An alternative therapy is isopropyl alcohol (40 to 70%), which is not recommended for *Chironex.* For *Chrysaora* or *Cyanea,* a slurry of baking soda (sodium bicarbonate) is effective. Vinegar is not very effective for seabather's eruption, for which papain solution may be much more effective. The detoxicant should be applied continuously for at least 30 min or until there is no further pain. Once the nematocysts have been inactivated, the easiest way to remove them is to apply shaving cream or a paste of baking soda, flour, or talc and then shave the area with a razor or similar instrument. Topical anesthetics, antihistamines, or steroids may be of benefit. Prophylactic antibiotics are not needed, but standard antitetanus prophylaxis and diligent wound care should be carried out.

In general, only severe *Physalia* and box jellyfish stings will result in rapid decompensation. Other than the usual resuscitative measures and sheep-derived antivenom specific for *Chironex* envenomation (Commonwealth Serum Laboratories, Melbourne, Australia), there are no new therapies on the horizon. Pain can be excruciating and requires narcotic analgesia. For such severe envenomations, it may be useful to apply the pressure-immobilization technique to the envenomed extremity. This is done by wrapping the limb with a venous-lymphatic occlusive bandage and then applying a splint. The wrap is maintained until the victim is brought to a medical facility where intensive care and antivenom can be provided. Corneal envenomations can be irrigated with an isotonic solution and treated judiciously with topical steroids.

PORIFERA   The phylum *Porifera* contains approximately 4000 species of sponges that are composed of horny but elastic skeletons. [10] Embedded in the connective tissue matrices are spicules of silicon dioxide or calcium carbonate. Secondary coelenterate inhabitants are responsible for the dermatitis and local necrotic skin reaction termed *sponge diver's disease.* A number of sponges produce crinotoxins that may be direct dermal irritants.

Two general syndromes are induced by contact with sponges. The first is a pruritic dermatitis similar to plant-induced allergic dermatitis. Within a few hours after skin contact, itching and burning develop, which may then progress to local joint swelling and stiffness, soft-tissue edema, and vesiculation, particularly if small pieces of broken sponge are retained in the skin near the interphalangeal or metacarpophalangeal joints. The skin may become mottled or purpuric. Untreated mild reactions will subside within 3 to 7 days. With large-surface-area exposure, the victim may complain of fever, chills, malaise, dizziness, nausea, and muscle cramps. Bullae may become purulent. Erythema multiforme or an anaphylactoid reaction may develop 1 to 2 weeks after a severe exposure.

The second syndrome induced by contact with sponges is an irritant dermatitis and follows the penetration of small spicules of silica or calcium carbonate into the skin. Crinotoxins enter microtraumatic lesions caused by the spicules. In severe cases, superficial desquamation of the skin may follow in 10 days to 2 months. There is no medical intervention that can prevent this process. Recurrent eczema and persistent arthralgias are rare complications.

Because it is usually impossible to distinguish clinically between the allergic and spicule-induced reactions, it is safest to treat for both. The skin should be gently dried. Spicules should be removed, if possible, using adhesive tape, a thin application of rubber cement, or a facial peel. Beginning as soon as possible, 5% acetic acid (vinegar) soaks should be applied for 10 to 30 min three to four times daily to affected areas. Isopropyl alcohol (40 to 70%) is a reasonable second choice. Although topical steroids may help to relieve the secondary inflammation, they are of no initial value. If steroids are applied before the vinegar soaks, they appear to worsen the primary reaction. Delayed primary therapy or inadequate decontamination may result in the persistence of bullae. Erythema multiforme may require supportive care, including intravenous hydration, particularly if mucosal surfaces are involved, and topical steroids for symptomatic relief. The use of systemic steroids for erythema multiforme is controversial. If the allergic component is severe, systemic glucocorticoids (prednisone 40 to 80 mg per day tapered over 2 weeks) may be beneficial. Severe itching may be controlled with an antihistamine.

ECHINODERMATA   The phylum Echinodermata has five classes: sea lilies, brittle stars, starfish, sea urchins, and sea cucumbers. [10] Only the latter three are of emergency medical interest. The venom apparatuses of sea urchins consist of the sharp, brittle, venom-filled spines and the triple-jawed globiferous pedicellariae. Venomous spines cause immediate, intense pain. Burning pain rapidly evolves into severe local muscle aching, with erythema and swelling of the skin surrounding the puncture sites. Frequently, spines break off and lodge in the victim. If a spine enters a joint, it may rapidly induce severe synovitis. If multiple spines have penetrated the skin, particularly if they are deeply embedded, the victim may rapidly develop systemic symptoms, including nausea, vomiting, paresthesias, muscular paralysis, abdominal pain, syncope, hypotension, and respiratory distress. Pedicellariae can cause more severe symptoms, which are predominantly neurologic.

Starfish (Asteroidea) are covered with thorny spines that deliver a slimy venom produced in special glandular tissue. The crown-of-thorns sea star, *Acanthaster planci,* is a particularly venomous species. The sharp, rigid, venomous aboral spines of this animal may grow to 4 to 6 cm. As the spines enter the skin, they carry venom into the wound, causing immediate pain, copious bleeding, and mild edema. The wound may become dusky or discolored. Multiple puncture wounds may result in acute systemic reactions, including paresthesias, nausea, vomiting, lymphadenopathy, and muscular paralysis.

Sea cucumbers (Holothuroidea) produce a toxin that is concentrated in the tentacular organs. Direct contact may induce a contact dermatitis, which is usually mild, since the venom is diluted in seawater. The greater risk is to the corneas and conjunctivae, which may become intensely inflamed.

Treatment of echinoderm wounds consists of immediate immersion in hot water to tolerance [45°C (113°F)] for 30 to 90 min or until there is significant pain relief. Prompt removal of pedicellariae and spines, especially those in intraarticular areas, is necessary. Soft-tissue radiographs or magnetic resonance imaging are helpful in locating retained spines. Treatment of systemic symptoms is supportive, and analgesia may be needed. Granuloma formation occurs and may require excision. Sequelae that reflect an immune response, such as erythema nodosum or tenosynovitis, may require therapy with glucocorticoids. Since sea cucumbers dine on coelenterates and secrete the nematocyst venom, topical vinegar or isopropyl alcohol may provide some symptomatic relief.

ANNELIDA   The phylum Annelida contains the fireworms, or bristleworms, which are segmented worms covered with cactuslike bristles that can penetrate the skin. [10] These bristles easily detach in the skin and can be difficult to remove. Envenomation causes intense inflammation with a burning sensation and erythema. Untreated, the pain generally resolves within a few hours, but erythema may last for 2 to 3 days. Bristles should be removed with forceps, a thin application of rubber cement, a facial peel, or adhesive tape, and topical vinegar or isopropyl alcohol may be applied. The inflammatory response may require a course of glucocorticoids.

MOLLUSCA   The phylum Mollusca contains two potentially envenoming classes: the gastropods (cone shells and nudibranchs) and the cephalopods (octopuses). [10] Cone shells are beautiful, univalve creatures found in shallow Indo-Pacific waters. They are predators that feed by injecting a potent neurotoxin via detachable, dartlike, radular teeth. Mild stings resemble hymenopteran envenomations. More severe reactions include local and then generalized paresthesias and muscular paralysis, with ventilatory failure.

The Australian blue-ringed octopus produces the neurotoxin tetrodotoxin. Octopus bites typically occur on the upper extremity and consist of two small puncture wounds. Local reactions are often absent, and generalized paresthesias may be the first indication of an envenomation. Further neurologic symptoms may develop, with flaccid paralysis and ensuing ventilatory failure. Treatment is supportive, with mechanical ventilation as needed, and full recovery is expected. No antivenom is available. Wide excision of the bite wound has been done to remove sequestered venom. However, there is no scientific evidence of speedier recovery to support this practice.

For both cone shell and paralytic octopus envenomations, the most commonly recommended field first aid technique is pressure-immobilization, described above.

Vertebrate Envenomations

Stingrays are the most common group of fish to inflict human envenomations. The venom organ of stingrays consists of one to four venomous spines on the dorsum of a whiplike tail. [10] When an unwary human handles, corners, or steps on a ray, the tail reflexively whips upward and accurately thrusts the spines into the victim, producing a puncture wound or jagged laceration in addition to an envenomation. On occasion, the entire spine tip is broken off and remains in the wound. Envenomation causes immediate local intense pain, edema, and variable bleeding. The pain, which may radiate centrally, peaks at 30 to 60 min and may last for up to 48 h. The wound is initially dusky or cyanotic and rapidly progresses to become erythematous and hemorrhagic, with fat and muscle involvement and possible

necrosis. Systemic manifestations include weakness, nausea, vomiting, diarrhea, diaphoresis, vertigo, headache, syncope, seizures, muscle cramps, fasciculations, generalized edema (with truncal wounds), paralysis, hypotension, arrhythmias, and death.

Scorpionfish are found in tropical and, less commonly, temperate oceans and, unfortunately, in private aquariums. [10] They can be grouped according to the severity of their envenomation in ascending order from the beautifully ornate lionfish (mild) to the camouflaged scorpionfish (moderate to severe) to the motionless stonefish (severe to life-threatening). The venom organs consist of 12 or 13 dorsal, 2 pelvic, and 3 anal spines with associated venom glands. Although they are frequently large, plumelike, and ornate, the pectoral spines are not associated with venom glands.

Scorpionfish venom has been likened in potency to cobra venom. Its principal action appears to be direct muscle toxicity, resulting in paralysis of cardiac, involuntary, and skeletal muscles. The presentation of injury is similar to stingray envenomation. Pain is immediate and intense, with radiation centrally. Untreated, the pain peaks at 60 to 90 min and persists for 6 to 12 h. In the case of the stonefish, the pain may be severe enough to cause delirium and may persist at high levels for days. The wound and surrounding area are initially ischemic and then cyanotic, with surrounding areas of erythema, edema, and warmth. Vesicles may form, and rapid tissue sloughing, with surrounding areas of cellulitis, may develop within 48 h. Systemic effects are similar to those of coelenterate envenomation.

Other venomous fish that sting in a manner similar to scorpionfish include catfish, weeverfish, surgeonfish, homed sharks, toadfish, ratfish, rabbitfish, stargazers, and leatherbacks. Approximately 1000 species of catfish inhabit both fresh- and saltwater. Catfish venom apparatus consists of a single dorsal and two pectoral fin spines and the axillary venom glands. Catfish also produce a crinotoxin that can be introduced into the wound during envenomation. The sting of the marine catfish is usually more severe than that of its freshwater counterpart. The weeverfish, the most venomous fish in the temperate zone, is found in the Mediterranean and European coastal areas. Weeverfish are bottom dwellers that sting when stepped on. The five to seven envenoming dorsal spines can penetrate a leather boot and create a substantial puncture wound.

The success of therapy for stings from marine animal spines depends on rapid initiation. Treatment is directed at combating the effects of the venom, alleviating pain, and preventing infection. The wound should be irrigated immediately, and any visible pieces of the spine or integumentary sheath should be removed. As soon as possible, the wound should be immersed in hot water to tolerance [45°C (113°F)] for 30 to 90 min or until there is pain relief. During the hot-water soak, the wound should be explored and foreign material removed.

Narcotics may be necessary for pain control. Local infiltration of the wound with lidocaine without epinephrine or a regional nerve block may be very useful.

After the soaking procedure, the wound should be prepared in an aseptic fashion, reexplored, and thoroughly débrided. Soft-tissue radiography should be employed to visualize calcified matter. Wounds should remain open for delayed primary closure or sutured loosely, ensuring adequate drainage. Prophylactic antibiotics are recommended because of the high incidence of ulceration and necrosis with subsequent secondary infection. If a victim is to be treated and released, he or she should be observed for at least 4 h for systemic side effects. A stonefish antivenom is available for severe systemic reactions to stonefish or other scorpionfish.

Sea snakes (family Hydrophidae) are the most abundant venomous reptiles. [10] There are 52 species of sea snakes, all of which are venomous. The snakes are distributed in the tropical and warm temperate Pacific and Indian Oceans. None are found in the Atlantic Ocean, the Caribbean, or North American coastal waters. Hawaii is the only US state that has sea snakes.

Most sea snakes are 3 to 4 ft (about 1 m) long, although some attain lengths of up to 9 ft (3 m). They can be distinguished from land snakes by their flat tails and valvelike nostril flaps and from eels by the presence of scales and the absence of gills and fins. Sea snakes swim in an undulating fashion and can move backward or forward in the water with equal speed. The venom apparatus consists of two to four hollow maxillary fangs and a pair of associated venom glands. The fangs are short and easily detached. Approximately 80 percent of bites do not result in significant envenomations.

Sea snake venom contains a peripherally acting neurotoxin that causes paralysis and a myotoxin that causes muscle necrosis. Due to the lack of an immediate local reaction, the bite often goes unnoticed. Symptoms typically become apparent 2 h after the bite but may begin as soon as 5 min or as late as 8 h afterward. The first complaint may be of euphoria, malaise, or anxiety. Classic muscle aches then develop, along with a "thick tongue" and sialorrhea. Ascending flaccid or spastic paralysis follows shortly and is accompanied by other neurologic signs and symptoms, such as ophthalmoplegia, ptosis, facial paralysis, and pupillary changes. Death is most commonly due to ventilatory failure.

Diagnosis of a sea snake bite is based on the combination of snake identification and the presence of a multiple-puncture bite wound that was initially painless and occurred in the water. Envenomation should be suspected if the characteristic symptoms, primarily myalgias, develop. The presence of myoglobinuria and elevated hepatic enzyme levels is also typical. Neurotoxic symptoms are rapid in onset and usually appear within 2 to 3 h. If no symptoms develop by 6 to 8 h, envenomation did not occur.

Treatment of a sea snake bite involves pressure-immobilization of the affected limb to provide venom sequestration. Incision and suction therapy are not recommended. Supportive measures are necessary but are not an adequate substitute for sea snake antivenom, which is absolutely indicated. With any clinical evidence of envenomation, polyvalent sea snake antivenom should be administered after skin testing. Tiger snake (*Notechis scutatus*) antivenom is also available as a second choice. If neither of these is available, Crotalidae polyvalent antivenin can be used.

The administration of antivenom should begin as soon as possible but remains useful up to 36 h after envenomation. Intensive supportive care and monitoring of renal, metabolic, and respiratory function are critical. Since the relatively small molecular weight of sea snake neurotoxin makes it dialyzable, hemodialysis may be of benefit. Figure 190-1 provides an algorithmic approach to unidentified marine envenomation.

191 HIGH ALTITUDE MEDICAL PROBLEMS

Peter H. Hackett
Mark B. Rabold

Many millions of visitors annually visit the mountainous areas of the western United States at altitudes over 8000 feet (2440 meters). In addition, tens of thousands travel to high altitude regions in other parts of the world.

Physicians working or traveling in or near these locations are increasingly likely to encounter persons ill with a high altitude illness or suffering an untoward effect of altitude on a preexisting condition. Although the focus of this chapter is hypoxia-related problems, patients in the mountain environment also may require care for associated illnesses such as hypothermia, frostbite, trauma, ultraviolet keratitis, dehydration, and lightning injury, which are covered elsewhere in this text.

High altitude is a hypoxic environment. Because the concentration of oxygen in the troposphere remains constant at 21 percent, the partial pressure of oxygen decreases as a function of the barometric pressure. In Denver (1610 m), air pressure is 17 percent less than at sea level and therefore contains 17 percent less oxygen. The air of Aspen, Colorado (2438 m) has 26 percent less oxygen, and the barometric pressure on top of Mt. Everest is merely one-third that of sea level. Paul Bert, in his classic experiments of the late nineteenth century, showed that supplemental oxygen prevented symptoms of altitude illness during hypobaric exposure and concluded that hypoxia, not hypobaria, was responsible for illness.

For the purposes of discussion, altitude may be divided into stages according to physiologic effects. *Intermediate altitude,* 5000 to 8000 feet (1500 to 2440 meters), produces decreased exercise performance and increased alveolar ventilation, without major impairment in arterial oxygen transport. Medical sickness due to altitude is rare in this range, although mild illness may develop in individuals with decreased cardiopulmonary reserve. *High altitude,* 8000 to 14,000 feet (2440 to 4270 meters), is associated with a decrease in arterial oxygen saturation, and hypoxemia may occur during exercise and sleep. Most cases of medical problems associated with altitude occur in this range because of the availability of overnight tourist facilities located at these heights. *Very high altitude,* 14,000 to 18,000 feet (4260 to 5490 meters), is difficult to find in the United States, but is encountered by visitors to the mountainous regions of South America and the Himalayas. Abrupt ascent can be dangerous and a period of acclimatization is required to prevent illness. *Extreme altitude,* over 18,000 feet (5490 meters), is available to only mountain climbers and accompanied by severe hypoxemia and hypocapnia. At this height, progressive physiologic deterioration eventually outstrips acclimatization and sustained human habitation is impossible.

ACCLIMATIZATION TO HIGH ALTITUDE

Persons rendered acutely hypoxic become dizzy, faint, and rapidly unconscious if hypoxic stress is sufficient ($Sa_{O_2} < 65\%$). These same individuals, given days to weeks to develop the exact same degree of hypoxia, are able to function quite well. While the fundamental process of this acclimatization takes place in the metabolic machinery of cells and mitochondria, acute "struggle" responses are critical while allowing the cells time to adjust.

Ventilation

Defense of alveolar Pa_{O_2} through increased ventilation is the primary initial adaptation. The hypoxic ventilatory response (HVR) is effected by the carotid body, which senses a decrease in arterial oxygenation and inputs to the central respiratory center in the medulla to increase ventilation. The vigor of this inborn response is related to successful acclimatization and increased performance. Respiratory depressants or stimulants may affect HVR, as does chronic hypoxia, which eventually blunts the response. A low hypoxic drive may allow extreme hypoxemia to develop during sleep. The initial hyperventilation is quickly attenuated by respiratory alkalosis, which acts as a brake on the respiratory center. As renal excretion of bicarbonate compensates for the respiratory alkalosis, pH returns toward normal, and ventilation continues to increase. This process of maximizing ventilation, termed ventilatory acclimatization, culminates after four to seven days at a given altitude. With continuing ascent to higher altitudes, the central chemoreceptors reset to progressively lower P_{CO_2} values, and the completeness of acclimatization can be gauged by the arterial P_{CO_2}. Acetazolamide, which forces a bicarbonate diuresis, greatly facilitates this process. An appreciation of the normal values for blood gases and acid-base status with acclimatization at various altitudes is necessary in order to distinguish abnormalities (Table 191-1).

Altitude (meters)	Pa_{O_2} (mmHg)	Sa_{O_2},%	Pa_{CO_2} (mmHg)
Sea level	90–95	96	40
1524 (5000 ft)	75–81	95	35.6
2286 (7500 ft)	69–74	92–93	31–33
4572 (15,000 ft)	48–53	86	25
6096 (20,000 ft)	37–45	76	20
7620 (25,000 ft)	32–39	68	13
8848 (29,029 ft)	26–33	58	9.5–13.8

TABLE 191-1   Blood Gases and Altitude

Blood

The hematopoietic response to altitude was first observed in 1890 by Viault. We now know that within two hours of ascent to altitude, erythropoietin is increased in plasma and, over days to weeks, results in increased red cell mass. This adaptation has no importance during initial acclimatization when altitude illness develops and, when excessive, results in chronic mountain polycythemia. Shifts in the oxyhemoglobin dissociation curve are thought to be minimal in vivo at altitude, because the increase in 2,3-diphosphoglyceric acid, which is proportional to the severity of hypoxia and shifts the curve to the right, is offset by the respiratory alkalosis, which shifts the curve to the left. Naturally occurring left-shifted hemoglobin is an advantage at high altitude.

Fluid Balance

Peripheral venous constriction on ascent to altitude causes an increase in central blood volume, which triggers baroreceptors to suppress antidiuretic hormone (ADH) and aldosterone and induce a diuresis. Combined with the bicarbonate diuresis from the respiratory alkalosis, this can result in decreased plasma volume and hyperosmolality (serum osmolality of 290 to 300 mOsm/L), which the body appears to permit by a reset of the osmol center of the brain. Clinically, diuresis and hemoconcentration is considered a healthy response. Antidiuresis is a hallmark of acute mountain sickness.

Cardiovascular

Stroke volume is decreased initially, and an increased heart rate maintains cardiac output. Maximum exercising heart rate declines at altitude proportional to the decrease in maximum oxygen consumption (V_{O_2} max). Cardiac muscle in healthy persons is able to withstand extreme levels of hypoxemia ($Pa_{O_2} < 30$ mmHg) without evidence of ST segment changes or ischemic events. Blood pressure is mildly elevated on ascent secondary to increased sympathetic tone.

The pulmonary circulation constricts with exposure to hypoxia. This is an advantage during regional alveolar hypoxia, such as pneumonia, but is a disadvantage during the global hypoxia of altitude exposure. As a result, pulmonary pressure increases. This degree of hypertension is quite variable, with those having a hyperreactive response much more susceptible to high altitude pulmonary edema.

Cerebral blood flow transiently increases on ascent to altitude (despite the hypocapnic alkalosis), which increases oxygen delivery to the brain. This response, however, is limited by the increase in cerebral blood volume, which may increase intracranial pressure and aggravate symptoms of altitude illness.

Effects on Exercise

Exercise capacity, as measured by V_{O_2} max, drops dramatically on ascent to altitude, approximately 10 percent for each 1000-m altitude gain above 1500 m. During acclimatization, submaximal endurance increases appreciably after 10 days, but V_{O_2} max does not. The mechanism of this decrement might be lack of adequate oxygen supply to the muscle cells due to the low driving pressure for diffusion of oxygen from the capillary. Another theory suggests that the CNS limits muscle activity to preserve its own oxygenation.

Limitations

There are limits to acclimatization. Even those who are by nature good acclimatizers cannot tolerate the hypoxia of extreme altitude for long. Miners from South America report that they cannot live at altitudes above 5800 m because of weight loss, increasing lethargy, poor quality sleep, weakness, and headache. High altitude mountaineers cannot survive for more than a few days above 8000 m without supplemental oxygen because of more acute deterioration in physiologic functioning. Considerable weight loss, both of fat and lean body mass, are unavoidable at extreme altitude, and help contribute to demise. Other factors limiting ability to acclimatize to extreme altitude include right ventricular strain from excessive pulmonary hypertension, intestinal malabsorption, impaired renal function, polycythemia and microcirculatory sludging, and prolonged cerebral hypoxia. Even at more modest altitudes, some individuals are very slow or poor acclimatizers for reasons not entirely known but, at least in part, due to poor carotid body function and inadequate ventilation.

Sleep at High Altitude

Sleep stages III and IV are reduced at altitude, while sleep stage I is increased. More time is spent awake, with a significant increase in arousals, but with only slightly less rapid eye movement (REM) time. The frequent arousals are a common source of bitter complaints from skiers and others, but they are innocuous and improve with time at altitude. The typical periodic breathing (Cheyne-Stokes) in those sleeping above 2700 m (9000 ft) consists of 6- to 12-s apneic pauses interspersed with cycles of vigorous ventilation. Interestingly, the frequent awakenings are not necessarily related to the sleep periodic breathing, and neither are they related to acute mountain sickness. Presumably, the mechanism of the lighter sleep is related to cerebral hypoxia. Quality of sleep and arterial oxygenation during sleep improves with acclimatization and with acetazolamide.

HIGH ALTITUDE SYNDROMES

High altitude syndromes of primary concern are those attributed directly to the hypoxia: acute hypoxia; acute mountain sickness; pulmonary edema; cerebral edema; retinopathy; peripheral edema; sleeping problems; and a group of neurologic syndromes. The other syndromes, not necessarily related to hypoxia, include thromboembolic events (which may be attributable to dehydration, prolonged incapacitation, polycythemia, and cold), high altitude pharyngitis and bronchitis, and ultraviolet keratitis. Although the different hypoxic clinical syndromes overlap, all share a fundamental mechanism, all are seen in the same setting of rapid ascent in unacclimatized persons, and all respond to the same essential therapy: descent and oxygen.

Acute Hypoxia

The syndrome of acute hypoxia occurs in the setting of sudden and severe hypoxic insult, such as accidental decompression of a pressurized aircraft cabin or a failed oxygen system in a pilot or high altitude mountaineer. Sudden overexertion precipitating arterial desaturation, acute onset of pulmonary edema, carbon monoxide poisoning, and sleep apnea may result in relatively acute hypoxia as well. Unacclimatized persons become unconscious at an arterial oxygen saturation of 50 to 60 percent, an arterial Pa_{O_2} of less than about 30 mmHg, or a jugular venous Pa_{O_2} less than 15 mmHg. Acute hypoxia is reversed by immediate administration of oxygen, rapid descent, and correction of the underlying cause, such as removal of the carbon monoxide source or repair of the oxygen delivery system. Symptoms of acute hypoxia reflect the sensitivity of the CNS to this insult: dizziness, light-headedness, and dimmed vision progressing to loss of consciousness. Hyperventilation has been shown to increase the time of useful consciousness during acute alveolar hypoxia.

Acute Mountain Sickness (AMS)

INCIDENCE   AMS occurs in the setting of more gradual and less severe hypoxic insult than with acute hypoxic syndrome. Its incidence varies by location, depending on ease of access, rate of ascent, and sleeping altitude reached. A recent study at 2100 m (6900 ft) found a 25 percent incidence of AMS in physicians attending a continuing-education meeting in Colorado. Other studies at resorts between 2220 and 2700 m (7200 and 9000 ft, respectively) claimed an incidence between 17 and 40 percent, and a sleeping altitude of 2750 m (9000 ft) seemed to be a threshold for increased attack rate. [1] Approximately 40 percent of trekkers in Nepal on the path to Mt. Everest suffer AMS, while climbers on Mt. Rainier have the very-high incidence of 70 percent because of the rapidity of ascent.

SUSCEPTIBILITY   In addition to rate of ascent and sleeping altitude, inherent factors determine individual susceptibility to acute mountain sickness. Factors identified so far are low hypoxic ventilatory response and low vital capacity. Age has little influence on incidence, with children being as susceptible as adults. Women are just as likely, if not more so, to develop mountain sickness but appear to have less pulmonary edema. Susceptibility to AMS is generally reproducible in an individual on repeated exposures. Persons living at intermediate altitudes of 1000 to 2000 m already are acclimatized partially and do much better than lowlanders upon ascent to higher altitudes. There is no relationship of susceptibility to AMS and physical fitness.

CLINICAL PRESENTATION   The diagnosis of AMS is based on the setting, symptoms, and physical findings. The setting is rapid ascent of an unacclimatized person to 2000 m (6600 ft) or higher. Typically, the person on arrival feels lightheaded and slightly breathless, especially with exercise. One to six hours later, but sometimes delayed for one day or more (and especially after a night's sleep), the typical symptoms of mild AMS develop; they are similar to an alcohol hangover. The headache

usually is described as bifrontal and worsened with bending over and the Valsalva maneuver. Gastrointestinal symptoms include anorexia, nausea, and sometimes vomiting, and the chief constitutional symptoms are lassitude and weakness. The person with AMS is often irritable and wants to be left alone. Sleepiness and a deep inner chill, also are common. If the illness progresses, the headache becomes more severe, and vomiting, oliguria, and increased dyspnea develop. Lassitude may progress to the victim requiring assistance for eating and dressing. The most severe form of AMS, high altitude cerebral edema (HACE), is heralded by onset of ataxia and altered level of consciousness; coma may ensue within 12 h if treatment is delayed. The diagnosis can be difficult in preverbal children. [2]

Physical findings in mild AMS are nonspecific. Heart rate and blood pressure are variable, and usually in the normal range, although postural hypotension may be present. Localized rales are detectable in up to 20 percent of persons with AMS. Body temperature may be slightly elevated (up to 38.5°C) in AMS, and more so in high altitude pulmonary edema (HAPE) and HACE.[3] Funduscopy reveals venous tortuosity and dilatation, and retinal hemorrhages are common over 5000 m or in those with pulmonary and cerebral edema. Fluid retention is a hallmark of AMS, in contrast to the usual diuresis of acclimatization, and may result in peripheral edema, especially of the face. Differential diagnosis in this setting includes hypothermia, carbon monoxide poisoning, pulmonary or CNS infection, dehydration, and exhaustion.

The natural history of AMS at a Colorado resort (3000 m or 10,000 ft) recently was documented. Mean duration of symptoms was 15 h, with a range to 94 h, despite the fact that one-half of those with symptoms self-medicated.[4] At higher sleeping altitudes, the illness may last much longer, even weeks if untreated, and is more likely to progress to pulmonary or cerebral edema. Eight percent of those with AMS at 4243 m (14,000 ft) in Nepal developed cerebral or pulmonary edema, or both.

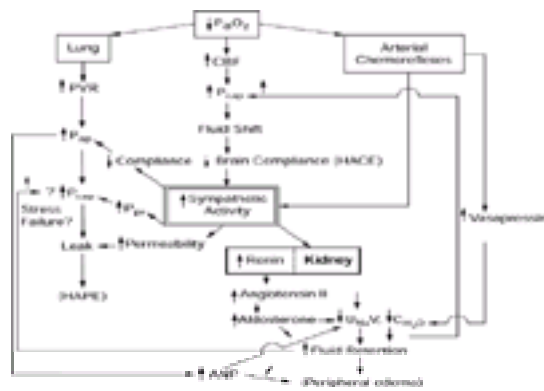
PATHOPHYSIOLOGY   AMS is due to hypobaric hypoxia, but the exact sequence of events leading to illness is unclear. Figure 191-1 offers a schema for the pathophysiology. The symptoms indicate a neurologic etiology; scans confirming cerebral edema have been obtained in persons severely ill. Whether the more common mild illness of headache, anorexia, and malaise is due to mild cerebral edema has yet to be confirmed, but seems likely. Two types of cerebral edema have been proposed. One is cytotoxic edema, due to failure of the sodium-potassium pump with subsequent intracellular accumulation of sodium and water. The other is a vasogenic edema, due to a leaky blood-brain barrier.


FIG. 191-1. High altitude illnesses. Central role of elevated sympathetic activity in the edemas of altitude: Hypoxemia ($\bar{P}a_{O_2}$) elevates cerebral blood flow (CBF), which in turn raises cerebral capillary hydrostatic pressure (P_{cap}) such that a transcapillary fluid shift occurs. The resulting high-altitude cerebral edema (or AMS) reduces brain compliance. Elevated intracranial pressure and distortion of CNS structures provokes elevation of peripheral sympathetic activity above levels normally produced by stimulation of peripheral chemoreflexes. Hypoxia raises pulmonary vascular resistance, which raises pulmonary artery pressure (P_{ap}). Elevated sympathetic activity to the lungs decreases compliance of pulmonary arteries and provokes pulmonary venous constriction and increased capillary permeability. The precise influence of hypoxic pulmonary vascular responses combined with increased pulmonary sympathetic activity on pulmonary hydrostatic pressure is unclear. The relative importance of pulmonary capillary stress failure is uncertain (?). Only small elevations of P_{cap} are required to cause large fluid fluxes if permeability is increased such that HAPE occurs. Increased sympathetic activity is associated with a neurogenic anti-natriuresis such that fluid retention and peripheral edema occur. Increased aldosterone from sympathetic stimulation of renin or from ACTH, and increased vasopressin from stimulation of chemoreflexes add to the tubular a-adrenergic antinatriuresis and opposes natriuretic effects from atrial natriuretic peptide (ANP) released by elevated central blood volume. However, ANP could contribute to peripheral edema, HAPE, or HACE. Renal fluid retention contributes to elevated P_{cap} in lung, brain, and peripheral tissues. (From Krasney JA: A neurogenic basis for acute altitude illness. *Med Sci Sport Exerc* 26:195, 1994.)

No direct evidence for cytotoxic edema in humans at altitude has been reported, but a large shift of fluid into the total intracellular space, presumably including the brain, was demonstrated to take place over the first three days at altitude, when AMS occurs. The time required for fluid shift and overhydration of the brain may explain the time lag in onset of symptoms, which distinguishes AMS from acute hypoxia. In support of the vasogenic theory, white-matter brain edema on magnetic resonance imaging (MRI) recently was demonstrated in persons with high altitude cerebral edema, and it may also occur in AMS. [5] The leaky blood-brain barrier is due either to loss of autoregulation and overperfusion or to hypoxia-induced increased permeability. The fact that corticosteroids so effectively treat AMS also supports the notion of vasogenic edema, since this is the only type of cerebral edema responsive to steroids. Further research is likely to reveal that brain swelling is due to both cytotoxic and vasogenic mechanisms.

The cerebral edema, interstitial pulmonary edema, peripheral edema, and the antidiuresis observed in AMS all point to an abnormality of water handling by the body. The mechanism is thought to be increased renin-angiotensin, aldosterone, and ADH in contrast to the normal ADH and aldosterone suppression at high altitude, and usual diuresis. A decrease in glomerular filtration also has been observed. The effectiveness of diuretics in prevention and treatment of AMS reinforces the importance of fluid retention in the pathophysiology. Increased sympathetic activation is thought to play a role in the pulmonary and renal circulations contributing to the pathophysiology[6] (see Fig. 191-1).

Relative hypoventilation due to a sluggish hypoxic ventilatory response is a characteristic of AMS-susceptible individuals and has been linked to fluid retention. Hypoventilation, of course, results in greater hypoxic stress and is equivalent to being at a higher altitude. Higher Pa_{CO_2} and lower Pa_{O_2} also increases cerebral blood flow and aggravates brain swelling. Less hypocapnia also may reduce the stimulus for bicarbonate diuresis and aggravate fluid retention.

TREATMENT (Table 191-2)   **Descent and Oxygen**   The goals of treatment are to prevent progression, abort the illness, and improve acclimatization; early diagnosis is essential. Initial clinical presentation does not predict eventual severity, and all persons with AMS must be observed carefully for progression. The three principles of treatment are: (1) to not proceed to a higher sleeping altitude in the presence of symptoms; (2) to descend if symptoms do not abate or become worse despite treatment; and (3) to descend and treat immediately in the presence of a change in consciousness, ataxia, or pulmonary edema. Mild AMS is self-limited and generally improves with an extra 12 to 36 h of acclimatization if ascent is halted. Descent is the definitive treatment for all forms of altitude illness, although it is not always an option, nor always necessary. Remarkably, a drop in altitude of only 500 to 1000 m usually is effective promptly. Evacuation to a hospital or to sea level is unnecessary except in the most severe cases. To simulate descent, portable hyperbaric bags are being used in various locations to treat AMS. The patient is inserted into the fabric chamber, and a pressure of 2 psi is achieved by means of a manual or automated pump; the pressure is equivalent to a drop in altitude of 1500 m (5000 ft). A valve system creates sufficient ventilation to avoid CO_2 accumulation or O_2 depletion.

Mild AMS	Stop ascent
	Descend to lower altitude or acclimatize at same altitude
	Acetazolamide 125–250 mg bid to speed acclimatization
	Symptomatic treatment as necessary with analgesics and antiemetics
Moderate AMS	Immediate descent for worsening symptoms
	Low flow oxygen if available
	Acetazolamide 250 mg bid and/or dexamethasone 4 mg q6h
	Hyperbaric therapy
HACE	Immediate descent or evacuation
	Oxygen 2–4 L/min or titrated to Sa_{O_2} >90%
	Dexamethasone 8 mg po, IM, or IV, then 4 mg q6h
	Hyperbaric therapy if cannot descend
HAPE	Immediate descent or evacuation to medical facility
	Oxygen 4 L/min or titrated to Sa_{O_2} >90%
	Nifedipine 10 mg po q4–6h or 30 mg extended release q12h if no oxygen or descent
	Hyperbaric therapy if cannot descend
	Continuous positive airway pressure
	Minimize exertion and keep warm
Periodic breathing	Acetazolamide 125 mg at bedtime as needed

TABLE 191-2 Suggested Treatment of High Altitude Illness

Oxygen effectively relieves symptoms, but it often is unavailable in the field and generally reserved for moderate to severe AMS in order to conserve supplies. Oxygen promptly relieves headache, dizziness, and most other symptoms, although ataxia may resolve more slowly. Nocturnal low flow oxygen (0.5 to 1 L/min) is particularly helpful and efficient. The combination of oxygen and descent provides optimal therapy, especially in more severe cases.

Medical Therapy Pharmacologic treatment offers an alternative to descent or oxygen in mild to moderately severe AMS. Acetazolamide is very helpful in speeding acclimatization and aborting illness, especially when used early. The drug acts by inhibiting the enzyme carbonic anhydrase, slowing the hydration of carbon dioxide to hydrogen and bicarbonate ions. In the kidney, acetazolamide reduces reabsorption of bicarbonate, causing a bicarbonate diuresis and metabolic acidosis, which stimulates ventilation. The drug essentially mimics the process of ventilatory acclimatization. As a result, arterial P_{O_2} is higher, and sleep oxygenation remains high and stable, without periods of apnea. The drug also maintains cerebral blood flow despite greater hypocapnia, and because of its diuretic action, it counteracts the fluid retention of AMS. Many trials have shown its value for prevention; and recently treatment.[7] Current indications for acetazolamide are: (1) a history of altitude illness; (2) abrupt ascent to over 3000 m (10,000 ft); (3) for treatment of AMS; and (4) bothersome sleep periodic breathing. The dosage regimen varies; 5 mg/kg per day in two or three divided doses is sufficient, whether for prevention or treatment; or 125 mg bid, which is empirically effective.[8] Treatment should be continued until symptoms of AMS resolve, and then the drug should be restarted if symptoms return. Because the drug acts by improving acclimatization, fear of masking serious illness is unwarranted. Common side effects of acetazolamide include peripheral paresthesias and sometimes nausea or drowsiness, and the usual precautions of sulfa drugs apply to acetazolamide because of the sulfhydryl moiety. Because the drug inhibits the instant hydration of CO_2 on the tongue, the carbon dioxide in carbonated beverages can be tasted, ruining the flavor of beer and other drinks.

Symptomatic treatment of AMS is sometimes sufficient. Aspirin 650 mg, acetaminophen 650 to 1000 mg (with or without codeine), or ibuprofen 600 to 800 mg can be given for headache. Aspirin also effective for prevention of headache.[9] Prochlorperazine 5 to 10 mg intramuscularly is useful for nausea and vomiting, and has the advantage of augmenting the hypoxic ventilatory response. The short-acting benzodiazepines such as triazolam 0.25 mg and temazepam 15 mg also can be used to treat the complaint of frequent wakening, but they are potentially dangerous in ill persons because of respiratory depression and may decrease oxygenation even in persons acclimatizing well. A combination of acetazolamide and benzodiazepine may work very well for bothersome insomnia.

Dexamethasone 4 mg PO, IM, or IV every six hours is quite effective therapy for mountain sickness, but it is best reserved for moderate to severe AMS, because it may be associated with significant side effects and does not aid acclimatization, sometimes resulting in rebound symptoms when discontinued. A short taper period may prevent this rebound phenomenon. The mechanism of action of dexamethasone may be to reduce vasogenic edema, to lower intracranial pressure, or to act as an antiemetic and mood elevator. The use of acetazolamide to speed acclimatization and a brief course of dexamethasone to treat illness can be a useful combination. The use of diuretics is reasonable because of the fluid retention associated with mountain sickness. Furosemide 20 to 40 mg every 12 h until improved was reported effective by the Indian army, although other investigators have not been enthusiastic about its use because of concerns for avoiding hypovolemia, hypotension, and incapacitation.

PREVENTION Graded ascent with adequate time for acclimatization is the best prevention. A recommendation for those visiting medium altitude resorts in the western United States is to spend a night at an intermediate altitude of 1500 to 2000 m (Denver or Salt Lake City) before sleeping at altitudes above 2500 m (8200 ft). Mountaineers and trekkers should avoid abrupt ascent to sleeping altitudes over 3000 m and then allow two nights for each 1000-m altitude gain in camp altitude, starting at 3000 m. Other preventative measures include avoiding overexertion, alcohol, and respiratory depressants, and eating a high-carbohydrate diet. Acetazolamide is a useful prophylactic agent for those with a history of AMS or for forced abrupt ascent without acclimatization stages. The drug should be started 24 h before the ascent and continued for the first 2 days at altitude. The medication then can be discontinued and started again if illness develops. Acetazolamide can be expected to reduce the symptoms of AMS by approximately 75 percent in persons ascending rapidly to sleeping altitudes of over 2500 m. An alternative for those allergic to sulfa is dexamethasone 4 mg every 12 h starting the day of ascent and continuing for the first 2 days at altitude.

Neurologic Syndromes of High Altitude

Until recently, most neurologic events at high altitude were attributed to HACE or AMS. Clearly, this has been a diagnostic oversimplification. Other syndromes now recognized as related to high altitude include altitude syncope, cerebrovascular spasm (migraine equivalent), cerebral arterial or venous thrombosis (infarct), transient ischemic attack, and cerebral hemorrhage. These syndromes are characterized by more focal neurologic findings than in cerebral edema, though differentiation in the field may be impossible.

Other problems may be due to exacerbation or unmasking of underlying disease, such as previously asymptomatic brain tumors and epilepsy. Presumably, space-occupying lesions become symptomatic because of increased brain volume at altitude. Hyperventilation (hypocapnic alkalosis), which is commonly used to induce seizure activity on electroencephalography, may explain unmasking of a seizure disorder at altitude, while changes in cerebral blood flow may exacerbate vascular lesions.

High Altitude Cerebral Edema

HACE is defined clinically as the presence of progressive neurologic deterioration in someone with AMS or HAPE. It is characterized by altered mental status, ataxia, stupor, and progression to coma if untreated. Headache, nausea, and vomiting are not always present. Because of raised intracranial pressure, focal neurologic signs such as third and sixth cranial nerve palsies may result from distortion of brain structures or by extraxial compression.

HACE is usually associated with pulmonary edema. Pathologically, necropsies have described severe, diffuse cerebral edema with multiple small hemorrhages and sometimes thrombosis.

The treatment of HACE is the same as for severe AMS: oxygen, descent, and steroids (Table 191-2). Descent is the highest priority. Acetazolamide may be an adjunct, but immediate reversal of the illness is the goal; improving acclimatization comes later. In acutely ill patients who cannot descend, the combination of steroids, supplemental oxygen, and a hyperbaric bag is optimal therapy, but rarely available. Persons remaining ataxic or confused after descent should be admitted to the hospital. Comatose patients require additional airway management, bladder drainage, and other coma care. For coma, the use of hyperventilation to decrease intracranial pressure is a reasonable approach, keeping in mind that the Pa_{CO_2} is already low and pH high in these individuals. Additional acute hyperventilation could produce cerebral ischemia; monitoring of arterial blood gases and, if available, cerebral blood velocities by transcranial Doppler ultrasonography may be advisable. Loop diuretics such as furosemide 40 to 80 mg or bumetanide 1 to 2 mg may help reduce brain overhydration, but hypoperfusion must be avoided. Hypertonic solutions of saline, mannitol, or urea have been used too infrequently to establish clinical guidelines. In the hospital setting, mannitol in a patient who does not respond immediately is worth considering. Coma may persist for days, even for weeks after evacuation to lower altitude, and the patient may still recover, only sometimes with permanent sequelae. Persistent coma is unusual, however, and mandates exclusion of other possible etiologies.

Cerebrovascular Syndromes of Altitude

Strokes, due both to infarct and hemorrhage in the arterial circulation, as well as venous thrombosis have been reported in young healthy persons at altitude who otherwise would not be considered at risk for such conditions. Transient ischemic attack, cortical blindness, and various focal neurologic signs, such as hemiparesis or hemiplegia of a transient nature, also occur. Because these latter events are reversible, they suggest etiologies such as vasospasm, watershed hypoxia between arterial zones, or transient ischemic attack.

Differentiation of the various neurologic syndromes may be impossible in the field, and treating as if cerebral edema were present may be reasonable, with a rapid descent to lower altitude, oxygen, and steroids, and evacuation to a hospital if symptoms persist despite treatment. Fortunately, focal neurologic signs usually resolve spontaneously and do not recur upon reascent. However, a thorough cerebrovascular evaluation before advising reascent may be prudent.

High Altitude Pulmonary Edema

HAPE is the most lethal of the altitude illnesses. Because the condition is easily reversible with descent and oxygen, the cause of death is usually lack of early recognition, misdiagnosis, or inability to descend to a lower altitude. Litigation commonly results from HAPE deaths, a fact worth considering for physicians involved in such cases.

EPIDEMIOLOGY   The incidence of HAPE varies from less than 1 in 10,000 skiers in Colorado to 2 to 3 percent of climbers on Mt. McKinley, and was reported as high as 15 percent in some regiments in the Indian army who were airlifted to high altitude during the Indian/Chinese war. Women appear less susceptible than men. Risk factors include heavy exertion, rapid ascent, cold, excessive salt ingestion, use of sleeping medication, and a previous history indicating inherent individual susceptibility. Such susceptibility was recently related to immunogenetic factors, [10] as well as to physiologic factors. [11] Preexisting respiratory infection predisposes children to HAPE. [12]

CLINICAL PRESENTATION (Table 191-3)   Early in the course of illness, when the edema is still interstitial or localized, the victim develops a dry cough, decreased exercise performance, dyspnea on exertion, increased recovery time from exercise, and localized rales, usually in the right midlung field. Late in the course of the illness, there develops tachycardia, tachypnea, and dyspnea at rest, marked weakness, productive cough, cyanosis, and more generalized rales. As hypoxemia worsens, consciousness becomes impaired. Victims usually become comatose and then die. Early diagnosis is critical, and decreased exercise performance and dry cough is enough to raise the suspicion of early HAPE. The typical victim is strong and fit and may or may not have symptoms of AMS before onset of HAPE. The condition typically worsens at night and is noticed most commonly on the second night at a new altitude. Unfortunately, rales may not be audible in 30 percent of persons with HAPE at rest but can be elicited immediately after a short bout of exercise. Fever up to 38.5°C is common, and tachycardia and tachypnea generally correlate with the severity of illness. On cardiac auscultation, a prominent P2 and right ventricular heave may be appreciated. ECG generally reveals right axis deviation and a right ventricular strain pattern consistent with acute pulmonary hypertension. Chest x-ray findings progress from interstitial to localized alveolar to generalized alveolar infiltrates as the illness progresses from mild to severe. [13]

TABLE 191-3   Severity Classification of HAPE

PATHOPHYSIOLOGY   The pioneering work of Hultgren established HAPE as a noncardiogenic edema. Left ventricular function is normal. Left ventricular end diastolic pressure, wedge pressures, and left atrial pressures are low to normal, cardiac output is low, and pulmonary vascular resistance and pulmonary artery pressure are markedly elevated. The exact cause of the edema is still unclear. Pulmonary hypertension is an essential component, and persons with a history of HAPE have been shown to have exaggerated pulmonary pressor responses to hypoxia. Whether this represents one end of a normal distribution or a pathologic subpopulation is unknown. However, not all persons with pulmonary hypertension develop HAPE; another factor must also be present, which induces a change in capillary membrane permeability. Pulmonary venous constriction, fibrin and platelet thrombi, and uneven arterial vasoconstriction leading to overperfusion of some areas of the vasculature have all been proposed. Predisposed individuals have a low hypoxic ventilatory response, an abnormal pulmonary circulation, and tend to suffer HAPE on repeated exposures.

TREATMENT   The key to successful treatment of HAPE (Table 191-2) is early recognition, because the condition in its early stage is easily reversible. The optimal therapy depends upon the environmental setting, evacuation options, availability of oxygen or hyperbaric units, and ease of descent. Immediate descent is the treatment of choice, but this is not always possible. During descent, exertion by the victim must be minimized. Reports of victims dying during descent probably are related to overexertion offsetting the benefit of lower altitude. With descent, oxygen is unnecessary except in severe cases. Oxygen provides excellent results and can completely resolve pulmonary edema without descent to a lower altitude, but may require 36 to 72 h to do so. Such quantities of oxygen rarely are available to trekking, mountaineering, and skiing groups, but they may be available at ski resorts or medical facilities. Oxygen immediately lowers pulmonary artery pressure and improves arterial oxygenation. Its use is life saving when descent is not an option; in such cases, rescue groups should make delivery of oxygen to the victim the highest priority. As in the treatment of AMS and HACE, the portable hyperbaric bag is a very useful adjunct to therapy when immediate descent is not possible.

Bedrest may be adequate for very mild cases, and bedrest with supplemental oxygen may suffice for moderate illness, as long as the safety of the patient can be assured by the presence of a medical facility, adequate oxygen, or immediate descent capability should the patient's condition deteriorate. [14] Because cold stress elevates pulmonary artery pressure, the patient should be kept warm. The use of an expiratory positive airway pressure (EPAP) mask has been shown to increase arterial oxygen saturation by 10 to 20 percent in HAPE patients by enhancing alveolar recruitment. The mask is lightweight, well tolerated, and may be a useful adjunct to descent.

Because oxygen and descent are so effective, experience with drugs has been limited. Morphine and furosemide were used with good results by the Indian army, and both seem physiologically reasonable because they augment venous pooling, reduce pulmonary blood flow, and therefore reduce hydrostatic force for fluid extravasation in the lung. However, patients with HAPE often are dehydrated intravascularly, and caution must be exercised to avoid hypotension. Several studies have demonstrated that nifedipine, either 10-mg capsule or 30-mg extended-release formulation, orally, was of clinical benefit in reducing pulmonary artery pressure by 30 to 50 percent, and in increasing arterial oxygen saturation. Nifedipine, at a dose of 20 mg slow-release preparation every eight hours while ascending, has also been shown to be an effective prophylactic agent in those who have had previous episodes of HAPE. [15] Other vasodilators, such as hydralazine and phentolamine, show promise, as well, in the treatment of HAPE. [16] The mechanism presumably is by lowering pulmonary pressure and, therefore, the pressure gradient for flux of fluid across the membrane. Nitric oxide also lowers pulmonary artery pressure, and redistributes blood away from edematous areas. [17] Hypotension is a potential problem with nifedipine, and the results are not nearly as dramatic as with oxygen or descent, which still remain the treatments of choice.

Hospitalization may be warranted for severe cases that do not respond immediately to descent, especially if cerebral edema is present. Intubation, high $F_{I_{O_2}}$, and positive end-expiratory pressure ventilation are rarely required. Antibiotics are indicated for coexisting infection when present. Occasionally pulmonary artery catheterization is useful to exclude a cardiac component to the edema in persons with heart disease. The patient with HAPE who does not make the usual rapid improvement (or develops HAPE at altitudes <2500 m [8200 ft]) should be evaluated for pulmonary emboli, mediastinal pulmonary artery obstruction, or other pulmonary circulatory abnormalities, such as congenital absence of a pulmonary artery. Echocardiography can assess presence or absence of shunting from a patent foramen ovale or other cardiac abnormality. Adequate discharge criteria are progressive clinical and radiographic improvement, and an arterial Pa_{O_2} of 60 mmHg or arterial oxygen saturation greater than 90 percent. Residua such as fibrosis and impaired pulmonary function tests have not been reported. Patients are advised to resume activities gradually and are warned that they may feel weak for one to two weeks. An episode of HAPE is not a contraindication to subsequent ascent, but patients should be advised on staged ascent, acetazolamide and/or nifedipine prophylaxis, and recognition of early signs and symptoms.

Peripheral Edema

Swelling of the face and distal extremities is common at high altitude. Peripheral edema was reported in 18 percent of trekkers at 4200 m in Nepal and was twice as likely in women. It was often associated with AMS, but not necessarily. The presence of peripheral edema should raise suspicion of altitude illness and prompt a thorough examination for pulmonary and cerebral edema. The problem can be treated with diuretics, but if left untreated, it will resolve spontaneously with descent.

The mechanism is presumably similar to that of the fluid retention of AMS but with edema formation peripherally rather than in the brain and lung.

High Altitude Retinopathy

Retinal abnormalities described at high altitude include retinal edema, tortuosity and dilatation of retinal veins, disc hyperemia, retinal hemorrhages, and, rarely, cotton-wool exudates. Retinal hemorrhages are asymptomatic, except for rarely occurring macular hemorrhages, and are not considered an indication for descent unless visual changes are present. They resolve spontaneously in 10 to 14 days. Hemorrhages are common above a sleeping altitude of 5000 m and occur at lower altitudes in persons with altitude illness.

High Altitude Pharyngitis and Bronchitis

Most unacclimatized persons exercising at altitudes over 2500 m develop a dry, hacking cough. With exposure to extreme altitudes for prolonged periods of time, a purulent bronchitis and a painful pharyngitis become nearly universal. These problems may not be of an infectious nature; high volumes of dry, cold air through the lungs may induce respiratory heat loss and cause purulent secretions on that basis alone. Bronchospasm may also be triggered by respiratory heat loss. Severe coughing spasms can result in cough fracture of the ribs.

Pharyngeal membranes become dry, painful, and cracked because of the dehydration and high ventilation. Mucosal cracks may be an entry for pathogens, or the erythema and dryness may cause discomfort strictly on a mechanical basis. Antibiotics generally are not helpful, supporting the concept of a noninfectious etiology. Breathing of steam, ingesting hard candies or lozenges to increase salivation, and forcing hydration may provide some benefit with systemic analgesics as necessary. A silk Balaclava or similar material across the nose and mouth that is sufficiently porous to allow large volume ventilation but trap some moisture and heat helps ameliorate these bothersome high altitude conditions.

Chronic Mountain Polycythemia (CMP)

Monge's disease, also called chronic mountain sickness or CMP, has now been recognized in all high altitude locations of the world. Both long-term high altitude residents and lowlanders who relocate to high altitude may develop this condition after variable length of residence. The incidence is much higher in males and increases with age. The disease is characterized by excessive polycythemia for a given altitude, which causes symptoms such as headache, muddled thinking, difficulty sleeping, impaired peripheral circulation, drowsiness, and chest congestion. The diagnosis is made by the characteristic symptoms and a hemoglobin value greater than expected for the altitude, generally over 20 to 22 g/dL. Any problem causing hypoxemia at sea level causes greater hypoxemia at altitude, and the etiology of CMP can be traced to problems such as chronic obstructive pulmonary disease (COPD) and sleep apnea in 50 percent of patients. The etiology of pure CMP is attributed to idiopathic hypoventilation on the basis of diminished respiratory drive.

Therapy includes phlebotomy, relocation to lower altitude, or home oxygen use. Respiratory stimulants such as acetazolamide (250 mg twice a day) and medroxyprogesterone acetate (20 to 60 mg/day) have also been employed successfully. The response to respiratory stimulants supports the role of hypoventilation in this disorder.

Ultraviolet Keratitis (Snow Blindness)

Ultraviolet light (UVA and UVB) penetrates the atmosphere to a greater degree at high altitude because of less cloud cover, less water vapor, and less particulate matter in the air. Radiation increases roughly 5 percent for every 300 m (1000 ft) gained, and it is exacerbated by reflection back from snow. UV radiation below 300 nm (UVB) is absorbed by the cornea, and high exposure levels can cause corneal burns in 1 h, although symptoms do not become apparent for 6 to 12 h. The typical symptoms of photokeratitis are severe pain, a foreign body or gritty sensation, photophobia, tearing, marked conjunctival erythema, chemosis, and eyelid swelling. UV keratitis generally is self-limited and heals within 24 h, but the condition is sufficiently painful to warrant systemic analgesics. Cold compresses may also provide some relief, and eye patches may be necessary for comfort. Prevention is obviously of great importance, since this condition can be disabling, especially in hazardous terrain. Adequate sunglasses should transmit less than 10 percent of UVB light. Side shields are necessary if traveling on snow, and polarizing lenses help by absorbing glare. Makeshift protection can be fashioned by cutting narrow horizontal slits in cardboard, foam, or any available material (Eskimo sunglasses).

ILLNESSES AGGRAVATED BY HIGH ALTITUDE

Chronic Lung Disease

COPD patients ascending to altitude often report increased dyspnea and reduced exercise ability. Those with hypoxemia, pulmonary hypertension, disordered control of ventilation, and sleep-disordered breathing at sea level might have greater problems at altitude because of the greater alveolar hypoxia. Such patients may require supplemental oxygen at altitude when they do not at sea level (and avoid having to descend), and oxygen-dependent patients at sea level may need to increase the FI_{O_2}. The required FI_{O_2} can be calculated by multiplying low-altitude FI_{O_2} by the ratio of low altitude barometric pressure divided by high altitude barometric pressure. This will ensure the delivery of the same partial pressure of oxygen as at low altitude. There are no data to suggest that persons with COPD are more likely to develop AMS or HAPE, although such persons may be self-selected to avoid travel to high altitude locations. In fact, persons with mild to moderate COPD already are partially acclimatized and may do well at modest altitude, as suggested by Graham and Houston. High altitude per se does not exacerbate asthma, and persons with chronic bronchospasm often report easier breathing at high altitude, due to lower air density and/or cleaner air.

Arteriosclerotic Heart Disease (ASHD)

The healthy heart and cardiovascular system tolerates even extreme hypoxia very well. Numerous ECG studies, echocardiograms, heart catheterizations and exercise tests do not demonstrate cardiac ischemia or cardiac dysfunction in healthy persons at high altitude, even when arterial Pa_{O_2} was less than 30 mmHg. Those with arteriosclerotic disease may not have the same adaptive capabilities and intuitively seem more likely to suffer from acute cardiac events. Epidemiologic data, however, do not support this supposition. Morbidity and mortality from arteriosclerotic heart disease is reduced in persons with long-term residence at high altitude, and visitors apparently do not have increased risk of acute myocardial infarction. Recent work, however, suggested earlier onset of angina at high altitude compared with sea level during the first few days at 2500 m. After five days, an elderly group with CAD acclimatized well, and performed at sea-level exercise capacity without increased or early-onset angina.[18] Even men with coronary artery disease and low LV ejection fraction (mean = 39%) but without overt heart failure tolerated exercise at 2500 m as well as at low altitude.[19] Congestive heart failure (CHF) may worsen in tourists arriving at the medium altitude of ski resorts, and it is related apparently to fluid retention rather than depressed ventricular function from hypoxia. Patients with CHF should therefore maintain or increase their diuretic regimen during travel to high altitude, and clinicians may want to consider low flow oxygen during sleep for CHF patients, at least for the first few nights. Patient status-post coronary artery bypass grafting have trekked to altitudes over 5000 m without problems, the issue of safety having generated much debate. Overall, high altitude does not impose as much stress on the heart as would seem intuitively obvious. Further study will more clearly define subcategories of cardiac patients at risk.

Ascent to altitude produces a mild increase in blood pressure in normotensive persons, secondary to increased sympathetic tone; the same was found in hypertensives. However, blood pressure response was quite variable, with a large increase in some patients' blood pressure. Patients should continue hypertensive medications at altitude. No data suggest that hypertensives are more likely to succumb to any of the altitude illnesses, and in general, hypertension would not seem to be a contraindication to altitude exposure.[20]

Sickle Cell Disease

Even the modest simulated altitude of a pressurized aircraft (1500 to 2000 m) may cause persons with hemoglobin SC and sickle-thalassemia to have a vasoocclusive crisis. High altitude exposure without supplemental oxygen is considered a contraindication in these persons. Sickle cell trait is not considered an increased risk, although splenic infarction syndrome during heavy exercise at altitude has been reported in those with trait.

Pregnancy

Pregnant residents of high altitude have an increased prevalence of hypertension, low-birthweight infants, and neonatal hyperbilirubinemia. However, an increased incidence of pregnancy complications in lowlanders who visit high altitude has not been reported. The normal Pa_{O_2} of the fetus is 29 to 33 mmHg, and the mild

maternal hypoxia induced by traveling to resort-type altitudes does not generate significantly more hypoxic stress. The few studies available suggest that exercise in pregnant women at altitudes of 2500 m is safe for mother and fetus.[20] Until more data become available, pregnant patients should not be advised to curtail reasonable activities they wish to undertake. Perhaps of more concern than mild hypoxia is the fact that high altitude locations are often remote from medical facilities, and patients need to be aware that without access to sophisticated medical care, complications could have more serious consequences than at home.

192 DYSBARISM

Kenneth W. Kizer

DYSBARIC DIVING CASUALTIES

There are now over 4 million recreational scuba[1] divers in the United States, and over 400,000 new sport divers are certified each year. In addition, diving is an integral part of many commercial and scientific activities (Table 192-1).

TABLE 192-1   Types of Commercial and Scientific Diving

The health problems associated with diving are due to the hazards of the aquatic environment and the breathing of compressed gases at higher than normal atmospheric pressure. Table 192-2 categorizes the majority of diving-related medical problems.

TABLE 192-2   Medical Problems of Scuba Divers

Physical Principles

Many adverse physical conditions are encountered in the underwater environment. These include cold, wetness, changes in light and sound conduction, increased density of the surrounding environment, and increased atmospheric pressure. Of these, the indirect or direct effects of pressure account for the majority of serious diving medical problems.

PRESSURE   Pressure is force per unit area and is measured in a number of different units (Table 192-3). The weight of air at sea level is equal to 14.7 lbs/in^2 (psi) or 1 atm absolute (ATA). Under water, pressure increases because of the weight of the water. Because water is much denser than air, large changes in pressure will accompany small fluctuations in depth. Thus, at a depth of 33 ft of seawater (fsw) the pressure is 2 ATA, and at 165 fsw it is 6 ATA (Table 192-4).[2] The proportionate change in pressure per unit depth is greatest near the surface and progressively diminishes with increasing depth. Because fresh water is less dense than saltwater, it takes a depth change of 34 ft of fresh water (ffw) to change the pressure 1 ATA. Scuba diving is generally done at pressure of less than 6 ATA, with the overwhelming majority in the 2- to 4-ATA range.

TABLE 192-3   Pressure Equivalents

	Depth, fsw	Gauge Pressure, atm*	Absolute Pressure, atm	Gas Volume, %	Bubble Diameter, † %
Air	0	0	1	100	100
Seawater	33	1	2	50	79
	66	2	3	33	69
	99	3	4	25	63
	132	4	5	20	58
	165	5	6	17	54

*Gauge pressure is always 1 atm less than absolute pressure.
†Bubble diameter is probably more important than volume in consideration of the ability of recompression to restore circulation to a gas-embolized blood vessel.

TABLE 192-4 Pressure-Volume Relationships According to Boyle's Law

Because body tissues are composed mostly of water, which is not compressible, they are not directly affected by pressure changes. However, gases are compressible, and, consequently, gas-filled organs of the body are directly affected by pressure changes.

GAS LAWS   Diving physiology is largely explained by three gas laws.

The first is *Boyle's law,* which states that the volume of a gas is inversely proportional to its pressure at a constant temperature. This is expressed by the equation.

$$PV = K$$

where *P* is pressure, *V* is volume, and *K* is a constant. Thus, as shown (see Table 192-4), when the pressure is doubled the volume of a unit of gas is halved, and conversely when the pressure is decreased in half, the volume doubles. Boyle's law explains the basic mechanism of all types of barotrauma.

The second is *Dalton's law,* which states that the pressure exerted by each gas in a mixture of gases is the same as each gas would exert if it alone occupied the same volume, or, alternatively, the total pressure of mixture of gases is equal to the sum of the partial pressures of the component gases. This is mathematically stated as

$$P_t = P_{O_2} + P_{N_2} + P_x$$

where P_t is the total pressure, P_{O_2} is the partial pressure of oxygen, P_{N_2} is the partial pressure of nitrogen, and P_x is the partial pressure of the remaining gases in the mixture. This law explains why the partial pressures of component gases in a mixture change proportionately to changes in ambient pressure even though their absolute concentrations remain constant. This law is fundamental to the understanding of decompression sickness and other breathing gas-related problems.

Henry's law states that the amount of gas dissolved in a given volume of fluid is proportional to the pressure of the gas with which it is in equilibrium. The formula is

$$C_X = P_X \times \text{solubility}$$

where C_X is the concentration of gas dissolved in a liquid and P_X is the partial pressure of gas *X*. This law explains why more inert gas (e.g., nitrogen) dissolves in the diver's body as ambient pressure is increased with descent and, conversely, is released from tissue with ascent.

Direct Effects of Pressure—Barotrauma

The pressure-related diving syndromes can be divided into problems caused by the mechanical effects of pressure (i.e., barotrauma) and problems caused by breathing gases at elevated partial pressures (i.e., gas toxicities and decompression sickness [DCS]).

Barotrauma is the most common affliction of divers. It is defined as tissue damage resulting from contraction or expansion of gas spaces that occurs when the gas pressure in the body, or its compartments, is not equal to ambient pressure. For purposes of discussion, barotrauma can be viewed according to whether it occurs during descent or ascent.

BAROTRAUMA OF DESCENT   Barotrauma of descent, or "squeeze," as it is known in common diving parlance, results from the compression of gas in enclosed spaces as ambient pressure increases with underwater descent. Gas pressure in the various air-filled spaces of the body is normally in equilibrium with the environment; however, if something obstructs the portals of gas exchange, pressure equalization is precluded. If the air-filled space is not collapsible, the resulting pressure imbalance will cause tissue distortion, vascular engorgement and mucosal edema, hemorrhage, and other tissue damage. The ears and paranasal sinuses are most likely to be affected by such a process.

Aural barotrauma is the most common type of barotrauma and is a major cause of morbidity among divers, experienced by essentially all divers at one time or another. There are three main types of aural barotrauma, depending on which part of the ear is affected, and they may occur singly or in combination.

The first type involves the external auditory canal and is generally referred to as *external ear squeeze,* or *barotitis externa.* The external ear canal normally communicates with the environment and, consequently, the air in the canal is replaced by water when a diver is submerged. However, if the external ear canal is occluded (e.g., by cerumen, foreign bodies, exostoses, or earplugs), water entry is prevented, and compression of the enclosed air with descent will have to be compensated for by tissue collapse, outward bulging of the tympanic membrane, or hemorrhage. This is typically manifested by pain or bloody otorrhea. Physical examination may reveal petechiae or blood-filled cutaneous blebs along the canal, along with erythema or rupture of the tympanic membrane. Treatment involves keeping the canal dry, prohibiting swimming or diving until healed, and, in special cases, taking antibiotics and analgesics.

The next, and by far the most common, type of aural barotrauma is *middle ear squeeze,* or *barotitis media.* This results from a failure to equalize the middle ear and environmental pressures because of occlusion or dysfunction of the eustachian tube.

The eustachian tubes normally open and allow equalization of middle ear pressure when the pressure difference between the middle ear and pharynx reaches about 20 mmHg. This can be facilitated by yawning, swallowing, or using various autoinflation techniques (e.g., the Valsalva or Frenzel maneuvers). If middle ear pressure equalization is not achieved, the diver will notice discomfort or pain when the pressure differential reaches 100 to 150 mmHg or, roughly, when there has been a 20 percent reduction in middle ear gas volume. As the pressure differential is increased, mucosal engorgement and edema, hemorrhage, and inward bulging of the tympanic membrane develop. Eventually, these will be inadequate to compensate for the gas volume contraction, and the tympanic membrane ruptures. Fortunately, this is uncommon.

A number of factors may cause eustachian tube blockage or dysfunction—mucosal congestion secondary to upper respiratory infection, allergies, or smoking; mucosal polyps; excessively vigorous autoinflation maneuvers; and previous maxillofacial trauma. Persons with such conditions are at increased risk of middle ear barotrauma.

Divers having a middle ear squeeze usually complain of ear fullness or pain. As would be expected from the way that pressure changes with depth (Table 192-4), most problems occur near the surface. The pain is substantial and usually causes the diver to abort the dive. If not, it will continue to worsen until the eardrum ruptures, at which time the diver may feel air bubbles escaping from the ear and experience disorientation, nausea, and vertigo secondary to the caloric stimulation of cold water entering the middle ear. This sequence has been responsible for cases of panic and near drowning.

The otoscopic appearance of the tympanic membrane in cases of middle ear squeeze varies according to the severity of the injury and can be graded according to the amount of hemorrhage in the eardrum, with grades running from 0 (symptoms only) to 5 (gross hemorrhage and rupture). Physical examination may also disclose blood around the nose or mouth and a mild conductive hearing loss, which is usually only temporary.

Treatment of middle ear squeeze involves abstinence from diving until the condition has resolved and use of decongestants, which may be combined with antihistamines if there is an allergic component to the eustachian tube dysfunction. A combination of oral and long-acting spray decongestants is usually most efficacious. Antibiotics should be used when there is a tympanic membrane rupture or a preexisting infection. No diving should be done until a perforated eardrum has healed. Oral analgesics or topical aural anesthetics may be needed for a couple of days. In general, eardrops should not be used when there is a tympanic membrane perforation. Ideally, an audiogram should be obtained in anyone having more than a trivial middle ear squeeze, and serial audiograms should be obtained in patients having hearing loss. Most middle ear squeezes will resolve without complication in three to seven days. Prevention is preferable; a diver should refrain from diving when unable to easily equalize pressure in the ears and should always heed warning signs of ear pain.

Although less common, the third type of aural barotrauma, *inner ear barotrauma,* is much more serious than middle ear barotrauma because of possible permanently disabling injury to the cochleovestibular system. Inner ear barotrauma typically results from the sudden or rapid development of markedly different pressures between the middle and inner ear, such as may occur as a result of an overly forceful Valsalva maneuver intended to equalize the pressure in the middle ear or an exceptionally rapid descent during which the middle ear pressure is not equalized.

Patients with inner ear barotrauma typically are quite symptomatic, having a feeling of fullness or "blockage" of the affected ear, nausea, vomiting, nystagmus, diaphoresis, disorientation, or ataxia. The classic triad of symptoms indicating inner ear barotrauma is tinnitus, vertigo, and deafness. The onset of these symptoms may occur soon after the injury or may be delayed many hours, depending on the specific type of inner ear injury and the diver's activities during and after the dive. Findings on physical examination may be normal or may reveal signs of middle ear barotrauma or vestibular dysfunction, and audiometry may demonstrate a mild to severe sensorineural hearing loss. Any scuba diver with a hearing loss or vestibular symptoms following a nondecompression dive should be considered to have inner ear barotrauma until shown otherwise.

Clinically, there appear to be four categories or mechanisms for these injuries: hemorrhage within the inner ear (especially in the basal turn of the cochlea); rupture of Reissner's membrane, resulting in the mixing of endolymph and perilymph; fistulation of the round or oval window; and a mixed injury involving a combination of any or all of the other three. Injury to the membranous labyrinth may be either implosive or explosive.

Hemorrhage within the inner ear usually is associated with findings of middle ear barotrauma, no (or transient) vestibular symptoms, and a diffuse mild to severe sensorineural hearing loss (SNHL). Treatment of these patients should consist of bed rest with head elevated, avoidance of strain or strenuous activities, and symptomatic measures, as needed. The potential for full recovery is excellent, with the hearing loss usually completely resolved in three weeks to three months.

Manifestations of a tear in Reissner's membrane are similar to those of inner ear hemorrhage, although a persistent localized SNHL remains commensurate with the area of membrane tear. Treatment is similar to that of inner ear hemorrhage.

Inner ear fistulas typically present with a mild high-frequency SNHL or a marked cochleovestibular deficit and no or little evidence of middle ear barotrauma. Initially, these should be treated with bedrest, avoidance of strain, and other symptomatic measures, as needed. Worsening of hearing or vestibular symptoms or persistence of significant vestibular symptoms after a few days indicates the need for surgical exploration and repair. Some authorities, however, recommend immediate tympanotomy if severe symptoms are present initially. Importantly, recompression is contraindicated unless DCS or air embolism is also suspected to be present.

Any of the paranasal sinuses may fail to equalize pressure during descent. Manifestations of sinus squeeze include a sensation of fullness or pressure in the affected sinus, pain, or hemorrhage. Predisposing conditions for barosinusitis include upper respiratory infections, sinusitis, nasal polyps, or anything else that impairs the free flow of air from sinus cavity to nose. The maxillary and frontal sinuses are most often affected. Treatment for sinus squeeze is much the same as for middle ear squeeze, although antibiotics are usually indicated in cases involving the frontal sinuses.

Squeeze can also affect any other gas space that does not equilibrate with ambient pressure. For example, conjunctival, scleral, and periorbital hemorrhage may result if the diver fails to exhale into the mask during descent, resulting in telltale erythema, ecchymosis, and petechiae of the part of the face enclosed by the face mask—"face mask squeeze." If an area of skin is tightly enclosed by a dry diving suit a "suit squeeze" may occur. Although the appearance of these injuries may be spectacular, no special treatment is required, and they usually resolve in a few days.

Another special kind of squeeze may occur in divers who, while holding their breath, descend below the depth at which their total lung volume is reduced to less than residual volume. As occurs in other types of barotrauma of descent, the underventilated lung air spaces fill with tissue fluids and blood in an attempt to relieve the negative pressure. Clinical manifestations include chest pain, cough, hemoptysis, dyspnea, and pulmonary edema. Treatment includes administration of 100% oxygen, fluid replacement, and other supportive measures as clinically indicated. Because of the intrinsic lung injury and consequent potential for gas embolism, positive-pressure breathing (e.g., positive end-expiratory pressure or continuous positive airway pressure) should be avoided if possible. Very few divers attempt to free dive to depths likely to cause lung squeeze, and it is rare.

BAROTRAUMA OF ASCENT   If there has been adequate equilibration of the pressure in the body's air-filled spaces during descent, the gas in those spaces will expand according to Boyle's law as ambient pressure decreases with ascent. The resulting excess gas is normally vented to the atmosphere. However, if this is prevented by obstruction of the air passages, the expanding gases will distend the tissues surrounding them; the resulting damage is known as *barotrauma of ascent* and is the reverse process of squeeze.

Although the ears and sinuses may be affected by barotrauma of ascent, this is unusual, because impediment of air egress is highly unlikely if pressure equalization is achieved with descent. However, middle ear and sinus barotrauma of ascent, or *reverse squeeze,* can occur, especially in divers having upper respiratory congestion treated with a short-acting nasal spray whose vasoconstrictive effect wears off while the diver is submerged. Similarly, *alternobaric vertigo* (ABV) resulting from unequal vestibular stimulation due to asymmetric middle ear pressure may occur during ascent. Although usually only transient, ABV may be severe enough to cause panic. Rarely, it may last for several hours, or even a day or two, after a dive.

Three other types of barotrauma of ascent should be discussed. The first may occur with either ascent or descent, although more commonly with ascent, and is known as *barodontalgia,* or, less accurately, "tooth squeeze." Several specific conditions are associated with this problem (e.g., pulp decay, peridontal infections, or recent extraction sockets or fillings), but it may be due to anything that causes a pressure disequilibrium in an air-filled space in or about a tooth. Although rare and usually self-limited, anyone presenting with a toothache after diving should be referred for dental evaluation after maxillary sinus squeeze has been excluded.

Another unusual type of barotrauma of ascent is gastrointestinal (GI) barotrauma, which is also known as *aerogastralgia,* or "gas in the gut." This occurs most commonly in novice scuba divers, who are more prone to aerophagia, and is caused by expansion of intraluminal bowel gas as ambient pressure is decreased during ascent. Other predisposing conditions include repeated performance of the Valsalva maneuver in the head-down position (which forces air into the stomach), drinking carbonated beverages or eating a heavy meal before diving (especially one containing legumes or other flatogenic substances), or chewing gum while diving. Symptoms of gastrointestinal barotrauma include abdominal fullness, colicky abdominal pain, belching, and flatulence. It is rarely severe because most divers will readily vent any excess bowel gas during ascent; however, it has been know to cause syncope and shocklike states. Actual gastric rupture from GI barotrauma has occurred, but this is exceedingly rare.

The last and most serious type of barotrauma of ascent is pulmonary barotrauma (PBT). Several different injuries can result from PBT of ascent, and these are collectively referred to as the pulmonary overpressurization syndrome (POPS) or "burst lung" (Table 192-5).

TABLE 192-5   Manifestations of Pulmonary Barotrauma

Diving equipment is designed to deliver compressed gas to the diver at the same pressure as the surrounding environment (e.g., at 33 fsw the diver breathes gas at a pressure of 2 ATA). Consequently, the compressed gas will expand during ascent according to Boyle's law, and the diver must allow the expanding gas to escape from the lungs, or it will rupture and dissect into the surrounding tissue. The resultant injury will depend on the location and amount of escaped gas. Symptoms of PBT sustained during ascent can appear immediately on surfacing or develop later.

Mediastinal and subcutaneous emphysema are the most common forms of the POPS. The patient usually presents with gradually increasing hoarseness, neck fullness, and substernal chest pain several hours after diving. Dyspnea, dysphagia, syncope, and other symptoms may be present as well. The history is usually diagnostic, although radiographs are indicated to verify the location of gas and exclude the presence of a pneumothorax.

The development of a pneumothorax as a result of PBT is uncommon but especially serious, for intrapleural gas cannot be released to the environment and is likely to progress to tension pneumothorax during ascent, leading to syncope, shock, or unconsciousness on surfacing.

Except for pneumothorax, which may require needle aspiration or tube thoracostomy, treatment of uncomplicated POPS typically requires only observation, rest, and, sometimes, supplemental oxygen. Recompression is necessary only in extremely severe cases.

Arterial Gas Embolism

The most feared complication of PBT is air embolism. Indeed, dysbaric air embolism (DAE), or arterial gas embolism (AGE), is one of the most dramatic and serious injuries associated with diving and is a major cause of death and disability among sport divers.

AGE results from the entry of gas bubbles into the systemic circulation through ruptured pulmonary veins. This usually occurs at the alveolar or terminal bronchiole level. After passing through the heart, bubbles lodge in small arteries, occluding the more distal circulation. The resulting manifestations will depend on the location of the occlusion. Depending on the site, even minute quantities of gas can have disastrous consequences. AGE can occur at depths as shallow as 1 m.

AGE usually presents immediately after a diver surfaces, at which time the high intrapulmonic pressure resulting from lung overexpansion is relieved, which allows air bubble-laden blood to return to the heart. Although the classic history is that the diver ascends rapidly because of running out of air, panic, or some similar circumstance, this is not always the case. Localized overinflation also may result from focally increased elastic recoil of the lungs in some divers. It is axiomatic that symptoms of AGE develop within 10 min of surfacing from a dive, although most often they are clearly evident within 2 min.

The presenting manifestations of AGE are sudden, dramatic, and often life-threatening. Coronary occlusion and cardiac arrest or arrhythmias may occur, although the brain is by far the most often affected organ. The neurologic manifestations are typical of an acute stroke, such as mono- or multiplegia, focal paralysis, sensory disturbance, blindness, deafness, vertigo, dizziness, confusion, convulsions, or aphasia. Asymmetric multiplegias are the most common presentation, and the differentiation of AGE from severe neurologic DCS is sometimes impossible. *Sudden loss of consciousness on surfacing should always be assumed to be due to gas embolism until proved otherwise.* Other reported clinical findings such as visualization of bubbles in the retinal arteries or Liebermeister's sign (a sharply circumscribed area of glossal pallor) are exceedingly rare. Patients with diving-related AGE may be intravascularly volume depleted and have similar laboratory abnormalities as seen with decompression sickness; except for hemoconcentration, the clinical significance of these abnormalities is unclear.

All cases of suspected AGE must be referred for recompression treatment—hyperbaric oxygen treatment—as quickly as possible. This is the primary and essential treatment for this condition, as is discussed later. Hyperbaric oxygen should also be used for cases of delayed AGE; it may be effective even up to 10 days after the event.

Some patients with very severe initial neurologic symptoms may improve spontaneously. The mechanism of spontaneous recovery is not clear. Nonetheless, such patients should still be referred for recompression because even subtle dysbaric injuries may become irreversible without definitive care. Before recompression, pneumothorax should be ruled out.

Indirect Effects of Pressure

Nitrogen narcosis and DCS sickness may develop as a result of breathing gases at higher-than-normal atmospheric pressure.

NITROGEN NARCOSIS   Nitrogen and other lipid-soluble inert gases have an anesthetic effect at elevated partial pressures. The narcotic effects are similar to those of alcohol and become evident in most divers between 90 and 100 fsw. Many divers are so impaired at 200 fsw that they can do no useful work, and at depths over 300 to 350 fsw unconsciousness ensues. Although narcotic effects are reversed as the P_{N_2} decreases with ascent, nitrogen narcosis is not an uncommon precipitating factor in diving accidents and may impair a diver's memory of the circumstances leading up to the accident.

DECOMPRESSION SICKNESS   Decompression sickness is a multisystem disorder resulting from the liberation of inert gas from solution with the formation of gas bubbles in blood and body tissues when ambient pressure is decreased. The critical factor in its pathogenesis is increased tissue absorption of inert gas, which in most diving situations is nitrogen.

As an air-breathing diver descends, ambient pressure increases, and the diving equipment delivers air to the lungs at increasing pressure, giving rise to a positive pressure gradient of nitrogen from alveoli to blood to tissue. After a time at depth this gradient will diminish, eventually becoming zero as a new equilibrium is reached. The time that it takes for the new equilibrium to be achieved will depend on the alveolar-to-tissue inert gas gradient, the tissue blood flow, and the ratio of blood-to-tissue inert gas solubility. Consequently, the rate at which a diver reaches a new inert gas equilibrium will be an exponential function of the diffusion and perfusion characteristics of the different tissues.

The tissue absorption of inert gas is the first step toward DCS, but it is only when ambient pressure is, in turn, decreased too rapidly to allow the diffusion of inert gas from tissues that DCS occurs.

The pathophysiology of decompression sickness results from both the mechanical and biophysical effects of bubbles (Fig. 192-1). The major mechanical effect of bubbles in DCS is vascular occlusion. Of note, the bubbles in DCS form primarily in the venous circulation and thus impair venous return, in contrast to the more usual arterial occlusion that occurs in most other conditions. However, the bubbles in DCS can form anywhere, such as in lymphatics, or intracellularly or extravascularly. Lymphedema, cellular distension and rupture, and intercellular dislocation can all compound the effects of vascular occlusion. Also, venous gas emboli may cause paradoxical arterial embolization via intrapulmonic and intracardiac shunts. Indeed, it is now clear that some dysbaric cerebral injuries are due to paradoxical embolization through previously unrecognized right-to-left intracardiac shunts that may only be open during abnormal pressure conditions found during diving. Since a patent foramen ovale (PFO) has been shown to be present in about 30 percent of the normal population, it can be assumed that about 30 percent of divers are likely

to have a PFO. The presence of a PFO has been reported to produce a 2.5 times increase in the odds ratio for developing serious DCS. Such paradoxical embolization may help explain the high frequency of apparent combined DCS/air embolism noted in some series.
FIG. 192-1. Schematic representation of the pathogenesis of decompression sickness. (Adapted from Kizer KW: Management of dysbaric diving casualties. *Emerg Med Clin North Am* 1:659, 1983. Used by permission.)

Bubbles also exert a variety of biophysical effects due to blood-bubble surface interaction. In essence, bubbles are viewed by the immune system as foreign matter, and they incite an inflammatory reaction. The key step in the process is activation of Hageman factor, which, in turn, activates the intrinsic clotting mechanisms and kinin and complement systems, which results in platelet activation, cellular clumping, lipid embolization, increased vascular permeability, interstitial edema, and microvascular sludging. The net effect of all these processes is decreased tissue perfusion and ischemic injury.

The clinical manifestations of DCS are protean (Table 192-6), but the joints and spinal cord are most often affected. Technically, the term *bends* refers only to the musculoskeletal form of DCS, but it is commonly used in a generic sense to mean any type of DCS. The various forms of DCS have also been arbitrarily categorized as either types I or II, with type I referring to the mild forms of DCS (skin, lymphatic, and musculoskeletal systems) and type II including the neurologic and other serious types. Although this latter categorization is firmly entrenched in the literature, it is clinically more meaningful to refer to the systems affected when discussing patients with DCS.

TABLE 192-6   Clinical Forms of Decompression Sickness

In recent years, approximately 30 percent of DCS cases reported to the Divers Alert Network (DAN), have been Type I, and about 70 percent have been Type II.

Cutaneous manifestations of DCS include pruritus, subcutaneous emphysema, and scarlatiniform, erysipeloid, or mottled rashes. Localized swelling or peau d'orange may result from lymphatic obstruction.

Periarticular joint pain is typically described as a deep, dull ache, although it may be throbbing or sharp. There may be a vague area of numbness or dysesthesia around the affected joint. Movement of the affected extremity usually aggravates the pain, but inflation of a blood pressure cuff around the involved joint may relieve the pain for as long as the cuff is inflated. The shoulders and elbows are the joints most often affected in scuba divers, although essentially any joint may be involved.

Neurologic DCS may be manifested by a vast array of symptoms and signs. In fact, essentially any symptom is compatible with neurologic DCS. Classically, however, neurologic DCS involves the lower thoracic, lumbar, and sacral portions of the spinal cord and produces paraplegia or paraparesis, lower extremity paresthesias, and bladder dysfunction. Historically, urinary retention was such a frequent manifestation of spinal cord DCS that a urethral catheter used to be part of the diver's standard equipment. Hallenbeck and colleagues have convincingly demonstrated that at least some cases of spinal cord DCS result from venous infarction of the cord due to obstruction of venous drainage in the epidural vertebral venous plexus.

Pulmonary DCS results from massive venous air embolization and usually does not become symptomatic until at least 10 percent of the pulmonary vascular bed is obstructed. Signs and symptoms include chest pain, cough, dyspnea, shock, and pulmonary edema. The clinical course is often fulminantly downhill.

Many divers develop intravascular bubbles but no apparent illness; these have been called "silent bubbles" and their clinical significance is unclear.

A variety of laboratory abnormalities may be demonstrated in DCS, but most of them have little clinical relevance to acute care. Two tests that may be useful, though, are the urine specific gravity and hematocrit, because intravascular volume depletion and hemoconcentration are common in serious DCS. (This hemoconcentration may exacerbate the increased erythrocyte aggregation that has been demonstrated to occur at mild increased ambient pressure.) These two tests can help guide fluid replacement, which is an integral part of therapy.

Dysbaric casualties should be rapidly referred for hyperbaric treatment. However, the patient should also be evaluated for life-threatening nondysbaric injuries and, if present, resuscitation commenced.

Treatment of Diving Casualties

THE DIVING ACCIDENT HISTORY   Most diving problems can be properly diagnosed by history and physical examination alone. The specific diving accident history should encompass these key points:

1. The type of diving engaged in and the equipment used. Some kinds of diving or certain types of equipment are associated with specific problems (e.g., hypercarbia or oxygen toxicity with rebreathing apparatus). Nitrox diving (aka enriched air nitrox or oxygen-enriched air diving) has become quite popular in recent years and requires special equipment and decompression tables.
2. The number, depth, bottom time, and surface interval between repetitive dives for all dives in the 72 h preceding symptom onset. Even if this information is not especially meaningful to you, having it available will facilitate communication with the diving medicine consultant who will want to ascertain whether required decompression was omitted.
3. In-water decompression. Again, this is relevant to the determination of the likelihood of the diver having DCS.
4. In-water recompression. Except in very unusual situations using 100% oxygen, full face mask, and other specialized support, in-water recompression should never be attempted. Recompression with compressed air should not be done, for it almost always leaves the diver in worse condition than originally and is

fraught with other hazards.

5. Site of diving (e.g., ocean, lake, or quarry) and environmental conditions (e.g., water temperature, amount of current) associated with the dive. Other things being equal, DCS is more likely to occur after diving into very cold water, but nondysbaric problems related to the environment (e.g., motion sickness) must be excluded.
6. Primary diving activity (e.g., spearfishing, photography). DCS is more likely after an arduous dive.
7. Presence of predisposing factors. A number of factors have been anecdotally related to the development of DCS. These include advanced age (decreased tissue perfusion), obesity (increased absorption of inert gas), dehydration, recent alcohol intoxication, cold water (decreased peripheral perfusion), vigorous underwater exercise (increased gas uptake), local physical injury (decreased local perfusion), and multiple repetitive dives in unacclimatized individuals (gradual buildup of inert gas).
8. Dive complications. These include running out of air, marine animal envenomation, mechanical trauma, or some other unexpected event. Musculoskeletal pain may be due to overexertion or muscle strain, and numbness in an extremity may be from a jellyfish sting rather than DCS.
9. Predive and postdive activities. Activities such as jogging and unpressurized airplane travel after diving may precipitate DCS. Likewise, trivial dysbaric symptoms may become severe after similar activities.
10. Onset of symptoms. Certain conditions are more likely to occur at given times in the dive profile, and a differential scheme can be derived on the basis of time of symptom onset.

DIFFERENTIAL DIAGNOSIS OF DIVING ACCIDENTS   Classically, a scuba dive is divisible into five stages, each of which is associated with characteristic problems.

The Predive Surface Phase   The predive surface phase includes all activities prior to going underwater and beginning to breathe compressed air. This often involves considerable surface swimming to the dive site. The most often encountered problems during this phase of the dive are motion sickness, hyperventilation, mechanical trauma, near drowning, and untoward marine animal encounters.

Descent Phase   The primary problems associated with descent are the squeeze syndromes, especially aural barotrauma, although inner ear barotrauma and ABV may also occur. Similarly, carbon monoxide poisoning, hypoxia, or other breathing gas problems may develop early in the dive.

At-Depth or Bottom Phase   Overall, few problems occur "on the bottom," and the most likely ones are mechanical trauma or encounters with dangerous marine life. Nitrogen narcosis may contribute to an underwater accident. Inner ear barotrauma or gas mixture problems may first become symptomatic at this time even though they occurred earlier.

Ascent Phase   Again, barotrauma is the problem most often encountered with ascent although much less frequently than during descent. The relationship of POPS, AGE, and inner ear barotrauma with ascent have already been discussed. Gas mixture problems may become manifest at this time, and hypercarbia can be experienced toward the end of a dive. DCS rarely occurs while a diver is still submerged; if this happens, it usually implies a very serious problem.

Postdive Surface Phase   The postdive surface phase is divided into immediate (within 10 min of surfacing) and delayed (after 10 min). Any symptom occurring in the immediate postdive phase should be considered an air embolism until shown otherwise. Any symptom that begins more than 10 min after the dive should be viewed as DCS until otherwise explained. More than half of all DCS patients will become symptomatic in the first hour after surfacing, with most of the rest experiencing symptoms within six hours. A few patients (1 to 2 percent) may first note their symptoms 24 to 48 h after diving. Other problems that may be first noted in the delayed postdive phase include mild forms of the POPS, sequelae of barotrauma, inner ear barotrauma, motion sickness, exhaustion, irritant or venomous dermatoses, and nondysbaric conditions related to physical activity.

Of note, in sport diving, relatively few divers follow this classical dive profile; instead, they are much more likely to be repeatedly ascending and descending during the dive.

IMMEDIATE MANAGEMENT   The victim should be rescued from the water and life support measures begun as needed. Hypothermia should be considered an aggravating factor in every aquatic accident victim.

If AGE is suspected, it is recommended that the patient be maintained supine in the field and during transport. Placement in the Trendelenburg or Durant positions is no longer recommended because of the uncertain benefit of such maneuvers and concerns about causing or aggravating cerebral edema (especially if left in the head-down position for longer than 30 to 60 min) and the increased respiratory difficulty attendant to being in such positions.

Supplemental 100% oxygen should always be given as soon as possible, being best administered by mask at 6 to 8 L/min. This facilitates offgassing of the nitrogen bubbles and improves oxygenation of damaged tissues.

Depending on local circumstances, patients with suspected AGE or DCS may be taken directly to the recompression chamber or may need emergency department intervention. Whichever is the case, transportation should be as expeditious as possible. If air transportation is used, the patient should be subjected to the least possible pressure reduction so as not to cause any further gas expansion. Either a low-flying helicopter or light airplane capable of flight at 1000 ft (300 m) or less should be used. Alternatively, aircraft that can be pressurized to 1 ATA (e.g., Lear jet, Cessna Citation, or C-130 Hercules) can be used.

Advanced life support drugs should be administered according to the victim's condition and standard protocols. In general, most DCS victims are at least mildly volume depleted, so parenteral and oral (if the patient is alert) fluids should be given at a brisk rate unless they are contraindicated for other reasons.

Although high-dose parenteral corticosteroids have been widely recommended and used in the past as an adjunct to recompression treatment of both neurologic DCS and AGE, little objective evidence supports their benefit. The use of glucocorticoids became prevalent based on the belief that they were beneficial in the treatment of cerebral edema, shock, and other conditions pertinent to DCS, but their benefit in many of these other conditions is now questioned. A few anecdotal cases suggesting that steroids are beneficial, either alone or with other pharmacologic interventions combined with standard recompression therapy, have been reported, but there have been no published clinical series or controlled trials demonstrating their efficacy. In contrast, controlled studies of high-dose parenteral dexamethasone or methyl prednisolone in DCS-affected dogs showed that the use of glucocorticoids as an adjunct to conventional hyperbaric oxygen treatment produced no benefit.

If the need for recompression or the location of the nearest hyperbaric treatment facility is uncertain, assistance is available 24 h a day through the Divers Alert Network (DAN) at Duke University, Durham, NC, (919) 684-8111.

HYPERBARIC TREATMENT   Pressure and oxygen are the keystones of treatment for DCS and AGE and are administered according to well-established protocols. Various types of hyperbaric chambers may be used for treatment, and the relative merits of one type or another need not be recounted here.

The outcome of recompression treatment will, of course, depend on the severity of the disease, the delay in commencing hyperbaric treatment, and the victim's health prior to the accident. Overall, 80 to 90 percent success rates have been reported from a variety of sources, and even though recompression is generally believed to be more likely beneficial the sooner that it is commenced after the onset of symptoms, it should not be refused to someone who presents 2, 3, or more days after an accident, for dramatic recoveries have been reported after treatment delays of 10 days or longer. It is not possible to determine in advance what the effect of a delay in recompression will be for any individual patient.

POSTRECOMPRESSION EVALUATION   Because recompression treatment does not always result in complete resolution of dysbaric neurologic injury and because occasional situations arise when the differential diagnosis of acute diving-related neurologic dysfunction includes intracranial hemorrhage, trauma, or other nondysbaric injury, it is sometimes important to characterize the site, extent, and origin of central nervous system (CNS), lesions beyond what can be achieved by the traditional means of history and physical examination.

Both computed tomography (CT) and magnetic resonance imaging (MRI) have been used in this regard. Regrettably, conventional CT has not been found to be an efficient investigative tool for the posttreatment evaluation of DCS, and CT imaging of spinal cord lesions (which constitute the majority of neurologic DCS) is not feasible. In contrast, limited clinical data support the feasibility and efficacy of MRI of these conditions, especially when intracranial injury is present.

In contrast, CT of the chest, and especially spiral volumetric CT, is very helpful in demonstrating bullae, including subpleural blebs or cysts, as the cause of

pulmonary barotrauma.

BLAST INJURY

The phenomenon of blast injury has been recognized for as long as human beings have used explosives although it has been mainly a wartime concern. However, in the past few decades there has been a dramatic increase in the incidence of peacetime civilian explosive blast injuries because of the popularity of the homemade bomb as a vehicle of social protest or terrorist activity, and the continued hazard of explosions in mining, grain storage, and other industries. In addition, blast injuries remain a prominent cause of fire-related morbidity.

Blast Physics and Terminology

Explosives are materials that are rapidly converted into gases when detonated. *Blast* and *blast injury* are, respectively, general terms used to describe this gaseous decomposition and the damage occurring in an organism subjected to the pressure field produced by an explosion.

Blasts are characterized by the release of large quantities of energy in the form of pressure and heat, with the exact amount depending on the type and amount of explosive. If the explosion is confined within some sort of casing (e.g., a bomb), the pressure will rupture the housing and eject the resulting fragments at high velocity. The remaining energy is transmitted to the surrounding environment in the form of a blast wave, blast winds, ground shock, and fire.

The *blast wave* begins as a single pulse of increased pressure that rises to peak levels within a few milliseconds and then rapidly falls to a minimum pressure that is lower than the original atmospheric pressure (Fig. 192-2). It is propagated outward radially from the explosion, with the sharply marginated periphery of the sphere becoming the blast, overpressure, or shock wave, as it has been variously called. The duration and level of the high-pressure peak depends on the nature of the explosive, the conducting medium, and the distance from the detonation point. This blast wave pressure peak determines the *overpressure* that an object in its path is subjected to and is the main determinant of primary blast injury. Conversely, the negative pressure wave, or suction of the blast wave, lasts several times longer than the high-pressure wave but can never be greater than –760 mmHg (–14.7 psi). Representative pressure effects are listed in Table 192-7.
FIG. 192-2. The general form of a blast wave. (From Stapczynski JS: Blast injuries, in Edlich RF, Spyker DA (eds): *Current Emergency Therapy '85.* Rockville, MD, Aspen Systems Corporation, 1985, p 294.)

Pressure, psi*	Effect
5	Possible tympanic membrane rupture
15	50% incidence of tympanic membrane rupture
30	Possible lung injury
75	50% incidence of lung injury
100	Possible fatal injuries
200	Death more likely than not

*1 psi = 51.7 mmHg.

TABLE 192-7   Selected Effects from Blast Waves

The rapidly expanding gases from an explosion also displace air, causing it to move away at very high velocity and produce transient *blast winds* that travel immediately behind the shock front of the blast wave. The blast wave may also accelerate loose objects (e.g., people) through the air, causing acceleration-deceleration injuries. In the immediate vicinity of an explosion, this *windage* can cause atomization, or total disintegration, of a body, evisceration, or traumatic amputations, depending on the force of the explosion. Illustrative of the force of such winds, an overpressure of about 5200 mmHg (100 psi) produces a blast wind having a velocity of about 2400 kph (1500 mph).

In addition to the amount and duration of overpressure caused by an explosion, the overall effect of the blast wave also depends on the exact waveform of the overpressure (i.e., its rise time), the victim's body mass and orientation to the explosion, the presence of deflecting and reflecting surfaces in the environment, and the medium through which the shock wave is conducted. For example, because of the greater density of water and its relative incompressibility, blast waves produced by underwater explosions travel much faster and farther than those produced by terrestrial explosions. Consequently, blast injuries in water occur at greater distances from the detonation point and tend to be more severe. Underwater blast injury has other peculiarities, too, but these are beyond the scope of this discussion.

Categories and Manifestations of Blast Injury

Explosive blast injuries can be divided into four categories (Table 192-8).

Category	Injury Caused by	Primary Target Organs
I. Primary blast injury	Blast wave	Ears, lungs, GI tract, CNS
II. Secondary blast injury	Victim struck by flying debris	Integument, CNS, eyes, musculoskeletal system
III. Tertiary blast injury	Bodily displacement, i.e., victim impact with stationary objects	Abdominal viscera, CNS, lungs, integument, musculoskeletal system
IV. Miscellaneous	Inhalation of dust or toxic gases, thermal burns, radiation, other	Lungs, integument, eyes

TABLE 192-8   Categories of Blast Injury

PRIMARY BLAST INJURY   *Type I,* or *primary, blast injury* results directly from the sudden changes in environmental pressure caused by the blast wave. Tissues vary in their susceptibility to primary blast injury, with homogeneous or solid tissues being at least risk because they are essentially noncompressible and merely vibrate as a whole when subjected to a blast wave. Conversely, gas-filled organs are compressible and have tissue-gas interfaces, which means that displacement occurs wherever tissues of different densities interface, resulting in tissue distortion and tearing. Thus, primary blast injury mainly affects organs containing air and causes the most severe damage at the junctions between tissues, where loose, poorly supported tissue is displaced beyond its elastic limit.

There are three general mechanisms whereby a blast shock wave can damage living tissue. The first of these is known as *spalling* and occurs when a shock wave traveling through a medium of higher density (e.g., liquid) passes into a medium of lower density (e.g., gas), creating a negative reflection at the interface and, thus, fragmenting the surface of the heavier medium. This is analogous to hitting the outside of a rusty bucket with a hammer, which causes flakes to come off inside the bucket.

The second mechanism is implosion of gas-filled spaces as the high pressure in the surrounding fluid or solid compresses these spaces. Similarly, because there is a pressure differential between the air-filled and vascular spaces, blood and fluid are forced into the air-filled spaces. This mechanism is of particular importance in the lungs, where it contributes to pulmonary hemorrhage. In addition, as the negative pressure wave follows the initial positive pressure, smaller internal secondary explosions occur as the compressed gas reexpands.

Third, tissues of different densities will be accelerated and decelerated at different rates relative to each other, producing shearing forces that can tear or otherwise damage the tissue.

The organs most vulnerable to primary blast injuries are the ears, lungs, CNS, and gastrointestinal tract. Abdominal visceral injury is relatively rare in air blast casualties but is of considerable concern in persons exposed to underwater blasts.

Otolaryngologic Manifestations   The ears are most often affected by explosive blasts, with hearing loss being the primary manifestation. Hearing can be damaged in one of three ways. First, the tympanic membranes may rupture. This usually occurs in adults at a pressure differential between the middle and external ears of around 360 mmHg (7 psi), and most often presents as a linear perforation of the pars tensa. The second way is dislocation of the ossicles, which may accompany tympanic membrane rupture or occur as the sole injury. Finally, deafness may result from blast effects on the inner ear, causing perilymph fistula and other damage. In addition to hearing loss, primary symptoms of inner ear damage include vertigo and tinnitus.

The paranasal sinuses are also susceptible to blast injury, usually manifesting barotraumatic damage similar to the squeeze syndromes that occur with compressed air diving.

Pulmonary Manifestations   The lungs are generally the organs most severely affected by blast injury, and these injuries are likely to present a threat to life. (Of course, the severe injuries resulting from windage in the immediate vicinity of the explosion are also life-threatening). The blast wave causes widespread alveolar damage because of its effects on tissue-gas interfaces, producing interstitial and intra-alveolar hemorrhage and edema, parenchymal and pleural lacerations, and alveolar-venous fistulas. Because of the widespread nature of this damage a variety of specific injuries may be found, including pulmonary edema, pneumothorax and other extra-alveolar air syndromes, and air embolism. Similarly, pulmonary contusions result from compression of the lung between the spine, thoracic wall, and rising diaphragm, as well as from being thrown against solid objects in the environment.

The actual symptoms experienced by victims of blast lung injury will vary with the severity and nature of their specific injuries, but, in general, they will present with dyspnea, shortness of breath, chest pain, hemoptysis, rales, rhonchi and signs of pulmonary edema or hemorrhage, as well as symptoms of the POPS.

Gastrointestinal Manifestations   Blast injuries to the stomach and bowels are due to damage at tissue-gas interfaces, producing hemorrhage into the wall and lumen along with perforations, which tend to be multifocal. Because the large bowel usually contains more gas than the small bowel, it tends to be more severely affected. Common clinical manifestations include abdominal pain, melena, signs of peritonitis, and free air in the abdomen. Evisceration and other gross damage may be found in victims who were very close to the detonation site, but these types of injury are nearly always fatal.

Neurologic Manifestations   Blast injuries of the CNS are of two main types. First are the direct shock wave effects, which produce a concussion syndrome and various types of intra- and extra-axial hemorrhage, and second are the effects of cerebral air embolism. As with dysbaric diving casualties, the specific neurologic manifestations of air embolism are myriad.

OTHER CATEGORIES OF BLAST INJURY   *Type II,* or *secondary, blast injuries* are due largely to the blast wind and result from the victim being struck by flying debris. Conversely, *type III,* or *tertiary, blast injuries* are those that result from the victim being displaced through space by the blast wind and impacting a stationary object; this sudden deceleration usually causes more harm than the acceleration through space. *Type IV blast injuries* include a wide variety of injuries resulting from inhalation of dust and toxic gases, exposure to radiation, thermal burns, and so on.

The myriad number of bodily insults that can result from these latter types of blast injury are far too numerous to list here. Of particular concern, though, are the traumatic amputations, occurring in about 25 percent of severely wounded victims, and liver, spleen, or other visceral injuries produced from the acceleration-deceleration forces of the blast wind. Likewise, bomb-casing fragments or missiles, such as nails, nuts and bolts, screws, ball bearings, etc., can cause high-velocity missile injuries.

Management of Blast Casualties

Analysis of urban bomb blast injuries from Israel, Ireland, and the United Kingdom have identified common patterns:

1. Most victims are far enough from the explosion that they sustain only minor injuries, usually from flying debris.
2. Injuries most often affect the face, neck, and exposed extremities, indicating the protective role of ordinary clothing.
3. Injuries to the chest and abdomen are uncommon, but are associated with increased morbidity and mortality.
4. Injuries to the head are associated with the highest mortality.
5. While tympanic membrane rupture is common, primary blast injuries to other organs are unusual.

Blast injury victims should be managed in the same manner as any multiple trauma victim, except that particular attention should be directed to the respiratory system. This includes giving special attention to maintenance of a patent airway (especially when maxillofacial, cervical spine, or other head and neck injuries are present); administering supplemental oxygen; judiciously using intravenous fluids and analgesics; evacuating pneumo- and hemothoraces; and promptly implementing mechanical ventilation if signs of respiratory failure or inadequate oxygenation are present. Although positive pressure ventilation may be necessary to maintain adequate oxygenation, its use is fraught with hazard because the diffuse alveolar-capillary damage present in blast lung greatly increases the risk of causing extra-alveolar extravasation of air, including air embolism.

Systemic air embolization presents particular problems in the management of blast casualties, because the effects on the brain, heart, and viscera caused by air emboli may be indistinguishable from other types of injury. Yet, the preferred therapy for air embolism is hyperbaric oxygen treatment, which may not be readily available or may be impractical because of coexistent injuries or other logistical problems. Whenever possible, though, hyperbaric oxygen treatment should be implemented as expeditiously as possible, being given in a manner similar to the treatment of dysbaric diving casualties, because of its potential to reverse cerebral or coronary injuries if administered soon after the injury.

Tympanic membrane rupture and other otolaryngologic trauma, as well as most other types of blast injury, should be treated essentially the same as they are treated when due to other causes. Closed abdominal injuries are always of particular concern and should be treated according to the patient's signs and symptoms, with prompt surgical exploration being undertaken whenever there are signs of peritonitis or peritoneal free air. Abdominal visceral injuries should be especially looked for in victims of underwater explosion. Lacerations, fractures, amputations, and missile wounds should be treated in the usual manner, except for delayed primary closure being the generally preferred method of wound management.

Explosions in closed spaces produce greater injury and death than those occurring in the open. Primary blast injuries are especially common. Closed-space

explosions also expose the victim to dust, smoke, and toxic gases, increasing the incidence of inhalation injury. Again, though, the inhalation injury is treated essentially the same as that resulting from other circumstances.

Because primary blast injuries may not always be present when the victim is first evaluated, all blast-injured patients should be closely observed for at least 6 to 12 h after the accident. This is particularly true if there is perforation of the eardrums, which is generally an indication of significant exposure to high pressure.

193 NEAR DROWNING

Bruce E. Haynes

Drowning, like other causes of accidental death, often strikes young, otherwise healthy individuals, and prevention is the most important way to reduce these unnecessary deaths. The patient's prognosis after near drowning depends on the speed of rescue and resuscitation, emphasizing the role of emergency medical care.

DEFINITIONS

Almost as many definitions of drowning exist as authors in the field. One approach is to define *drowning* as death from suffocation after submersion, while those who suffer *near drowning* survive, at least temporarily, after suffocation by submersion. A few use the more generic term *immersion syndrome* to highlight the blurred margins between the two entities, although this term also has been used to refer to sudden death after immersion in cold water. *Postimmersion syndrome,* or *secondary drowning,* refers to the deterioration of a seemingly well patient after immersion.

EPIDEMIOLOGY

Drowning is the third leading cause of accidental death in the United States, killing about 4500 people each year. Although the exact number is uncertain, many more individuals survive serious near-drowning episodes.

Freshwater drowning, especially in pools, is more common than saltwater drowning, even in coastal areas. There is a bimodal age distribution, with large numbers of deaths among children under age 4 and then later among teenagers, although risk climbs again in the elderly from bathtub drowning. Young children are also at risk for drowning in a bathtub, even in the presence of siblings, and neglect or intentional injury should be considered in such cases. [1] Responses to a careful history may change over time and reveal inconsistencies, especially in regard to developmental age. Caretakers must ensure constant attention by an individual of appropriate age.

Alcohol or drug use by victims or even by supervising adults often plays a role in drowning and boating accidents. Consistent use of personal flotation devices by adults and children when boating is crucial. Children may be oblivious to potentially dangerous situations, especially in rivers and lakes. Some cases follow traumatic injury in or around the water, including spinal injury. Hypothermia is a factor in some drownings, while causes of syncope, including hyperventilation before underwater swimming, are responsible for a few cases. Patients with seizure disorders must receive careful supervision if swimming and should, depending on seizure control, probably bathe in showers or tubs with open drains and plastic stalls. This patient education is important when first-time seizure patients are discharged from emergency departments.

Drowning deaths may be prevented by adequate, well-maintained fencing with self-locking gates that surrounds pools themselves, rather than simply isolating the backyard, leaving access to the pool from the house and yard. However, fencing is not a complete answer. [2] Childhood pool drowning occurs rapidly and silently, and caretakers must not be diverted by chores, socializing, telephone calls, or other seemingly momentary distractions. Cardiopulmonary resuscitation (CPR) is frequently not started by rescuers, and pool owners should be encouraged to learn CPR and have telephones in the pool area. Swimming lessons for young children are controversial. Toddlers cannot understand their true skill level, nor the danger posed by water, nor do they have the strength to exit a pool. Swimming lessons, or more accurately, floating lessons, may induce a dangerous false sense of security among caretakers, putting the child at even more risk. On the other hand, there is evidence that trained children entering the water accidentally may have the skill to remain on the surface longer. [3]

PATHOPHYSIOLOGY

Respiratory failure and ischemic neurologic injury are the threats to life after submersion although associated injuries are occasionally present. Older victims who are not immediately unconscious may panic, struggle in the water, hold their breath, or hyperventilate. Once under water, involuntary breathing resumes at a break point determined by the Pa_{O_2} or Pa_{CO_2}. This soon leads to vomiting and aspiration of water and emesis. "Dry drowning" without aspiration results from laryngospasm and glottal closure. Whatever the mechanism, the final common pathway is profound hypoxemia.

Initial hypoxemia results from flooding of alveoli and impairment of gas exchange. Although both seawater and fresh water wash surfactant out of alveoli, fresh water also changes the surface tension properties of surfactant. Surfactant loss leads to atelectasis, ventilation perfusion mismatch, and breakdown of the alveolar capillary membrane. [4] Hypoxemia follows aspiration of small amounts of water and is seen experimentally with aspiration of 2.2 mL/kg of either fresh water or saltwater. Contributing to pulmonary injury may be aspiration of bacteria, algae, sand, particulate matter, emesis, and chemical irritants. Noncardiogenic pulmonary edema results from direct pulmonary injury, surfactant loss, inflammatory contaminants, and cerebral hypoxia.

Poor perfusion and hypoxemia lead to metabolic acidosis in a majority of patients, yet perhaps as a result of the young age of most victims, the cardiovascular status is remarkably stable. Blood volume shifts depend on the nature and quantity of the fluid aspirated, although life-threatening changes are unusual in resuscitated patients, because most human drowning victims aspirate quantities of water below those which produce significant disturbances. Electrolyte abnormalities in near-drowning patients are seldom significant, and hematologic values are usually normal, although the clinician occasionally will see hemoconcentration or hemolysis that results in anemia. Rarely, disseminated intravascular coagulation will occur.

Renal function is usually adequate, although proteinuria may occur, and hemoglobinuria can follow hemolysis. Acute tubular necrosis can result from hypoxia or myoglobinuria.

TREATMENT

Prehospital Care

Treatment of near drowning begins at the scene with rapid, cautious removal of the victim from the water (Table 193-1). Spinal precautions should be observed if the mechanism of injury, such as diving or surfing, raises suspicion of such injury. The vast majority of spinal injuries are to the lower cervical spine after diving. Clues to spinal injury may be paradoxical respiration (abdominal breathing without movement of intercostal muscles), flaccidity, priapism, or unexplained hypotension or bradycardia. Lifeguards and emergency medical technicians should maintain spinal precautions during rescue if possible. Initial history may be unreliable, and the physician should have a low threshold for obtaining cervical spine x-rays.

TABLE 193-1 Prehospital Care of Near-Drowning Victims

A patent airway must be maintained and ventilation assisted as needed; patients should receive supplemental oxygen. CPR should be started on any arrested patient with even a remote possibility of success. Sodium bicarbonate may be considered in hemodynamically unstable patients. Any patient with a significant episode, including those asymptomatic at the scene, should be transported to the hospital for evaluation.

In-water CPR is generally ineffective and dangerous for the rescuer and should not be attempted unless a firm, stable surface is available. Human near-drowning victims aspirate small quantities of water; postural drainage or the abdominal thrust (Heimlich maneuver) is of unproven efficacy in removing water from the lungs or improving oxygenation. No drainage procedure appears to significantly affect oxygenation in experimental preparations. Field limitations to postural drainage include the danger of aspiration from an uncontrolled airway, interruption of ventilation or CPR, the danger of spinal injury, and the possibility of aggravating other undiagnosed injuries. An appropriate maneuver for airway obstruction should be used only if ventilation is obstructed.

Hospital Care

Hospital evaluation and care of drowning victims emphasizes initial resuscitation, treatment of respiratory failure, and evaluation of associated injuries (Table 193-2).

Clear spine
Laboratory studies:
    CBC, electrolytes, glucose, PT/PTT, urinalysis
    Arterial blood gases, pulse oximetry
    Chest x-ray
    Electrocardiogram
Pulmonary support:
    Supplemental oxygen on all patients
    High-flow O₂ as needed
    Intubation and positive pressure (PEEP, CPAP)
Nasogastric tube
Foley catheter
Monitor:
    Oxygenation
    Acid-base balance
    Temperature
    Volume status
Evaluate and treat:
    Associated injuries
    Specific conditions: hypovolemia, hypothermia, hypoglycemia, etc.

Abbreviations: PT = prothrombin time; PTT = partial thromboplastin time.

TABLE 193-2 Hospital Care of Near-Drowning Victims

Although patient survival in a persistent vegetative state is a concern, substantial numbers of patients, predominantly children, requiring CPR on emergency department arrival have survived with good outcomes, and physicians should err on the side of providing resuscitation. [4,5 and 6] The physician should gather sufficient history to allow an estimate of prognosis and gauge the patient's response to resuscitative efforts.

On the victim's arrival in the emergency department, adequate oxygenation should be ensured, the integrity of the patient's spine should be confirmed if necessary, and associated injuries should be sought. Pulmonary insufficiency may be indicated by dyspnea, tachypnea, or use of accessory muscles of respiration. Physical examination may reveal wheezing, rales, or rhonchi, although the chest may be normal to auscultation after aspiration.

All patients should receive supplemental oxygen during evaluation, and those with more than mild symptoms should be on 100% oxygen until adequate oxygenation is documented. If high-flow oxygen (40% to 50%) cannot maintain the arterial P$_{O_2}$ greater than 60 mmHg in adults or 80 mmHg in children, the patient should be intubated and mechanical ventilation used.

Intubated patients generally require positive end-expiratory pressure (PEEP) or continuous positive airway pressure (CPAP). Occasionally, a patient may require only increased oxygenation and CPAP without mechanical ventilation. Only patients who are alert and unlikely to vomit are candidates for mask or nasal CPAP or other noninvasive ventilation.

All patients need an accurate temperature that reflects core temperature, since resuscitation may be impossible until hypothermia is treated. Hypothermia can immobilize a swimmer, resulting in drowning, may cause ventricular fibrillation, or may be responsible for a variety of adverse metabolic effects. Hypothermic patients have body temperatures less than 30°C (86°F), after submersion in water less than 20°C (68°F). Severe hypothermia often indicates prolonged submersion and is a bad prognostic sign. Despite this, individuals have survived after prolonged submersion (more than 60 min) in cold or icy water. Aspiration of cold water in concert with intact circulation for several minutes rapidly cools the body to low temperatures. [7] The nature of the protective effect of hypothermia is unclear. It is most likely generalized slowing of metabolism, but preferential shunting of blood to the brain, heart, and lungs (diving reflex) may play some role. Hypothermic near-drowning victims in whom resuscitation is attempted should be warmed to at least 30 to 32.5°C (86°–90.5°F) before resuscitation efforts are abandoned. In selected cases of submersion in extremely cold water, extracorporeal rewarming may be helpful. [8]

Appropriate laboratory data should be obtained (see Table 193-2). Direct measurement of oxygenation and acid-base status by arterial blood gas analysis and pulse oximetry guide pulmonary therapy and the need for sodium bicarbonate.

Roentgenograms of the chest may be normal after a significant near-drowning incident or may show generalized pulmonary edema (Fig. 193-1), perihilar infiltrates, or other patterns. Chest films do not necessarily correlate with arterial Pa$_{O_2}$, making direct measurement of oxygen saturation important, although many patients with significantly abnormal films will require intubation.

FIG. 193-1. Chest roentgenogram of near-drowning patient demonstrating diffuse noncardiogenic pulmonary edema.

Standard treatment of hypothermia, hypotension and hypovolemia, bronchospasm, electrolyte imbalance (including hypoglycemia), seizures, and arrhythmias should be undertaken. Some patients may need fluid resuscitation in the face of noncardiogenic pulmonary edema. To avoid inducing arrhythmias, central venous catheters, if used, should not enter the heart in hypothermic patients. A nasogastric tube will empty the stomach and help prevent vomiting, and a Foley catheter will help to monitor urine output. Neither antibiotics nor steroids alter the course of aspiration pneumonia or pulmonary edema in drowning, and they should not be given prophylactically.

PROGNOSIS AND CEREBRAL RESUSCITATION

Statistics on survival and the incidence of severe neurologic deficits after near drowning are difficult to interpret. They vary with regard to definitions, patient age, water temperature, treatment regimens, and many other variables.[9,10 and 11] Almost all patients who are alert and fully conscious will survive without sequelae, as will the vast majority of victims who are obtunded but have a purposeful response to pain. As many as 24 percent of children admitted to intensive care units who required full CPR and had an initial Glasgow Coma Scale score of 3 in the referring emergency department have survived with intact neurologic function.[5] CPR, requiring cardiotonic medications, or unreactive pupils all indicate a poor prognosis, but no one indicator or scoring system fully differentiates survivors with acceptable neurologic outcome from children who die. Quan and Kinder have suggested resuscitation is indicated if the time of submersion is likely to be 10 min or less, and that patients not responding to advanced life support measures within 25 min will not live.[12]

Life support can be withdrawn in the intensive care unit once the patient's condition is stable, the likely outcome more clear, and the family has had time to consider treatment options.[6]

Outcome depends primarily on the duration of submersion but also on the amount of time until resuscitative efforts begin.

DISPOSITION

Most older reports on drowning recommend admission and monitoring of all near-drowning victims. This recommendation arose from descriptions of "secondary drowning" in which 2 to 25 percent of near-drowning patients deteriorated significantly or died after a seemingly successful rescue or resuscitation. Most of the patients in these reports, however, simply had pulmonary insufficiency that progressed and symptoms or signs that today would be discovered easily by an adequate evaluation.[13,14] The decision of whom to admit must focus on those at risk for pulmonary insufficiency or other complications.

Patients at risk have undergone a "significant" episode and display symptoms such as coughing, dyspnea tachypnea, or have historical factors such as unconsciousness in the water. Occasionally, patients who suffered transient severe hypoxia or who have underlying cardiovascular disease will fall into the same group.

The physician's approach should depend on the patient's symptoms and the results of screening examinations. For convenience, patients may be separated into four groups, although one should take particular care in evaluating young children. One group will have no evidence of significant submersion and may be discharged quickly. Chest roentgenograms and arterial blood gas determinations are unnecessary in the face of a benign history, but the studies or pulse oximetry may lend weight to the decision to discharge.

A second group will be asymptomatic or have mild symptoms after a significant episode. They can frequently be observed in the emergency department for several hours and then discharged if their social situation allows adequate follow-up. The third group will have mild to moderate hypoxemia corrected by oxygen therapy. These patients are admitted and then discharged when the hypoxemia resolves if no complications ensue.

The final group is composed of patients who require intubation and mechanical ventilation whose prognosis usually depends more on their neurologic status than on pulmonary injury, unless they develop serious aspiration pneumonia or progressive, irreversible lung injury.

194 THERMAL BURNS

Lawrence R. Schwartz
Chenicheri Balakrishnan

EPIDEMIOLOGY

Approximately 1.25 million patients present to the emergency department (ED) with burn injuries in the United States each year and about 50,000 are hospitalized. [1] The majority of burn patients are treated and discharged from the ED to be followed as outpatients.

The risk of burns is highest in the 18- to 35-year-old age group. There is a male to female ratio of 2:1 for both injury and death. There is higher incidence of scalds from hot liquids in children 1 to 5 years of age and in the elderly. The death rate in patients over 65 years of age is much higher than that in the overall burn population.[2]

Significant strides have been made in the overall care of the burn patient during the last two decades. [3] These advances are reflected in a decreased mortality rate among patients with major thermal injury; only about 4 percent of those treated in specialized burn treatment centers die from their injuries or associated complications.[4] The incidence of inpatient admissions has decreased over time owing to improvements in outpatient care both in the ED and in the burn unit. [1,3]

PATHOPHYSIOLOGY

Skin consists of two layers: the epidermis and dermis. In the very young and the elderly, the skin thickness is less than that of a person in the prime of life. Skin thickness also varies significantly throughout the body. The skin is very thick in the palm of the hand and the sole of the foot. The upper part of the back is thicker than other parts of the body. Thus exposure to same temperature for same duration will lead to different depths of injury in different parts of the body.

Skin functions as a semipermeable barrier to evaporative water loss. Other functions of the skin include protection from the adversities of the environment, control of body temperature, sensation, and excretion. Partial-thickness thermal injury can result in disruption of the barrier function and contribute to free water deficits. The effect may be significant in moderate to large burns.

Thermal injury results in a spectrum of local and systemic homeostatic derangements that contribute to burn shock. These include disruption of normal cell membrane function, hormonal alterations, changes in tissue acid-base balance, hemodynamic changes, and hematologic derangement. [5]

Fluid and electrolyte abnormalities seen in burn shock are largely the result of alterations of cell membrane potentials with intracellular flux of water and sodium and extracellular migration of potassium secondary to dysfunction of the sodium pump. In burns of greater than 60 percent of body surface area, depression of cardiac output is frequently observed with lack of response to aggressive volume resuscitation. Although disputed by others, Baxter and Shires have explained this phenomenon on the basis of circulating myocardial depressants. [6] Also, there is increased systemic vascular resistance. A significant metabolic acidosis may be present in early stages of a large burn injury.

Hematologic derangements associated with massive thermal injury vary from an increase in hematocrit with increased blood viscosity during the early phase followed by anemia from erythrocyte extravasation and destruction. However, transfusion is infrequently required for patients with isolated burn injury. [3]

Thermal injury is a progressive injury. Local effects of thermal injury include liberation of vasoactive substances, disruption of cellular function, and edema formation. The systemic response consists of responses by the neurohormonal axis and profound alterations of all organ systems. Substances implicated in these events are histamine, kinin, serotonin, arachidonic acid metabolites, and free oxygen radicals. These substances exert their primary effects at the local level and cause progression of the burn wound. Preservation of the blood supply by decreasing the inflammatory response has been attempted with pharmacologic manipulations using drugs such as nonsteroidal anti-inflammatories. [5]

Although many factors may influence prognosis, the severity of the burn, presence of inhalation injury, associated injuries, patient's age, preexisting disease, and acute organ system failure are most important.[2] The burn's size and depth are functions of the burning agent, its temperature, and the duration of exposure. Cell damage occurs at a temperature greater than 45°C (113°F) owing to denaturation of cellular protein. The burn wound is described as having three zones: the zone of coagulation, where tissue is irreversibly destroyed with thrombosis of blood vessels; the zone of stasis, where there is stagnation of the microcirculation; and the zone of hyperemia, where there is increased blood flow. The zone of stasis can become progressively more hypoxemic and ischemic if resuscitation is not adequate. In the zone of hyperemia, there is minimal damage to the cells and spontaneous recovery is likely.

CLINICAL FEATURES

Burn Size

The size of a burn injury is quantified as the percentage of body surface area (BSA) involved. [7] One method of calculating the percentage of BSA burned is to use the rule of nines (Fig. 194-1). This method divides the body into segments that are approximately 9 percent or multiples of 9 percent, with the perineum forming the remaining 1 percent. In infants and children, this method must be modified because of their larger heads and smaller legs.
FIG. 194-1. Rule of nines to estimate percentage of burn.

Another method is based on the fact that the area of the back of a patient's hand is approximately 1 percent BSA. The number of "hands" that equal the area of the burn can approximate the percentage of BSA burned.

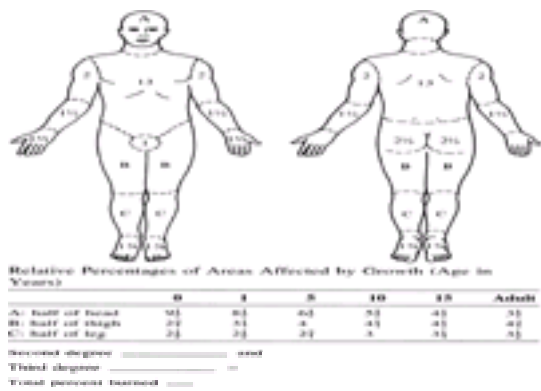
A more precise estimation of the percentage of BSA burned is obtained by using a Lund and Browder burn diagram (Fig. 194-2). This allows for accurate determination of the size and depth. These charts are age-adjusted, hence allowing for changes in children at different ages.


FIG. 194-2. Lund and Browder diagram to estimate percentage of pediatric burn.

Experienced burn-care nurses and physicians are reliable in estimating burn size regardless of the method used. [8] However, it is common for inexperienced individuals to estimate burn size incorrectly when patients are first assessed in the ED.

Burn Depth

The depth of a burn has been historically described in degrees: first, second and third. [9] However, a classification of burn depth according to the need for surgical intervention has become the accepted approach in burn treatment centers: superficial partial-thickness, deep partial-thickness, and full-thickness burns. [3] Determination of burn depth requires judgment, using the commonly seen clinical features; there is no objective method of measuring burn depth, and burn wound biopsy has not become routine practice.

A first-degree burn involves only the epidermal layer of skin. Sunburn is usually given as a common example of a first-degree burn, although sunburn is caused by ultraviolet light instead of thermal injury. [9] The burned skin is red, painful, and tender without blister formation. First-degree burns usually heal in about 7 days without scarring and require only symptomatic treatment.

Second-degree burns extend into the dermis and are divided into superficial partial-thickness and deep partial-thickness burns.

In superficial partial-thickness burns, the epidermis and the superficial (papillary layer) dermis are injured. The deeper layers of the dermis, hair follicles, and sweat and sebaceous glands are spared. Superficial partial-thickness burns are often caused by hot water. There is blistering of the skin and the exposed dermis is red and moist at the blister's base. These burns are very painful to touch. There is good perfusion of the dermis with intact capillary refill. Superficial partial-thickness burns heal in 14 to 21 days, scarring is usually minimal, and there is full return of function.

Deep partial-thickness burns extend into the deep (reticular layer) of the dermis. There is damage to hair follicles as well as sweat and sebaceous glands, but their deeper portions usually survive. Hot liquids, steam, grease, or flame usually causes deep partial-thickness burns. The skin may be blistered and the exposed dermis is pale white to yellow in color. The burned area does not blanch; it has absent capillary refill and absent pain sensation. Deep partial-thickness burns may be difficult to distinguish from full-thickness burns. Healing takes 3 weeks to 2 months. Scarring is common; it is related to the depth of the dermal injury. Surgical debridement and skin grafting may be necessary to obtain maximum function.

Third-degree or full-thickness burns involve the entire thickness of the skin. All epidermal and dermal structures are destroyed. Full-thickness burns are usually caused by flame, hot oil, steam, and contact with hot objects. The skin is charred, pale, painless, and leathery. These injuries will not heal spontaneously, as all dermal elements are destroyed. Surgical repair and skin grafting are necessary and there will be significant scarring.

Fourth-degree burns are those that extend through the skin to the subcutaneous fat, muscle, and even bone. These are devastating, life-threatening injuries. Amputation or extensive reconstruction is required.

SPECIFIC ISSUES

The American Burn Association has devised a classification of burns, dividing them into major, moderate, and minor. [7] Criteria for burn unit transfer are listed in Table 194-1. Children younger than 10 years of age and adults above age 50 are considered high-risk patients. Patients with underlying medical illnesses such as heart disease, diabetes, or chronic pulmonary problems are considered poor-risk.

1. Partial- or full-thickness burns involving greater than 10 percent of body surface area (BSA) in patients under 10 or over 50 years of age.
2. Partial- or full-thickness burns of greater than 20 percent of BSA in other age groups.
3. Partial- or full-thickness burns with the threat of functional or cosmetic impairment that involve face, hands, feet, genitalia, perineum, or major joints.
4. Full-thickness burns of greater than 5 percent of BSA in any age group.
5. Electrical burns, including lightning injury.
6. Chemical burns with the threat of functional or cosmetic importance.
7. Inhalation injury with burns.
8. Circumferential burns of the extremities or chest.
9. Burn injury in patients with preexisting medical disorders that could complicate management, prolong recovery, or affect mortality.
10. Any burn patient with concomitant trauma, such as fractures.
11. Hospitals without qualified personnel or equipment for the care of children should transfer burned children to a burn center with these capabilities.

TABLE 194-1   American Burn Association Criteria for Transfer to a Burn Unit

Major Burns

Major burns are defined as (1) partial-thickness burns greater than 25 percent BSA in the 10- to 50-year-old age group; (2) partial-thickness burns greater than 20 percent BSA in children under 10 or adults over 50; (3) full-thickness burns of greater than 10 percent BSA in anyone; (4) burns involving the hands, face, feet, or perineum; (5) burns crossing major joints; (6) circumferential burns of an extremity; (7) burns complicated by inhalation injury; (8) electrical burns; (9) burns complicated by fractures or other trauma; (10) burns in infants and the elderly; and (11) and burns in poor-risk patients.

Moderate Burns

Moderate burns are (1) partial-thickness burns of 15 to 25 percent BSA in the 10- to 50-year-old age group; (2) partial-thickness burns of 10 to 20 percent BSA in children under 10 or adults over 50; and (3) full-thickness burns of less than 10 percent BSA in anyone. Partial-thickness burns of the hands, face, feet, or perineum or circumferential burns of an extremity are excluded.

Minor Burns

Minor burns include (1) partial-thickness burn of less than 15 percent BSA in the 10- to 50-year-old age group; (2) partial-thickness burn of less than 10 percent BSA in children under 10 or adults over 50; and (3) full-thickness burns of less than 2 percent BSA in anyone without associated injuries. These burns imply outpatient treatment.

Inhalation Injury

With improvements in the treatment of burn shock and sepsis, inhalation injury has emerged as the main cause of mortality in the burn patient. [2,4] Despite advances in respiratory support, smoke inhalation injury significantly increases mortality; half of all fire-related deaths are due to smoke inhalation. Inhalation injuries are associated with closed-space fires, and conditions that decrease mentation—such as overdose, alcohol intoxication, drug abuse, and head injury. Exposure to smoke includes exposure to heat, particulate matter, and toxic gases. [11]

There is general consensus that direct thermal injury is limited to the upper airway. Thermal injuries below the vocal cords occur only in cases of steam inhalation.

Smoke contains particulate matter, usually less than 0.5 μm in size, which is formed from incomplete combustion of organic material. Small particles may reach the terminal bronchioles, where they can initiate an inflammatory reaction leading to bronchospasm and edema.

Toxic inhalants are divided into three large groups: tissue asphyxiants, pulmonary irritants, and systemic toxins. The two major tissue asphyxiants are carbon monoxide and hydrogen cyanide.

Carbon monoxide poisoning is a well-known consequence of smoke inhalation injury. [11] Severe carbon monoxide poisoning will produce brain hypoxia and coma. Comatose patients lose airway protective mechanisms, which may result in aspiration, thus further exacerbating the pulmonary injury from smoke inhalation. All patients with suspected carbon monoxide exposure should be started on 100% oxygen by non-rebreathing mask. Further details of treatment of carbon dioxide poisoning are discussed in Chap. 198.

Hydrogen cyanide is formed when nitrogen-containing polymers—such as wool, silk, polyurethane, or vinyl—are burned. Cyanide binds to and disrupts mitochrondrial oxidative phosphorylation, leading to profound tissue hypoxia. Further discussion of management of cyanide poisoning is discussed in Chap. 182.

Inhalation injury damages endothelial cells, produces mucosal edema of the small airways, and decreases alveolar surfactant activity leading to bronchospasm, airflow obstruction, and atelectasis. With time, tracheal and bronchial epithelial sloughing occurs. As these patients are resuscitated with large quantities of fluid for their burn injury, pulmonary edema develops. Hence, the potential for adult respiratory distress syndrome (ARDS) from inhalation injury should be recognized and careful fluid management instituted with emphasis on hemodynamic monitoring.

Bronchospasm may occur early, but lower airway edema is usually not clinically evident for up to 24 h. Upper airway edema, however, can occur rapidly. Although the injury is mainly to the airways, pulmonary vascular changes do occur. There is no single method capable of demonstrating the extent of inhalation injury. Diagnosis of smoke inhalation is made from the history of a fire in an enclosed space and physical signs that include facial burns, singed nasal hair, soot in the mouth or nose, hoarseness, carbonaceous sputum, and expiratory wheezing. Carboxyhemoglobin levels are useful to document prolonged exposure within an enclosed space with incomplete combustion. The chest radiograph may be normal initially; bronchoscopy and radionuclide scanning are useful in determining the full extent of injury.

Treatment of suspected inhalation injury should be instituted prior to definitive diagnosis. Humidified oxygen (100%) should be administered by mask. Arterial blood gases including carboxyhemoglobin levels should be obtained. In suspected cases, control of upper airway is achieved by prompt endotracheal intubation. Indications for intubation include (1) full-thickness burns of the face or perioral region, (2) circumferential neck burns, (3) acute respiratory distress, (4) progressive hoarseness or air hunger, (5) respiratory depression or altered mental status, and (6) supraglottic edema and inflammation on bronchoscopy.

TREATMENT

The management of patients with *moderate to major* burns can be divided into three phases: (1) prehospital care, (2) emergency department resuscitation and stabilization, and (3) admission or transfer to a specialized burn center.

Prehospital Care

The following principles are the basis of prehospital care for burn patients: (1) stop the burning process, (2) establish the airway, (3) initiate fluid resuscitation, (4) relieve pain, (5) protect the burn wound, and (6) transport the patient to an appropriate facility.

On-site assessment of a burned patient is divided into primary and secondary surveys. In the primary survey, immediate life-threatening conditions are quickly identified and treated. Initial management of the burned patient should be the same as for any other trauma patient, with emphasis on airway, breathing, circulation, and cervical spine immobilization. During the secondary survey, a thorough head-to-toe evaluation is carried out.

The patient must be removed from the burning process and burning clothing must be immediately removed and the remainder of the clothing removed after the airway, breathing, and circulation (ABCs) are secured. All rings, watches, jewelry, and belts should be removed, as they can retain heat and produce a tourniquet-like effect on the extremity causing ischemia. A 100% oxygen mask should be applied. Thought should be given to an airway that has potential to swell rapidly, even though initial assessment may be acceptable. Prophylactic intubation should be considered in burns about the face sustained in a closed-space fire. Intravenous fluids are started with isotonic crystalloid: usually Ringer's lactate solution. The patient should be covered with clean sheets to protect the wound. Early cooling can reduce the depth of burn and reduce pain, but uncontrolled cooling will result in hypothermia. Analgesia can be given upon direction of the on-line medical control physician. The patient should be transported to the nearest hospital capable of caring for a burn patient, or, if none is available, the nearest hospital for stabilization.

Emergency Department Management

Upon arrival at the ED, a directed history should be obtained from the patient and emergency medical services (EMS) personnel. What was the burning agent? Were

chemicals involved? What was the duration of exposure? Was the fire in an open or enclosed space? If the fire was in an enclosed area, what substances were burned? Was there an explosion causing the patient to suffer a blast injury? Was there any contact with electricity? Was there any other trauma or loss of consciousness? A general history including past medical and surgical illnesses, chronic disease, allergies, medications, and tetanus immunization status should be obtained from the patient or family.

The ABCs should be reassessed and stabilized. The adequacy of or need for cervical immobilization should also be reassessed. The patient should be examined for signs of inhalation injury, evidence of facial burn, carbonaceous sputum, singed nasal hair, and soot in the mouth. If there is any evidence of airway compromise with swelling of the neck, burns inside the mouth, or wheezing, endotracheal intubation should be performed.

The adequacy of circulation is initially assessed by the blood pressure, pulse rate, capillary refill time, mental status, and urinary output. Intravenous lines can be inserted though a burned area if required and resuscitation started according to the burn resuscitation formula.

During the secondary examination, the patient needs a head-to-toe assessment. The eyes should be examined for corneal burns. The size of the burn and its depth should be estimated and recorded. Patients with a greater than 20 percent partial-thickness burn routinely require a nasogastric tube, as ileus frequently occurs. A Foley catheter should be inserted to measure urinary output and prevent urinary retention in patients with perineal burns.

Routine laboratory tests including a CBC, electrolytes, BUN, creatinine, and glucose should be obtained. In patients with suspected inhalation injury, arterial blood gases, carboxyhemoglobin, chest radiograph, and ECG should be obtained. Fiberoptic bronchoscopy is indicated where there is a suspicion of inhalation injury and in intubated patients, as this is both diagnostic and therapeutic in clearing the airways. A urinalysis, urine for mycoglobin and creatine kinase (CK) levels are obtained along with an electrocardiogram (ECG) in patients with electrical injury to assess muscle or cardiac injury. Additional radiographs should be taken as indicated for other suspected trauma.

The burn shock resuscitation formulas in use today are based on laboratory studies of burn shock and resuscitation. The purpose of these formulas is to provide a *guide* for fluid resuscitation. The Baxter or Parkland formula is probably the most widely used thermal injury resuscitation regimen in North America. [3] This formula calls for 4 mL of lactated Ringer's solution multiplied by the percent BSA burned multiplied by body weight in kilograms. Half of this total is given in the first 8 h after injury and the rest during the next 16 h (Table 194-2). The amounts may be large and hemodynamic monitoring techniques are now commonly used to protect against inadvertent volume overload.

Adults
Lactated Ringer's 4 mL × weight (kg) × % BSA over initial 24 h
Half over the first 8 h from the time of burn
Other half over the subsequent 16 h
Example 70 kg adult with 40% burn
4 mL × 70 kg × 40 = 11200 mL over 24 h

Children
Lactated Ringer's 3 mL × weight (kg) × % BSA over initial 24 h plus
  maintenance
Half over the first 8 h from the time of burn
Other half over the subsequent 16 h

TABLE 194-2   Parkland Formula

Electrical injuries, incineration burns, and associated crush injuries may produce rhabdomyolysis and myoglobinuria, leading to renal failure. See Chap. 271 for further discussion.

Thermal injury in the presence of concomitant multisystem trauma generally requires fluids in excess of calculated needs. Inhalation injuries have been shown to increase total fluid needs. Burn patients with preexisting cardiac or pulmonary disease require much greater attention to fluid management. Fluid resuscitation should be monitored closely by frequent assessment of the patient's vital signs, signs of cerebral and skin perfusion, and urinary output as well as hemodynamic monitoring. The urinary output should be 0.5 to 1.0 mL/kg per hour.

There are several methods of calculating fluid resuscitation for infants and children. One method is to use the Parkland formula and modify it to maintain urinary output of 1 mL/kg per hour. Alternatively, a pediatric maintenance rate for 24 h can be calculated plus an additional amount of 2 to 4 mL/kg multiplied by percent of BSA burned, with the entire amount infused over the first 24 h. In children weighing less than 25 kg, a urine output of 1.0 ml/kg per hour is necessary.

It is possible for patients with major burns to receive excessive intravenous fluids during the prehospital and ED phases, particularly if two large-bore peripheral catheters are in place with fluid infusing wide open. Total fluids infused should be documented and titrated to the patient's response.

Two additions or modifications to isotonic crystalloid resuscitation have been studied—adjuvant colloid and hypertonic saline. However, neither improves patient outcome. Adjuvant colloid given along with isotonic crystalloid resuscitation has not proven beneficial and is associated with increased accumulation of water in the lungs and decreased glomerular filtration rate. [12] Hypertonic saline has produced an increased rate of renal failure and death. [13]

Routine tetanus toxoid prophylaxis should be administered based on the patient's immunization history. Tetanus immune globulin should be administered in patients without a history of primary immunization. The use of systemic prophylactic antibiotics is inappropriate.

Treatment of inhalation injury includes humidified oxygen, intubation and ventilation, bronchodilators, pulmonary toilet, and hyperbaric oxygen for severe carbon monoxide poisoning.

Burns to a pregnant patient are associated with significant morbidity to mother and child. The outcome of the pregnancy is determined by the extent of mother's injury; spontaneous termination of pregnancy is the common outcome in large-BSA burns. Fluid requirements may exceed the estimated formula. Fetal monitoring and early consultation with the obstetrician is mandatory.

Wound Care

After evaluation and resuscitation, the burn wounds are addressed. [14] Initially in the ED, the wound is best covered with a clean, dry sheet. Later, small burns can be covered with a moist saline-soaked dressing while the patient is awaiting admission or transfer. The soothing effect of cooling on burns is most likely due to local vasoconstriction. Studies have shown that cooling stabilizes mast cells and reduces histamine release, kinin formation, and thromboxane B_2 production. In large burns, sterile drapes are better, as saline-soaked dressings applied to a large area can cause hypothermia. The admitting service should be consulted early. The use of antiseptic dressing should be avoided in the ED as the admitting service will need to assess the wound. If the patient is going to be transferred, the accepting burn unit should be contacted for specific instructions regarding burn care. Do not delay transfer for debridement of the wound. The transferring facility should utilize the regional burn center's treatment protocol.

Patients with circumferential deep burns of the limbs may develop compromise of the distal circulation. Distal pulses need to be monitored closely; a Doppler flow probe may be very helpful. If there is compromise to the circulation, escharotomy will be needed. The eschar needs to be incised on the midlateral side of the limb, allowing the fat to bulge through. This may be extended to the hand and fingers (Fig. 194-3). Escharotomy may provoke substantial soft tissue bleeding, often calling for electrocautery.

FIG. 194-3. Escharotomy of the hand.

If there are circumferential burns of the chest and neck, the eschar may cause mechanical restriction to ventilation. An escharotomy of the chest wall needs to be done to allow adequate ventilation. Incisions need to be made at the anterior axillary line from the level of the second rib to the level of the twelfth rib. These two incisions should be joined transversely so that the chest wall can expand (Fig. 194-4).

FIG. 194-4. Escharotomy of the chest wall.

Pain Control

All burns are painful and superficial partial-thickness burns are most painful. Burn injury not only makes an injured area and surrounding tissue more painful but also causes hyperalgesia, chiefly due to the A fibers. Pain management should not be neglected.

During the emergency phase, the preferred route for most medication is intravenous, because of the potential problems with absorption from the muscle and gastrointestinal tract related to decreased perfusion. Morphine is the most widely used drug for relief of pain, and relatively large doses may be required. Anxiolytic agents should be used as adjuvants in pain management.

During the acute phase and for ambulatory patients treated in the ED, narcotic analgesics are required for procedural pain. Oral analgesics like codeine, hydrocodone, oxycodone, or nonsteroidal anti-inflammatory drugs may be used for the background pain.

CARE OF MINOR BURNS IN THE EMERGENCY DEPARTMENT

The American Burn Association has defined minor burns that can be treated on an outpatient basis. [7] To qualify as a minor burn, the injury should be isolated and not involve hands, face, feet, or perineum. The burn should not cross major joints or be circumferential. In treating a minor burn, the patient's social and medical situation should be considered. An elderly patient or one with medical problems is best treated as an inpatient even though the burn involves less than 10 percent of the BSA. The patient's reliability should be considered as an important factor for outpatient treatment. Care of minor burns requires coordination between the ED and the referral specialist who will see the patient in follow-up. [14]

As burns are painful, appropriate analgesia is required. After appropriate analgesia, the burn wound is cleaned with mild soap and water or dilute antiseptic solution. Blisters may be left intact or drained, or the overlying epithelium may be debrided; the decision depends on size and location. Large blisters or those over very mobile joints should be debrided. Small blisters on nonmobile areas should be left intact. Where compliance is questionable, patients should have the blisters debrided, because an intact or spontaneously collapsed blister may serve as a nidus for wound infection. The patient's tetanus immunization status should be assessed and tetanus toxoid and/or immunoglobulin should be administered as needed.

Topical antimicrobials have an important role in reducing bacterial colonization and enhancing the rate of healing in burns. [3,15] A wide variety of topical agents are commonly used for minor burns. The most common is 1% silver sulfadiazine because it is easy to apply and has relatively little toxicity. The usual practice is to apply a thin layer of silver sulfadiazine cream to the burn and then cover it with gauze dressing. Silver sulfadiazine should not be used in patients with sulfa allergy or on the face because of potential staining. Alternative topical agents to use in these circumstances are bacitracin or triple-antibiotic (neomycin, polymixin B, and bacitracin zinc) ointments. Although 11.1% mefanide acetate and 2% furacin ointments are available for topical use, these should be used with caution if applied to large burns in an outpatient setting. Mafenide is a carbonic anhydrase inhibitor and can cause metabolic acidosis. Furacin is in a polyethylene glycol vehicle which can be toxic if absorbed in patients with compromised renal function. Mafenide penetrates the eschar well and has utility in treating patients with invasive infections. Dressings are ideally changed twice daily as long as the wounds continue to weep; then they are changed daily until the burn is healed.

Synthetic occlusive dressing is an alternative method of managing partial-thickness burns in outpatients. The wounds are cleansed and debrided prior to application of these dressings (e.g., Biobrane, Dow Hickan Pharmaceuticals; Tegaderm, 3M Health Care). This method is most successful for clean burns on flat surfaces. The goal is to have the dressing adherent to the wound so that it acts as artificial skin. Adherence is important, as most of the bacteria causing infection produce fibrinolytic agents. Wounds are checked at 24 to 48 h for adherence and the dressing is left in place until spontaneous separation occurs.

Patients must be given discharge instructions that explain home burn care and symptoms and signs of infection. The patient should be advised to return to the ED immediately if there are any signs or symptoms of infection. Extremity burns should be elevated for 24 to 48 h to prevent edema. All burn wounds should be reassessed at 24 h for depth and extent of burn. The follow-up visit schedule should be clearly explained and analgesics prescribed. Deep partial-thickness, full-thickness, and mixed-thickness burns should be referred to a plastic surgeon or burn-care specialist in 2 to 4 days for reevaluation and consideration of skin grafting.

195 CHEMICAL BURNS

Fred P. Harchelroad, Jr.
J. Michael Ballester

Chemical burns occur in the home, industrial, agriculture, and military settings, school and research laboratories, and as a result of civilian assaults, hobby accidents, and other accidents. Chemical burns also occur as a result of innocent application of products for medical purposes and for hair, skin, and nail care.

More than 25,000 products are capable of producing chemical burns. Both occupational exposure and contact with numerous chemicals during daily life contribute to the large number of chemical injuries to the skin. There are no good epidemiologic data on the incidence of toxic cutaneous exposure in the nonoccupational setting. However, about 40 percent of all occupationally related diseases reported concern the skin, and about 25 percent of these are due to chemical burns.

Common household chemical burns are caused by lye (drain cleaners, paint removers, urine sugar reagent test tablets), phenols (deodorizers, sanitizers, disinfectants), sodium hypochlorite (disinfectants, bleaches), methacrylic acid (artificial nail products), and sulfuric acid (toilet bowl cleaners). In industries, chemicals are used for cleaning, tanning, curing, extracting, preserving, soldering, and other functions. The most commonly used industrial acids are tungstic, picric, sulfosalicylic, tannic, formic, sulfuric, acetic, cresylic, trichloroacetic, chromic, hydrochloric, and hydrofluoric. Widely used alkalis are the hydroxide salts of sodium, potassium, ammonium, lithium, barium, and calcium. White phosphorus used in munitions was the most common cause of chemical burns to military personnel during times of armed conflict in the 1960s. White phosphorus is also found in rodenticides, pesticides, and fireworks.

The body sites most often burned by chemicals are the face, eyes, and extremities. Fewer than 5 percent of patients admitted to major burn centers suffer from chemical burns. In general, chemical burn average sizes are small, and the mortality rate is lower than for thermal burns, but wound healing and hospital stay times are higher.

PATHOPHYSIOLOGY

The skin interfaces with the external environment and constitutes a barrier and transition zone between the internal and external milieus. The outer stratum corneum layer of the skin functions as an excellent barrier against certain chemical agents, whereas others may penetrate readily. The skin contains three main layers: an outer layer of epithelial tissue (epidermis), a loose connective tissue layer (dermis), and a variable-thickness inner layer containing adipose and connective tissue (hypodermis or panniculus adiposus).

Chemicals can produce burns, dermatitis, allergic reaction, thermal injury, or systemic toxicity. Pathophysiologically, burns produced by all chemicals are similar.[1] The skin has a limited variety of toxic responses, corresponding to the major patterns of possible structural or functional changes. Toxic reactions are described mainly on the basis of morphologic rather than functional responses.[2] There are morphologic, physiologic, and biochemical protective mechanisms and elements in the skin which include the epidermal barrier, eccrine sweating, phagocytic cells, metabolic detoxification, immunologic processes, and melanin pigmentation. However, these vary on a phenotypic basis and may be affected by systemic or local disease.

Skin damage by chemicals may demonstrate the classic manifestations of thermal injury (erythema, blistering, or full-thickness loss); however, an acute injury may be deceptively mild, only to be followed by extensive skin damage and systemic toxicity. A superficial (first-degree) burn causes capillary and arterial dilatation. Initially, this involves only the superficial vessels, but then extends to the deeper subcutaneous vessels by both direct and reflex action. Tissue hyperemia and congestion results in symptoms of itching, burning, or pain. More extensive inflammatory reactions result in an outpouring of fluid into the extracellular space, causing edema and vesicle or bulla formation characteristic of partial-thickness (second-degree) burns. Continued chemical damage through the dermis or into the hypodermis results in a full-thickness (third-degree) burn. Tissue damage is determined by

- Strength/concentration of the agent
- Manner of contact
- Quantity of agent
- Duration of contact
- Mechanism of action
- Extent of penetration

Factors enhancing percutaneous absorption of chemical are body site (areas of thin skin, i.e., genitalia, face; chemical contact between skinfolds; amount of surface area exposed); integrity of skin (traumatized skin, elderly skin, decreased lipid, dehydration, inflammation); nature of the chemical (lipid solubility, pH, concentration); and occlusion (garments, occlusive dressings).

The majority of chemical burns are caused by acids or alkalis. At similar volumes and manner of contact, alkalis usually produce far more tissue damage than acids. Acids in general cause coagulation necrosis with protein precipitation. Tough leathery eschar may form with development of underlying ulcers. The eschar limits spread of the agent. Heat may be released during reaction of acid with skin. Alkalis produce liquefaction necrosis with loosening of material that allows deeper penetration of the unattached chemical into tissue. Not all chemicals causing burns can be considered acid or alkali. A useful classification by Jelenko groups chemicals by the manner in which they damage protein:[3]

1. Oxidizing agents: Damage is produced when a chemical becomes oxidized in contact with tissue. Often a toxic moiety is released during this reaction.
2. Corrosives: Extensive protein denaturation is produced, resulting in soft eschar and shallow, indolent ulcers.
3. Reducing agents: Protein denaturation is produced by binding of free electrons in tissue protein.
4. Desiccants: Severe cellular dehydration is produced, and thermal injury occurs due to exothermic reaction.
5. Vesicant: Blisters are produced, tissue amines are liberated, local ischemia and anoxic tissue damage and pandermic inflammation occurs.
6. Protoplasmic poisons: Protein is denatured by salt formation or by metabolic competition/inhibition (i.e., binding calcium or other inorganic ions necessary for tissue viability and function).

GENERAL APPROACH

The goal of treatment is to minimize any area of irreversible injury and maximize salvage of the zone of reversible damage. With few exceptions, hydrotherapy is the cornerstone of initial treatment for chemical burns. Chemical agents may continue to damage tissue until they are removed or inactivated. The first priority is to stop the burning process. Immediate removal from the offending chemical, removal of garments, and counteraction of the chemical remaining on the body by dilution, debridement, or neutralization are important measures. Dry chemical particles such as lime should be brushed away before irrigation. Initially sodium metal and related compounds should be covered with mineral oil or excised, since water can cause a severe exothermic reaction. Dilution of phenol (carbolic acid) with water may enhance penetration. For the most part, however, use of water or saline to irrigate a chemical burn should not be delayed while searching for a neutralizing agent

and should begin at the scene of the accident. In general, the earlier the irrigation, the better is the prognosis.

The amount of elapsed time to initiate dilution or removal of chemical agents relates to the depth and degree of injury. Wounds irrigated 3 min after contact with some chemicals have a twofold greater chance of becoming full-thickness burns than wounds irrigated within 1 min of chemical contact. When using agents to neutralize a chemical burn, additional tissue injury may occur through heat production. In some cases, heat of dilution may be produced using water irrigation, but copious amounts will decrease the rate and amount of chemical reaction and dissipate the heat. Irrigation should be maintained at a gentle flow to avoid driving the chemical deeper into tissue or splashing chemical into the victim's or rescuer's eyes. The time required for irrigation varies; irrigation may need to be continued for hours in the case of alkali burns. Use of pH litmus paper may help determine continued presence of alkali or acid in burn wounds. A more accurate pH result will be obtained if the test is performed 10 to 15 min after completion of irrigation. This will allow residual chemical in the deeper areas to diffuse to the surface.

After irrigation and debridement of remaining particles and devitalized tissue, topical antimicrobial agents should be used and tetanus immunization should be updated as needed. Other than measures specific for a particular chemical burn, treatment following initial therapy is basically the same as for thermal burns. Patients sustaining chemical burns require the same aggressive fluid replacement as those with thermal burns. Analgesics may be needed, and, in the case of allergic responses to chemicals, antihistamines, steroids, and epinephrine may be required. Hemodialysis may be required in cases of severe systemic toxicity and renal failure. Autografts, heterografts, homografts, or synthetic material may be necessary for full-thickness burns. Hyperbaric oxygen may be utilized to assist healing of resistant burn wounds.

SPECIFIC CHEMICALS

Acids

With the exception of hydrofluoric acid, strong acids produce coagulation necrosis from the desiccating action of the acid on proteins in the superficial tissue. Injury severity is related to the physical characteristics of the acid. Most substances with a pH less than 2 are strong corrosives. Other important tissue-damaging properties of acids include concentration, molarity, and complexing affinity for hydroxy ions. The higher each of these factors is, the greater is the tissue damage. Contact time with the skin is the most important chemical burn feature that health care professionals may alter. Instantaneous skin decontamination of 18 M sulfuric acid will cause no burn; however, a 1-min exposure can cause full-thickness skin damage. Examination of a patient with a significant chemical burn from these acids should not be limited to observation of the skin, because several of these acids are respiratory and mucous membrane irritants as well. Furthermore, skin absorption of some compounds may occur and result in systemic signs and symptoms. The most commonly used chemicals that cause burns are listed in Table 195-1.

TABLE 195-1   Chemicals That Cause Burns

ACETIC ACID   The dilute (<40%) acetic acid solution found in hair-wave neutralizer solutions is perhaps the most common cause of chemical burns to the scalp in women. Prolonged contact, especially with an already damaged scalp, may cause a partial-thickness burn that heals slowly because of the constant bacterial flora on the hair. Initial treatment is copious water irrigation. As trimming the hair is not a viable option in these patients, oral antibiotics are often given if the entire scalp is involved.

PHENOL   Phenol (carbolic acid), a corrosive organic acid used widely in industry and medicine, denatures proteins and causes chemical burns characterized by a white or brown coagulum that is relatively painless. Systemic absorption may result in life-threatening complications. Its unpleasant, acrid odor, detectable in air at 0.047 parts per million, and its low volatility help prevent airborne exposure. Though commercially available in concentrations of 1 to 90%, even dilute solutions of 1 to 2% phenol may cause a burn if contact is prolonged. Hexylresorcinol is a bactericidal phenol derivative. Chemically related phenolic compounds that induce skin damage include cresol, creosote, and cresylic acid.

Coagulation necrosis of the involved area is common. Necrotic tissue may delay absorption temporarily, but phenol may become entrapped under the eschar. Contaminated clothing should be removed and water lavage begun immediately. Water lavage alone may be ineffective, presumably because the necrotic coagulum inhibits water penetration to the deeper layers. Paradoxically, dilute phenol penetrates tissue more readily than when concentrated.

More effective decontamination has been demonstrated with a 5- to 10-min swab with a combination of polyethylene glycol 300 (PEG 300) and industrial methylated spirits (IMS) in a 2:1 mixture. This should not only reduce the extent of cutaneous corrosion but also decrease systemic toxicity. The PEG 300 is mixed with the IMS for a more liquid (and therefore easier to use) formulation. However, the viscous PEG 300 or PEG 400 may be used alone, and, indeed, glycerol is an acceptable substitute if the PEG-IMS mixture is not available. The use of an isopropyl alcohol rinse appears to be equal to PEG-IMS in removing phenol.[4] The advantage of isopropyl alcohol is its easy availability.

CHROMIC ACID   The toxicity of chromium compounds is related to the powerful oxidizing action of the hexavalent compounds (Cr^{6+}). The chromate ion in chromic acid will produce a chronic penetrating ulcerating lesion of the skin. Associated signs and symptoms are conjunctivitis, lacrimation, ulceration of the nasal septum, and systemic chromium toxicity. A 10-percent total body surface area cutaneous burn caused by chromic acid can be fatal due to systemic toxicity. Any acute skin exposure to chromic acid should be treated with copious water irrigation and observation for systemic effects.

FORMIC ACID   Formic acid in 60% solution is used by acrylate-glue makers, cellulose formate workers, and tanning workers. Formic acid produces coagulation necrosis of the skin. Systemic effects including decreased respirations and an anion-gap metabolic acidosis have been reported.[5] Treatment includes immediate decontamination and irrigation with water. Open lesions should be treated like any damaged skin: with debridement of devitalized tissue, prevention of further damage and infection, and skin grafting if the defect is full thickness and of a size requiring closure.

HYDROCHLORIC AND SULFURIC ACIDS   The dermal toxicity of hydrochloric acid and sulfuric acid is so well recognized that early decontamination and water irrigation usually prevent severe burns to the skin. These acids can burn the skin dark brown or black. Toilet bowl cleaners may contain 80% solutions of sulfuric acid. Some drain cleaners may be 95 to 99% sulfuric acid solutions. Munitions, chemical, and fertilizer manufacturers commonly use 95 to 98% sulfuric acid solutions in their industrial processes. Automobile battery fluid is 25% sulfuric acid. Most household bleaches are only 3 to 6% hypochlorite solutions, which, though acidic, cause little damage unless they are in contact with skin for a prolonged time. Treatment is the same as for formic acid burns.

HYDROFLUORIC ACID   Hydrofluoric acid (HF) is unique among the corrosives in its mechanism of action and degree of toxicity. HF acts like alkalis and will cause progressive tissue loss, including bony destruction. HF, considered a protoplasmic poison, penetrates the skin, dissociates, and releases fluoride ions. Fluoride ions immobilize intracellular calcium and magnesium and poison cellular enzymatic reactions. Potassium permeability is increased and results in spontaneous depolarization of nerve tissue and pain.

Industrial applications include use in production of high-octane fuel, etching and frosting glass, semiconductors, microelectronics/microinstruments, germicides, dyes,

plastics, tanning, and fireproofing material and use in cleaning stone and brick buildings. It is also a very effective rust remover.

HF rapidly penetrates the skin and causes both local and systemic toxicity. Its systemic effects include hypocalcemia, hypomagnesemia, and hyperkalemia. The dermal effects may not be immediately noted and appear to be more related to the concentration of HF than to the duration of exposure. Solutions greater than 50% produce immediate pain and tissue destruction; solutions less than 20% may not produce signs and symptoms until 12 to 24 h after exposure. The skin may develop a blue-gray appearance with a surrounding region of erythema.

Unlike the treatment of dermal injury caused by other acids, the treatment of HF burns consists of two phases. The first, which should be immediate, is copious water irrigation of the affected skin for 15 to 30 min. This may be the only treatment that is needed if the HF solution is less than 20% concentrated, the duration of exposure was very brief, and decontamination is begun immediately. Unfortunately, this is rarely the case. Severe, persistent pain denotes a more serious injury requiring the second phase of treatment.

The second phase of treatment is aimed at detoxifying the enzyme-poisoning fluoride ion. Two ions—calcium (Ca^{2+}) and magnesium (Mg^{2+})—have been shown to be beneficial in binding the fluoride and curtailing its toxic effects. However, the overwhelming clinical experience to date has been with the use of calcium gluconate, and it should be considered the agent of choice at present. Several therapeutic modalities are available for using calcium gluconate: topical, subcutaneous/intradermal injection, or intraarterial infusion. An intravenous regional perfusion technique based on Bier's method has been described and reported effective.[6] High-dose intravenous magnesium sulfate appears to be effective in animal models, but human data are lacking. [7]

A calcium gluconate gel made of either Surgilube (E. Fougera & Co.) or dimethyl sulfoxide (DMSO) in a 2.5 to 10% concentration may be applied directly to the affected area.[8] The main limitation of topical therapy is the impermeability of the skin to calcium. Penetration into the dermis and subcutaneous tissues may be enhanced if the formulation with DMSO is used. The topical therapy can be used in the outpatient setting, and industries utilizing HF should keep this topical formulation on hand for emergency use.

Subcutaneous and intradermal injection of a 5 to 10% calcium gluconate solution through a 30-gauge needle into the HF-burned skin is the most widely used treatment. A maximum dose of 0.5 mL of 10% calcium gluconate per square centimeter of burned skin is recommended. Pain relief is nearly immediate, and indeed, the elimination of pain may be used as a guide for further therapy. Recurrence of pain indicates the need for further therapy. Unfortunately, injection therapy has several disadvantages: (1) only limited amounts of calcium are delivered to the tissue; (2) hyperosmolarity and inherent toxicity of free calcium ions cause more pain initially, and more tissue damage is possible if calcium is not bound to fluoride; (3) vascular compromise can result if too much fluid is injected, especially into digits; and (4) rapid penetration of HF beneath the nail requires nail removal to administer the calcium gluconate into the nailbed adequately.

Intraarterial infusion of calcium gluconate may be used to prevent tissue necrosis and stop the pain associated with HF burns. This should be performed as soon as possible after the initial burn, preferably within 6 h of insult. An intraarterial catheter should be placed in the appropriate vascular supply (the brachial artery if the entire hand is affected) and connected to a three-way stopcock to which is attached an arterial pressure-monitoring device and the infusion syringe of calcium gluconate. A 50-mL syringe may be filled with 10 mL of a 10% calcium gluconate solution and 40 mL of 5% dextrose. This should be infused over 2 to 4 h. The arterial pressure-monitoring device ensures that the catheter has not dislodged from the lumen of the cannulated artery. Infusion of the calcium solution into the deep tissues may cause further tissue damage. Repeat infusion may be needed if pain recurs within 4 h. This intraarterial infusion avoids the disadvantages of local infiltration therapy; however, it has its own disadvantages: an invasive vascular procedure (1) may result in arterial spasm or thrombosis and (2) requires more time and resources, including hospital admission.

Nebulized calcium gluconate is a recognized treatment for inhalational exposures to HF. Ocular exposure to HF requires water irrigation for at least 30 min. Treatment with calcium chloride or magnesium chloride by subconjunctival injection or irrigation may increase corneal damage. There is a reported case, however, of complete and quick recovery by utilizing 1% calcium carbonate eyedrops in a patient who had sustained a large corneal erosion due to a 49% HF burn.

Systemic toxicity related to dermal HF exposure has resulted in death. This appears to be related to myocardial irritability and subsequent ventricular fibrillation as a result of systemic acidosis, hyperkalemia, hypomagnesemia, and hypocalcemia. Cardiac monitoring, intravenous access, and electrolyte monitoring should be performed in cases of all significant HF dermal burns.

NITRIC ACID   Nitric acid is used in industry for casting iron and steel, electroplating, engraving, and fertilizer manufacturing. Upon contact with skin, nitric acid can produce tissue damage by oxidation and may turn the skin yellowish as it is burned.

OXALIC ACID   Oxalic acid is used for leather tanning and blueprint paper. Like hydrofluoric acid, it poisons enzymatic processes. Oxalic acid binds calcium and prevents muscle contraction. The burn wounds should be irrigated with water, intravenous calcium may be required. Serum electrolytes and renal function should be checked, and cardiac monitoring should be performed after serious dermal exposure.

METHACRYLIC ACID   Methacrylic acid found in many artificial nail cosmetic products can produce severe dermal burns, usually in preschoolers. [9]

Alkalis

Alkalis penetrate skin much more deeply and longer than acids, causing liquefaction necrosis of tissue, with danger of toxicity from systemic absorption. Wounds may look superficial and in 2 to 3 days become full-thickness burns. Alkalis combine with protein and lipids in tissue to form soluble protein complexes and soaps that permit passage of hydroxyl ions deep into tissue. Soft, gelatinous, friable, brownish eschars are often produced. Strong alkalis have a pH ³12.

LYES   Strong, corrosive alkalis ("lyes") include ammonium, barium, calcium, lithium, potassium (caustic potash), and sodium (caustic soda) hydroxides. Lyes are widely used in industry and found in home products (drain and toilet cleaners, washing powders, and paint removers). The urine sugar reagent tablet Clinitest (Bayer) contains anhydrous sodium hydroxide. As a mode of assault, lyes have a lower mortality rate than gunshot wounds or stabbings, but victims often suffer long-term pain, scarring, and blindness. [10] Lyes are extremely corrosive and penetrating, and burns require copious irrigation for long periods. Suicidal ingestion of lye requires aggressive airway management. Early death results from upper airway occlusion. Late morbidity related to esophageal and gastric necrosis may be minimized by early surgical intervention with esophagogastrectomy.

LIME   Lime (calcium oxide) is found in agriculture products and cements. It is converted by water to the alkali calcium hydroxide. Contact with lime draws water out of the skin. All dry particles should be brushed away prior to irrigation. Paradoxically, a small amount of water may generate an exothermic reaction with tissue injury secondary to calcium hydroxide formation. A large amount and strong stream of water (taking care to avoid splashing in eyes) should be used and will permit dissipation of heat. There is considerable variability of lime content in different grades of cement, with fine to textured masonry cement having more than concrete.

PORTLAND CEMENT   Portland cement, which accounts for a major proportion of the cement used in the United States, is a mixture of sand, lime, and other metal oxides. In the presence of water, calcium hydroxide, sodium hydroxide, and potassium hydroxide may all be formed. Workers who kneel in wet cement or get cement in their boots may discover burns hours after initial contact. In addition, skin may become irritated from gritty material, and a contact dermatitis may develop in individuals sensitive to the chromate contained in the material.

Metals

Foundry workers are sometimes burned by molten metal, which may spill or splash on body parts and run down into the boots. Elemental metals, sodium, lithium, potassium, magnesium, aluminum, and calcium may all cause burns. When exposed to air, some elemental metals spontaneously ignite. Water is generally contraindicated in extinguishing burning metal fragments embedded in the skin, because the explosive exothermic reaction that may result can lead to significant tissue injury. Burning metal may be extinguished with a class D fire extinguisher or smothered with sand. Covering metal fragments with mineral oil, however, appears to be the favored treatment method. Wound debridement should include excision of metal fragments that cannot be wiped away. Metal fragments should be placed in mineral oil to prevent further accidents.

Others

HYDROCARBONS   Hydrocarbons will cause a fat-dissolving corrosive injury to the skin. In our present petroleum-dependent society, gasoline is a common agent of burns. Patients sustaining gasoline immersion burns usually have undergone some other traumatic insult (e.g., a motor vehicle accident). Gasoline is a complex mixture of alkanes, cycloalkanes, and aromatic hydrocarbons. A hydrocarbon chemical burn resembles either a thermal scald or a partial-thickness burn. [11] Full-thickness burns secondary to prolonged contact with gasoline have been reported. Topical gasoline exposure in cold weather can result in frostbite of the digits due to rapid evaporation of gasoline resulting in heat loss from the skin. Any potential for systemic effects of the involved hydrocarbon (or what it was a solvent for) must be recognized, as this may expose the patient to greater morbidity than the skin damage. Dehydration of the skin associated with solvent contact contributes to injury. Treatment involves decontamination; otherwise, management is as for a thermal burn.

Hot tar is derived from long-chain petroleum and coal hydrocarbons. Roofing tars and asphalt are heated to temperatures in excess of 500°F (260°C) and the burns sustained are usually thought of more as thermal than chemical. Liquefaction injury to tissue can occur. Though the surface area size of the burn is usually small, solidified material stuck to skin and hair is hard to remove. The tar should be cooled to prevent continued thermal injury. Manual mechanical debridement can be painful and destructive to skin structures. Polyoxylene sorbitan (polysorbate) contained in Neosporin is an emulsifying agent that can be used to remove tar. De-solv-it, a citrus and petroleum distillate, is also reported effective in tar removal. Mayonnaise has been reported as a home remedy used topically in a similar fashion.

DMSO, CANTHARIDES, AND MUSTARD GAS   DMSO, cantharides, and mustard gas are considered to be vesicant agents. Skin burns with edema and blister formation can occur due to production of ischemia and anoxic necrosis at the site of contact. DMSO is a water-soluble organic solvent that has been used industrially since the 1940s. General therapeutic interest in DMSO began in the 1960s, when it was used topically by thousands of patients for sprains, bruises, minor burns, and arthritis. Its use has declined substantially because of eye toxicity, although it is still used for research and some clinical problems. Cantharides ("Spanish fly") is used as a veterinary aphrodisiac and occasionally by human beings as well for its supposed aphrodisiac effects. Mustard gas is a war gas that is unlikely to be seen in civilian practice. Historically, the most important of these agents, and still used in battle most often, is sulfur mustard. [12] Burns resulting from vesicants should be irrigated copiously with water or saline. Skin can be decontaminated by using absorbent powders (flour, talcum powder, Fuller's earth) if the supply of water is limited. The powder adsorbs the mustard from the skin and should be wiped away with a moist towel. The military uses M258A1 kits for skin decontamination. These kits contain three sets of towelettes, one for each containing phenol, hydroxide, and chloramine. Chloramine produces "free" chlorine, which inactivates sulfur mustard. Mineral oil is also recommended for treatment of mustard gas burns.

POTASSIUM PERMANGANATE   Potassium permanganate is an oxidizing agent that is mildly irritating in dilute solution but in concentrated solution can produce dermal burns with a thick, brownish purple eschar of coagulated protein. Burns should be copiously irrigated.

ALKYL MERCURY COMPOUNDS   Alkyl mercury compounds, which are reducing agents used in disinfectants, fungicides, and wood preservatives, can produce dermatitis or burn lesions. Lesions typically are erythematous with blister formation. The blister fluid is high in metallic mercury content. The burning process continues as long as the agent remains in contact with skin. Partial-thickness burns deepen if the blister fluid is allowed to remain. The treatment is to debride, remove blister fluid, and irrigate copiously.

DIQUAT DIBROMIDE   Full-thickness skin burns have been reported to occur after prolonged exposure to the herbicide diquat dibromide. These burns were treated with skin grafting. It is unknown whether earlier therapy would have prevented the chain of events.

LACRIMATORS (CHLOROACETOPHENONE, CHLOROBENZYLIDENEMALONITRILE, AND DIBENZOXAPINE)   Lacrimators (tear gas) such as chloroacetophenone (CN), chlorobenzylidenemalonitrile (CS) and dibenzoxazepine (CR) cause skin and mucosal irritation and contact dermatitis. The epidermal injury is limited, in contrast to the possible pulmonary parenchymal damage. Burns to the skin are treated with standard water irrigation. Ocular irritation is treated with copious water irrigation, followed by slit-lamp exam for corneal damage. Structural damage to the cornea occurs at high concentrations of these lacrimators. Pepper gas (trichloronitromethane), so named because of its pepper-like odor and propensity to induce sneezing, is used in some areas by law enforcement agencies. As with the other lacrimators, it will cause mucous membrane, occular, and upper airway irritation (as well as bronchospasm in susceptible patients). Treatment is copious irrigation with saline and removal of the patient from the offending agent.

WHITE PHOSPHORUS   White phosphorus is a chemical used as an incendiary and in insecticides, rodenticides, and fertilizers. It can ignite spontaneously when exposed to air and is rapidly oxidized to phosphorus pentoxide. White phosphorus is commonly found in hand grenades and other warfare munitions and thus is implicated in wartime and accidental burns to military personnel. In munitions, white phosphorus is solid, but some of it may liquefy with detonation. Burns may be caused by liquid or solid forms. White phosphorus burns may be complicated by multiple traumatic injuries as a result of shell fragments and the force of weapon explosions. Because of its many uses, white phosphorus burns also occur in civilians.

Flaming droplets of inorganic phosphorus may embed beneath the skin. The heat of reaction can be directly destructive to tissue. Particles continue to oxidize slowly until either debrided, neutralized, or completely oxidized. Contaminated clothing should be removed. Debride visible particles and irrigate the burns copiously with normal saline or water. A brief rinse with 1% copper sulfate solution may be helpful. Copper sulfate combines with phosphorus to form a dark-copper phosphide coating on the particles that makes them easier to see and debride and also impedes further oxidation. After copper sulfate use, the burn should be irrigated again to remove copper and prevent systemic copper toxicity. Some investigators have found copper sulfate ineffective in preventing death and also toxic in animal studies.

Airbag Burns

Approximately 8 percent of individuals suffering injuries related to airbag deployment are burned. Airbags deploy by ignition of a solid propellant—sodium azide—that creates an exothermic reaction leading to quick inflation of the airbag. Many other gases are created during activation, including corrosives such as sodium hydroxide, nitric oxide, ammonia, and multiple hydrocarbons. An airbag is deflated within 2 s of inflation through exhaust side ports on the bag. Burns associated with airbags include friction, thermal, and chemical. [13] Sodium hydroxide has been implicated in the chemical keratitis reported after airbag deployment. Sodium azide may cause cutaneous burns in addition to severe systemic effects, but its contribution to airbag chemical burns is limited. Treatment of airbag chemical burns is similar to any alkali burn: immediate and copious water irrigation.

OCULAR BURNS

Chemical burns to the eyes are common and considered true ocular emergencies requiring immediate treatment. [14] Typically, chemical burns to the eye occur in the industrial setting, in laboratories, or as a result of accidents such as battery explosion and intentional assaults. Rupture of automobile airbags with spillage of chemicals onto the face represents a new potential for ocular as well as skin burns. Early signs and symptoms of eye burns include tearing, rubbing, redness, pain, and blepharospasm. Conjunctivas, if severely injured, may appear pale due to ischemia. Swelling of the corneal epithelium, clouding of the anterior chamber, pupillary dilatation, and corneal ulceration may all occur.

If the nature of the chemical is not known, pH paper should be used to determine the presence of acid or alkali. Acid quickly precipitates the superficial tissue proteins of the eye, producing the typical "ground glass" appearance of the cornea. Penetration is limited by local buffering and barrier effects of the precipitated proteins. The damage sustained secondary to acid burns in most cases is immediate and limited to the area of contact. The posterior segment of the eye rarely suffers injury, and there are usually no late effects such as cell disruption or tissue softening.

Alkali burns are much more serious, and results are frequently unsightly and disastrous. In general, the higher the pH of the alkali, the more damage occurs. In a short period, strong alkali can penetrate the cornea, anterior chamber, and the retina, with destruction of all sensory elements, thus causing complete blindness. Alkali combines with cellular membrane lipids, resulting in cell disruption and tissue softening. The stromal mucopolysaccharides of the cornea are severely disrupted. The penetration of alkali can continue for hours to days. An opaque, marbled appearance of the cornea and even perforation may occur with deep injury. Conjunctival and scleral blood vessels and collecting veins of the anterior chamber may be destroyed, leading to secondary glaucoma.

Chronic inflammation of the iris and ciliary body (iridocyclitis) and adhesions between lens and iris (posterior synechiae) are complications. Other complications of eye burns include ectropion (lid deformity), cataract formation, scarring and marked revascularization of the cornea, and scarring of both palpebral and bulbar conjunctiva with resulting adhesions between the lids and globe (symblepharon).

Treatment of eye burns should begin immediately, with the rare exception of burns from chemicals that react violently with water. Immediate treatment is copious and

continuous irrigation at the scene, in transport, and at the hospital. Time should not be wasted in search for a neutralizing substance. Special eye-irrigating kits may be used, but in general intravenous tubing set up using 1 to 2 L of normal saline for 30-min continuous irrigation is the minimum treatment, particularly for alkali burns.

Acid burns may not require as much volume or treatment time. For treatment of alkali burns, 24 h or more of continuous irrigation has been recommended by some. Checking the pH in the conjunctival sac to see whether it has returned to normal may be helpful in determining need for further irrigation (tears have a pH between 7.3 to 7.7). The eyelid may have to be held open manually or with retractors, due to severe orbicularis spasm. The eyelids should be everted if they are not too edematous. All particulate matter should be removed by using a moistened cotton applicator or forceps.

Pain control with topical anesthetics initially and subsequently; systemic analgesics may be necessary. Cycloplegics, mydriatics, and antibiotics should be used, and the use of an eye patch may encourage corneal reepithelialization. The patient should be hospitalized and ophthalmology consultation obtained for severe burns.

Another treatment modality is the use of collagenase inhibitors such as cysteine and acetylcysteine (Mucomyst) to prevent loss of corneal stroma, which occurs with liberation of collagenase from injured corneal and conjunctival epithelium. Topical steroids may reduce iridocyclitis but may also exacerbate collagenase-induced corneal ulceration. Use of scleral contact lens may reduce adhesions and scarring. Agents to reduce intraocular pressure should be used if glaucoma develops. Paracentesis may be required in severe alkali burns to introduce sterile phosphate buffer solution into the anterior chamber in attempt to reduce the pH of the inner eye. Surgery to the eye is usually not indicated during the early phase of burn management unless for corneal grafting following corneal perforation. Blepharoplasty, keratoplasty, or keratoprosthesis may be eventually required.

IATROGENIC CHEMICAL BURNS

Iatrogenic chemical burns have been caused by the use of potassium permanganate for dermatologic problems at an inappropriately high concentration. DMSO used as a transcutaneous vehicle for minor sprains has caused burns. Patients in the operating room may develop burns from skin-prep solutions. Thimerosal, which has a high mercury content, is the most common agent implicated. Mechanical abrasion of the skin from scrubbing and from pooling of the skin-prep agent under the torso or tourniquet predisposes patients to burns. Blister formation, skin sloughing, and eschar development have been reported in neonates when isopropyl alcohol pledgets were substituted for conducting paste beneath limb electrocardiograph electrodes. Silver nitrate utilized to cauterize umbilical granulomas in infants reportedly has caused periumbilical burns.

SYSTEMIC TOXICITY

Death early after severe chemical burns is usually related to hypotension, acute tubular necrosis, and shock as a result of fluid loss. However, systemic toxicity and subsequent morbidity and mortality may also occur with some chemicals that are absorbed through denuded dermis. Acidosis, hypotension, and shock can occur with significant absorption of acids. Hypocalcemia has been reported with both oxalic acid and hydrofluoric acid burns. Profound hypocalcemia and hypomagnesemia may be accompanied by hyperkalemia, cardiac arrhythmias, and sudden death. Tannic acid, chromic acid, formic acid, picric acid, and phosphorus may cause hepatic necrosis and nephrotoxicity. Cresol can cause methemoglobinemia, massive hemolysis, and multiple organ failure. Gasoline immersion with large surface area exposure and absorption of hydrocarbon aromatic components may result in severe pulmonary, cardiovascular, neurologic, renal, and hepatic complications. The gasoline lead additives such as tetraethyl and tetramethyl can cause lead encephalopathy. Carburetor-cleaning solvent containing phenol and methylene chloride may cause renal and hepatic failure. Phenol (carbolic acid) when absorbed can lead to intravascular hemolysis, cardiovascular, pulmonary, and central nervous system toxicity. The use of phenolkin disinfectant by medical personnel in the 1800s caused chronic toxicity (carbolic marasmus) characterized by weight loss, vertigo, salivation, and increased skin and scleral pigmentation.

Sodium nitrate and potassium nitrate can cause a severe toxic methemoglobinemia from absorption with refractory cyanosis. Significant absorption of dichromate solution can result in liver failure and acute tubular necrosis and death despite hemodialysis.

Just as with thermal burns, overwhelming sepsis can be a systemic complication with chemical burns.

196 ELECTRICAL INJURIES

Ann S. Chinnis
Janet M. Williams
Kimberly N. Treat

The spectrum of electrical injuries ranges from local cutaneous burns secondary to household current to severe, deep, and extensive muscle, nerve, and vascular injury or even death from high-voltage sources. The evaluation and treatment of electrical injuries require an understanding of the unique pathophysiology of this type of injury.

EPIDEMIOLOGY

There are no precise figures on the number of electrical injuries treated in US emergency departments each year, but estimates are as high as 17,000 victims per year who require emergency treatment. Electrocution accounts for 3 to 6 percent of admissions to burn centers and, since an estimated 50,000 patients are admitted to US burn centers each year, about 1500 to 3000 individuals sustain electrical injuries severe enough to require specialized care. Three distinct populations are at highest risk for electrical injury. The first trimodal injury peak occurs in toddlers who sustain electrical injuries from household electrical sockets and cords, accounting for about 20 percent of electrical injuries. The second peak is in adolescents who engage in risky behavior or have motor vehicle collisions involving high-voltage wires, accounting for an estimated 25 percent of electrical injuries. The third peak occurs in those who work with electricity for a living, accounting for about 25 percent of electrical injuries.

Unintentional electrocution caused 560 deaths in the United States in 1995: 144 were related to generating plants and transmission lines, 84 to domestic wiring and appliances, 42 to industrial wiring and machines, and 291 to unspecified electrical events. [1] The annual occupational death rate from electrocution is approximately 1 per 100,000, with utility workers having the highest death rate (10 per 100,000), followed by miners (5.9 per 100,000) and construction workers (2.5 per 100,000). [2] Fatal unintentional household electrocutions are most commonly related to unsafe hair dryer use in bathtubs.

PATHOPHYSIOLOGY

Electrical *current* is the movement of electrical charge from one location to another; this flow is measured as amperes (A) (defined as 1 coulomb per second). Current flows when there is a *potential difference* between two locations; this potential difference is measured as volts (V). The intervening material resists the flow of electrical current; this resistance is measured as ohms. Ohm's law describes the relation between potential difference (V), current (I), and resistance (R) for simple materials: $V = I \times R$.

Materials that allow electrical current to flow easily with low resistance are called *conductors.* Conductors include the metals copper and aluminum and electrolyte solutions such as normal saline. Materials that do not allow electrical current flow are called *insulators.* Most biologic materials conduct electricity to some extent and can be classified as having low, moderate, or high resistance (Table 196-1). Tissues with a high fluid and electrolyte content conduct electricity better than tissues with less fluid and electrolyte content. Bone is the biologic tissue most resistant to the passage of electricity. Skin resistance varies widely (Table 196-2). Moist skin has reduced resistance that, according to Ohm's law, enables more current to flow such that voltages that ordinarily would not cause much damage can now become fatal.

Most	Bone
	Fat
	Tendon
Intermediate	Dry skin
Least	Muscle
	Blood vessels
	Nerves

TABLE 196-1 Body Tissue Resistance

Callused skin	1,000,000 ohms
Normal dry skin	40,000 ohms
Sweaty skin	300 ohms
Wet skin (pool or bathtub)	150 ohms

TABLE 196-2 Skin Resistance

As current flows through a resistor, energy is deposited into the material in the form of heat. The amount energy can be calculated according to Joule's law: energy = $I^2 \times R \times time$.

High voltage is usually defined in the medical literature as greater than 1000 V. However, there is evidence that the risk for serious and fatal electrical injury increases significantly with voltages above 600 V; therefore, for medical decision making, a value of 600 V is a more appropriate threshold to separate low from high voltage. [3] Interestingly, the National Electric Code defines high voltage as greater than 600 V. Power lines in US residential areas are typically 7620 V that is stepped down by transformers to 220 V as they enter a home (Table 196-3). The voltage in US household circuits is 110 V. Clothes dryers, electric ranges, heavy-duty appliances, and many air conditioners operate on special circuits that carry 220 V. Although high voltage is more dangerous than low voltage, because low voltage is more accessible

to the population, 40 to 60 percent of electrical injuries and 50 percent of the deaths are due to low-voltage electricity.

Long-distance communication lines	24 V
Telephone Lines	65 V
Household circuits and appliances	110 V
Electrical range or dryer	220 V
House power lines	220 V
Subway third rails	600 V
Residential trunk lines	7620 V

TABLE 196-3   Levels of Electrical Exposure

Contact with electrical current causes injury through thermal heating, induced muscle contraction, thermal burns, and blunt trauma (Table 196-4). Direct tissue heating, predicted by Joule's law, has been generally implicated as the direct etiology of tissue damage from electricity, although that concept has been challenged when contact time is brief.[4] Regardless, current intensity is the most critical determinant of tissue damage, but from a practical standpoint, while voltage is frequently known in an electrical exposure, current is not. Thus, voltage is usually used as a proxy for current in predicting the potential damage from an electrical shock.

Contact burns (entry and exit)
Thermal heating
Flash burns
Arc burns
Ignition and flame thermal burn
Blunt trauma
Prolonged muscular tetany

TABLE 196-4   Mechanisms of Electrical Injury

As high current passes through the body, the tissues through which it passes are heated. This heating produces neural injury, vasospasm, vascular thrombosis, and myonecrosis. Current flow through a body region with a small cross-sectional diameter (e.g., a finger) may result in more tissue destruction than current flow through a body portion with a large cross-sectional diameter (e.g., the thorax).

Contact burns occur at entry and exist points where the victim makes contact with the electrical source. These lesions are typically charred in the center and surrounded by a zone of grayish-white necrosis, with only mild damage in the periphery of these wounds. Extensive contact burns usually indicate severe underlying pathology. However, not all serious injuries display cutaneous injury. A patient with low skin resistance (e.g., sitting in the bathtub) may sustain a low-voltage injury (e.g., radio falls in the bathtub) and not have a contact lesion.

Arc burns cause the most destructive indirect injury. An electrical arc is a spark of high-voltage current through the air between objects of differing electrical potential that are not in contact with one another. Usually a typical arc burn is from an electrical source through the air to the patient. Arcs can extend through the air for distances of approximately 25 cm per 100,000 V of potential difference. The temperature of an arc ranges from 500° to 2500°C. The arc may ignite clothes, causing thermal burns. Such high voltages produce falls and tetanic musculoskeletal injuries.

In addition to current flow, other factors affect the injury severity from electrical exposure (Table 196-5). Prolonged contact leads to more severe injury secondary to heat production and the concomitant thermal burn. The type of current, whether alternating or direct, contributes to the duration of the exposure. Electric current can be either continuous in one direction (direct current or DC) or with a periodic reversal of the direction of current flow (alternating current or AC). DC is used in medical devices such as defibrillators and pacemakers. AC is found in electricity supplied to homes and businesses. The frequency of the AC is the time during which the current cycles through both positive and negative voltages. In the United States, most AC (including standard home current) is 60 cycles per second (hertz or Hz). At 60 Hz, household current has the same frequency response as skeletal muscle and can produce tetany beginning at 10 mA (Table 196-6). With muscular tetany in an extremity, the flexors overpower the extensors and the patient is drawn closer to the electrical source. This tetanic phenomenon can cause injuries such as scapular fractures and shoulder dislocations. In contrast, a high-voltage AC or DC injury usually produces a single violent skeletal muscle contraction that tends to throw the victim away from the source.

Current intensity (A)
Electrical potential (V)
Type of current (AC or DC)
Tissue resistance (skin and internal)
Duration of contact (instantaneous versus prolonged)
Area of contact (localized versus diffuse)
Current pathway—vertical ("hand to foot" or "head to toe") more dangerous than horizontal ("hand to hand" or "foot to foot")
Multisystem involvement (cardiac and neurologic)
Environmental circumstances (water immersion)

TABLE 196-5   Factors Associated with Severity of Electrical Injuries

Current Intensity	Effect
1–5 mA	Tingling sensation
5–10 mA	Painful sensation
10–20 mA	If contacted by hand, induces tetanic muscle contraction and prevents voluntary release of grip from current source
30–50 mA	Respiratory arrest secondary to diaphragmatic and thoracic muscle tetany
30–90 mA	Respiratory arrest if current directed through medulla
50–100 mA	Ventricular fibrillation
2–5 A	Cutaneous burns
5–10 A	Asystole

TABLE 196-6   Effects of Electricity

The pathway that the current takes through the body also determines the nature of injury. Current that traverses the body vertically is more likely to induce cardiac damage or produce respiratory arrest than is current that transverses horizontally. [5]

Electric weapons, such as the stun gun and Taser, produce a series of damped sinusoidal electrical pulses, typically 10 to 15/s, designed to induce involuntary muscle contraction and incapacitation in the victim. [6,7] The amount of current delivered depends on the device output (typically 50,000 V for a Taser) and the nature of the electrical contact. Although most patients do not sustain demonstrable injury from electric weapons, several individuals have died within minutes of their use, presumably from cardiac arrhythmias. Most deaths were associated with concomitant drug use (usually phencyclidine), trauma due to struggling, or preexisting cardiac disease. [8]

CLINICAL FEATURES

Cardiac arrest is the primary cause of death caused by electrocution. The specific fatal arrhythmia varies according to the type (either AC or DC) and intensity (as predicted by the voltage) of the electrical current (Table 196-7). Low-voltage AC generally produces ventricular fibrillation. High-voltage AC that causes greater current intensity is more likely to produce asystole. DC is also more likely to cause asystole. The most common arrhythmia encountered in victims who sustain cardiac arrest from electrical injury is ventricular fibrillation. Electricity may also produce cardiac rhythm disturbances, although this is unlikely if the voltage is 120 or less and if water contact is not involved. [9] Arrhythmias are seen in 20 to 30 percent of high-voltage injuries. The most common disturbances are sinus tachycardia, but premature atrial contractions, premature ventricular contractions, supraventricular tachycardia, atrial fibrillation, and first- or second-degree atrioventricular block can be seen.

TABLE 196-7   Complications of Electrical Injury

Acute myocardial infarction is an uncommon complication of electrical injuries. [9] Those patients most at risk have sustained major cutaneous burns and a transthoracic current circuit. [5] Because of spurious elevation from extensive skeletal muscle damage, the CK-MB (MB isoenzyme of creatine kinase) fraction has limited value to detect myocardial damage.

Neurologic injury is reported in approximately 50 percent of patients with high-voltage electrical injuries. Transient loss of consciousness is common, and other behavioral manifestations include agitation, confusion, or prolonged coma, from which recovery may occur. Central nervous system manifestations include seizures, headaches, quadriplegia, hemiparesis, aphasia, tinnitus, and visual disturbances. High-voltage current that passes through the skull may cause subdural and epidural hematomas, as well as intraventricular hemorrhage.

Peripheral nerve injuries may be immediate in onset or delayed. The median nerve is the most common peripheral nerve affected. The peripheral neuropathies range from transient paresthesias to delayed, profound, permanent loss of sensory and/or motor function. Spinal cord injuries range from the immediate caused by direct trauma to delayed patterns of pathology that cause sclerosis, ascending paralysis, complete and incomplete cord syndromes, acute spasticity, transverse myelitis, and amyotropic lateral sclerosis.

Contact with electrical current produces cutaneous burns at the point of entry and exit of the current. The majority of entrance burns are on the upper extremity or the skull, and most exit burns are on the heels. These burns are painless, gray to yellow depressed areas of skin. It cannot be overemphasized that the underlying tissue damage is massive, and attempts to predict injury and gauge therapy by applying the thermal burn rules using percent of body surface area burned will grossly underestimate internal damage, morbidity, mortality, and fluid resuscitation needs.

Flexor crease burns occur as current arcs across the flexor creases of the knees, elbows, and axilla. These arc burns in a "kissing pattern" usually indicate extensive underlying tissue damage. Flash burns can cause metallic particles to become volatilized and may cause the skin to become discolored with a metallic sheen from the impregnation of tiny metallic particles. Thermal burns may occur from the combustion of clothing and heated materials on the skin.

Electrical current passing along peripheral arteries may cause arterial spasm, arterial thrombosis, or aneurysm formation. Whereas spasm may be apparently early, thrombosis and aneurysm formation are typically delayed. Extensive vascular damage may cause compartment syndromes with massive myonecrosis. Detection of an evolving compartment syndrome may be difficult in an extremity that has sustained an electrical burn and has insensate skin. Measurement of compartment pressures is usually necessary to detect a compartment syndrome and ensure timely fasciotomy. Delayed arterial thrombosis can convert partial-thickness cutaneous burns into full-thickness ones. Massive areas of deep tissue necrosis may result in clostridial infection, including tetanus and gas gangrene.

Blunt trauma is common in the setting of electrical injuries occurring from either the forcible thrust back away from a high-voltage AC or DC blast, from the tetanic contractions associated with an AC injury, or from a fall due to a loss of consciousness or balance. Tetanic contractions may produce compression fractures of the thoracic spine, long-bone fractures, and dislocations of the shoulder (particularly posterior).

An oral injury may occur when a child chews through the insulation on an electrical cord. The salivary electrolytes complete the electrical circuit and allow the propagation of current throughout the tissues of the lip. Current arcing can produce temperatures as high as 2500°C. Injuries may extend more than 2 cm from the vermilion border of the lip. Most injury sites are unilateral and involve the commissure, the tongue, and the alveolar ridge. Vascular injury to the labial artery is not immediately apparent due to vascular spasm, thrombosis, and the overlying eschar. Delayed hemorrhage may occur, usually after 5 days, as the thrombus lyses and

the eschar separates.

Cataracts may develop within 4 to 6 months following electrical injury to the head, neck, and upper chest. Retinal detachment, corneal burns, intraocular hemorrhage, and intraocular thrombosis may be seen after high-voltage injury.

Renal consequences of electrical injuries are secondary to myoglobinuria from massive muscle destruction. Abdominal injuries such as hollow viscous perforation or necrosis may occur after current traverses the abdominal wall. Parenchymal damage to the liver and pancreas, paralytic ileus, and stress ulcers of the stomach have been reported.

DIAGNOSIS

The diagnosis of an electrical injury is usually made based on history provided by the patient, bystanders, or emergency medical services. Occasionally, the history may be unclear if the patient is found unconscious in a bathtub or is amnestic to the event. If available, a history should be obtained as to the voltage, the type of current, the duration of contact, the likely pathway of the current, any skin resistance modifying factors (e.g., water or sweating), and any symptoms suggestive of the aforementioned complications. The presence of underlying disease, such as coronary artery disease, diabetes, and neurologic disease, should be determined.

The physical examination should assess tissue damage and identify associated complications. Airway, respiratory, and cardiovascular status should first be stabilized, followed by evaluation for cutaneous burns and secondary trauma. A careful vascular examination of injured extremities must be performed along with a detailed examination of peripheral nerve function. As noted above, occult and delayed injuries occur, and clinicians must be wary that the absence of physical findings does not exclude serious injury.

An electrocardiogram (ECG) and a period of cardiac monitoring is recommended for (1) all patients who have been exposed to high-voltage electricity (more than 600 V) and (2) all patients exposed to low-voltage electricity with suggestive symptoms or signs (loss of consciousness, amnesia, altered mental status, other neurologic symptoms, palpitations, chest pain, or irregular pulse).

Patients with high-voltage injury, extensive cutaneous burns, or evidence of systemic injury require laboratory investigation including a complete blood count and determination of electrolyte, calcium, blood urea nitrogen, creatinine, creatine kinase (CK), and serum myoglobin levels. Urinalysis and determination of the urine myoglobin level should be performed. Urine that tests positive for blood by urine dipstick but has no red blood cells on the microscopic examination is suggestive of myoglobin consistent with muscle damage. Liver function tests and an amylase evaluation should be obtained in those patients who are suspected of having an intraabdominal injury.

Cervical spine films must be obtained in patients who have altered levels of consciousness, neurologic deficits, neck pain or tenderness, or significant distracting injuries. Cranial computed tomography should be performed for those patients who show altered levels of consciousness. Additional studies such as plain films, arteriography for suspected vascular injury, and radionuclide scan to detect cardiac muscle damage should be ordered as needed.

SPECIAL PATIENTS

Electrical shock during pregnancy is felt to be associated with potential fetal demise, as amniotic fluid is an excellent conductor of electricity. This belief was substantiated in a review of 15 published cases of electrical injury during pregnancy, with 11 resulting in fetal death. [10] However, this summation of published cases may represent publication bias. In a recent prospective observational study of 31 pregnant women who sustained electrical shock (28 to household current), 28 gave birth to normal healthy infants and only one sustained a spontaneous abortion. [11] Thus, although the risk may be low, it is advisable to observe pregnant patients for a short period after an electrical shock. In patients with a fetus that is over 24 weeks of gestational age, fetal monitoring should be performed during this observation. Auscultation of fetal heart tones and ultrasound evaluation of a fetus less than 24 weeks of age is recommended. In general, obstetric consultation should be obtained for an electrical shock involving household current.

MANAGEMENT

When providing medical control of prehospital personnel, scene safety is paramount. Emergency medical service providers need to ensure that electrical power has been shut off by authorized personnel. The insulating material surrounding the wire should not be considered protective to rescuers; it merely protects the wire from the elements. "Insulated" objects such as rubber mats and ropes should not be used to extricate the patient from the power source, as these may be damaged or wet and may conduct high-voltage electricity.

The initial stabilization of an electrically injured patient should focus on the airway, breathing, and circulation. Respiratory arrest caused by current traversing the medulla or the chest wall is treated with immediate intubation and assisted ventilation. Electrical injuries alone do not usually cause upper airway edema, but thermal burns or inhalation injuries may cause airway obstruction. Spinal immobilization must be maintained if the possibility of cervical spine trauma exists. High-flow oxygen via face mask and continuous pulse oximetry should be provided. Cardiac arrhythmias should be treated with the advanced cardiac life support (ACLS) protocol, including standard doses of electrical shock. Cardiac monitoring should be instituted for all high-voltage patients, all symptomatic, and all high-risk low-voltage patients (Table 196-8).

Wet skin

Current traverses the thorax (vertical pathway)

220-V exposure

TABLE 196-8   High-Risk Patients with Low-Voltage Exposure

Fluid resuscitation should be commenced with two large-bore intravenous lines (IVs) infusing Ringer's lactate or normal saline. If possible, an IV should not be started on an extremity that was part of the current pathway, because delayed thrombosis may occlude the infusion line. Fluid requirements for victims of electrical burns are higher than the fluid requirements for victims of thermal burns, and formulas based on percent of body surface area involved will not provide enough volume to avert rhabdomyolysis and maintain tissue perfusion. An initial fluid challenge of 20 to 40 mL/kg over the first hour is appropriate for most patients. Further fluid requirements are guided by clinical and hemodynamic assessment. Central venous or pulmonary artery pressure monitoring may be necessary to guide fluid replacement and avoid volume overload in patients at risk for congestive heart failure.

Rhabdomyolysis with myoglobinuria should be treated with urinary alkalization; 44 to 50 meq of sodium bicarbonate added to each liter of intravenous (IV) fluid. Blood pH should be maintained 7.45 or greater and urine output at 1.5 to 2.0 mL/kg/h. IV mannitol may be administered to encourage urine flow at an initial dose of 25 g in adults and 0.5 to 1 g/kg in children. Mannitol infusions may be given until the urine is free of myoglobin, but it is very important that patients not become hypovolemic. If thermal burns are also present, mannitol should not be given, due to the risk of hypovolemia. (See Chap. 271, "Rhabdomyolysis.")

Wound care for minor localized and partial-thickness wounds consists of cleansing and application of silver sulfadiazine. Full-thickness burns with an eschar are better treated with mafenide acetate, because it penetrates eschar well. Side effects from mafenide are metabolic acidosis and pain with application. Tetanus

prophylaxis should be administered as indicated. For patients with extensive muscle damage and soil contamination, the risk of tetanus is such that tetanus immune globulin should be considered even if the patient's tetanus immunizations are up to date. There is no scientific evidence to support the prophylactic administration of parenteral antibiotics (e.g., high-dose penicillin) to prevent clostridial infection in patients with extensive devitalized tissue.

DISPOSITION

All patients with high-voltage exposure (more than 600 V) should be admitted for observation even if there is no apparent injury. Patients with serious high-voltage injuries (neurologic, cardiac, vascular, or muscle damage) should be admitted to a specialized burn center. Routine cardiac rhythm monitoring is not required for patients admitted with high-voltage injuries unless there is an initial abnormal ECG or arrhythmia. [12] Disposition of patients with a low-voltage injury is more problematic (Table 196-9).

High voltage >600 V

Symptoms suggestive of systemic injury
  Cardiovascular: chest pain, palpitations
  Neurologic: loss of consciousness, confusion, weakness, headache, paresthesias
  Respiratory: dyspnea
  Gastrointestinal: abdominal pain, vomiting

Evidence of neurologic or vascular injury to a digit or extremity

Burns with evidence of subcutaneous tissue damage

Arrhythmia or abnormal ECG

Suspected foul play, abuse, or suicidal intent

High-risk exposures

Associated injuries requiring admission

Comorbid diseases (cardiac, renal, neurologic)

TABLE 196-9 Indications for Admission

Adults with low-voltage injury (less than 600 V) and evidence of complications should be admitted. Multiple studies have substantiated the negligible risk of delayed arrhythmias in asymptomatic patients with a 110-V exposure and no tetany, wet skin, or vertical current flow. Asymptomatic adults who sustain a household shock may be discharged home if they have a normal ECG on presentation and normal examination findings. [9] Exposure to 220 V probably carries little risk for occult or delayed cardiac injury, although the published literature is less than definite. Two studies totaling 90 patients from Australia where household current is single-phase AC at 50 Hz with voltage varying between 220 and 260 V found that only one patient sustained an arrhythmia, and that was present on admission. [13,14]

Children with exposure or injury to 110-V household current usually sustain oral burns or minor hand burns and rarely develop cardiac or significant deep injury. [15,16 and 17] Children with an electrical cutaneous burn and a loss of consciousness, vertical current path, tetany, or wet skin should be admitted for a period of cardiac monitoring. [16,17] Likewise, a child with a home situation of equivocal safety or reliability should also be admitted, although cardiac monitoring is not routinely required for these "social" admissions. Children with minor hand burns from outlet injuries and no initial evidence of cardiac or neurovascular injury can also be sent home with local wound care. [18]

Oral electrical burns in children have been extensively studied. [19] Because of the risk of wound contracture and delayed hemorrhage, such children were formerly commonly admitted to the hospital for observation and the initiation of splinting. More recent series indicate that most children with oral electrical burns do not require admission, provided (1) there is no history of loss of consciousness, (2) there are no other injuries that require admission, (3) the ECG is normal, (4) the child is able to drink fluids, and (5) the parents are reliable. [17] These children can be discharged home with instructions to apply pressure should the oral burn bleed, return in 24 h for a wound check, and arrange follow-up with a plastic or oral surgeon. The risk of cardiac or muscle damage is so low that urinalysis, CK, and myoglobin testing is not required. [16] Prolonged cardiac rhythm monitoring is not necessary, provided the initial ECG is normal. Splinting for a minimum of 4 months is beneficial to control wound contracture and reduce the need for commissuroplasty. [20]

Since a large percentage of electrical injuries involve tort claims against employers, power companies, or manufacturers, the medical record must meticulously detail the history, clinical findings, and treatment.

PREVENTION
