Epidural hematomas are the result of blood collecting in the potential space between the skull and the dura mater. They occur in only 0.5 to 1 percent of all head-injured patients and in less than 10 percent of those with head injuries who are comatose. Most (80 to 90 percent) result from blunt trauma to the temporal or temporoparietal area with an associated skull fracture and middle meningeal arterial disruption (Fig. 247-7). Occasionally, trauma to the parietooccipital region or the posterior fossa causes tears of the venous sinuses with epidural hematomas. Almost all epidural hematomas are associated with skull fractures, and 80 percent will progress to uncal herniation. Additional cerebral lesions occur in 24 percent of patients, but they are usually not life-threatening. Epidural hematomas are rare in the elderly and children less than age two. In the elderly, the dura mater is firmly attached to the skull, which decreases the likelihood of dissection into the potential space. The less rigid skull of younger children protects against skull fractures and the resultant disruption of the middle meningeal artery.
FIG. 247-7. A typical epidural hematoma with a lenticular-shaped configuration.

The classic history of an epidural hematoma is for the patient to experience immediate loss of consciousness after significant blunt head trauma. The patient then awakens and has a lucent period prior to again falling unconscious as the hematoma expands. Unfortunately, this "classic" syndrome occurs in only about 20 percent of cases. The majority of patients either never loose consciousness or never regain consciousness after the injury.

The diagnosis of an epidural hematoma is based on CT scan and physical findings. On CT scans, epidural hematomas appear biconvex (football shaped), typically in the temporal region.

The high-pressure arterial bleeding of an epidural hematoma can lead to herniation. The sequence of epidural bleeding and herniation usually occurs within hours. Therefore, early recognition and intervention is key to reduce morbidity and mortality. More than 90 percent of patients with recognized epidurals will have the hematoma operatively evacuated within 48 h. One-third of these will be evacuated within the first 12 h. Bilateral emergency department trephination (burr holes) are only indicated if definitive neurosurgical care is not available. Full recovery can be expected if the hematoma is evacuated prior to herniation or to the presence of neurologic deficits. Otherwise, irreversible brain injuries from increased ICP may insue, resulting in a less favorable outcome.

Subdural Hematoma

Subdural hematomas (SDH) are caused by sudden acceleration-deceleration of brain parenchyma with subsequent tearing of the bridging veins. These vessels are located beneath the dura mater and result in blood clots forming between the dura mater and the arachnoid (Fig. 247-8). SDHs occur in approximately 30 percent of all severe TBI.

FIG. 247-8. A large acute subdural hematoma with a midline shift and ipsilateral ventricular effacement.

Brains with extensive atrophy, such as the elderly and alcoholics, are more susceptible to subdural hematomas because of the relatively smaller brain volume in a larger cranial vault. Children under the age of two are also at increased risk of subdural hematomas. This is related to transfer of the force that limits the risk of

sustaining epidural hematomas as discussed above. In addition, children have a larger head to body ratio than adults, which increases the overall risk of head injury.

Blood tends to collect more slowly than epidural hematomas because of its venous origin. However, unlike the epidural hematomas, SDH have more associated brain parenchyma injury so outcome is less favorable. The mortality rate averages 60 percent for patients with acute SDH, but can be significantly lowered with early surgical intervention.[9]

Traditionally, subdural hematomas have been classified as acute, subacute, and chronic, depending on time of presenting signs and symptoms. In acute SDH patients present between 3 and 14 days. After 2 weeks, patients are defined as having a chronic SDH. There is no specific clinical syndrome associated with a subdural hematoma. Acute cases usually present immediately after severe trauma and often, the victim is unconscious. However, chronic subdurals may present in the elderly or alcoholic with vague complaints or mental status changes. These patients often do not recall an injury. On CT scan, acute SDH are hyperdense (white), crescent-shaped lesions. Subacute SDH are isodense and more difficult to identify. A CT scan with intravenous contrast can assist in identifying a subacute SDH. A chronic SDH appears hypodense as the iron in the blood is phagocytized.

The definitive treatment of subdurals depends on the type and on associated brain injuries. Mortality and the need for surgical repair are greater for acute and subacute SDH. Chronic subdurals can sometimes be managed without surgery depending of the severity of the symptoms.

Diffuse Axonal Injury

Diffuse axonal injury (DAI) is the disruption of axonal fibers in the white matter and brainstem. Shearing forces on the neurons generated by sudden deceleration cause DAI. A relationship exists between the force of sudden deceleration and the amount of DAI observed in all cases of TBI except for assaults and whiplash. The classic cause of DAI is an MVC. In infants, the "shaken baby syndrome" is a well-described tragic cause.

Injury occurs immediately and is essentially irreversible. There is a rapid or immediate increase in ICP. Patients present unresponsive. The state may be prolonged or permanent until death. A CT scan of a patient with DAI may be normal, but the classic triad demonstrates hemorrhagic injury to the corpus callosum, the midbrain or pons, and retraction of the Balls of Cajal. The treatment options for DAI are very limited, but attempt to prevent secondary damage by reducing cerebral edema.

Penetrating Injury

In the United States, gunshot wounds (GSW) are now the leading cause of death from TBI; GSW result in more than 33,000 deaths annually. Of these, slightly more than half are from homicide, with most of the remaining suicides. As a bullet passes through the brain, it creates a cavity 3 to 4 times greater than its diameter. The damage, however, is due to more than just the penetration of the bullet. Also involved in a major transfer of kinetic energy of the bullet to the brain matter. The amount of transferred kinetic energy is dependent on the mass of the missile and the velocity squared ($E = \frac{1}{2}mv^2$). The result is that a small increase in bullet velocity results in large increases in energy delivered and resultant damage. The resulting concussive force can damage tissue outside of the bullet's path. (Wound ballistics is discussed in detail in Chap. 256.)

The prognosis of a patient with a GSW to the brain can be predicted by the GCS if they are not intoxicated. Patients with a GCS of greater than 8, and reactive pupils have a 25 percent mortality risk. Those with a GCS of less than 5 approach 100 percent mortality. All patients with a penetrating GSW to the brain should be intubated and treated with prophylactic antibiotics and anticonvulsants.

Stab wounds have very low energy and impart only direct damage to the area contacted by the penetrating object. Therefore, the morbidity and mortality from these injuries is much less than from those with GSWs. Essentially all patients sustain penetrating injury require operative intervention. Impaled objects should be left in place until surgical removal. Patients should receive broad-spectrum antibiotics and be admitted.

COMPLICATIONS/LONG-TERM PROBLEMS

Seizures

There are three periods in which patients with TBI are susceptible to seizures: acute, early, and late. Acute seizures occur within minutes of the head injury; early seizures occur within one week of head injury; late seizures occur after one week of head injury. Acute seizures are associated with a high mortality from expanding hematomas. However, if the patient survives, the situation is the least likely to be associated with a long-term seizure disorder. Late seizures are most likely to result in a prolonged seizure disorder. Seizures are four times more common following penetrating trauma than blunt trauma.

Because seizures result in hypoxia, increased cerebral ischemia, and increased ICP, the use of anticonvulsants, such as phenytoin, is recommended for all patients with severe TBI for one week after the injury. Indications include patients with intracranial hemorrhage or hematoma, depressed skull fractures or penetrating injuries, a posttraumatic seizure or any patients who are paralyzed. Long-term use of anticonvulsants has not been shown to decrease incidence of seizures beyond one week.[28] If the patient is no longer paralyzed, and not had a breakthrough seizure for one week, the anticonvulsant can be discontinued.

Concussion

A concussion is any brief and temporary interruption of neurologic function following head trauma. Concussions may occur with or without loss of consciousness. Symptoms of amnesia and confusion are the hallmarks of concussion. Duration of amnesia is predictive of injury severity. Other symptoms include dizziness, headaches, nausea, and vomiting. The patient with concussion may appear dazed with a blank stare while others may cry for no apparent reason. Most of these signs and symptoms may resolve prior to arrival in the emergency department and the patient's only complaint may be that of a headache. Most patients with brief loss of consciousness, GCS 15, and amnesia less than 1 h, recover within 6 to 12 weeks.[15]

SPORTS-RELATED CONCUSSION   Sports-related concussions are common injuries, but their true incidence is greatly underreported. Sports most commonly associated with concussion are boxing, football, soccer, baseball, and basketball. The management of any patient with TBI or concussion is the same as described above. However, for the athlete with a concussion, special consideration must be made for their safe return to a sporting activity. Based on degree of signs and symptoms of the athlete, a grading scale of 1 to 3 is used. A higher grade is associated with greater risk of sustaining permanent brain damage or even death if an additional injury is sustained (Table 247-4).

TABLE 247-4   Evaluation and Management of Patients with Concussions

POSTCONCUSSIVE SYNDROME   Regardless of the cause of head injury, patients with TBI may experience persistent symptoms postinjury. Despite exhaustive work-ups, postconcussive syndrome (PCS) patients may continue to have very vague complaints such as headaches, dizziness, inability to concentrate, and memory

changes. After one year, 85 to 90 percent of these patients effectively recover. The remaining 10 to 15 percent have persistent postconcussive syndrome (PPCS). Risk factors for patients developing PPCS from PCS are female sex, ongoing litigation, and low socioeconomic status. While all PCS and PPCS patients should be referred to their primary physicians or neurologist, amitriptyline at 25 to 50 mg/day has been shown to help patients with headaches, depression, and insomnia. [29] Regardless of treatment options, physicians need to relay two important messages to any patient with TBI. The symptoms usually clear, but the time needed is generally weeks to months.[15]

Infections

Patients with traumatic brain injuries are at increased risk for CNS infections. Several factors increase the risk. Skull fractures and CSF leaks, as discussed earlier, are risk factors for developing meningitis. In addition to CNS infections, patients intubated and on neuromuscular blockade are shown to have longer ICU stays, an increased risk for aspiration pneumonias, and, tend toward sepsis. Due to controversies regarding use of prophylactic antibiotics, consultation with the neurosurgeon or intensivist should be obtained prior to their administration.

Patients who present with a history of a skull fracture and fever or other symptoms of meningitis should be treated with antibiotics. The source of infection depends on the time since the injury. Within 72 hours, pneumococcus is generally the cause. After that, gram-negative organisms and *Staphylococcus aureus* become more common. Patients should given vancomycin and a third-generation cephalosporin, such as ceftazidime, until cultures confirm the cause.

Thomas M. Scalea

Spinal injuries are probably the most devastating of all trauma-related injuries. Treatment of multiple associated injuries often supersedes definitive management of spinal injuries. Emergency physicians must prioritize management yet not lose sight of the potential ramifications of spinal trauma. Stabilization of primary injury and prevention of secondary injury are the goals in order to optimize final outcome.

EPIDEMIOLOGY

The incidence of traumatic spinal cord injury (SCI) in the United States has been estimated at 30 cases per million population at risk. Thus, 8000 to 10,000 new cases can be expected annually. The actual incidence is probably higher. Minor injuries are often not reported, and those associated with trauma fatalities may go unnoticed. SCI is predominantly a disease of young men. The mean age has been reported as 33.5 years, [1] with a male-to-female predominance of 4 to 1. Spinal injury occurs more frequently on weekends and holidays and during summer months. The majority (90 percent) of cases are caused by blunt trauma with most of these from motor vehicle crashes.

FUNCTIONAL ANATOMY

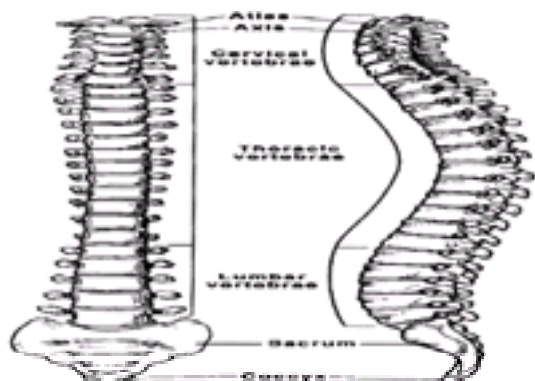
The vertebral column serves as the central supporting structure for the head and trunk and provides bony protection for the spinal cord. It consists of 33 vertebrae: 7 cervical, 12 thoracic, 5 lumbar, 5 sacral (fused to form the sacrum), and 4 coccygeal, which are usually fused (Fig. 248-1).


FIG. 248-1. The vertebral column. There are three vertebrae divided into cervical, thoracic, lumbar, sacral, and coccygial.

Vertebrae

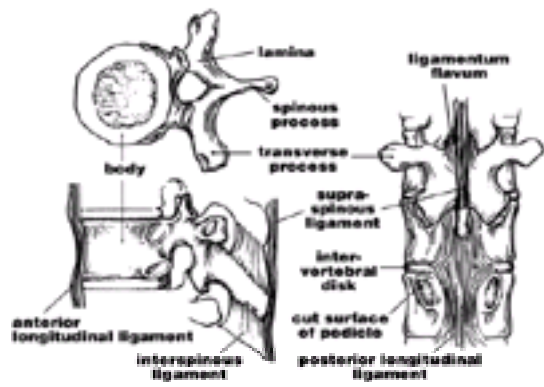
In accordance with their weight-bearing function, the vertebrae become larger toward the lower end of the column, but all are built on the same fundamental plan. A typical vertebra is composed of a body anteriorly and a vertebral arch posteriorly (Fig. 248-2). Between the body and arch is the vertebral foramen, through which the spinal cord runs. The vertebral arch is made up of two pedicles, two laminae, and seven processes (one spinous, two transverse, and four articular). The spine has the potential to move in flexion, extension, lateral flexion, rotation, or circumduction (combination of all movements). The articular processes form synovial joints that act as pivots of the spinal column. The orientation of these articular facet joints changes at different levels of the spine. Differences in orientation of the facet joints account for variations in motion of specific regions of the vertebral column. A series of ligaments serve to maintain the alignment of the spinal column. The anterior and posterior longitudinal ligaments run along the vertebral bodies. Surrounding the vertebral arch are the ligamentum flavum and the supraspinous, interspinous, intertransverse, and capsular ligaments. The intervertebral disks lie between adjacent vertebral bodies. Each disk consists of a peripheral annulus fibrosus and a central nucleus pulposus. The annulus fibrosus is composed of fibrocartilage. The nucleus pulposus is a semifluid, gelatinous structure made up of water and cartilage fibers. With advancing age, the proportion of water decreases and fibrocartilage increases. The disks act as shock absorbers to distribute axial load. When compressive forces exceed the absorptive capacity of the disk, the annulus fibrosus ruptures, allowing the nucleus pulposus to protrude into the vertebral canal. This may result in spinal nerve or spinal cord compression.


FIG. 248-2. Vertebra. Each vertebra consists of a vertebral body and posterior element. They are stabilized by an anterior lognitudinal ligament, posterior ligament, and interspinous ligament.

Spinal Stability

The determination of spinal stability is an important factor in the evaluation of the injured spine. White and Panjabi define stability as the ability of the spine to limit patterns of displacement under physiologic loads so as not to damage or irritate the spinal cord or nerve roots and to prevent incapacitating deformity or pain due to structural changes.[2] CT evaluation applied to Denis's three-column system for classification of thoracolumbar injuries can be used to assess spinal stability. According to Denis, the spine consists of three columns.[3] The anterior column is formed by the anterior part of the vertebral body, the anterior annulus fibrosus, and the anterior longitudinal ligament. The middle column is formed by the posterior wall of the vertebral body, the posterior annulus fibrosus, and the posterior longitudinal ligament. The posterior column includes the bony complex of the posterior vertebral arch and the posterior ligamentous complex. In order for an injury to be unstable, there must be disruption of at least two columns. In evaluating stability, it is also important to include the degree of compression of the vertebral body. Vertebral body compressions of more than 50 percent are generally considered unstable.

Thoracic and Lumbar Spine

The thoracic spine is a rigid segment. The additional support provided by its articulation with the rib cage imparts a stiffness to the thoracic spine 2.5 times that of the ligamentous spine alone. Relative to other regions of the vertebral column, a large force is necessary to overcome the intrinsic stability of the thoracic spine. While injury to the thoracic spine is less common than in other regions, when it does occur it is usually significant. The spinal canal is narrower than that found in either the cervical or lumbar spine. The large spinal cord diameter relative to canal diameter increases the risk of cord injury. When cord injuries occur, most are neurologically complete. Of additional importance is the association between fractures of the thoracic spine and severe pulmonary injuries, including mediastinal hemorrhage. Patients with blunt chest trauma and mediastinal widening should be evaluated for both aortic and thoracic spine injuries. [4]

The spine is divided into alternating mobile and fixed segments. The thoracolumbar junction (T11-L2) is considered a transitional zone between the fixed thoracic and mobile lumbar regions. This distinction is important because the transitional zones sustain the greatest amount of stress during motion. These areas are most vulnerable to traumatic injuries. In addition to this change in bony anatomy, the thoracolumbar junction serves as the level of transition from the end of the spinal cord (about L1) to the nerve roots of the cauda equina. Relative to the thoracic spine, the width of the spinal canal is greater. Despite a large number of vertebral injuries at the thoracolumbar junction, most are associated with normal neurologic exams or incomplete neurologic findings.

Relative to the thoracic and thoracolumbar regions, the lower lumbar spine is the most mobile. Isolated fractures of the lower lumbar spine rarely result in complete neurologic injuries. When neurologic injuries occur, they are usually complete cauda equina lesions or isolated nerve root injuries.

Sacrum and Coccyx

The sacrum supports the lumbar vertebral column and transmits loads from the trunk to the pelvic girdle and into the lower limbs. It consists of five rudimentary vertebrae fused to form a single wedge-shaped bone. The upper border articulates with the fifth lumbar vertebra. The inferior border articulates with the coccyx. Laterally, the sacrum articulates with the iliac bones to form the sacroiliac joints. The vertebral foramina together form the sacral canal. The sacral canal contains the nerve roots of the lumbar, sacral, and coccygeal spinal nerves and the filum terminale.

The coccyx consists of four vertebrae fused together to form a triangular bone, which articulates with the sacrum. Except for the first vertebra, the remaining coccygeal vertebrae consist of bodies only.

Injuries of the sacral spine and nerve roots are very unusual. When they occur, they are frequently associated with fractures of the pelvis. There are multiple different classification schemes of sacral fractures that help to predict neurologic deficits and establish treatment protocols. In general, transverse fractures through the body are most significant in that they cause injury to part or all of the cauda equina. Longitudinal fractures may cause radiculopathy. If there is involvement of the central sacral canal, however, bowel or bladder dysfunction may also occur.[5] Careful neurologic evaluation is essential. Motor and sensory evaluation of the sacral nerve roots should be performed. Rectal examination will assess anal sphincter tone and the bulbocavernosus reflex.

Coccygeal injuries are usually associated with direct falls onto the buttocks. Patients typically describe intense pain with sitting and straining. Diagnosis of fracture is made on rectal examination. Pain will be elicited with motion of the coccyx. X-rays are not needed. Treatment is symptomatic, and includes analgesics and use of a rubber doughnut pillow.

Spinal Cord

The spinal cord is a cylindrical structure that begins at the foramen magnum, where it is continuous with the medulla oblongata of the brain. Inferiorly, it terminates in the tapered conus medullaris at the lower border of the first lumbar vertebra. The conus is continued at its apex by a prolongation of the pia mater, the filum terminale, which extends to the base of the coccyx. The spinal cord gives rise to 31 pairs of spinal nerves: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal. Each spinal nerve emerges through the intervertebral foramen corresponding to the appropriate spinal cord level. There is disproportionate growth in the length of the spinal cord and the vertebral column. As a result of this inequality, the length of the nerve roots increase and at lower levels, both progressively. The lower nerve roots, inferior to the conus medullaris, form an array of nerves around the filum terminale; this is called the *cauda equina*.

CLINICAL FEATURES

Damage to the spinal cord is the result of two types of injury. First is the direct mechanical injury from traumatic impact. This insult sets into motion a series of vascular and chemical processes that lead to secondary injury. The initial phase is characterized by hemorrhage into the cord and formation of edema at the injured site and surrounding region. Local spinal cord blood flow is diminished owing to vasospasm and thrombosis of the small arterioles within the gray and white matter. Extension of edema may further compromise blood flow and increase ischemia. A secondary tissue degeneration phase begins within hours of injury. This is associated with the release of membrane-destabilizing enzymes, mediators of inflammation, and disturbance of electrophysiologic coupling by disruption of calcium channel pathways. Lipid peroxidation and hydrolysis appear to play a major role in this secondary phase of spinal cord injury. [6]

Spinal Cord Lesions

It is important to distinguish between complete and incomplete spinal cord injuries. The severity of injury determines the prognosis for recovery of function. The American Spinal Injury Association defines a complete neurologic lesion as the absence of sensory and motor function below the level of injury. This includes loss of function to the level of the lowest sacral segment. In contrast, a lesion is incomplete if sensory, motor, or both functions are partially present below the neurologic level of injury. This may consist only of sacral sensation at the anal mucocutaneous junction or voluntary contraction of the external anal sphincter upon digital

examination.[3] In assessing neurologic function, spinal shock must be considered. Patients in spinal shock lose all reflex activities. This generally resolves, with the return of the bulbocavernosus reflex occurring first. Lesions cannot be deemed complete until spinal shock has resolved. Complete lesions have a minimal chance of functional motor recovery. Patients with incomplete lesions are expected to have at least some degree of recovery.

Clinical syndromes classify incomplete spinal cord lesions. Damage to specific sections of the spinal cord results in predictable physical findings (Table 248-1).

Syndrome	Etiology	Symptoms	Prognosis
Anterior cord	Direct anterior cord compression / Flexion of cervical spine / Thrombosis of anterior spinal artery	Complete paralysis below the lesion with loss of pain and temperature sensation / Preservation of proprioception and vibratory function	Poor
Central cord	Hyperextension injuries / Disruption of blood flow to the spinal cord / Cervical spinal stenosis	Quadriparesis - greater in the upper extremities than the lower extremities, Some loss of pain and temperature sensation, also greater in the upper extremities	Good
Brown-Séquard	Transverse hemisection of the spinal cord / Unilateral cord compression	Ipsilateral spastic paresis, loss of proprioception and vibratory sensation and contralateral loss of pain and temperature sensation	Good
Cauda equina	Peripheral nerve injury	Variable motor and sensory loss in the lower extremities, sciatica, bowel/bladder dysfunction and "saddle anesthesia"	Good
Spinal shock	Partial or complete injury at the T6 level and above	Areflexia, loss of sensation, and flaccid paralysis below the level of the lesion, a flaccid bladder and loss of rectal tone, bradycardia and hypotension	Complete lesions have a poor prognosis. Incomplete lesions have some degree of recovery

TABLE 248-1   Spinal Cord Syndromes

A discussion of the anatomy may be helpful.

A large number of descending and ascending tracts have been identified in the spinal cord. The three most important of these in terms of neuroanatomic localization of cord lesions are the corticospinal tracts, spinothalamic tracts, and dorsal (posterior) columns.

The corticospinal tract is a descending motor pathway. Its fibers descend from the cerebral cortex through the internal capsule and the middle of the crus cerebri. The tract then breaks up into bundles in the pons and finally collects into a discrete bundle, forming the pyramid of the medulla. In the lower medulla, approximately 90% of the fibers cross (decussate) to the side opposite that of their origin and descend through the spinal cord as the lateral corticospinal tract. These fibers synapse on lower motor neurons in the spinal cord. The 10 percent of corticospinal fibers that do not decussate in the medulla descend in the anterior funiculus of the cervical and upper thoracic cord levels as the ventral corticospinal tract. Damage to the corticospinal tract neurons (upper motor neurons) in the spinal cord results in ipsilateral clinical findings such as muscle weakness, spasticity, increased deep tendon reflexes, and a Babinski sign.

The two major ascending pathways that transmit sensory information are the spinothalamic tracts and the dorsal columns. The first neurons of both of these afferent systems begin as sensory receptors situated in the skin and stretch receptors of muscles. Their cell bodies are located in the dorsal root ganglia of the spinal nerves. The spinothalamic tract transmits pain and temperature sensation. As the axons of the first neurons enter the spinal cord, most rise one or two levels before entering the dorsal gray of the spinal cord, where they synapse with the second neuron of the spinothalamic tract. The second neuron immediately crosses the midline in the anterior commissure of the spinal cord and ascends in the anterolateral funiculus as the lateral spinothalamic tract. When the spinothalamic tract is damaged in the spinal cord, the patient experiences loss of pain and temperature sensation in the contralateral half of the body. The sensory loss begins one or two segments below the level of the lesion. The dorsal columns transmit vibration and proprioceptive information. Neurons enter the spinal cord proximal to pain and temperature neurons. They differ from pain and temperature neurons in that they do not immediately synapse. Instead, these axons enter the ipsilateral dorsal column and do not synapse until they reach the gracile or cuneate nuclei of the medulla. From these nuclei, fibers cross the midline and ascend in the medial lemniscus to the thalamus. Injury to one side of the dorsal columns will result in ipsilateral loss of vibration and position sense. The sensory loss begins at the level of the lesion. Light touch is transmitted through both the spinothalamic tracts and the dorsal columns. Therefore, light touch is not completely lost unless there is damage to both the spinothalamic tracts and the dorsal columns.

Concerning the spinal nerves and their relationship to the vertebrae, each spinal nerve is named for its adjacent vertebral body. Because there is an additional pair of spinal nerve roots compared to the number of vertebral bodies, the first seven spinal nerves are named for the first seven cervical vertebrae, each exiting through the intervertebral foramen above its corresponding vertebral body. The spinal nerve exiting below C7, however, is referred to as the C8 spinal nerve, though no eighth cervical vertebra exists. All subsequent nerve roots, beginning with T1, exit below the vertebral body for which they are named.

During fetal development, the downward growth of the vertebral column is greater than that of the spinal cord. Because the adult spinal cord ends as the conus medullaris at the level of the lower border of the first lumbar vertebra, the lumbar and sacral nerve roots must continue inferiorly below the termination of the spinal cord to exit from their respective intervertebral foramina. These nerve roots form the cauda equina. A potential consequence of this arrangement is that injury to a single lower vertebra can involve multiple nerve roots in the cauda equina. For example, an injury at the L3 vertebra can involve the L3 nerve root as well as the lower nerve roots that are progressing to a level caudal to the L3 vertebra.

Anterior Cord Syndrome

The anterior cord syndrome results from damage to the corticospinal and spinothalamic pathways with preservation of posterior column function. This is manifest by loss of motor function and pain and temperature sensation distal to the lesion. Only vibration, position, and crude touch are preserved. This syndrome may occur following direct injury to the anterior spinal cord. Flexion of the cervical spine may result in cord contusion or bone injury with secondary cord injury. Alternatively, thrombosis of the anterior spinal artery can cause ischemic injury to the anterior cord.[7,8] Immediate evaluation with computed tomography CT or magnetic resonance imaging MRI may reveal an extrinsic mass that is amenable to surgical decompression. The overall prognosis for recovery of function historically has been poor and remains so today.[5]

Central Cord Syndrome

The central cord syndrome is usually seen in older patients with preexisting cervical spondylosis who sustain a hyperextension injury. The injury preferentially involves the central portion of the cord more than the peripheral. The centrally located fibers of the corticospinal and spinothalamic tracts are affected. The neural tracts providing function to the upper extremities are most medial in position. The thoracic, lower extremity, and sacral fibers have a more lateral distribution. Clinically, patients present with decreased strength, and to a lesser degree, decreased pain and temperature sensation, more in the upper than the lower extremities. Spastic paraparesis or spastic quadraparesis can also be seen. The majority will have bowel and bladder control, although this may be impaired in the more severe cases. Prognosis for recovery of function is good; however, most patients do not regain fine motor use of their upper extremities. [7,9,10]

Brown-Séquard Syndrome

The Brown-Séquard syndrome results from hemisection of the cord. It is manifest by ipsilateral loss of motor function, proprioception, and vibratory sensation, and contralateral loss of pain and temperature sensation. The most common cause of this syndrome is penetrating injury. It can also be caused by lateral cord compression secondary to disk protrusion, hematomas, bone injury, or tumors. Of all of the incomplete cord lesions, this has the best prognosis for recovery. [7,9]

Cauda Equina Syndrome

The cauda equina is composed entirely of lumbar, sacral, and coccygeal nerve roots. An injury in this region produces a peripheral nerve injury rather than a direct injury to the spinal cord. Symptoms may include variable motor and sensory loss in the lower extremities, sciatica, bowel and bladder dysfunction, and "saddle anesthesia" (loss of pain sensation over the perineum).[7] Because peripheral nerves possess the ability to regenerate, the prognosis for recovery is better than that for spinal cord lesions.

MECHANISM OF INJURY

Accidents involving motor vehicles are the principal cause of traumatic injury to the spinal cord. Other etiologies, in descending order of frequency, include falls, gunshot wounds, and injuries secondary to sports or recreational activities.

Fractures of the spine can be divided into minor and major injuries. Minor injuries are those that are localized to part of a column and do not cause instability. These fractures often result from direct blunt trauma to the posterior elements of the spine. Minor injuries include isolated fractures of the transverse, spinous, and articular processes. Major spinal injuries can be classified into four categories: (1) compression (wedge) fractures, (2) burst fractures, (3) flexion-distraction (seat belt–type injuries) and (4) fracture/dislocations. [11]

Compression fractures result from axial loading and flexion, with subsequent failure of the anterior column (Fig. 248-3). The middle column remains intact. These injuries are usually stable unless they are greater than 50 percent. They are unlikely to be directly responsible for neurologic damage.

FIG. 248-3. Wedge compression fractures are often caused by axial unloading with failure of the anterior column. **A,** Schematic of a compression fracture. **B,** Lateral reconstruction of a CT demonstrating the anterior wedging. **C,** Demonstrates the anterior wedging and vertebral body fracture. Note the lack of retropulsion of elements into the spinal canal.

Burst fractures occur following failure of the vertebral body under axial load (Fig. 248-4). In contrast to compression fractures, both the anterior and middle columns fail. There is retropulsion of bone and disk fragments into the canal. This may cause spinal cord compression.
FIG. 248-4. Burst fractures are also caused by axial unloading. Both anterior and middle columns have failed. **A,** Schematic of the forces transmitted. **B,** Lateral reconstruction CT scan demonstrating failure of both the anterior and middle columns. **C,** Demonstrates the burst vertebral body. Note the retropulsion of elements into the spinal canal.

Flexion-distraction injuries are commonly seen following seat belt–type injuries, particularly where lap belts alone are used (Fig. 248-5). The seat belt serves as the axis of rotation during distraction, and there is failure of both the posterior and middle columns. The intact anterior column prevents subluxation. Typical radiographic findings reveal increased height of the posterior vertebral body, fracture of the posterior wall of the vertebral body, and posterior opening of the disk space.

FIG. 248-5. Flexion-distraction injuries involve rotation of forces. This results in failure of both the posterior and middle columns. **A,** Schematic of the forces transmitted. **B,** Plain films demonstrating a flexion distraction injury. **C,** Lateral CT reconstruction confirming the pattern, also demonstrating posterior opening of the disc space. **D,** Shows loss of the middle column with fracture through the lateral elements.

Fracture-dislocations are the most damaging of injuries (Fig. 248-6). Compression, flexion, distraction, rotation, or shearing forces lead to failure of all three columns. The end result is subluxation or dislocation.
FIG. 248-6. Fracture dislocations are the most damaging of injuries leading to failure of all three columns. **A,** Demonstrates these injuries schematically. **B,** Lateral CT reconstruction demonstrating loss of all three columns. **C,** Demonstrates the dislocation and displacement of the vertebral body.

Blunt Injury

MOTOR VEHICLE–RELATED INJURIES   Motor vehicle crashes usually result in acceleration-deceleration injuries. Multiple vertebral structures are subjected to the forces involved, including the anterior and posterior bony elements, disks, interspinous ligaments, and musculature. The cervical spine is the most susceptible to injury by this mechanism, but the thoracic and lumbar regions are also at risk. The majority of victims are involved in low-impact crashes. Most commonly, the soft tissues are injured. Patients complain of pain in the posterior neck and back. High-speed, high-energy crashes are more likely to result in structural damage to the spine. Lap-only seatbelts have been associated with thoracolumbar injuries.

Pedestrians struck by vehicles and motorcyclists are at considerable risk for multiple skeletal injuries, including spinal injuries. These patients have no protective structure surrounding them and are therefore subject to forces applied directly to their bodies.

The challenge to the emergency physician is to distinguish between minor injury and an unstable spine. Obvious neurologic deficits mandate emergent treatment for an unstable injury. In the absence of deficits, the mechanism of injury with an understanding of the forces involved should guide management. When in doubt, it is best initially to overtreat and overstudy in order to avoid missing a significant injury.

Falls

Falls from a height are associated with fractures of the lower extremities, pelvis, and spine. Scalea et al. studied 161 patients who fell from a height of one or more stories, nearly one-fourth of whom suffered spine fractures.[12] Of the latter, 74 percent sustained a major compression or burst fracture. The most common site of injury was the thoracolumbar junction. A thorough neurologic evaluation must be part of the early assessment of patients with vertical deceleration injury. All patients must be presumed to have unstable spine fractures until proven otherwise.

Sports Injuries

Spinal injuries occur in both contact and noncontact sports. The specific injury is related to the mechanism, the force involved, and the point of application of the force rather than to the specific sport. Injuries can occur to the supporting tissue, the disk, or the bone. The majority of injuries are self-limiting soft tissue injuries. Injuries at the level of the disk result in disk herniation or degeneration. Those that occur at the level of the bone can range from minimal avulsion-type fractures to compressions or fracture dislocations. Most bony injuries are not associated with neurologic sequelae. Rarely, however, sports injuries do result in significant neurologic compromise. When neurologic impairment occurs, it is usually secondary to direct axial forces. Catastrophic injuries have been associated with football, water sports (especially diving), gymnastics, rugby, and ice hockey.[13]

Penetrating Injury

The majority of penetrating spinal cord lesions are caused by gunshot wounds. These wounds may be localized to the spine or may involve transperitoneal trajectories. The spinal cord may be injured by direct contact with the bullet, by bony fragments, or from concussive forces.[14] Most gunshot wounds result in stable vertebral injuries, although cord lesions are often complete. Stabbing injuries are much less common. These may be inflicted by a variety of implements including knives, axes, icepicks, screwdrivers, and glass fragments. The majority of stab wounds involve incomplete Brown-Séquard lesions of the thoracic cord. These have the best prognosis of incomplete spinal injuries. The prognosis for patients with stab injuries to the spine and incomplete paralysis is significantly better than that for patients with gunshot wounds to the spine and a similar extent of paralysis.

TREATMENT

The initial care of a patient with a spinal cord injury must be performed in conjunction with the evaluation and treatment of coexisting injuries, both potential and diagnosed. As with all multiply injured patients, this involves prehospital evaluation and triage, which should be designed to deliver the patient to the most appropriate level of care for the compendium of injuries. In addition, prehospital therapy must include stabilization of the patient as well as control of the underlying problem if possible. Emergency department (ED) evaluation must be tailored to rapidly identify injuries and institute early therapy.

Prehospital Care

The prehospital treatment of patients with spinal cord injury involves recognition of patients at risk, proper triage, and early care. All patients who have complaints of neck or back pain or who have tenderness on prehospital assessment must be presumed to have a spine injury until proven otherwise. Traditionally, all patients with significant injury above the clavicle are also presumed to have cervical spine injury regardless of related complaints. All patients with neurologic complaints must be presumed to have a spinal cord injury. Sometimes this is obvious, as in a patient with flaccid paraplegia. More often, symptoms are much more subtle (numbness or tingling in an extremity). Appropriate triage is imperative, as the results of the treatment for spinal cord injury are somewhat time-related. Therefore, initial triage to a center that is capable of rapid diagnostics and therapeutics is essential to optimize outcome following spinal cord injury.

Triage can be difficult. Patients may be asymptomatic or may have suffered a concomitant head injury that makes them unable to describe their injuries and hence does not allow for neurologic assessment in the field. Other injuries may preclude accurate hospital assessment. The mechanism of injury is an important criterion on which prehospital providers can rely. High-speed or roll-over vehicular accidents are commonly associated with spinal injury. Even more commonly, axial loading injuries such as substantial falls from a height produce spinal cord injuries, generally in the area of the thoracolumbar junction. Diving and surfing accidents, where force is transmitted through the cranium and into the cervical spine, typically produce cervical spine injuries. Any patient at risk by mechanism of injury must be presumed to have a spinal cord injury. While this may result in a substantial rate of overtriage, the consequences of undertriage can be devastating.

Prehospital care for spinal injuries involves immobilization of the entire spine and initial fluid therapy as proposed by the American College of Surgeons.[15] The entire cervical spine can be immobilized with a rigid cervical collar supplemented with sandbags and tape. The thoracic and lumbar spine can be immobilized utilizing a long backboard. Patients are "papoosed" onto the boards to maintain spinal alignment. Patients should be transported completely immobilized. Fluid therapy is begun and tailored to avoid hypotension. While there is little scientific evidence to support any single target for systolic or mean arterial blood pressure in patients with spinal cord injuries, a mean arterial pressure of 65 to 70 mmHg seems a reasonable target. Optimal perfusion of the spinal cord is one of the therapies that can be implemented in the field to lessen the chances of secondary spinal injury.

Prehospital personnel must balance the issues of time of transport with the level of expertise of the various hospitals within their system. All efforts should be made to deliver patients with symptomatic spinal injuries to the areawide spine center. Delays engendered by transport to a different site can be costly. Clearly, patients who

are not hemodynamically stable must be taken to the closest available hospital.

ED Stabilization

ED evaluation should not differ substantially from any patient with multiple injuries (see Chap. 243). It involves a stepwise search for immediately life-threatening injuries. Airway concerns are paramount. Real consideration should be given to immediate airway control in patients with cervical spine injuries no matter how stable they seem at the time of presentation. The higher the level of spinal injury, the more compelling the indication for early airway intervention. The roots of the phrenic nerve, which supplies the diaphragm, emerge at the third, fourth, and fifth cervical vertebral levels. Thus, any patient with an injury at C5 or above should be intubated. It may be prudent to intubate parents with cervical cord lesions even below this level. Significant spinal cord edema may progress rostrally to involve the roots of the phrenic nerve. Many patients can initially support ventilatory function utilizing intercostal muscles or abdominal breathing, but they eventually tire and then develop respiratory failure. As the evaluation process for these patients often involves transport outside of the ED, the authors feel strongly that early airway control is the safest route. Patients who develop respiratory failure in the CT scanner or the MRI suite may suffer respiratory arrest before it can be recognized and the airway secured. This risks anoxic brain damage and worsening spinal cord injury from hypoxia.

AIRWAY   It is important to try to perform a complete neurologic assessment if possible before patients are intubated and sedated. The spine must be kept immobilized while the airway is managed. In general, this is accomplished using orotracheal intubation with in-line cervical stabilization (without distraction force) and cricoid pressure. Nasal intubation can be performed in patients while maintaining spine immobilization, though it is not our preferred method and presents considerable difficulties. Nasal intubation is generally a blind technique. Virtually all patients with potential cervical spine trauma require sedation before nasal intubation can be accomplished; but if respirations become substantially depressed, nasotracheal intubation may not be possible. If patients are inadequately prepared they may resist intubation. Motion of an unstable fracture can worsen spinal injury. If patients are over-sedated, they may become hypoxic and lose the ability to protect the airway. Also, nasal intubation is performed with a smaller endotracheal tube, which can compromise respiratory therapy later during the hospitalization. Fiberoptic bronchoscopy (FOB) may be required, particularly in those with pulmonary injuries or significant atelectasis. Bronchoscopy can be used for diagnostic purposes or to facilitate removal of inspissated mucous plugs or blood. A relatively large endotracheal tube (8.0 mm or greater in size) is needed during FOB in order to ensure that ventilation is not compromised during the procedure. An 8.0 mm endotracheal tube is often too large for nasotracheal intubation. In addition, the limiting factor in minimizing tube size is the increasing respiratory resistance to gas flow imposing increased work for the patient with each spontaneous breath. Thus, the work of breathing is greater with tubes of 6 to 7 mm internal diameter, sometimes used for nasal intubation, than with tubes of 8 mm or greater internal diameter. The most limiting aspect of nasal intubation is the inability to move the cervical spine to attain the "sniff" position, optimal for the procedure. Finally, nasal intubation increases the risk of sinusitis, which later becomes symptomatic.

Nasal intubation with fiberoptic guidance is a useful technique. It does carry many of the concerns of nasal intubation previously mentioned. It is, however, not a blind technique and can be directed, maximizing the chances of successful airway management.

Patients with spinal cord injuries often have concomitant chest injuries and/or abdominal injuries. A careful survey must be completed for each of these. Respiratory failure in a spinal cord–injured patient can certainly come from tension pneumothorax or blood loss into the chest.

HYPOTENSION   Following airway stabilization, hemodynamic stability is the most pressing concern. Fluid therapy is generally the treatment of choice to support cardiovascular functioning. Patients with spinal cord injuries often present with hypotension, which must be differentiated as to its cause: spinal cord injury, blood loss, or both. Injury to the spinal cord at the level of the cervical or thoracic vertebrae causes sympathetic denervation. There is a loss of a-adrenergic tone and dilatation of the arterial and venous vessels. Elimination of sympathetic arterial tone results in hypotension. Systemic vascular resistance is reduced. Loss of sympathetic innervation to the heart (T1 through T4 cord levels) leaves the parasympathetic cardiac innervation via the vagus nerve unopposed, resulting in bradycardia. While it is true that neurogenic shock is associated with bradycardia, it should never be assumed that a patient with hypotension and bradycardia is suffering from isolated neurogenic shock. Vital signs are often nonspecific. Patients with neurogenic shock may have concomitant hemorrhagic shock and may not be able to mount a tachycardic response. Blood loss must be presumed to be the cause of hypotension until proven otherwise. In general, patients with neurogenic shock are warm, peripherally vasodilated, and bradycardic. They seem to tolerate hypotension relatively well. This makes some sense, as peripheral oxygen delivery is presumably normal. They have incurred mechanical sympathectomy, thus cardiovascular function is not impaired.

The mechanism of injury is important in determining whether hypotension is from spinal cord injury or blood loss. Soderstrom et al. have demonstrated that 70 percent of patients with blunt trauma have hypotension secondary to the spinal cord injury.[16] However, in almost one-third of the patients, blood loss at least partly explained the hemodynamic instability. Hypotension from spinal cord injury is highly unusual in patients with penetrating injury. Zipnick et al. have demonstrated that over 90 percent of hypotensive patients with penetrating spinal cord injury have blood loss to at least partly explain their hypotension. [17]

In all patients, a rapid search for potential blood loss should be undertaken. A chest x-ray will identify blood loss within the thorax. Retroperitoneal blood loss can come from concomitant pelvic fractures or may be secondary to lumbar arterial bleeding from spine fractures, especially in patients with substantial falls from a height. This can be a difficult diagnosis to make. Every patient with a spinal fracture should have an abdominal investigation. In hemodynamically unstable patients, CT scanning is too time-consuming; therefore ultrasound or diagnostic peritoneal lavage should be used (see Chap. 252). Retroperitoneal bleeding should be suspected in patients without evidence of intraabdominal blood loss who develop abdominal distention or tenderness. [12] Plain x-rays that demonstrate spinal fractures should help with the diagnosis. Angiography may be necessary for both diagnosis and treatment of ongoing bleeding.

NEUROLOGIC EXAMINATION   Once patients are stabilized and other life-threatening injuries have been excluded or treated, a detailed neurologic examination should be performed if still possible. Details of history include whether the patient has had a loss of consciousness. Ask about the presence or absence of sensory or motor symptomatology in the field. A patient who was asymptomatic in the field and has neurologic deterioration in the ED requires emergent therapy. The presence of neck or back pain, or urinary or fecal incontinence clearly defines the patient at risk for spinal cord injury.

Physical examination should delineate the level of spinal cord injury, if any (Fig. 248-7). Document the initial neurologic performance. If patients deteriorate later, a complete initial neurologic examination must be documented for comparison purposes. The presence or absence of neck or back tenderness should be noted. A careful motor examination should be performed. Motor function for muscle groups should be tested and recorded on a scale of 0 to 5 (Table 248-2). The level of sensory loss should be determined. Gross proprioception or vibratory function must be investigated to examine posterior column function. Deep tendon reflexes should be tested. Anogenital reflexes should also be tested, because "sacral sparing" with preservation of the reflexes denotes an incomplete spinal cord level even if the patient has complete sensory and motor loss. The neurosurgeon must be notified emergently. To test the bulbocavernosus reflex, squeeze the penis to determine whether the anal sphincter simultaneously contracts, and assess rectal tone at the same time. Priapism implies a complete spinal cord injury. The cremasteric reflex is tested by running a pin or a blunt instrument up the medial aspect of the thigh. If the scrotum rises, there is some spinal cord integrity. The area around the anus should be tested with a pin. An "anal wink" (contraction of the anal musculature) indicates some sacral sparing.

FIG. 248-7. Spinal cord level. This level can be delineated by physical examination, including a detailed neurologic examination.

DIAGNOSTIC IMAGING

Certainly one of the real dilemmas facing the clinician in the ED is which patient requires evaluation for a potential spinal cord injury (Fig. 248-8). A multiplicity of examinations exists. Blind application of expensive diagnostic testing risks inappropriately increasing the cost of medical care and potentially rendering resources unavailable to other patients. Diagnostic testing must evaluate the possibility of injury to both bone and spinal cord. While these often occur in concert, this is not always the case. While one would always like to limit diagnostic testing to those who require it, the consequences of a missed spinal cord injury can be devastating. Removing a collar or allowing a patient to walk with an unstable spine risks converting a patient with no spinal cord injury to one with a complete level. Thus, it is prudent to completely image and evaluate all patients with the possibility of spinal cord pathology.

FIG. 248-8. Algorithm for blunt spinal trauma.

In general, an x-ray of the cervical spine is part of the standard triage for blunt trauma. The utility of plain films of the cervical spine over the clinical examination to identify injury in patients who are alert, oriented, and have no neck or back pain is questionable. [18],[19] Many centers have abandoned use of cervical spine x-rays in such patients. There is a substantial difference, however, in patients who are not alert and awake. The frequency of cervical spine injury in association with blunt head trauma is about 2 to 5 percent. However, it increases to almost 9 percent in patients with significant head injury, defined as a Glasgow Coma Scale score <10. [20]

Plain x-rays are clearly indicated in all patients with neck pain or cervical tenderness. The presence of pain or tenderness has over an 80 percent sensitivity for cervical spine injury. Cervical spine injury is very unusual in patients without pain or tenderness but may occur in approximately 1 percent. [19] Thus, the mechanism of injury should also be taken into account when the decision is made whether to image a patient's cervical spine. In a study of 233 patients, nine variables correlated significantly with cervical spine injury. They were: falls, symptoms of numbness, sensory loss, weakness, neck spasm, neck tenderness, objective sensory and motor loss, and weakness or loss of anal sphincter tone. Correlation of cervical injury with involvement in a motor vehicle crash approached statistical significance. [21] Unfortunately, there are significant limitations to the study that do not allow accurate assessments. Apart from a paucity of patient-related information, the study appears to show that falls greater than 10 ft are not significantly associated with spine injury. The question of how much force is required before cervical spine injury is likely remains largely unanswered at this time, but studies are underway to develop decision guidelines.

The "gold standard" for the identification of bony cervical injury includes three views of the cervical spine: AP, lateral, and odontoid. They allow for imaging of the entire cervical spine. It is important that all seven cervical vertebrae be imaged, including the junction between the seventh cervical and the first thoracic vertebrae. A single lateral cervical spine film is important as an initial screening radiograph. It will identify 90 percent of injuries to bone and ligaments. Cervical immobilization must be maintained until the patient also has an AP and open-mouth odontoid view. If the initial lateral view is normal and the patient is neurologically intact, the AP and open-mouth views can be delayed until other injuries are adequately stabilized. The combination of lateral, AP, and odontoid views is generally adequate to identify or at least raise the suspicion of cervical spine injury.

Visualization of the entire cervical spine often can be problematic. Patients' body habitus or the presence of upper extremity injuries may limit the clinician's ability to pull on the arms, a maneuver necessary to visualize all seven vertebral bodies. An alternative is a swimmer's view, which is aimed through the axilla in an attempt to image the lower cervical spine. Oblique views (45°) can also be obtained. These views have the added advantage of showing the neural foramina well. They demonstrate the pedicles as well as the laminae, which should stack like shingles on a roof. A newer technique is CT scanning of the cervical spine which can visualize the entire cervical spine well but not the atlantooccipital junction.

Patients can have cervical spine injury even with normal plain films. In fact, a normal lateral cervical spine film may only identify 90 percent of significant bony and ligamentous injuries. The film must be examined for the presence or absence of prevertebral swelling. The prevertebral space anterior to C3 should be less than 5 mm. The predental space should be less than 3 mm. The open-mouth odontoid view will identify many of the remaining abnormalities. [22] Still, plain films of the neck may not identify patients with pure ligamentous injuries. In these patients, ligaments are disrupted but the spine spontaneously reduces to a normal position. Motion, however, risks neurologic injury.

Flexion and extension views demonstrate the degree of spinal column stability. In general, these views are obtained when patients have pain or tenderness but normal plain films. [23] They can only be obtained in a fully awake, unsedated cooperative patient. The patient carefully and slowly flexes and extends the neck. Motion should be limited by increasing pain or the appearance of any neurologic symptomatology. A stepoff of 3.7 mm or an angulation of greater than 11° denotes cervical spine instability. [24] It is possible to have ligamentous injury even with normal flexion/extension films, since muscle tone can splint the bones in a stable configuration. Most patients in this latter category note pain improvement with analgesics after a few days. Reliable patients without a substantial mechanism of injury with persistent pain but normal radiographs, including flexion/extension views, can be discharged in a hard collar with outpatient follow-up. Most patients' symptoms will resolve over a few days. A patient with persistent symptoms will require additional outpatient workup. Unreliable patients or those with a significant mechanism of injury or risk factors, such as advanced age, should undergo MRI.

Plain films of the thoracic and lumbar spine are the initial examinations generally utilized to image these spinal levels. Many of the same principles used for cervical spine imaging are important for thoracic and lumbar imaging. All patients with a mechanism of injury, those with complaints of back pain, and those who have tenderness on physical examination must be assumed to have a fracture of the thoracic or lumbar spine. They must be kept immobilized. AP and lateral films are generally obtained and examined for abnormality. In general, the lateral x-rays are much more easily obtained with patients still on a backboard. Skin breakdown and pressure sores can develop very quickly, particularly in obese patients. Our goal is to remove patients from the backboard in less than 2 h. Patients can then be nursed supine in a bed as long as they are logrolled. A standard hospital mattress provides adequate spinal support. However, patients must be carefully moved and care must be taken to keep spinal immobilization complete in transfers from bed to stretcher. It may be helpful to place patients back on a backboard for the

transportation phases of their care. Alternatively, a scoop stretcher may be used for transport.

It can be difficult to image the upper thoracic spine adequately, even if maximal power of the x-ray beam is used. One alternative is to clear the reliable patient by physical examination. Unreliable or unexaminable patients with a concerning mechanism should be log-rolled until they become examinable. Patients with point tenderness and normal films are a special subset. CT scanning can be useful in this subset, though the yield is low. The thoracic spine has inherent stability from the rib cage. Few fractures in these patients will be unstable. Alternatively, patients can be treated with analgesics and investigated selectively if symptoms persist.

More recently, CT has assumed a much more important role in the imaging of spine injuries. Plain films can be imperfect and may miss a number of such patients. Newer-generation helical scanning is rapid, and CT allows for a complete three-dimensional imaging of bony structures. CT scanning is indicated in almost all patients with proven bony spinal injury, as it allows for more precise anatomic description of the fractures. CT can reveal the exact anatomy of an osseous injury and the extent of spinal canal impingement by bone fragments. CT is vital in helping to determine the stability of an injury. CT scans are indicated for all patients with subluxations or fractures that can be seen on plain films. CT scans are also useful in patients with neurologic deficits but no apparent abnormalities on plain films, those with severe neck or back pain and normal plain films, and those in whom the thoracic and lumbar spine should be examined to define the anatomy of a fracture and the extent of impingement on the spinal canal. CT is especially useful when the lower cervical spine cannot be adequately visualized on plain films because of overlying soft tissues.

MRI is not as sensitive as CT for picturing bone injuries precisely. On the other hand, MRI is superb at defining neurologic, muscular, and soft tissue injury. It is the diagnostic test of choice for describing the anatomy of nerve injury. Entities such as herniated disks or spinal cord contusions are easily seen on MRI. Many of these require only supportive therapy. However, some require acute surgical intervention. Early identification helps plan therapy. MRI may also be used to identify ligamentous injury and it is indicated in all patients with neurologic symptoms or physical findings but no clear explanation on plain films and/or CT scanning.

MRI is indicated and should be part of the ED workup in patients with neurologic findings with no clear explanation following plain films and CT scanning. CT myelography is an alternative when MRI is unavailable and immediate diagnosis of a neurologic lesion is required. If the patient is neurologically stable and MRI is unavailable, delayed MRI and/or transfer to a tertiary care facility may be appropriate.

The determination of a spinal column injury at one level should prompt imaging of the remainder of the spine. Approximately 10 percent of patients with one spine fracture will have a second fracture. Often plain films will suffice, but multilevel CT scanning and/or MRI may be necessary to investigate such patients completely.

TREATMENT

The goals of treatment are to prevent secondary injury, alleviate cord compression, and establish spinal stability. Spinal immobilization must be maintained. Unnecessary movement of a potentially unstable spine must be avoided in order to prevent additional injury.

Once the patient is stabilized, it should be determined whether the patient has a neurologic deficit and/or the spinal column is unstable. If either of those conditions exists, subspecialty consultation should be requested emergently. The consultant, be it a neurosurgeon or orthopedic surgeon, must have the opportunity to perform a detailed neurologic examination early in the patient's course, so as to optimize outcome. Patients with progressive neurologic deterioration require urgent surgical intervention. The method of stabilization (collar or traction) must be determined, as must the need for further CT or MRI imaging.

Corticosteroids

High-dose methylprednisolone has been shown to be effective in the treatment of blunt spinal cord injury. The National Acute Spinal Cord Injury Study (NASCIS) group conducted a series of multi-institutional studies to evaluate the efficacy of methylprednisolone in spinal trauma. [2] Methylprednisolone infusion resulted in improvement of both motor and sensory function in patients with complete and incomplete neurologic lesions. This positive outcome was dependent upon dosage of steroids and time of administration. The current recommended steroid protocol for victims of spinal injury with neurologic deficits is as follows:

1. Treatment must be started within 8 h of injury.
2. Methylprednisolone (30 mg/kg) bolus administered intravenously over 15 min.
3. This is followed by a 45-min pause.
4. A maintenance infusion of methylprednisolone (5.4 mg/kg per hour) is continued for 23 h.

NASCIS evaluated only blunt spinal cord injury. Patients with penetrating injuries were excluded from the study. The role of steroids in the treatment of penetrating cord injury is currently unclear.

The major neuroprotective mechanism of high dose methylprednisolone is its inhibition of free radical-induced lipid peroxidation. [25] Other proposed beneficial actions of methylprednisolone include its ability to increase levels of spinal cord blood flow, increase extracellular calcium, and prevent loss of potassium from injured cord tissue. Methylprednisolone is advocated in preference to other steroids because it crosses cell membranes more rapidly and completely.

Penetrating Injury

Treatment goals are the same for penetrating and blunt spinal injury. There are, however, additional considerations in penetrating trauma (Fig. 248-9). Optimal treatment of these injuries has been the subject of debate. One concern is that of infectious complications related to the presence of foreign bodies. Additional contamination is associated with transperitoneal and transintestinal trajectories of gunshot wounds to the spine. Intravenous antibiotics should be given in the ED. Surgical debridement with laminectomy has not proven effective in reducing the incidence of infectious complications, as most are managed nonoperatively. If the patient requires laparotomy for abdominal trauma, irrigation and debridement of the spinal injury through the missile tract may be appropriate. [14]

FIG. 248-9. Algorithms for gunshot to spine.

As with blunt trauma, there is general agreement that progressive neurologic deficits warrant surgical decompression. The indication for removal of bullet and bone fragments in those patients with nonprogressive neurologic deficits is less clear. Wound location may determine the need for surgical intervention. Bullet removal has not been shown to significantly improve the neurologic status of patients with stable cervical and thoracic spinal cord lesions. In contrast, a collaborative study by the National Spinal Cord Injury Model Systems demonstrated that bullet removal from the thoracolumbar spine significantly improved motor recovery in both complete and incomplete injuries.[26] Most vertebral injuries to the spine following penetrating trauma are stable and require only symptomatic treatment with a supportive orthosis and analgesics.

Nonoperative Spinal Stabilization

The goal of stabilization is to reduce deformities and then restrict motion and maintain alignment. In the cervical spine, it is important to determine the adequacy of cervical bony reduction. Subluxations are generally reduced using Gardner-Wells tongs, which are placed into the soft tissue of the temples under local anesthesia. The location and type of injury determine the amount of weight applied. The upper cervical spine generally requires less weight for traction than the lower cervical spine. Depending upon location, initial weight should be started at 5 to 10 lb. Weight should be increased in 2.5-to 5-lb increments. Ideally, this should be done under fluoroscopic guidance. If fluoroscopy is unavailable, radiographs and neurologic examinations should be performed after each increment of weight. The radiographs should be evaluated for alignment of the spinal column and to ensure that overdistraction has not occurred. Neurologic performance can improve if reduction is achieved. Inability to achieve adequate reduction is an indication for early spinal decompression and fusion.

Spinal orthoses are used to immobilize well-reduced cervical fractures. The cervical spine is the region most effectively stabilized by external splinting devices. There is less soft tissue separating the brace from the spine at this level. In addition, some braces can be solidly secured by fixation points at the cranium and the thoracic cage. Cervical orthoses consist of cervical and cervicothoracic types. Cervical collars fit around the neck and contour to the mandible and occiput. They restrict flexion and extension in the middle and lower cervical spine. Lateral bending and rotational movements, however, are poorly controlled. Examples of cervical orthoses include the hard collar, the Philadelphia collar, and the Miami J collar. Cervicothoracic braces provide additional support. The "gold standard" is the halo cervical immobilizer, which provides the most rigid stabilization. Consisting of a halo ring pinned to the skull, a vest, and upright posts, it can be used for traction and reduction of unstable fractures as well as immoblization.

Immobilization of the upper thoracic spine by orthoses is difficult. Fortunately, an intact rib cage and sternum provide relative stability. Although brace immobilization is not always necessary in the treatment of these fractures, braces can provide additional comfort. Thoracic corsets provide minimal control of motion and are appropriate only for minor injuries. Jewett and Taylor braces provide intermediate control of spinal motion. Maximum limitation of motion is provided by the Risser jacket and the body cast.

The thoracolumbar junction and lower lumbar regions are also difficult to immobilize externally. The splints are limited by the lack of an adequate caudal fixation point. The functions of most thoracolumbosacral orthoses (TLSOs) are the following: to create an awareness and remind the patient to restrict movements, to support the abdomen and relieve some of the load on the lumbosacral spine, to provide some restriction of motion of the upper lumbar and thoracolumbar spine by three-point fixation, and to reduce lumbar lordosis in order to provide a straighter, more comfortable lower back.

Complications of external immobilization devices include pain, pressure, muscle weakness and disuse atrophy, venous compromise, psychological dependence, ineffective stabilization, and pin-site complications (halovest). [27]

Operative Management of Spine Injuries

The indication for operative stabilization is somewhat controversial and varies from institution to institution. Those favoring an aggressive approach stress the importance of early mobilization of the multiply injured patient as it helps decrease pulmonary problems, skin breakdown, deep venous thrombosis, and pulmonary embolus. Early stabilization allows for this early mobilization. Rigid fixation may also decrease time in hospital as well as long-term pain and deformities.

Those advocating a nonoperative approach point out the possibility of worsening neurologic performance by operative manipulation. In addition, the long-term results with operative intervention may not be substantially better than with nonoperative therapy.

All would agree that progressive neurologic deterioration is an indication for urgent surgery. In addition, spinal instability should most often be managed operatively even in the case of a complete spinal cord level. This helps prevent long-term deformity.

AGE CONSIDERATIONS

Elderly

Osteoporosis and degenerative bone changes predispose the elderly to injury from low-energy trauma. A significant number of injuries occur following falls. Central cord syndrome is the most common incomplete lesion. Compression fractures are the most common bone injuries in the thoracic and lumbar spine. In addition to decreased bone density, pathologic lesions may also be responsible for compression fractures. If a minor mechanism of injury results in a fracture, metastatic disease and multiple myeloma should be excluded as causes. The most important principle of therapy in the elderly is early mobilization and rehabilitation. Prolonged immobilization results in more systemic complications and higher mortality. Decisions involving operative versus nonoperative treatment should take this into account.

Children

Anatomic and biomechanical features unique to the immature spine account for differences in injury patterns between pediatric and adult patients. The pediatric spine has increased phyisologic mobility because of several factors. Laxity of the interspinous ligaments and joint capsules, the horizontal orientation of facet joints, incompletely ossified wedge-shaped vertebrae, and the underdeveloped neck and paraspinous musculature all contribute to increased flexibility, particularly of the cervical spine. This elasticity affords children some protection against spinal trauma. When spinal injury occurs in the pediatric population, however, it is generally secondary to mechanisms involving considerable force. The resulting injuries are associated with a high degree of neurologic compromise at presentation. In addition, there is an increased occurrence of spinal cord injury without radiographic evidence of abnormality (SCIWORA) in patients younger than 10 years. [26] Growth plate fractures are most common, but these are difficult to detect on plain radiographs. If spinal cord injury is suspected, based on history or results of the neurologic examination, normal spine radiographs cannot be used to exclude injury. Immobilization must be maintained. Neurologic deficits should be aggressively evaluated with CT scan and MRI.

An additional concern in the pediatric population is child abuse. Vigorous shaking of infants, termed "shaken baby syndrome," may result in avulsion or compression fractures of the spine. A history that is inconsistent with the nature and extent of the injuries should raise the suspicion of child abuse. A thorough search for associated injuries should be undertaken, and appropriate governmental agencies notified.

249 MAXILLOFACIAL TRAUMA

Stephen Colucciello

Up to 60 percent of patients with severe facial injuries have multisystem trauma and have potential for airway compromise. The alarming nature of facial injuries may divert attention from more occult life threats. Management requires a coordinated team approach, necessitating involvement of emergency physicians, and surgical specialists in ear-nose-throat (ENT), trauma, plastics, and oral surgery (Table 249-1).

TABLE 249-1   Pitfalls in the Management of Maxillofacial Injuries

ETIOLOGY/INCIDENCE

The etiology of facial fractures varies between urban and rural environments. Penetrating trauma and assault-related injuries are more common in cities, whereas motor vehicle crashes (MVCs), sporting, and other recreational injuries are seen frequently in community hospitals. In community emergency departments (EDs), the nose and mandible are the most common facial fractures; in trauma centers, however, midface and zygomatic injuries are more frequent. Domestic violence and elder and child abuse are important causes of facial trauma. Facial injury accounts for the majority of ED visits related to domestic violence. As many as one-fourth of women with facial trauma are victims of domestic violence.[1] If a woman has an orbital fracture, the likelihood of sexual assault or domestic violence rises to more than 30 percent.[2] Falls are also an important cause of facial injury in the very young and the elderly.

Potential injuries associated with facial trauma are those of the head, cervical spine, and eye. As many as 20 to 50 percent of victims of facial trauma sustain concurrent brain injury, especially those with upper face and midface fractures.

Although most series show no increased incidence in cervical spine injury with facial trauma (1 to 4 percent), this is of statistical interest only. One must consider possible spinal injury in all patients with significant or suspected maxillofacial fractures, because it takes considerable force to shatter the midface or upper face. Always rule out cervical spine injury clinically or radiographically in such patients. One study has linked carotid artery injury to severe facial trauma. [3]

Periorbital fractures may be associated with globe disruption. The dangerous triad of limited extraocular movement, limited visual acuity, and limited visual fields should be checked in all those with facial injury.

Blindness occurs in 0.5 to 3 percent of patients with facial fractures and is most frequent in patients with LeFort III (2.2 percent), LeFort II (0.64 percent), and zygomatic fractures (0.45 percent).[4] MVCs and gunshot injuries are responsible for most cases of visual loss.

In addition to the physical consequences of facial trauma, there are psychological costs as well. More than one-quarter of patients with significant facial trauma may develop posttraumatic stress disorder.[5]

ANATOMY

The facial buttresses, bony arches joined by suture lines, provide vertical and horizontal support. Vertical stability depends on the zygomatic-maxillary buttress laterally and the frontal process of the maxilla medially. The zygomatic-maxillary arch and the hard palate bolster the horizontal face. Sutures linking these facial bones rupture in predictable fashion during trauma. Knowledge of their location enables one to palpate these sutures to detect diastasis or tenderness.

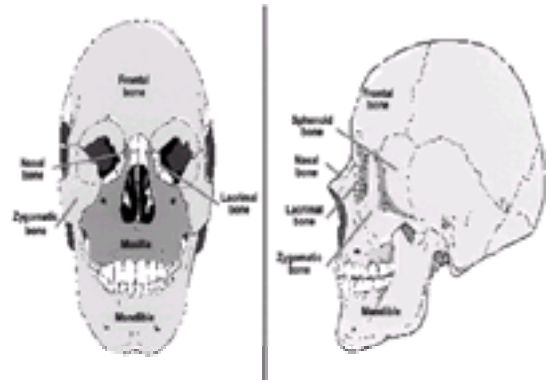
Sutures found at borders of the sphenoid wings, pterygoid plate, and the zygomatic arch anchor the face to the skull. These are the structures disrupted in LeFort injuries (Fig. 249-1).


FIG. 249-1. Coronal and lateral facial bone anatomy. (Reprinted with permission from Isenhour J, Colucciello S: Maxillofacial trauma, in Ferrera P et al: *Trauma Management.* St. Louis, Mosby, 2000.)

The most complex aspect of facial anatomy is the orbit, an elaborate structure comprised of seven different bones: maxilla, zygoma, frontal, sphenoid, palatine, ethmoid, and lacrimal. Between these bones lie the orbital foramina, through which course cranial nerves II, III, and VI and branches of V. Rupture of orbital bones may compress these fissures and cause blindness through traction, rupture, or compression of the optic nerves.

PREHOSPITAL CARE

The major concern in prehospital care is control of the airway. The mouth should be cleared of any foreign body or debris and suctioned of blood. The tongue may block the airway, and a jaw thrust or modified chin lift without neck extension often relieves the obstruction. With severe mandible fractures, these maneuvers may not elevate the tongue, necessitating manual extraction. As a rule, any patient with trauma above the clavicles should have the cervical spine immobilized.

If there is copious bleeding and massive facial injury, early notification allows the ED to prepare for a difficult airway.

EMERGENCY MANAGEMENT: RESUSCITATION

The compelling and sometimes grotesque nature of facial injuries must not distract physicians from following the routine, sequential trauma protocol. The most urgent complication of facial trauma is not shock, but airway compromise, particularly with midfacial and lower facial trauma.

Airway

Simple intervention, such as the chin lift without neck extension, jaw thrust, and oropharyngeal suctioning, often clears the airway. In mandibular fractures, however, loss of bony support may result in a *flail mandible,* leaving the tongue to obstruct the airway.[6] In this case, open the mouth and pull the tongue forward with a gauze pad, towel clip, or a large suture placed through the anterior tongue. When the cervical spine has been cleared, clinically or radiographically, allow the patient to sit up and lean forward, and give the patient a tonsil-tip suction. This position may be lifesaving in patients with significant mandible fractures. Patients who do not respond to simple maneuvers may require intubation.

Intubation Considerations

Because the cribriform plate may be disrupted, avoid nasotracheal intubation in patients with midface trauma. Nasotracheal intubation can result in nasocranial intubation or dramatic nasal hemorrhage. Admittedly, these complications are rare, and some patients have successfully intubated via the nasotracheal route.[7] Nonetheless, orotracheal intubation is often successful even with severely distorted facial anatomy.

Rapid-sequence intubation carries particular risk in facial trauma. These dangers include the failure to intubate and subsequent failure to ventilate with a bag-valve mask. Before paralyzing any patient, evaluate the degree of difficulty anticipated for mask ventilation. Patients with distortion of the maxilla or mandible may be impossible to bag, because the mask will not fit tightly on an unstable face.

In such cases, consider an awake intubation. Options include sedation with a benzodiazepine, droperidol, or other induction agent in a dose that minimizes respiratory depression. If a patient with severe maxillofacial trauma is given paralytics, prepare for immediate backup cricothyroidotomy. *Preparation* in this case implies more than locating a surgical tray: it extends to povidone-iodine on the neck, a ready blade, an opened cricothyroidotomy tray, and a tracheostomy tube at the bedside.

Some authors describe creative approaches to intubation in facial trauma. Fiberoptic intubation with patients in the semiprone position may be useful in penetrating injuries of the face.[8] The traditional supine intubating position may be impossible with a ruined maxilla that falls into the airway. Such airways may clear when a patient lies on his or her side (although this may be both awkward and disconcerting to the physician). The Bullard intubating blade and the laryngeal mask airway are all used to manage a difficult airway in patients with a crushed face.

Other alternatives include percutaneous transtracheal ventilation and retrograde intubation as a temporizing measure. Both require considerable preparation, and the most dependable alternative airway is surgical. Emergency cricothyroidotomy, being faster and associated with fewer complications, is preferable to emergency tracheostomy.

Hemorrhage Control

Patients rarely develop shock from facial bleeding. In hypotensive patients, look for other sources of blood loss, such as intrathoracic, intraabdominal, and retroperitoneal hemorrhage. Control maxillofacial bleeding with direct pressure, and avoid blind clamping in wounds, because important structures such as facial nerve or parotid duct may be injured. Severe pharyngeal bleeding may require packing of the pharynx and hypopharynx around a cuffed endotracheal tube. In patients with LeFort fractures, manual reduction of the face should stem bleeding. Grasp the anterior hard palate at the maxillary arch and realign the fragments.

Severe nasal bleeding requires direct pressure to the nares, or combined posterior and anterior packing, taking care not to pack the cranium. In the case of massive nasopharyngeal bleeding, a Foley catheter placed along the floor of the nose and inflated with saline may be lifesaving. Nasopharyngeal dual-lumen balloons are commercially available for this purpose.

Once the airway is secure and gross hemorrhage controlled, only then search for life threats in the chest, abdomen, and pelvis.

HISTORY

Obtain a history regarding the injury from the patient, witnesses, and prehospital care providers. It is important to determine the mechanism and time of injury and to assess for loss of consciousness. Allergies and tetanus status are standard inquires.

The following three "face-oriented" questions are essential: (1) "How is your vision?" (2) "Is any part of your face numb?" and (3) "Are your teeth meeting normally?" These questions target eye involvement, injury to facial nerves, and alignment of central and lower face.

Question the patient regarding vision, diplopia, and whether there is pain with eye movement. Monocular double vision occurs with lens dislocation or with corneal or retinal injury, whereas binocular double vision implies dysfunction of the extraocular muscles or nerves. Pain on eye movement suggests injury to the orbit or globe.

There should be a high index of suspicion for domestic violence. If the mechanism of injury is not an MVC, ask women about domestic violence. Although a victim of domestic violence may tell the triage nurse that they fell or "ran into a door," most patients reveal the true etiology if directly questioned by a physician. Child abuse and elder abuse are important considerations when patients at the extremes of age present with facial trauma. More than half of all abused children are injured in the head, face, mouth, or neck.[9]

PHYSICAL EXAMINATION

Inspection

Begin the examination by viewing the patient from the front. Facial elongation occurs with high-grade LeFort fractures. Then view the face from above looking down (bird's-eye view) and from below up (worm's-eye view). These perspectives reveal subtle asymmetries. Because posttraumatic Bell palsy occurs with fractures of the temporal bone, test the muscles of facial expression. Ask patients to smile, frown, whistle, raise their brows, and close their eyes tightly. Look for ecchymosis around the eyes (raccoon eyes) and over the mastoid area (Battle sign) for associated basilar skull fracture. These findings usually develop over several hours and are often absent on admission, despite serious facial trauma.

Palpation

Palpation will disclose the majority of facial fractures. The entire face should be palpated carefully for tenderness, bony crepitus, and subcutaneous air. The presence of subcutaneous air is pathognomonic for fracture of a sinus or nose.

During palpation, target vulnerable sutures such as those on the infraorbital rim and the zygomatic-frontal suture located on the upper lateral aspect of the orbit. Simultaneous palpation of the zygomatic arches will reveal any asymmetry. The best way to distinguish tenderness of the soft tissues of the cheek from bony tenderness is by intraoral palpation. Place a gloved finger inside the patient's mouth and on the buccal surface of the upper molars (outside the teeth). In this position, locate the examining finger under the zygomatic arch. This method will identify displacement or collapse of the arch.

To assess facial stability, open the patient's mouth and grasp the maxillary arch (*not* the central incisors—which might pull out). LeFort fractures are best diagnosed by rocking the maxillary arch and simultaneously feeling the central face for movement with the opposite hand. This maneuver is more sensitive for maxillary fractures than are plain films.

Test sensation. Although anesthesia of the face may be secondary to nerve contusion, it often signifies a fracture. Damage to the infraorbital nerve (often due to blowout or rim fractures) results in anesthesia of the ipsilateral upper lip, nasal mucosa at the vestibule, lower eyelid, and maxillary teeth. Lower lip and lower dental anesthesia occurs with mandibular fractures.

Periorbital and Orbital Exam

The eye exam deserves particular attention, especially when there is periorbital injury. The exam should be performed early during the ED encounter, because, if not timely, progressive lid edema may prevent further examination. If lids are already swollen, lid retractors help visualize the globe. The bird's-eye and worm's-eye views help detect exophthalmos or enophthalmos.

The pupil exam includes reactivity, and whether the pupils line up in the horizontal plane. A teardrop-shaped pupil indicates a ruptured or otherwise penetrated globe in patients without preexisting iridectomy. Examine for hyphema, although this usually requires a patient to be sitting. The presence of a hyphema correlates with significant visual loss. The Snellen chart, either standard or hand held, if feasible to administer, should be used to document visual acuity. If the patient cannot see the chart, record finger counting or, barring that, the presence or absence of light perception. Early recognition of traumatic optic neuropathy should trigger an emergency consultation, because timely decompressive surgery may prevent blindness.

The best way to detect damage to the optic nerve or retina is the swinging-flashlight test. An abnormal pupil (Marcus Gunn) initially dilates (rather than constricts) when first exposed to a light that swings between both eyes.

Subconjunctival hemorrhage is often present with periorbital fractures, and lateral hemorrhage frequently accompanies zygomatic fractures. Soft tissue bruising provides other important clues. Periorbital ecchymosis (raccoon eyes) result from a variety of insults, including basilar skull fracture, as well as direct trauma to the periorbital area. Fractures of the orbit, nose, and midface also produce raccoon eyes.

In patients with severe periorbital trauma, measure the distance between the medial canthi. In average adults, the intercanthal distance should be 35 to 40 mm—or approximately the width of a patient's eye. Widening of this distance is called telecanthus and portends serious orbital injury. In patients with telecanthus, the bridge of the nose appears wide, but the distance between the pupils is unchanged. This is usually seen with naso-ethmoidal-orbital (NEO) trauma. A more serious condition known as hypertelorism occurs when the interpupillary distance increases. In this case, the orbits are dislocated and literally "blown apart." This devastating injury usually results in blindness.

Extraocular motions must be evaluated for restriction. Fractures of the zygomatic and infraorbital floor frequently cause diplopia, especially on upward gaze. Significant pain with extraocular motions provides a clue to occult injury.

Palpate the entire orbit for tenderness, subcutaneous air, and deformity. Inexperienced physicians frequently neglect the superior and lateral rims.

Bimanual Palpation Test

One of the most important concerns is the status of the medial orbital area (the NEO complex). Consider this injury if the medial canthus is tender, or if the patient has telecanthus. When an NEO injury is suspected, the bimanual nasal palpation test is a helpful adjunct (Fig. 249-2).

FIG. 249-2. Intranasal palpation test. (Reprinted with permission from Isenhour J, Colucciello S: Maxillofacial trauma, in Ferrera P et al: *Trauma Management.* St. Louis, Mosby, 2000.)

To perform this test, anesthetize the nose with either cocaine or lidocaine. Then insert a clamp or long cotton swab into nose. Use the clamp or swab to press intranasally against the medial orbital rim (just inside the medial canthus). Simultaneously use the other hand to press the medial canthus. If the bone moves, the NEO complex is fractured.

Penetrating Injuries

With periorbital penetrating injuries, consider occult globe penetration. When the orbital septum is violated, fat protrudes from the wound, signaling possible globe perforation. Injuries to the medial third of the eyelids often damage the lacrimal apparatus and should be considered high risk. Check all lid lacerations for disruption of levator palpebral muscle and tarsal plate.

Nose

Inspect the nose from various angles to detect any deformity. Posttraumatic edema often obscures nasal deviation. The patient can assist in the exam by identifying preexisting nasal deformity. Palpation will detect crepitus, subtle deformity, and subcutaneous air. The two most important potential findings are septal hematoma and cerebrospinal fluid (CSF) rhinorrhea. Septal hematoma appears as a bluish, bulging mass on a widened septum. If in doubt, palpate the septum with a cotton swab to appreciate the doughy swelling.

CSF mixed with blood forms a double ring or *halo sign* when dropped on a paper towel or a bed sheet. This occurs because blood and CSF have different diffusion properties. This finding is *not* specific for CSF and will occur with traumatized rhinorrhea. Unlike CSF, simple rhinorrhea (absent blood) does not contain glucose. Unfortunately, the bedside glucose tests cannot distinguish between spinal fluid and rhinorrhea. However, a standard laboratory glucose test can make the distinction.

Ears

Examine the pinna for subperichondral hematoma. The ear canals should be inspected for lacerations and CSF leak. Hemotympanum appears as a purple (not red), often bulging, eardrum. Tympanic membrane ruptures are also seen in conjunction with fractures of the mandibular condyle. In the presence of a basilar skull fracture, the mastoid area may be ecchymotic (Battle sign.)

Oral and Mandibular Exam

During inspection, determine whether the jaw is deviated. Deviation results from either a condylar fracture or dislocation. The chin will point away from a dislocation and toward a fracture. While the patient opens and closes the mouth, look for malocclusion. With LeFort fractures, patients may be unable to close the mouth due to premature occlusion of the molars. Zygomatic fractures also prevent jaw closure if the bone fragment either presses against the masseter or impinges on the coronoid process of the mandible. Test for anesthesia of the lips and gingiva, usually due to a fracture-associated nerve injury.

An intraoral exam may reveal significant pathology. The exam should include manipulation of each tooth, a search for intraoral lacerations, and stress of the mandible. Essentially all fractures can be detected or excluded by both palpating and stressing the jaw. By placing a finger in the external ear canal while a patient opens and closes the mouth, one can palpate the mandibular condyle during jaw motion.

Tongue-Blade Test

The tongue blade, or spatula, test is a useful technique to detect mandibular fractures (Fig. 249-3). Although unnecessary in patients with an obvious fracture, it enables physicians to determine the need for x-rays in patients with jaw pain and no obvious instability. The patient should be asked to bite down forcefully on a tongue blade. The physician then twists the tongue blade in an attempt to break the blade. Patients with a broken jaw will reflexively open their mouth, whereas those with an intact mandible will break the blade. In one study, this test was more than 95 percent sensitive and nearly 65 percent specific for mandibular fracture. [10]

FIG. 249-3. Tongue blade test. (Reprinted with permission from Isenhour J, Colucciello S: Maxillofacial trauma, in Ferrera P et al: *Trauma Management.* St. Louis, Mosby, 2000.)

RADIOLOGY

The choice and timing of radiographic studies depends on the clinical stability of the patient. Management of head, chest, and abdominal trauma takes precedence over facial imaging. In the critically injured, diagnostic imaging of the face, including computed tomography (CT), may be deferred for days, until the patient's condition has stabilized.

It is not always clear which patients require facial imaging. In one study, physical examination alone detected 90 percent of clinically significant fractures. [11] However, management was altered in 17 percent of patients based on either CT or plain films. [11] CT scan is not always required before surgical repair. Some authorities consider scans expensive, time consuming, and labor intensive, adding little information to that gained from physical examination and plain films.

Because immediate surgical intervention is rarely indicated for patients with facial trauma, some argue that most x-rays or CTs may be deferred in the ED. If adequate follow-up is available, a facial surgeon could determine the need for imaging studies at the time of outpatient consultation. On the other hand, because many patients with facial fractures are noncompliant when it comes to follow-up, definitive ED diagnosis of an injury *theoretically* prompts patients to keep the consultative appointment.

Plain Films

Plain films are useful screens for maxillofacial injury and are available in all hospitals. For the uninitiated, the numerous overlapping lines and complex shadows make interpretation challenging.

One of the most useful approaches is to assess symmetry. Consider the right and left sides as mirror images. Are there lucencies or shadows that are unilateral? Are the sutures and sinuses symmetrical? Look for bony integrity and subcutaneous air. While air/fluid levels in the sinuses may occur with acute sinusitis, in the presence of trauma they are nearly pathognomonic for sinus fracture. Clouding of a sinus may be secondary to soft tissue swelling, or due to complete filling of the sinus with blood. When seen in the superior aspect of the maxillary sinus, a soft tissue density may represent herniation of orbital contents through the orbital floor (Fig. 249-4).

FIG. 249-4. Orbital tomogram showing classical "teardrop" herniation of orbital tissue into the maxillary sinus.

Radiographic Views of the Face

The Waters or occipital-mental view is the single most valuable study of the midface. It evaluates continuity of orbital rims, provides an initial diagnosis of blowout fractures, and will demonstrate air/fluid levels in maxillary sinus.

The posterior-anterior (PA or Caldwell) view, which best details the bones of the upper face, confirms ethmoidal and frontal sinus fractures, as well as lateral orbital injuries.

The cross-table or upright laterals are difficult to read and are not very helpful. On occasion, they suggest elongation of the face in LeFort injuries or disruption of the posterior sinus wall. Look for air/fluid levels in sphenoid or ethmoidal sinuses.

The submental-vertex view, known colloquially as the "jug handle" or zygomatic arch view, shows the base of the skull and the zygomatic arches. It may be the only film necessary for suspected arch fractures.

The Towne view is useful for evaluating the mandibular ramus and condyles, as well as the base of the skull.

Computed Tomography

CT provides a conclusive diagnosis of complex maxillofacial fractures. Opinions regarding the role of CT vary widely. Some authorities recommend routine CT scanning for every case of significant facial trauma, whereas others feel it is superfluous. Its greatest utility lies in evaluating patients with known or suspected periorbital and midface fractures. Scans are especially useful to evaluate the globe and orbital fissures. Specialized views—such coronal, sagittal, or parasagittal cuts, thin-slice scans, and three-dimensional reconstruction—are useful in particular circumstances. In general, the slices should be in a plane 90° to that of the suspected fracture—and not parallel to the fracture line. Three-dimensional CT is superior to two-dimensional CT for serious midface fractures, such as tripod and complex maxillary fractures.[12]

Multiply injured patients, who are intubated, unconscious, or sedated, frequently have significant and unsuspected facial fractures. If they require a CT of the head, consider adding a scan of the face for clinically stable patients. Slightly more than 10 percent of such patients may have unsuspected facial fractures needing surgical repair.[13] However, an unstable patient with severe concomitant injuries should not receive a facial scan if it delays emergency surgery.

CT with various manipulations, such as coronal and axial views, is essential for management of particular complex fractures. However, plain films still have an important role in screening for maxillofacial injury. In the case of clinically obvious, complex facial injuries (in particular, periorbital and midface fractures), plain films may be eliminated and CT performed directly. Coronal films should be ordered for periorbital fractures, and thin-slice scans may be appropriate in this area.

Cost

Although charges vary among institutions, a full CT of face with coronals results in a charge of approximately $900. This contrasts with the average charge of $100 to $200 for plain film of the face.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is useful to consultants who wish to visualize the soft tissues of the face, particularly the optic nerve or retrobulbar hemorrhage. MRI does *not* adequately delineate fractures, however.

SPECIFIC FACIAL FRACTURES

Frontal Sinus/Frontal Bone Fractures

This injury commonly results from a direct blow to the frontal bone with a blunt object—classically, a lead pipe or brick. This fracture is frequently associated with intracranial injury, secondary to disruption of the posterior table of the sinus. Dural tears are frequent, and patients may have associated injuries to the orbital roof (leading to blindness), as well as to the brain.[14] Late complications include cranial empyema or mucopyoceles. Mucopyoceles are collections of pus and mucus that occur when fractures block the nasal frontal duct, preventing sinus drainage.

Physical examination may reveal disruption or crepitance of the supraorbital rims or subcutaneous emphysema. Fractures are often overlooked because of traditional prohibitions against skull films for head trauma. Patients with a suggestive mechanism or examination benefit from skull films or a Caldwell view of the face. If a depressed or posterior wall fracture is seen on plain film, obtain CT. Patients with hard signs of a frontal bone fracture (subcutaneous air, bony step-off, etc.) require

only a CT.

Consult with an ENT specialist or a neurosurgeon regarding antibiotic use in patients with frontal sinus fractures. Many specialists recommend antibiotics that cover common sinus pathogens, although the literature lacks definitive evidence on this issue. Frequently prescribed antibiotics include first-generation cephalosporins, amoxicillin-clavulanate, erythromycin, and trimethoprim-sulfamethoxazole. Patients with depressed fractures, or those who have posterior wall involvement, require intravenous antibiotics, admission, and consultation. Those with isolated fracture of the anterior wall may be treated as outpatients.

Naso-Ethmoidal-Orbital Injuries

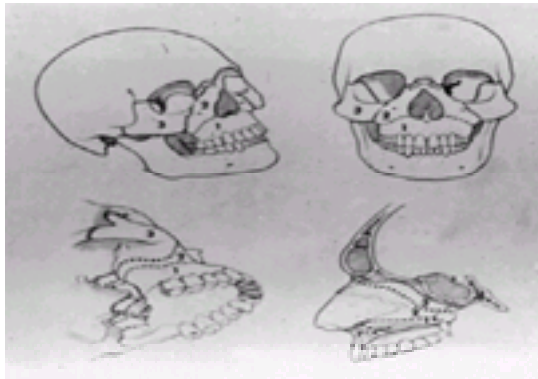
Suspect NEO injuries in those with trauma to the bridge of the nose or medial orbital wall (Fig. 249-5). The mechanism of injury is usually dramatic, and these fractures are not likely due to fisticuffs. NEO fractures are frequently associated with lacrimal disruption and dural tears. Patients may complain of pain on eye movement, and physical examination may reveal traumatic telecanthus or epiphora (tears spilling over the lid).


FIG. 249-5. Schematic of midfacial fracture lines: Le Fort I, II, and III. (Reprinted with permission from Dingman RO, Natvig P: *Surgery of Facial Fractures.* Philadelphia, Saunders, 1964, p 248.)

If the medial canthus is tender, perform the intranasal palpation test and examine for CSF rhinorrhea. Plain radiographs are insensitive. [15] If the examination is suggestive, order a CT of the face to include coronal sections and thin axial slices through the medial orbital wall.

If an NEO fracture is present, consult a maxillofacial surgeon. As with many facial fractures, antibiotics are frequently prescribed for CSF leaks; however, no controlled studies have proven their efficacy. Some believe prophylactic antibiotics increase the risk of resistant organisms.

Orbital Fractures

Blowout fractures are the most common orbital fractures. These injuries occur when a blunt object strikes the globe, resulting in expansion of orbital contents and subsequent rupture through the bony floor. A direct blow to the orbital rim will also result in a blowout. Four clinical findings suggest the diagnosis. (1) Rare patients may have enophthalmos, or sunken globe, when a large section is ruptured. (2) Infraorbital anesthesia is a more common finding and develops when the infraorbital nerve is contused by the initial trauma or when compressed by bony fragments. Anesthesia of the maxillary teeth and upper lip is more reliable than numbness over the cheek. (3) Diplopia, particularly on upward gaze that usually indicates inferior rectus muscle entrapment, is another important clinical finding. However, the etiology of diplopia may be multifactorial and does not necessarily imply entrapment of extraocular muscles. True entrapment occurs in only a small minority of patients with diplopia, and etiologies that are more common include direct muscle injury, damage to the third nerve, or entrapment of periorbital fat. Mechanical entrapment is readily diagnosed by the forced duction test. To perform this test, apply a few drops of ophthalmic anesthetic in the conjunctival sac, grasp the inferior sclera with a toothed forceps, and gently tug upward. In true entrapment, the eye remains fixed. It is not imperative that an emergency physician perform this test, because CT scanning and consultation are necessary for patients with posttraumatic diplopia. (4) Occasionally, a step-off deformity can be palpated over the intraorbital rim. Subcutaneous emphysema is pathognomonic for fracture into a sinus or nasal antrum.

Plain films are useful in the diagnosis of blowout fractures. The "hanging teardrop" sign is seen with herniation of orbital fat into the maxillary sinus, whereas the "open bomb-bay door" results from bone fragments that protrude into the sinus. Air/fluid levels in the maxillary sinus are frequently seen in association with these signs. At least one author suggests that only patients with well-defined indications for surgery (enophthalmos of more than 2 mm and/or persistent diplopia) require any imaging studies at all. [16] This is perhaps a minority view.

Once a blowout fracture is confirmed either radiographically or clinically (i.e., diplopia or subcutaneous air), obtain a CT scan with coronal sections to determine the surface area of the broken floor. This film could be done as an outpatient study, but it may be expedient to obtain it during the ED stay. Patients with orbital fractures tend to have low compliance with follow-up. [17] Some centers have used ultrasound to evaluate orbital floor fractures, but this is not as sensitive as CT.

There is significant controversy as to timing and necessity of orbital floor repair. Some specialists use CT to determine the need for surgery, whereas others repair the orbit only if there is enophthalmos or persistent diplopia. Although enophthalmos mandates surgical repair, most diplopia (up to 70 percent) resolves spontaneously within several months.

Many consultants recommend antibiotics active against sinus pathogens for patients with subcutaneous emphysema. Patients with fractures into the sinus should avoid blowing their nose to prevent accumulation of subcutaneous air.

In rare circumstances, malignant periorbital emphysema may jeopardize vision by injuring the retina or optic nerve. In such cases, emergency cantholysis may salvage the patient's vision. In patients with massive emphysema, and no evidence of an open globe, measure the intraocular pressure. If the pressure is significantly elevated, immediately consult an ophthalmologist and discuss the need for an emergency cantholysis.

Orbital Fissure Syndromes

The oculomotor and ophthalmic divisions of the trigeminal nerve course through the superior orbital fissure. A fracture of the orbit involving this canal compresses these nerves, leading to the superior orbital fissure syndrome. This condition is characterized by paralysis of extraocular motions, ptosis, and periorbital anesthesia.

A more serious variant is the orbital apex syndrome, which involves the optic nerve. Patients with the orbital apex syndrome have all the aspects of the superior orbital fissure syndrome, plus blindness or decrease in visual acuity. The swinging-flashlight test and visual acuity testing are crucial to the diagnosis. Patients with these syndromes need emergent ophthalmic intervention to save their vision. Although few emergency practioners have experience, cantholysis can be considered an ED procedure. It involves anesthetizing then crushing the lateral canthal fold to achieve hemostasis. The lateral canthal ligament is cut and the lids spring apart relieving intraocular pressure.

Nasal Fractures

Cosmesis and the ability to breathe through the nose are key issues in nasal fractures. Apart from management of a septal hematoma, a fractured nose is of little medical concern, unless deformity or airway obstruction is present. Ask the patient several key questions to evaluate nasal fractures: (1) "Have you ever broken your nose before?" (2) "How does your nose look to you?" (3) "Are you having trouble breathing through your nose?" Because nasal deformity may be due to either new or old trauma, solicit the patient's opinion. On physical examination, observe for deformity and palpate for crepitus. The intranasal exam is key to detect septal hematoma, as described earlier. Drain any septal hematomas in the ED after anesthetizing with a topical anesthetic such as cocaine or benzocaine. Use a no. 11 blade to incise the inferior portion of the hematoma and allow it to drain. Packing the nose with Vaseline (petroleum jelly) gauze will prevent reaccumulation of blood.

After drainage, reevaluate the patient in 2 to 3 days or arrange for ear-nose-throat follow-up.

The need for nasal films remains controversial. Nasal films do not determine the need for intervention and do not affect surgical planning. Despite the presence of a fracture on x-ray, there is no need for intervention if there is no cosmetic deformity and no obstruction to airflow. Obvious nasal deformity (new or old) in the absence of radiographic findings may prompt rhinoplasty.

For these reasons, many physicians never, or only rarely, order nasal x-rays. Some might obtain nasal films because of patient insistence. Patients with obvious deformity or difficulty breathing through the nose should be referred to a consultant on an outpatient basis. Those with significant swelling or questionable deformity need reevaluation in 5 to 7 days, when edema has resolved. This follow-up is more valuable than radiographic imaging.

Zygomatic Fractures

Zygoma fractures occur in two major patterns: the most serious injury is the tripod fracture, whereas the most common is the arch fracture. The zygoma forms a tripod, which abuts the frontal, maxillary, and temporal bones. The classic tripod fracture involves the infraorbital rim, a diastasis of the zygomatic-frontal suture, and disruption of the zygomatic-temporal junction at the arch. The fragment may drop, and pull the lateral canthus, causing the eye to "tilt." Later, the cheek will flatten, but edema usually obscures this finding in the ED.

Look for lateral subconjunctival hemorrhage and infraorbital anesthesia. A significant percentage of patients with large lateral subconjunctival hematomas have associated zygomatic injury. Either trismus or an open bite will appear if the zygoma impinges on the masseter or coronoid process. Palpate the zygomatic arch from within the mouth to detect arch fractures.

Plain films, consisting of the jug-handle or arch view, are adequate for suspected arch fractures, and the Waters view can screen for tripod injury. Order CT scans for tripod fractures that are diagnosed or suggested by plain films. In those cases where tripod fractures are unmistakable on physical examination, plain films are superfluous and patients should go directly to CT. The scans delineate injury to the orbital floor and guide surgical planning.

Patients with tripod fractures require admission for open reduction and internal fixation of displaced fragments. Those with fractures of the arch may be scheduled for outpatient elevation and repair.

Maxillary Fractures

Fractures of the maxilla are high-energy injuries. An impact 100 times the force of gravity is required to break the midface. Accordingly, these patients often have significant multisystem trauma. Many require resuscitation and admission.

If the patient is conscious, inquire about malocclusion and visual symptoms. On physical examination, a patient may have an open bite, facial lengthening, CSF rhinorrhea, or periorbital ecchymosis. LeFort fractures are best diagnosed by grasping and rocking the hard palate. In most cases, parts of the midface will shift with this maneuver, but greenstick and impacted fractures may be immobile. Although the classic fracture patterns are diagrammed in this text (Fig. 249-5) they are more likely to be seen in print than in the ED. In clinical practice, fracture patterns are often mixed, with a low-grade LeFort on one side and a higher grade on the other.

In LeFort I, a transverse fracture separates the body of the maxilla from the lower portion of the pterygoid plate and nasal septum. With stress of the maxilla, only the hard palate and upper teeth move. A pyramidal fracture of the central maxilla and the palate defines a LeFort II injury. Facial tugging moves the nose but not the eyes. LeFort III, also called *cranial-facial disjunction,* occurs when the complete facial skeleton separates from the skull. The fracture extends through the frontozygomatic suture lines, across the orbit and through the base of the nose and ethmoid region. The entire face, including most of both orbits, shifts with mobilization. The LeFort IV fracture (not initially described by LeFort) involves the frontal bone as well as the midface.

These catastrophic injuries often require aggressive airway control and frequently intubation. Look for associated injuries, especially intracranial spinal thoracic, and abdominal. A test of visual acuity, if at all possible, is especially important for patients with LeFort III fractures, where the incidence of blindness is high. Plain films are unnecessary, and CT scans of the face may be ordered in conjunction with brain CT in clinically stable patients. Patients with complex maxillary fractures require admission for open reduction and internal fixation. Even if surgery is delayed, admission is prudent to monitor these often multiply injured victims.

Mandibular Fractures

After nasal bone injury, mandibular fractures are the second most common facial fracture. Assaults and falls on the chin are responsible for most injuries. Because of its ring shape, fractures are often multiple. Most injuries are to the body, angle, and the condylar process. An impact to the point of the jaw may transmit forces through the condyles that can fracture the temporal bone and rupture the eardrum.

History and physical examination will detect nearly all injuries. Ask patients whether their teeth approximate normally and whether they have pain on jaw movement. Evaluate jaw opening and search for intraoral lacerations to determine whether the fracture is open or closed. Gingival lacerations may be hidden between the teeth. Ecchymosis under the tongue is a sensitive finding for mandibular fracture, and fracture-induced injury to the mandibular nerve produces anesthesia of the lower lip.

Patients with normal occlusion and a negative tongue-blade test rarely require imaging studies. Radiography may include panorex, Towne, and lateral oblique views. If the symphysis is involved, consider occulusal films if other views are normal. Sometimes plain films are normal despite a condylar fracture. If films are normal but clinical suspicion remains high, consider a CT scan of the condyles.

Patients with open fractures require admission and intravenous antibiotics. Penicillin G (2 to 4 million units IV) or clindamycin (600 to 900 IV) is considered the drug of choice, but clindamycin and first-generation cephalosporins are good alternatives. Patients may be made more comfortable with a Barton bandage, which is an Ace bandage wrapped around the jaw and head. This prevents excessive jaw movement. Many patients with closed fractures may be managed as outpatients after consultation with an oral surgeon.

Temporomandibular Joint Dislocation

Dislocation of the temporomandibular joint (TMJ) may occur from blunt trauma to the jaw, seizures, or excessive mouth opening. Consider that patients who mumble after a seizure may not be postictal but instead be suffering from TMJ dislocation. Unlike condylar fractures, where the jaw points toward the side of injury, the chin deviates away from the side of the dislocation. In the less common bilateral dislocation, the chin juts forward. In a TMJ dislocation, the condyle becomes locked anterior to articular eminence and will not slide back secondary to muscle spasm. If a patient has jaw deviation and an open bite after a blow to the mandible, x-rays are indicated to detect fracture. However, films are not required to diagnose spontaneous or recurrent mandibular dislocations brought on by wide opening of the mouth.

Mandibular reduction is a simple ED procedure. The physician wraps his or her thumbs in gauze and stands behind the seated patient (Fig. 249-6). Standing on a footstool may increase the mechanical advantage if the physician is short or the patient is tall. Position the thumbs on either of the posterior molars or on the mandibular ridge. (The posterior molars are less slippery but will endanger the physician's digits when the jaw snaps into place.) To unlock the mandible, press downward and forward, and the joint should relocate. A rocking motion is helpful. If the patient has significant spasm or is difficult to reduce, inject the TMJ or lateral pterygoids with a local anesthetic, to facilitate relocation. Intravenous benzodiazepines are also helpful in this situation. Immediately after reduction, apply a Barton bandage to prevent repeat dislocation. Unless cautioned ahead of time, patients will test their jaw movement after reduction and re-dislocate the mandible. Patients must drink a liquid diet through a straw for several days and should follow up with an oral surgeon.

SPECIAL CIRCUMSTANCES

Penetrating Trauma to the Face

Over a third of patients with penetrating trauma to the face have significant complications, including intracranial injury, blindness, or infection.[18] Shotgun blasts to the face are especially problematic, and globe injury is common.

The most immediate concern is airway management, which often requires emergency intubation or cricothyroidotomy. Not only is the risk of intracranial injury high, but there is also the possibility of cavernous sinus fistulas. The bullet's path may endanger the great vessels of the neck, and zone III injuries to the carotid are common. Patients at risk require angiography.

Infection is also a concern in patients with gunshot wounds to the face, especially if there is intraoral trajectory. In this situation, administer intravenous antibiotics effective against oral flora.[19]

Children versus Adults

Pediatric anatomy and developmental concerns influence the management of facial fractures in children.

ETIOLOGY   Be suspicious of nonaccidental trauma in cases of pediatric maxillofacial injury. Associated skull fractures, a torn frenulum, and facial bruising may signify child abuse. Children with facial injuries should be completely undressed and examined for other stigmata of nonaccidental trauma. Some may require a radiographic skeletal survey to detect occult or prior trauma.

FRACTURE PATTERNS   Fracture patterns relate to developmental anatomy. Young children have a higher incidence of frontal bone injury due to its prominence. Infants and toddlers almost never suffer midface fractures. The dearth of maxillary fractures under age 6 is due to the lack of sinuses in the midface. It is these sinuses that weaken the facial buttresses and predispose adults and adolescents to LeFort injury. As the child grows, the sinuses pneumatize, and fractures shift to the midface and lower face. By age 12 to 15, the fracture pattern resembles that in adults.

ASSOCIATED INJURIES   Children with facial trauma also have dissimilar associated injuries than adults. Because the pediatric skull is more prominent, children have much higher incidence of intracranial injuries. Up to 60 percent of children with significant facial fractures have head injury. In addition, the dynamics of cervical injury vary between children and adults. Children are more likely to suffer an upper, rather than lower, cervical spine injury and are also prone to spinal cord injury without radiographic abnormality (SCIWORA).

AIRWAY MANAGEMENT   A young child's airway is subject to subglottic stenosis and tracheomalacia. For this reason, avoid cricothyroidotomy in children younger than age 12. Intubation is the definitive airway of choice in children who need emergency airway management. If intubation is impossible, percutaneous transtracheal jet ventilation provides temporary airway control until a formal tracheotomy is feasible.

COMPLICATIONS AND TIMING OF FOLLOW-UP   Because subsequent facial growth may be asymmetric, pediatric facial fractures can lead to serious cosmetic deformities. Subcondylar fractures of the jaw and displaced nasal fractures are of particular concern in children under age 5. Condylar fractures in this age group predispose children to facial deformity, micrognathia, and ankylosis of the TMJ. Consultation is essential.

Early follow-up is important in all pediatric facial fractures, because a child's facial skeleton heals faster than that of an adult. Within a week, early callous formation makes delayed reduction troublesome.

250 PENETRATING AND BLUNT NECK TRAUMA

Bonny J. Baron

The optimal management of patients with blunt or penetrating neck injuries is challenging. Seemingly minor injuries can quickly become life threatening. Missed injuries and delayed diagnosis can result in serious complications and death. While ultimate management goals are the same, each mechanism has its own special considerations.

EPIDEMIOLOGY

There is a paucity of data regarding the epidemiology of blunt and penetrating neck trauma. The demographics are expected to mirror those of other trauma victims, particularly in urban settings. There is a predominance of young males, especially those in the 21- to 30-year-old age groups. The incidence of gunshot versus stab wounds varies from study to study. Penetrating neck trauma is associated with a high incidence of simultaneous injuries to other systems. Multiple injuries occur 44 to 52 percent of the time.[1] Serious injuries following blunt trauma are not as common. The latter injuries are probably underreported because many are not recognized initially. About half of blunt neck trauma is related to motor vehicle crashes.

ANATOMY

The neck contains a high concentration of vascular, aerodigestive, and spinal structures in a relatively confined space. Other susceptible structures include the thyroid and parathyroid glands, lower cranial nerves, brachial plexus, and thoracic duct. Many of these structures are in close proximity to the skin, and therefore vulnerable to injury. Only the spinal cord has bony protection.

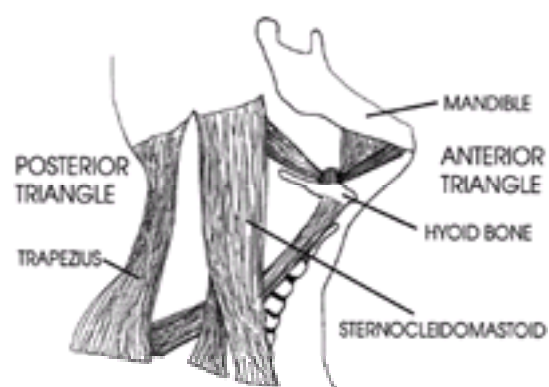
There are several anatomic classifications of the neck. Traditionally, anatomists have defined the neck in terms of anterior and posterior triangles, as divided by the sternocleidomastoid muscle (Fig. 250-1). The anterior triangle is bounded by the midline of the neck, the lower border of the mandible, and the anterior border of the sternocleidomastoid muscle. Within this triangle are most major vascular and aerodigestive structures. The carotid artery, internal jugular vein, vagus nerve, thyroid gland, larynx, trachea, and esophagus all lie in the anterior triangle. The boundaries of the posterior triangle are the middle third of the clavicle, the anterior border of the trapezius muscle, and the posterior border of the sternocleidomastoid muscle. The posterior triangle has few vital structures, except at its base where the subclavian artery and brachial plexus are located.


FIG. 250-1. Triangles of the neck.

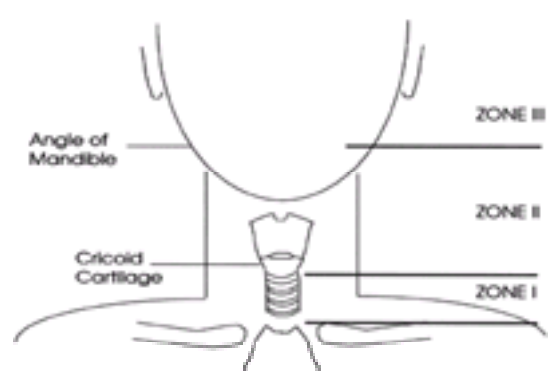
An alternative anatomic classification divides the neck into three zones (Fig. 250-2). This classification was established to guide the clinician in the diagnostic and therapeutic management of penetrating injuries. Various authors have defined the zones differently. The most widely used classification is that of Roon and Christensen.[2] By their definition, zone I extends from the clavicles to the cricoid cartilage. Zone I includes the vertebral and proximal carotid arteries, major thoracic vessels, superior mediastinum, lungs, esophagus, trachea, thoracic duct, and spinal cord. Zone II extends from the inferior margin of the cricoid cartilage cephalad to the angle of the mandible. Injuries in zone II may involve the carotid and vertebral arteries, jugular veins, esophagus, trachea, larynx, and spinal cord. Zone III is located between the angle of the mandible and the base of the skull. The distal carotid and vertebral arteries, pharynx, and spinal cord are all at risk of injury in zone III.


FIG. 250-2. Zones of the neck.

The structures of the neck are supported by a series of fascial layers (Fig. 250-3). The superficial fascia surrounds the platysma muscle. This thin muscle covers the entire anterior triangle and the anteroinferior aspect of the posterior triangle. The platysma is the most superficial structure beneath the skin and subcutaneous tissue, and serves as an important planar landmark when evaluating penetrating neck injuries. Beneath the platysma is the deep cervical fascia, a series of fascial compartments that support the muscles, vessels, and viscera of the neck. The deep cervical fascia divides into the investing, pretracheal and prevertebral layers. The investing layer splits to enclose the sternocleidomastoid and trapezius muscles. The pretracheal layer attaches to the thyroid and cricoid cartilage and blends with the pericardium in the thoracic cavity. The prevertebral layer covers the prevertebral muscles and blends with the axillary sheath, which encloses the subclavian vessels. All three layers of the deep cervical fascia combine to form the carotid sheath. The tight facial compartments provide a tamponade effect, which limits potential for external bleeding from vascular injuries. Bleeding within these narrow compartments, however, can result in extrinsic compression and airway compromise.

INITIAL MANAGEMENT

The initial approach to patients with neck injury is performed according to Advanced Trauma Life Support (ATLS) protocols. [3] A directed primary survey, resuscitation, and secondary survey must all be performed expeditiously. Once the initial evaluation is completed, decisions concerning optimal diagnostic studies and definitive care are made.

Airway

Neck injuries can create some of the greatest challenges to airway management. All agree that any patient with acute respiratory distress, airway compromise from blood or secretions, massive subcutaneous emphysema, tracheal shift, or severe alteration in mental status must have early airway intervention. Controversy arises when presented with patients who have significant injury mechanisms without any immediate evidence of vascular injury or airway compromise. There are no published data that definitively outline the optimal approach in such patients. It is important to realize how quickly blood or air dissecting into fascial compartments can distort normal anatomy. Once this occurs, airway management becomes difficult, if not impossible. The risk of performing an unnecessary intubation is minimal compared to the potential morbidity of a difficult intubation with respiratory distress and a distorted airway. It is particularly important to establish a definitive airway before a patient leaves the monitored setting of the Emergency Department for diagnostic studies. In most cases, orotracheal intubation with rapid sequence induction can be used.

If unsuccessful, the cricothyroidotomy is generally the next procedure of choice in adults. When performing a cricothyroidotomy care must be taken to avoid dislodging a contained hematoma. The integrity of the larynx should be evaluated prior to any intubation attempts, particularly in cases of blunt trauma. Intubation of a patient with a fractured larynx may result in complete transection or create a false passage, necessitating a tracheostomy. Occasionally, a tracheostomy site will be created by the injury itself. An existing tracheostomy may be intubated as a lifesaving means of securing the airway. [4] In all cases of blunt neck trauma, or in penetrating trauma in which a cervical spine fracture is suspected, immobilize the cervical spine in the neutral position.

Breathing

All patients should receive high-flow oxygen and be continuously monitored by pulse oximetry. Proximity of the base of the neck and the thorax predisposes both regions to injury. Difficulty ventilating a patient is indicative of either upper airway or thoracic injuries. Unequal breath sounds and asymmetric chest movement are signs of inadequate ventilation. These signs are associated with pneumo- or hemothoraces. Tracheal deviation may accompany a tension pneumothorax. Prompt recognition of these life-threatening complications and treatment with a tube thoracostomy will ensure adequate ventilation.

Circulation

Active bleeding is controlled by direct pressure at the site of injury. Do not clamp bleeding vessels, as additional damage to vascular or nervous structures may result. One should avoid placing intravenous access at a location where the IV fluid would flow toward the site of injury (for example, internal jugular or subclavian vein injury), and extravasate. Nasogastric tubes should be avoided during the initial resuscitation. Gagging and retching induced during NGT insertion could dislodge a clot and cause hemorrhage from a vascular injury.

Disability

A brief neurologic examination is mandatory. Neurologic deficits may indicate direct nerve or spinal cord injury, or they may result from cerebral ischemia caused by vascular injury. Early recognition of these deficits is important, particularly as patients are rapidly sedated and paralyzed for airway control.

Initial Radiographic Evaluation

The cervical spine must be imaged in all patients with a significant blunt trauma mechanism, particularly if they have an altered mental status. In cases of penetrating trauma, radiographs are evaluated for fractures and retained foreign bodies. Although the path of a missile is never known with certainty, localizing a bullet may determine or suggest a transcervical trajectory. In both blunt and penetrating trauma, the soft tissues should be examined for hematomas, air-column obstruction or deviation, subcutaneous emphysema, or retropharyngeal thickening. A chest radiograph must be obtained to evaluate for the presence of a pneumothorax, hemothorax, or air in the mediastinum.

Complete Evaluation

A complete history and thorough physical examination are performed. Information obtained from pre-hospital personnel should include mechanism of injury, symptoms, hemodynamic stability, and amount of blood loss at the scene. Once in the Emergency Department, if possible, the patient should be questioned about neck pain, difficulty breathing, dysphagia, odynophagia, hoarseness, hematemesis, hemoptysis, and any neurologic deficits. Examination of the neck requires a search for clinical signs of vascular, aerodigestive, and neurologic injuries. These include arterial bleeding, large or expanding hematomas, diminished pulses or bruits, lateralizing signs, tracheal deviation, air-bubbling through the wound, saliva in the wound, subcutaneous emphysema, and evidence of cranial nerve injuries.

These clinical signs can be divided into hard and soft signs of injury (Table 250-1).[5] All signs require diagnostic investigation, but hard signs are more often associated with significant injury.

Hard Signs	Soft Signs
Hypotension in Emergency Department	Hypotension in field
Active arterial bleeding	History of arterial bleeding
Diminished carotid pulse	Tracheal deviation
Expanding hematoma	Nonexpanding large hematoma
Thrill/bruit	Apical capping on chest x-ray
Lateralizing signs	Stridor
Hemothorax >1000 cc	Hoarseness
Air or bubbling in wound	Vocal cord paralysis
Hemoptysis	Subcutaneous emphysema
Hematemesis	Seventh cranial nerve injury
	Unexplained bradycardia (without CNS injury)

TABLE 250-1   Signs and Symptoms of Neck Injury

PENETRATING INJURY

Mechanisms of penetrating injury can be categorized as stab, gunshot, shotgun, or miscellaneous sharp implements. All mechanisms have potential for causing serious injury. Seemingly innocuous wounds may involve multiple structures. Gunshot wounds cause damage both from the bullet itself and from the blast effect. In addition, the path of a bullet is unpredictable. Localizing a bullet will not delineate which structures it has traversed or disrupted. If the bullet has crossed the midline of the neck, however, there is a high probability of injury. Transcervical gunshot wounds are twice as likely to cause injuries to vital structures in the neck as are gunshot wounds that do not cross the midline.[6] Damage caused by shotguns depends largely on weapon-victim range, and type of weapon and shot used. Multiple pellets scattered across all three zones of the neck characterize these wounds.[7] Although the course of stab wounds is more limited than that of gunshot wounds, there is still clear potential for major injury.

Despite differences in mechanism, treatment principles are the same. Initial stabilization is always the primary concern. Once this is accomplished, attention is turned to examination of the wound itself. If the platysma muscle is clearly intact, local wound repair is all that is required. If the platysma has been violated it must be assumed that significant injury has occurred. Neck wounds must never be probed beneath the platysma in order to avoid disrupting hemostasis. The next priority is establishing wound location and determining which zones are involved. Vital structures at risk for injury can then be identified. Careful physical examination may reveal hard and soft signs of injury. A diagnostic plan, which will evaluate vulnerable structures, is then implemented.

Consultation

If the platysma is violated, immediate surgical consultation is indicated. Similarly, early involvement of radiologists will facilitate a nonoperative diagnostic work-up. A team approach will expedite stabilization, diagnosis, and definitive treatment. If the treating facility is unable to provide adequate diagnostic and surgical support, transfer should occur immediately after initial stabilization.

Diagnosis and Management

There is general agreement that patients who are hemodynamically unstable or have obvious aerodigestive injury require immediate surgical intervention. In those who are stable, the diagnostic approach is determined by the location of the wound. Nonoperative studies are used to identify injuries in zones I and III. Vascular control is often difficult to obtain in these zones. Zone I injuries require a thoracic surgical approach to gain proximal vascular control, important for arterial injuries. Both proximal and distal vascular control is easily obtained in zone II. For zone III, arterial injury proximal control is actually gained in zone II. More distal injury presents a difficult problem in zone III. Disarticulation of the mandible may be required for adequate exposure. Given these technical difficulties, routine exploration of zones I and III is not indicated. Both of these zones should be studied with angiography, as physical examination is not always reliable in identifying vascular injuries.[8] Zone I also requires diagnostic evaluation of the esophagus, as early injuries are often asymptomatic. The operative difficulties encountered in zones I and III are usually not a problem in zone II injuries.

Controversy surrounds the management of stable patients with zone II injuries. Literature supports both mandatory exploration of all injuries that penetrate the platysma as well as selective operation based on diagnostic studies. Mandatory exploration was popularized during World War II, as this intervention lead to markedly reduced morbidity and mortality. Advocates of mandatory exploration describe low complication rates following negative operations, as well as significant morbidity associated with missed injuries. There is also concern that diagnostic modalities that are used to detect aerodigestive injuries are inaccurate. Opponents of mandatory exploration cite its high negative exploration rate. In addition, an injury may be missed during surgical exploration. Alternatively, an injury may be discovered that is difficult to control surgically, such as a vertebral artery injury. Surgical exploration alone is often technically difficult with these injuries, particularly if the vascular anatomy and possible vertebral artery anomalies are not first identified by angiogram. Angiography helps clarify management. Complete occlusion of a vertebral artery in an asymptomatic patient with a normal contralateral vertebral artery and no evidence of a distal AV fistula is usually managed conservatively. The patient with active arterial bleeding, AV fistula, or pseudoaneurysm of the vertebral artery is preferably treated by percutaneous transcatheter embolization of the proximal and distal vertebral artery. On occasion, angiographic procedures are used during surgery to aid in obtaining vascular control. Obviously, if angiography is unavailable or unsuccessful, surgical exploration and repair is performed.[9] Selective management results in minimal nontherapeutic operations and spares the patient a surgical scar. No definitive evidence exists to establish one treatment paradigm as being more cost effective than the other.

Further controversy in the management of zone II injuries focuses on the diagnostic role of physical examination. Some advocate observation alone in asymptomatic patients with zone II injuries.[10,11] Studies supporting this management have been largely retrospective or had small sample sizes. Missed arterial and esophageal injuries have been demonstrated in asymptomatic patients.[5,8] Clinical signs and symptoms have low sensitivity, specificity, and predictive value.[5,8,12] In addition, multiple-injury patients may have associated injuries that make physical examination of the neck less reliable. Selective exploration based on the results of diagnostic studies should be done. This will decrease the rate of negative explorations, yet avoid missing injuries. Evaluation of zone II injuries should routinely include vascular and esophageal evaluation.

Angiography is currently the gold standard for evaluating vascular injury and can also be therapeutic. Duplex sonography is being used with increasing frequency. It is noninvasive, but it is operator-dependent and its sensitivity at detecting small lesions or intimal flaps is not yet established.

Esophageal evaluation must be performed in all patients because esophageal injuries with injuries in zones I and II are initially notoriously asymptomatic. Delayed treatment of esophageal perforations will result in neck space infections and mediastinitis. Ideally, evaluation should include both an esophagram and esophagoscopy. Using this combination of studies, the sensitivity of detecting injury is increased to nearly 100 percent.[13] Flexible, rather than rigid, esophagoscopy is the current procedure of choice.

Laryngotracheal injuries are of concern in zones I and II. Significant laryngotracheal injuries are rarely occult. Diagnosis is usually easy due to the anterior and superficial position of the trachea. Air-bubbling through the wound, dyspnea, stridor, hemoptysis, and subcutaneous emphysema are the most common signs and symptoms. Although optimal management is controversial, diagnostic evaluation with laryngoscopy and bronchoscopy is generally reserved for those who are symptomatic.

In summary, stable patients with zone I injuries should undergo angiography and esophagram, and/or esophagoscopy. Those with zone III injuries should undergo angiography. Patients with zone II injuries can undergo mandatory exploration or be evaluated with angiography and esophagram, and/or esophagoscopy. Patients with symptoms suggestive of laryngotracheal injury require laryngoscopy and bronchoscopy (Fig. 250-4). Despite the presence of a single wound, multiple zones may be involved. This happens most often when the injury is caused by a gunshot. Diagnostic evaluation should be liberal and account for all structures that may have

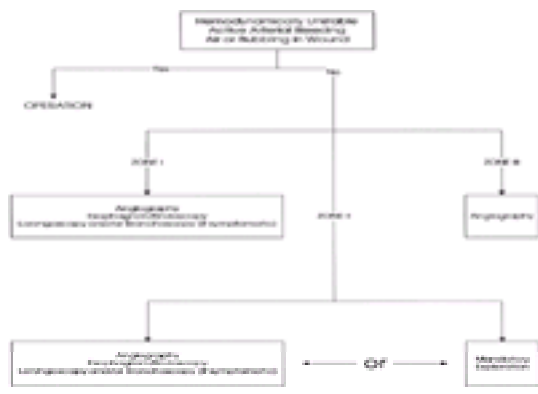
been in the pathway of a trajectory.


FIG. 250-4. Management of penetrating neck injury.

It is important to recognize that to a large degree diagnostic evaluation is institution- and personnel-dependent. Available resources often determine the optimal diagnostic regimen.

Pediatric Considerations

Initial management of children is identical to that of adults. In children, however, certain predisposing factors may alter the diagnostic evaluation. The diagnostic process itself may be associated with significant morbidity. Young children must often be anesthetized to undergo diagnostic procedures. Angiography is technically more difficult due to the smaller vessel size. Hall et al. have suggested observation alone in asymptomatic children with zone II penetrating injuries. [14] The authors caution that this practice should only be followed if close, active observation by skilled consultants can be performed and operative facilities are immediately available.

BLUNT INJURY

Blunt neck trauma is rare. The head, shoulders, and chest offer protection to the neck when it is in the neutral position. Hyperextension, hyperflexion, rotation, and direct blows contribute to blunt injuries. Most commonly, injury results from motor vehicle crashes, when the extended neck strikes the steering wheel or dashboard. [15] Shearing forces from shoulder safety belts are also responsible for injury. Motorcycles, snowmobiles, and all-terrain vehicles have been implicated in "clothesline" injuries. These occur when the exposed neck strikes a stationary cord. They are associated with severe laryngotracheal and esophageal injuries. Other mechanisms include direct blows sustained during sports (football, karate, hockey), handlebar injuries from bicycles, assaults, and strangulation. [16]

Though uncommon, blunt cervical trauma can be lethal or can result in significant morbidity. Symptoms are often minimal, or delayed, and the diagnosis can be easily overlooked. Head, facial, and cervical spine injuries frequently accompany blunt neck trauma. Symptoms of vascular or aerodigestive injuries may be misinterpreted in the context of these associated injuries. A high index of suspicion must be maintained. Signs and symptoms or a significant injury mechanism mandate aggressive diagnostic evaluation, and admission for observation. As with penetrating trauma, surgical consultants should be involved in the initial assessment and management of all patients.

Laryngotracheal Injury

Laryngotracheal injury can range from soft tissue edema and ecchymosis to mucosal lacerations, vocal cord avulsion, fractures of the thyroid and cricoid cartilage, recurrent laryngeal nerve laceration, or complete laryngotracheal disruption. Classic symptoms include dysphonia, hoarseness, dysphagia, odynophagia, dyspnea, pain, hemoptysis, and stridor. Signs of injury include tenderness, subcutaneous emphysema, deformities, contusions, and tracheal deviation. Unfortunately, in contrast to penetrating tracheal trauma, which is frequently associated with signs and symptoms, blunt injury may present with few or no signs. Diagnosis requires a high index of suspicion.

Establishing an airway is the initial focus in management. Opinions vary as to the optimal method of achieving airway control. Some advocate endotracheal intubation by the most experienced personnel. Others recommend immediate tracheostomy. Those advocating tracheostomy believe that attempts at intubation may result in a false passage, adding further injury to an already compromised airway. Cricothyroidotomy should be avoided as this may worsen laryngeal injury. Any patient with suspected laryngotracheal injury should undergo chest, cervical spine, and soft tissue lateral neck radiographs. Subcutaneous emphysema, narrowing of the subglottic airway, and hyoid bone fractures may be seen on radiographs. Diagnostic work-up will then focus on identification of specific injuries. Laryngoscopy and bronchoscopy will evaluate vocal cord function, luminal integrity, and level of injury. CT is indicated in hemodynamically stable patients with secure airways. CT delineates the type and degree of injury, and is helpful in deciding which injuries can be managed conservatively and which require immediate operative intervention.

Pharyngoesophageal Injury

Blunt pharyngoesophageal injuries generally present with few or no symptoms. As with penetrating trauma, untreated, these perforations lead to life-threatening infections. Pharyngoesophageal injuries are usually associated with laryngotracheal injury. Laryngotracheal injury should prompt diagnostic evaluation of the esophagus with esophagram and esophagoscopy.

Vascular Injury

High suspicion of injury, coupled with early diagnosis and treatment of carotid injuries improves outcome. Injuries are often missed because there is a delay in the onset of signs and symptoms, and when these signs do develop they are often attributed to an associated head injury rather than a vascular injury. Any movement that distracts or compresses the artery can create injury. Five mechanisms of injury have been described: hyperextension with compression of the artery against the transverse process of the cervical spine; hyperflexion, with compression of the artery between the mandible and the spine; direct blows; intraoral trauma; and basal skull fracture causing tearing of the intracranial portion of the carotid artery. [17]

Two different lesions may occur following trauma. A pseudoaneurysm may form[18] or the vessel wall might dissect and cause secondary thrombosis, resulting in distal emboli or occlusion.[19] Clinical findings associated with closed carotid injury include neck hematomas, bruits, pulse deficits, ipsilateral Horner's syndrome, transient ischemic attacks, and contralateral motor or sensory deficits. Neurologic symptoms may develop immediately, or they may be delayed for several weeks. Outcome may be compromised once a deficit develops. The first step in diagnosis is a head CT to eliminate closed-head injury as the cause of symptoms. This should be followed by angiographic evaluation of the carotid arteries. Once the diagnosis of carotid injury is confirmed, the first line of treatment is anticoagulation. The rationale for systemic anticoagulation is to minimize clot formation at the site of intimal injury, decrease further propagation of the clot that has formed, and prevent embolization of clot from any pseudoaneurysm sac.[20] Medical management has been shown to provide good results in patients with minimal neurologic deficits. Patients with severe neurologic deficits on initial examination may benefit from surgical intervention.

There are several cases in the literature of vertebral injury following chiropractic neck manipulation. Cases of severe neurologic deficit following vertebral artery injury have also been reported with Yoga exercises, calisthenics, archery, and painting a ceiling. [21,22] All mechanisms of injury involve either cervical hyperextension, excessive contralateral rotation, or, most commonly, both. The vertebral arteries are susceptible to mechanical injury because of their relationship to neighboring bony structures and ligaments. Traumatic intimal disruption may lead to complete thrombotic occlusion, subintimal hematoma, dissection, or pseudoaneurysm formation. Distal branch occlusions may result from dissecting aneurysms, thrombus propagation from the neck, or thromboembolism. Patients may be asymptomatic, or they may have transitory or delayed neurologic symptoms. Symptoms vary from neck pain and occipital headache to Wallenberg's syndrome and lethal stroke. Wallenberg's syndrome (lateral medullary infarction syndrome) may include ipsilateral loss of cranial nerves V, IX, X, and XI, cerebellar ataxia, Horner's syndrome,

and contralateral loss of pain and temperature sensation. Sudden death, quadriplegia, and "locked-in syndrome" (quadriplegia with loss of all lower cranial nerves) have also been described. Cerebral arteriography must be performed for any suspicion of vertebral artery injury. Anticoagulation and platelet aggregation inhibition are recommended, but the efficacy of this therapy has not been clearly established.

STRANGULATION

Significant external pressure applied to the neck results in strangulation. This is caused by hanging, ligature strangulation, manual strangulation, and postural strangulation. Circumstances surrounding strangulation injuries include homicides or assaults, suicides, accidents, and judicial executions. Depending on the method used, death from strangulation may occur by one of three mechanisms: injury to the spinal cord and brain stem; mechanical constriction of the neck structures; and cardiac arrest.[23] These are explained below.

Pathophysiology

Hanging occurs when pressure is exerted on the neck and then tightened by the weight of the victim's body. Hangings in which the body is suspended and the feet do not touch the ground are termed "complete." These generally occur with judicial hangings. All other positions of the body, when the feet are in contact with the ground, are referred to as "incomplete." The mechanism of death may differ depending on the method of hanging. If a victim drops a distance equal to his height, death usually results from fracture of the upper cervical spine and transection of the spinal cord. If a hanging is incomplete, or the victim drops a distance less than his height, the cervical spine is spared. Constriction causes jugular venous obstruction, stagnant cerebral blood flow and brain ischemia. Loss of consciousness results. Muscle tone decreases and compression of vital structures increases. Complete arterial occlusion and/or airway compromise result in death. Alternatively, cardiac arrest may occur due to carotid sinus stimulation and increased vagal tone.

In ligature and manual strangulation, the constricting force is external, but the weight of the body and head play no part. Postural strangulation is seen in infants. This results when the victim's neck is placed over an object and the weight of the body adds pressure to the neck. In all of these methods of strangulation, death probably results from airway obstruction (suffocation) or vascular occlusion, as previously described in incomplete hangings.

Fracture of the thyroid cartilage, hyoid, and larynx are associated with strangulation. Traumatic edema of the larynx and supraglottic tissue lead to airway compromise. Delayed mortality is often due to neurogenic pulmonary edema and aspiration pneumonia. Cerebral anoxia may cause neurologic damage. Neurologic deficits are not always immediately apparent, and may develop over time. Long-term psychiatric manifestations include psychosis, Korsakoff's syndrome, amnesia, and progressive dementia.

Clinical Presentation

Abrasions, ecchymosis, and a brownish compression groove may be apparent. A rise in venous pressure above the ligature can lead to the formation of Tardieu's spots. These petechial hemorrhages can best be seen in the skin and subconjunctival areas. Patients may complain of painful swallowing. Severe hoarseness and stridor are suggestive of an impending airway obstruction.

Treatment

Treatment is directed at airway, respiratory, cardiac, neurologic, and psychiatric complications. Endotracheal intubation should be performed if airway problems or severe blood gas abnormalities are evident. As noted above, C-spine fracture or instability is all but impossible except in judicial-style hangings, where a significant free-fall drop is designed to cause a death resulting in vertebral fracture. Thus, for most suicidal, and accidental hangings, cervical spine immobilization is unnecessary. Neurogenic pulmonary complications are best treated with controlled ventilation and positive end-expiratory pressure (PEEP). Cardiac monitoring is essential for the identification and management of dysrhythmias. Hyperventilation, fluid restriction, and diuretics will treat cerebral edema. Intracranial pressure monitoring may be useful in guiding therapy. Psychiatric support is often necessary in long-term survivors.

A high level of suspicion must be maintained in all patients who sustain compression injuries to the neck. Admission for 24 h is warranted to observe for delayed airway obstruction.

251 THORACIC TRAUMA

William M. Bowling
Robert F. Wilson
Gabor D. Kelen
Timothy G. Buchman

INTRODUCTION

Approximately 25 percent of nonmilitary trauma-related deaths are due to thoracic trauma. A majority of the deaths occur after the patient reaches the hospital. Mortality is relatively low (5 percent) for isolated chest injuries. With two or more organ systems involved, death will occur in about one-third. It is felt that as many as 10 percent of such deaths could have been prevented in the ED. [1]

Penetrating injuries have a different mechanism than blunt trauma. Nearly all penetrating injuries result in a pneumothorax, with hemothorax occurring in more than 75 percent. Blunt trauma causes injury by one or more of several mechanisms: compression (organ rupture), direct trauma (e.g., fracture), and acceleration/deceleration forces (vessel shear and tear). Penetrating trauma has the further distinction of being associated with abdominal injuries in about one-third of cases. Only 5 to 15 percent of patients with chest trauma will require a thoracotomy.

CHEST WALL, BRONCHI, LUNGS, AND DIAPHRAGM

Patients with chest trauma who develop acute, severe respiratory distress have a high mortality rate. About 10 percent of patients admitted with chest trauma required endotracheal intubation almost immediately upon entrance to the emergency department (ED). If shock is also present in addition to the respiratory distress, three-quarters will die. In patients with blunt chest trauma, the most frequent factors associated with acute respiratory distress included shock, coma, multiple rib fractures, and hemopneumothorax (Table 251-1). In patients with penetrating trauma, respiratory distress is usually associated with severe shock or hemopneumothorax (Table 251-2).

Injury	Incidence, %	Mortality Rate, %
Flail chest/multiple rib fracture	75	52
Hemopneumothorax	55	39
Lung contusion	39	45
Extremity fracture	30	53
Intraabdominal	23	46
Intracranial	23	46
Myocardial contusion	13	57
Diaphragm	9	20
Paraplegia	4	100
Other	7	100

TABLE 251-2   Injuries in Patients with Respiratory Failure after Penetrating Chest Trauma

Initial Resuscitation, Airway Control, and Ventilation

Diagnosis of the cause of respiratory distress must be made promptly. If the patient is making little or no effort to breathe, central nervous system dysfunction due to head trauma, drugs, or spinal cord injury is the most likely problem. If the patient is attempting to breathe but is moving little or no air, upper airway obstruction should be suspected.

The most common cause of upper airway obstruction in comatose patients is prolapse of the tongue into the pharynx. Other causes of upper airway obstruction

include dentures; vomitus; or blood clots in the pharynx, larynx, or upper trachea. Occasionally, direct trauma may cause fracture of the larynx or cricotracheal separation. Inspiratory stridor does not usually occur unless there is at least a 70 percent occlusion of the larynx or upper trachea. With any suspected laryngeal injury, cautious endoscopy should be performed in the operating room as soon as possible, but one must also be prepared to perform an emergency tracheostomy immediately if the airway occludes.

If the patient is attempting to breathe and the upper airway appears to be intact but the breath sounds are poor, thoracic problems such as flail chest, hemopneumothorax, diaphragmatic injury, or parenchymal lung damage should be considered. In all cases of respiratory distress, the airway must be secured. Following airway control, optimal oxygenation and ventilation should be provided.

CARDIAC ARREST DURING OR JUST AFTER ENDOTRACHEAL INTUBATION   Although Rotondo et al[2] have pointed out that urgent paralysis and intubation of trauma patients who are combative or have complex injuries is relatively safe, one of the most frequent times for an emergency department patient to have a cardiac arrest is during or right after endotracheal intubation. Table 251-3 lists common causes for cardiac arrest during intubation. If the patient has poor venous return because of hypovolemia, ventilation with excessive pressures can further reduce venous return and cause cardiac arrest. Hypovolemic patients should probably be ventilated with tidal volumes of only 5 to 8 mL/kg at 10 to 14 times per minute until venous return is improved.

Inadequate preintubation oxygenation and ventilation

Esophageal intubation

Intubation of the right (or left) main bronchus

Excess ventilation, further reducing venous return

Development of a tension pneumothorax

Systemic air embolism

Vasovagal response (rare)

Sudden development of severe alkalosis

TABLE 251-3   Causes of Cardiac Arrest with Endotracheal Intubation

If there is a lung injury or if there are fragile subpleural blebs, bagging the patient vigorously can also cause a tension pneumothorax to develop rapidly, further reducing venous return. Even if the lungs are normal, ventilatory pressure exceeding 70 to 80 cmH $_2$O can cause pulmonary damage. Excessive hyperventilation can also cause severe alkalosis, reducing ionized calcium levels and producing serious dysrhythmias.

Any patient with a lung injury, especially with hemoptysis, should be considered at risk for developing a systemic air embolus, particularly if high ventilatory pressures are used. Intrabronchial bleeding may also flood normal alveoli, causing severe hypoxemia.

Vasovagal responses are rare in injured patients, but they can occur during insertion of endotracheal, nasogastric, or chest tubes. One should be alert for the development of this problem in patients with nausea or inappropriate bradycardia that worsens as a procedure is being performed. Airway management techniques are discussed in Chap. 14, Chap. 15 and Chap. 16.

Initial Survey

Several life-threatening thoracic injuries should be recognized and treated during the initial survey. These are airway obstruction (noted above), tension pneumothorax, cardiac tamponade, massive hemothorax, open pneumothorax, and flail chest.

TENSION PNEUMOTHORAX   The diagnosis of tension pneumothorax should be suspected based on clinical grounds alone. The presentation includes dyspnea, hypoperfusion, distended neck veins, diminished or absent breath sounds on the affected side, a hyperresonant percussion note on the affected side, and tracheal deviation to the opposite side. Not all elements of the presentation need be present to suspect the diagnosis. For example, the noise in the resuscitation area makes the percussion note difficult to hear. Also, distention of the neck veins may be absent in the face of hypovolemia.

If a tension pneumothorax is suspected, the next intervention must be the insertion of a small cannula (typically a 14-gauge intravenous catheter) through the chest wall into the pleural space. The purpose of this intervention is to convert the tension pneumothorax into an open pneumothorax. Although the classic description of this maneuver places the insertion point at the second interspace in the midclavicular line, any point in the superior, anterior, or lateral chest wall may be selected. Once the tension pneumothorax is decompressed (a hiss of gas exiting the pleural space may be audible) the patient's perfusion often improves within seconds. The initial survey should be completed and a chest tube (tube thoracostomy) inserted on the side of the tension pneumothorax as soon as practicable. Lack of improvement following decompression means that another cause of hypoperfusion should be sought immediately. If the neck veins remain distended, cardiac tamponade from pericardial blood (pericardial tamponade) must be suspected and treated immediately.

An x-ray of the chest should not be obtained in the patient with a suspected tension pneumothorax until after tube thoracostomy has been performed and the patient's perfusion improved.

PERICARDIAL TAMPONADE (CARDIAC TAMPONADE)   Both blunt and penetrating thoracic injuries have the potential to cause blood to accumulate in the pericardium. Although stab wounds to the midchest are the most common cause, blunt compressive forces to the anterior heart can rupture the right atrium or its appendage while maintaining enough filling of the right ventricle to sustain life for a short interval. In either case, blood fills the poorly compliant pericardial sac, with pressure increasing sharply as each small increment of fluid accumulates.

The presentation of tamponade is similar to that of tension pneumothorax: both lesions cause obstruction of venous return to the heart. In addition to hypoperfusion and distended neck veins, the patient with tamponade may have "muffled" heart tones—muffling that is hard to hear in the busy environment of a trauma resuscitation. However, breath sounds should be audible bilaterally and the trachea should lie in the midline.

While the initial treatment of tamponade is emergency pericardiocentesis (described further on), immediate surgical intervention is required to control the bleeding. An intravenous bolus of fluid to transiently increase the pressure filling the right atrium may be helpful to increase cardiac output for a minute or two while preparations are being made for the pericardiocentesis and/or immediate surgical intervention.

Again, radiographs are conspicuous by their absence from this discussion. The poorly compliant pericardium, although full and under pressure from the blood within, casts a rather ordinary shadow on the chest x-ray. As little as 150 to 200 mL of blood may result in cardiac tamponade. Therefore, chest radiographs cannot be used to exclude this life-threatening diagnosis.

If surgery cannot be performed immediately, it may be wise to leave a cannula within the pericardial sac for serial aspirations as surgical preparations are being made. Aspiration of only 5 to 10 mL of fluid can substantially improve cardiac performance—again a consequence of the rigidity of the pericardium.

MASSIVE HEMOTHORAX   Each hemithorax can potentially hold about 40 to 50 percent of the human circulating blood volume. While the hemithorax is ordinarily filled with air, a small amount of blood, and the tissues of the lung, blood can accumulate rapidly in the pleural space. A massive hemothorax in an adult is defined as 1500 mL or more—that is, about two-thirds of the available space in the hemithorax is occupied by blood.

Massive hemothorax is life-threatening by three mechanisms. First, the acute hypovolemia renders preload inadequate to sustain effective left ventricular function. Second, the collapsed lung induces hypoxia by disturbing ventilation-perfusion matching. Third, the pressure of the hemothorax compresses the vena cava (further

impairing preload) and the pulmonary parenchyma, raising pulmonary vascular resistance.

If a radiograph of the chest has been obtained, the diagnosis of a massive hemothorax can be made if the aerated lung is completely surrounded by fluid (blood).

Immediate tube thoracostomy is required to initially manage the massive hemothorax. Surgical repair must be performed emergently. Common causes of massive hemothorax include injury to the lung parenchyma, to an intercostal artery, and to the internal mammary artery.

Patients with "ordinary" hemothorax will occasionally drain a moderate amount of blood but then rebleed or continue to bleed. If there is evidence of ongoing hemorrhage after initial drainage exceeding 600 mL/6 h (i.e., 100 mL/h for 6 h, 300 mL/h for 2 h, or 600 mL/h for 1 h), a "massive hemothorax equivalent" is diagnosed. In such cases of rebleeding/ongoing bleeding, conservative management requires thoracotomy, although occasional patients may be managed nonoperatively.

Since massive hemothorax is, by definition, associated with accumulation and subsequent drainage of large volumes of potentially "clean" blood, it is desirable to collect the effluent into an autotransfusion-prepared device. The decision to proceed with autotransfusion must be based on the patient's condition and the probability that the blood is free from contamination by enteral pathogens from an occult injury to the gastrointestinal tract.

OPEN PNEUMOTHORAX   Open pneumothorax (discussed in detail further on) is an open communication between the outer chest wall and the pleural space. Respiratory distress is due to inability to ventilate the affected side. The injury is sometimes referred to as a "sucking chest wound" because of the sound produced as air moves through the wound. On examination, this injury is usually obvious. However, it may be obscured by the patient's position or clothing. Air entry is diminished on the affected side, and chest wall motion is less dynamic. The injury is very often associated with a hemothorax. The initial maneuver in the ED is to cover the wound with a three-sided dressing so that air can escape but not enter through the wound. Complete occlusion may convert the injury into a tension pneumothorax.

FLAIL CHEST   The term *flail chest* refers to a free-floating segment of ribs that are no longer connected to the rest of the thorax. This entity is also described in detail further on. During the initial survey, the examiner must search for segmental paradoxical chest wall motion, which is easy to miss if not specifically sought. Air entry will be diminished on the affected side. Jugular venous pressure may be intermittently increased in rhythm with respirations due to pendelluft, as explained later in this chapter.

Ventilatory Support

In patients with chest trauma, impaired ventilation, in spite of measures to ensure an open airway, relief of chest wall pain, and drainage of hemopneumothorax, is an indication for ventilatory support. Respiratory failure associated with a flail chest is best treated by early endotracheal intubation and ventilatory assistance, particularly if there are associated injuries, and even if the patient's breathing intially seems adequate. Ventilatory assistance should also be strongly considered if the patient is in shock, has had multiple injuries, is comatose, requires multiple transfusions, is elderly, or has preexisting pulmonary disease. A respiratory rate greater than 30 to 35 breaths per minute, a vital capacity less than 10 to 15 mL/kg, and/or a negative inspiratory force (NIF) less than 25 to 30 cmH$_2$O can also be considered early indications for ventilatory support.

All trauma patients should be monitored by pulse oximetry. In patients with severe chest trauma, an arterial blood gas should be drawn soon after admission and at frequent intervals thereafter. If arterial P$_{O_2}$ is less than 50 mmHg while the patient is breathing room air or less than 80 mmHg while the patient is breathing supplemental oxygen (equivalent to an F$_{IO_2}$ of 0.4 or more), the patient should generally be given ventilatory assistance. Metabolic acidosis with an arterial P$_{CO_2}$ insufficiently decreased to compensate for the decrease in [HCO$_3^-$] is another indication for ventilatory support. Although there are several formulas relating the expected change in P$_{CO_2}$ to the magnitude of the decrease in [HCO$_3^-$], the simplest approach is to expect a 1:1 relationship. That is, for each milliequivalent per liter decrease in [HCO$_3^-$], ventilatory response should result in a decrease of P$_{CO_2}$ of 1 mmHg. Thus, in the face of metabolic acidosis, P$_{CO_2}$ less than 40 mmHg may still be inappropriately high. (See Chap. 21 for a detailed discussion.)

When used properly, pulse oximetry can also reduce the need for arterial blood gas (ABG) determinations; however, since the Sa$_{O_2}$ indicated by the pulse oximeter is often 2 to 3 percent higher than that seen with ABG, one should try to keep the saturation more than 92 to 93 percent.

Shock

At the same time that one is ensuring an adequate ventilation, efforts should be directed toward rapidly restoring a more than adequate tissue perfusion. After hemorrhagic shock, the cardiac output and oxygen delivery must be 25 to 50 percent greater than normal to adequately perfuse and oxygenate the intestinal mucosa and liver.[3]

Other preliminary studies indicate that capnometry to determine the end-tidal P$_{CO_2}$ (PET$_{CO_2}$), particularly if combined with arterial P$_{CO_2}$ determinations so that one can determine the arterial–end tidal CO$_2$ difference [P (a – ET)$_{CO_2}$] can also help monitor the adequacy of tissue perfusion ventilation. In general, a persistent PET$_{CO_2}$ < 28 mmHg or P (a – ET)$_{CO_2}$ > 10 mmHg is an indication of a poor prognosis.

If hypovolemic hypotension is present in patients with blunt chest trauma, it is most likely due to pelvic or extremity fractures, intraabdominal injuries, and/or intrathoracic bleeding.

In patients with penetrating chest trauma, the cause of shock will be intrathoracic injury in about three-quarters. The most frequent sources of intrathoracic bleeding are lung, heart, great vessels, and intercostal or internal mammary arteries. Up to one-half may have extrathoracic injuries contributing to the shock. When this occurs, it is most likely due to intraabdominal bleeding which often has a delayed diagnosis.

TREATMENT   **Fluids**   Failure to correct hypotension within 15 to 30 min greatly increases the mortality rate. In previously healthy patients requiring massive transfusions but having hypotension for less than 30 min, the mortality rate has averaged about 10 percent. However, if the hypotension is present for more than 30 min, the mortality rises to almost 50 percent. If the patient has preexisting disease or is over 65 years of age, the mortality with massive transfusions plus prolonged hypotension exceeds 90 percent.

To provide fluids rapidly in hypotensive patients, one usually needs at least two large intravenous catheters. If peripheral veins are not readily available, one may be forced to cannulate the subclavian or internal jugular veins. If a subclavian vein line is required, it should be inserted on the side of the injury. If one side of a chest is injured and the other lung is collapsed during insertion of a central intravenous line, impaired function of both lungs could be rapidly fatal.

Peripheral veins may be collapsed, unavailable, or inadequate. Especially in patients with thoracic trauma (and because of the activity required at the chest to deal with the direct consequence of that trauma) femoral venous cannulation is a preferred route of access for infusion of fluids. Seldinger technique is usually used (that is, "catheter over a guidewire") to insert a short, fat cannula, such as an "introducer" of the kind otherwise used in conjunction with pulmonary artery catheters. If percutaneous access to the femoral veins is difficult—as it often is when the patient has "bled out"—an experienced operator can place a cannula in the femoral vein via a saphenous vein cutdown in less than a minute. Such saphenous cutdowns are rare but can be lifesaving.

Irrespective of the route used to obtain vascular access, the goal is to stabilize the intravascular volume long enough to definitively manage the bleeding and only then to fully resuscitate the patient. Rapid resuscitation prior to control of the source can increase the rate and volume of blood loss, worsening hypothermia, immune suppression, and even mortality. Stopping the bleeding is the penultimate priority.

Chest Tube and Thoracotomy   A large hemothorax or pneumothorax can seriously interfere with ventilation and venous return; consequently, it should be evacuated as rapidly as possible. If blood is being removed rapidly through the chest tube, the vital signs should be followed very closely. If the vital signs are improving, one can continue to evacuate the blood. However, if the vital signs deteriorate as the blood is being evacuated, in spite of the rapid infusion of intravenous fluids, the patient may be exsanguinating via the chest tube because the tamponading effect of the hemothorax has been removed. In such circumstances, the chest tube should be clamped and the patient taken directly to the operating room for an emergency thoracotomy.

If it is thought that the bleeding is from an internal mammary or intercostal artery, one can insert a 30-mL balloon Foley catheter into the chest at the injured site, inflate the balloon, and pull it back tightly against the inside of the chest wall. The Foley catheter can also be used to drain blood or air from the pleural cavity, and if adequate pressure is applied with the inflated balloon against the chest wall for 12 to 24 h by taping the stretched tube to the chest wall, the bleeding will usually remain controlled.

Cardiac Arrest

EXTERNAL MASSAGE   In patients with cardiac arrest due to chest trauma, external cardiac massage is generally of no value and is in fact likely to be harmful. Since the trauma patient suffering cardiac arrest is generally hypovolemic, external massage is usually ineffective and may actually cause significant additional injury to the heart, liver, lungs, or great vessels. In addition, forced ventilation and external cardiac compression may result in air emboli in the coronary arteries.

INTERNAL (OPEN) MASSAGE   Resuscitative thoracotomy can be helpful in selected patients, i.e. those with signs of life within 5 min of arrival in the ED and penetrating wounds of the chest. However, a resuscitative thoracotomy is seldom of benefit in (1) patients with blunt trauma, (2) patients with penetrating abdominal or head injuries, and (3) patients "dead at the scene."

Open cardiac massage is usually performed through an anterolateral incision in the fifth intercostal space on the side of the injury. The pericardium is opened vertically 1 to 2 cm anterior to the phrenic nerve. The thoracic incision allows direct inspection of the heart, control of bleeding sites in the chest, and complete evacuation of any pericardial tamponade or hemopneumothorax. In addition, a left thoracotomy allows the physician to compress or clamp the descending thoracic aorta.

Since about 60 percent of the cardiac output normally goes to the tissues below the diaphragm, clamping of the descending thoracic aorta can increase coronary and carotid blood flow almost threefold. If the arterial systolic blood pressure does not rise to 90 mmHg within 5 to 10 min of aortic cross-clamping, further resuscitation will probably be of no avail. On the other hand, if the proximal aortic pressure rises above 160 to 180 mmHg in a previously normotensive individual, it can damage the brain and/or left ventricle.

Diagnosis of Thoracic Injuries

SYMPTOMS   The most frequent symptoms of thoracic trauma are chest pain and shortness of breath. The pain is usually well localized to the involved area of the chest wall, but not infrequently it is referred to the abdomen, neck, shoulder, or arms. Dyspnea and tachypnea are nonspecific and may also be caused by anxiety or pain from other injuries.

PHYSICAL EXAMINATION   A thorough physical examination, directed toward detecting the potential presence of the six major conditions to be sought during the primary survey, can be performed rapidly. There should not be an excessive reliance on chest x-rays. Tension pneumothorax, in particular, should be diagnosed and treated before obtaining a chest x-ray.

Inspection   CHEST WALL   Without careful inspection of the chest wall, one can easily overlook contusions, flail chest, intrathoracic bleeding, and open ("sucking") chest wounds. The paradoxical motion of a flail chest may be minimal when the patient is first seen, especially if it involves the lateral or posterior thorax.

Although external bleeding is easily recognized, it may be difficult to determine whether the source is intrathoracic or from the chest wall itself. Most chest wounds that communicate with the pleural cavity are readily apparent because of the noise air makes as it passes through the tissue of the chest wall during ventilatory efforts. However, some wounds are open only intermittently and may not be discovered until or unless the patient makes increased ventilatory efforts.

NECK   Distended neck veins, especially when the patient is sitting upright, may indicate the presence of pericardial tamponade, tension pneumothorax, cardiac failure, or air embolism. However, distended neck veins may not appear until hypovolemia has been at least partially corrected. If the face and neck are cyanotic and swollen, severe damage to the superior mediastinum with occlusion or compression of the superior vena cava should be suspected. Subcutaneous emphysema from a torn bronchus or laceration of the lung can cause severe swelling of the neck and face.

ABDOMEN   A scaphoid abdomen may indicate a diaphragmatic injury with herniation of abdominal contents into the chest. Excessive abdominal movement during breathing may indicate chest wall damage that might not otherwise be apparent. A rocking-horse type of ventilation may indicate a high spinal cord injury with paralysis of intercostal muscles.

PALPATION   Palpation of the chest should begin with determining whether the trachea is in its normal position, which is in the midline or slightly to the right. Palpation of the chest wall may reveal areas of localized tenderness or crepitus from fractured ribs or subcutaneous emphysema. Well-localized and consistent tenderness over ribs should be considered to be due to rib fractures, even if the initial x-rays appear to be normal.

Motion of a portion of the sternum or severe localized tenderness may be the only objective evidence of a fractured sternum. When a patient is coughing or straining, palpation can sometimes detect abnormal motion of an unstable portion of the chest wall better than visual inspection.

Percussion   Percussion of the chest wall can be of some help in differentiating between a hemothorax and pneumothorax. Dullness to percussion over one side of the chest following trauma may be the first evidence that a hemothorax is present; hyperresonance, on the other hand, may indicate the presence of a pneumothorax. A fairly large hemothorax can be missed if the chest x-ray is taken while the patient is lying supine.

If the pericardial cavity is greatly distended by an effusion or tamponade, the area of cardiac dullness may extend beyond the midclavicular line on the left or the sternal border on the right. This sign is especially helpful if the point of maximal impulse is located more than an inch inside the left border of cardiac dullness.

Auscultation   Whenever possible, the chest should be auscultated systematically and thoroughly, anteriorly, laterally, and posteriorly, and at both the bases and apices. If the breath sounds are equal bilaterally, the major bronchi are probably intact.

The presence of bowel sounds high in the chest may be the first indication of a diaphragmatic injury. Decreased breath sounds on one side usually indicate the presence of hemothorax or pneumothorax, but this may also occur if the endotracheal tube is in too far and only one lung is being ventilated. Before inserting a chest tube into a patient with an endotracheal tube and acute respiratory distress, with decreased breath sounds on one side, one should check the position of the endotracheal tube. Occasionally, persistently decreased breath sounds on one side are due to a bronchial foreign body or ruptured bronchus.

Injury to the Chest Wall

SOFT TISSUE INJURIES   **Bleeding**   Probing of a penetrating chest wound to determine its depth or direction can be dangerous because it can damage underlying structures and cause severe recurrent bleeding or a pneumothorax or air leak. Bleeding from chest wall muscles can be rather brisk at times and is best controlled initially by local pressure. Later, one can inspect the depths of the wound in the operating room and use ligatures to control the bleeding and carefully close the wound.

Open (Sucking) Chest Wounds   Small open chest wounds can act as one-way valves, allowing air to enter during inspiration but none to leave during expiration, thereby causing an expanding pneumothorax. This not only reduces tidal volume but can also interfere with venous return. If the open chest wound exceeds two-thirds the area of the trachea, air will preferentially enter the pleural cavity through the chest wall opening rather than through the tracheobronchial tree into the lungs.

Sucking wounds of the chest should be covered immediately by a sterile, airtight dressing, such as a petrolatum gauze, and a chest tube should be inserted almost simultaneously at a separate site to relieve the pneumothorax. The chest tube is not inserted through the trauma wound because it is then likely to follow the missile or knife tract into the lung or diaphragm. The occlusive dressing itself has the potential to cause a tension pneumothorax. Sudden deterioration following placement of the occlusive dressing but prior to insertion of the chest tube should suggest the possibility of a tension pneumothorax. In this case, relief is obtained simply by removing the occlusive dressing. In the prehospital setting, the occlusive dressing is fastened to the skin on only three sides so as to allow air to escape during

exhalation but none to enter during inhalation.

Tissue Loss   Injuries caused by close-range shotgun blasts or high-powered rifles may destroy such large quantities of chest wall that it may be impossible to close the chest wall in the usual manner. Intubation and mechanical ventilation will be required until the defect is definitively closed. It is important, however, to cover the lungs and heart and close the diaphragm. For small defects, resection of adjacent ribs and a thoracoplasty may be adequate. With large defects, rotated muscle flaps and/or Marlex mesh may be required.

Subcutaneous Emphysema   Subcutaneous emphysema usually develops because air from lung parenchyma or the tracheobronchial tree gains access to the chest wall through an opening in the parietal pleura. The air may also reach the chest wall from an interstitial lung injury by dissecting back along the bronchi into the hilum and mediastinum and then into the extrapleural spaces. Extensive subcutaneous emphysema should make one suspect an injury to the pharynx, larynx, or esophagus.

Patients with subcutaneous emphysema should be presumed to have an underlying pneumothorax, even if it is not visible on the chest x-ray. If the patient requires a general anesthetic or is to be placed on a ventilator, a chest tube should be inserted on the involved side(s), after inserting a finger to ensure that a pleural space is present. If subcutaneous emphysema is severe, a major bronchial injury should be suspected and sought by bronchoscopy.

If there appears to be any respiratory difficulty that may be due to mediastinal emphysema, a tracheostomy around which the skin and fascia are closed only loosely may serve to maintain adequate ventilation and also allow a route for air to escape from the mediastinum and subcutaneous tissue. Very rarely, linear incisions into the subcutaneous space of the chest wall may be required to relieve massive subcutaneous emphysema. Once the initiating cause is controlled, subcutaneous emphysema usually disappears gradually over a period of several days.

BONY INJURIES   **Clavicular Fractures**   Isolated clavicular fractures due to blunt trauma are usually relatively harmless. Occasionally, however, direct trauma produces sharp fragments that may injure the subclavian vein and produce a moderately large hematoma or venous thrombosis. Rarely, excess callus forming later at the site of a clavicular fracture may press against the subclavian artery or brachial plexus, producing a thoracic outlet syndrome.

Rib Fractures   SIMPLE FRACTURES   Rib fractures should be assumed to be present in any patient who has localized pain and tenderness over one or more ribs after chest trauma. Up to 50 percent of rib fractures (especially those involving the anterior and lateral portions of the first five ribs) may not be apparent on x-ray, particularly for the first few days after injury. Furthermore, injuries to the cartilaginous portions of the ribs may never be appreciated on x-ray.

The principal diagnostic goal with clinically suspected rib fractures is the detection of significant complications, especially hemopneumothorax, pulmonary contusion, or major vascular injury. If there is a suspicion of a pneumothorax that is not seen on the initial chest x-ray, the patient should also have inspiratory and expiratory films taken. As a general rule, a pneumothorax is seen better on expiratory chest films where the pneumothorax space takes up a larger percentage of the hemithorax. If the patient has severe trauma, if the rib fractures have sharp fragments, or if the patient has other injuries, serial chest roentgenograms (every 6 to 12 h for 24 to 48 h) should be obtained.

The pain of rib fractures can greatly interfere with ventilation. Strapping the chest with adhesive tape or a rib belt to relieve the pain may be effective in young, athletic individuals with only a few rib fractures; however, in less vigorous patients, strapping may significantly reduce ventilation and cause progressive atelectasis. Probably the best analgesic for mild to moderate chest wall pain is acetaminophen with codeine (Tylenol no. 3) or ibuprofen, 600 to 800 mg every 6 to 8 h as needed.

If the patient is admitted, an intercostal nerve block with bupivacaine (Marcaine) may dramatically relieve pain, muscle spasm, and ventilation for 6 to 12 h. Intrapleural catheters for administration of local anesthetics can also relieve chest wall pain quite well. Epidural analgesia usually works even better, but in many hospitals this requires admission to a step-down intensive care unit (ICU) for apnea monitoring. [4]

FIRST- AND SECOND-RIB FRACTURES   Except with direct trauma, as from a hammer blow, it takes great force to fracture the first and second ribs. It is frequently associated with significant injuries such as blunt myocardial injury (formerly referred to as myocardial contusion), bronchial tears, or a major vascular injury. There is conflicting evidence in the literature as to whether first- or second-rib fractures are more likely to be associated with mortality. Nevertheless, 15 to 30 percent of either fracture type is associated with poor outcome, usually from head injury or rupture of a major vessel.

MULTIPLE RIB FRACTURES   If a patient with fractured ribs, especially ribs 9, 10, and 11, becomes hypotensive and does not have a large hemothorax or tension pneumothorax, intraabdominal bleeding from the liver or spleen should be suspected.

In general, it is wise to hospitalize patients with fractured ribs for at least 24 to 48 h if they cannot cough and clear their secretions adequately, especially if they are elderly or have preexisting pulmonary disease. Admitting the patient also provides time to observe the patient for associated injuries that might not be apparent initially. Aspiration pneumonitis and fat embolism often do not become apparent clinically or on chest x-ray for at least 24 to 48 h.

Flail Chest   PATHOPHYSIOLOGY   Segmental fractures (i.e., fractures in two or more locations on the same rib) of three or more adjacent ribs anteriorly or laterally often result in an unstable chest wall and the phenomenon known as flail chest. This injury is characterized by a paradoxical inward movement of the involved portion of the chest wall during spontaneous inspiration and outward movement during expiration.

Although the paradoxical motion of the involved chest wall can greatly increase the work of breathing, the main cause of the hypoxemia of flail chest is the underlying lung contusion. In the past, pendelluft (a ventilatory phenomenon referring to movement of air back and forth between the injured and uninjured lungs with each breath) was considered to be an important cause of the hypoxemia seen with flail chest. However, pendulluft is probably significant only when the upper airway is partially obstructed.

Immediately after the injury, little flail may be apparent. Later, as fluid moves into the area of the pulmonary contusion, lung compliance falls, and more pressure is needed to inflate the lungs. The increasing pressure differential between intrathoracic and atmospheric pressure may then overcome the resistance of the muscles attached to the fractured ribs, thereby allowing the involved chest wall to develop increasing paradox. In addition, the patient may fatigue rapidly because of the decreased efficiency of ventilation and increased muscular effort. Thus, a vicious cycle of decreasing efficiency of ventilation, increasing fatigue, and hypoxemia may develop. In some instances, the increasing ventilatory fatigue can result in a sudden respiratory arrest.

TREATMENT   INITIAL THERAPY Historically, belts and adhesive tape were applied to "strap" and stabilize the chest. These interventions actually inhibit expansion of the chest and thereby aggravate the atelectasis of the underlying lung. The preferred intervention is analgesia adequate to allow the patient to fully expand the underlying lung, with a goal of improving ventilation and pulmonary toilet.

NONVENTILATORY THERAPY Patients with mild to moderate flail chest and little or no underlying pulmonary contusion or associated injuries can often be managed without a ventilator, by (1) relief of pain by analgesics or intercostal nerve block, (2) frequent coughing and chest physiotherapy, and (3) restriction of intravenous fluids to prevent volume overload. However, ventilatory support should be provided if, in spite of this regimen, the arterial P $_{O_2}$ remained less than 80 mmHg on supplemental oxygen.

VENTILATORY SUPPORT Indications for early ventilatory support of patients with flail chest include shock, three or more associated injuries, severe head injury, comorbid pulmonary disease, fracture of eight or more ribs, or age greater than 65 years. Early (prophylactic) ventilatory assistance in patients with flail chest and one or two additional injuries may reduce mortality to about 7 percent. This is in sharp contrast to a mortality rate of 69 percent in similar patients in whom ventilatory assistance is delayed until there is clinical evidence of respiratory failure. Ventilated patients seem to do better if intermittent mandatory ventilation (IMV), rather than controlled mandatory ventilation (CMV), is used.

One of the most controversial areas in the management of flail chest is the role of surgical fixation of the fractured ribs or the sternum. The aim of surgical fixation of the chest is to reduce the need for ventilatory assistance; however, this same objective can often be achieved with improved pain relief and ventilatory support. Although some European surgeons have claimed significant reductions in mortality and morbidity with surgical fixation of the flail chest, it is performed only infrequently in the United States. [5]

Sternal Fractures   Fracture of the sternum has long been considered a serious and life-threatening injury. Sternal fractures occur most often in motor vehicle accidents and have been thought to be associated frequently with cardiovascular injury, particularly blunt cardiac trauma and especially in older women wearing seat belts. Some authors have reported mortality rates in patients with sternal fractures to be as high as 45 percent. However, in a large recent study of patients with sternal fractures collected over $6\frac{1}{2}$ years, it was found that the incidence of sternal fracture as a result of motor vehicle collisions was 3 percent. [6] This series had a very low incidence of cardiac dysrhythmias requiring treatment [1.5 percent (4/272)], and mortality rate (0.7 percent).

The variability in the data likely reflect uneven definitions of blunt myocardial injury (BMI). Increasing evidence suggests that sternal fracture is not an indicator of significant blunt myocardial injury. [7,8] Authors of a small retrospective study have offered an algorithm approach to the consideration of BMI. Patients with blunt chest trauma without sternal fractures whose vital signs and ECG are normal require no further consideration of BMI. Patients with normal vital signs and ECG with sternal fractures should have repeat ECG alone in 6 h. If unchanged, then no further work up for BMI is required. [8] Institutional practices for the management of sternal fractures vary. Some admit for 24-h cardiac monitoring if the inner sternal cortex is disrupted.

TRAUMATIC ASPHYXIA   Sudden, severe crushing of the chest may cause subconjunctival hemorrhage or petechiae together with vascular engorgement; edema; and cyanosis of the head, neck, and upper extremities. This clinical picture appears to be due to an abrupt sustained rise in superior vena caval pressure and concurrent closure of the airway after deep inspiration. Although these patients often look moribund initially, neurologic impairment is usually only temporary, and long-term morbidity is due primarily to associated injuries. [9]

Injury to the Lungs

PULMONARY CONTUSION   Pulmonary contusions are a significant source of severe morbidity and mortality following penetrating and blunt trauma. While such trauma has long been recognized to be a source of deranged physiology, new diagnostic techniques, including computed tomography (CT), have made recognition of this common problem much more frequent. Prompt recognition and therapy can be lifesaving. Pulmonary contusion is defined as direct damage to the lung resulting in both hemorrhage and edema in the absence of a pulmonary laceration. The most typical cause of pulmonary contusion is a compression-decompression injury to the chest. In high-speed automobile crashes, airbags can attenuate but do not entirely prevent this injury. Consider the consequence of a rapid deceleration of the chest as causing a high-pressure wave that compresses the thoracic cavity. The force wave is transmitted directly to the lung because it is in contact with tissues of the chest wall. There is an instantaneous rise in intrathoracic pressure followed by a near instantaneous drop. The force wave coupled with the extraordinarily rapid changes in intrathoracic pressure are probably both necessary and sufficient to cause the injury.

Pathophysiology   There appear to be two significant stages in the pathophysiology of pulmonary contusion. The first is related to the direct injury, while the second is related to the resuscitative measures directed at associated injuries that ultimately prove harmful to the lung, in particular, the administration of intravenous fluid. Administration of fluid in the setting of unilateral pulmonary contusion can cause an extravasation of fluid into the contralateral (uninjured) lung, probably in association with reflex attempts to increase blood flow through this uninjured lung. The mechanism appears to be a fall in pulmonary vascular resistance in the uninjured lung, causing pressures exerted by the right heart to increase hydrostatic pressure in the capillaries enough to force both blood and fluid out of those capillaries into the interstitium and alveoli. Unfortunately, the process is self-perpetuating in that, as each proximate segment of lung sees the full force of the right heart activity, it becomes functionally congested and contused and the process continues to the next uninjured segment of lung.

The pathologic changes associated with pulmonary contusion seem to be primarily the result of capillary damage. There is both interstitial and intraalveolar extravasation of red blood cells and accumulation of edema fluid in the interstitium. These two processes typically do not occur simultaneously, but rather in sequence. Initially, the problem is primarily intraalveolar hemorrhage. The edema follows, as would be expected from the usual course of injury followed by fluid resuscitation. This accumulation of debris and mucus secretions causes further atelectasis, which leads, in secondary fashion, to large areas of unventilated but still perfused lung. Intrapulmonary shunting is increased, resistance to airflow is increased, the elasticity of the lungs is reduced, and the amount of respiratory work to move gases in and out of the lungs is markedly increased. Thus the work of ventilation becomes prohibitive and the patient becomes hypoxic, hypercarbic, and acidotic. Adaptive increases in cardiac output are usually insufficient to overcome the hypoxic process and cardiopulmonary decompensation can occur very quickly. With a significant blow to the chest, there may be accompanying myocardial dysfunction (attributable to blunt force to the heart), which, in combination with a severe pulmonary contusion, can synergistically lead to a rapid downward spiral.

Diagnosis   Areas of opacification of the lung seen on the chest x-ray within 6 h of blunt trauma are usually considered to be pulmonary contusions. The lung changes with aspiration pneumonia and fat embolism are not usually seen on chest x-rays for at least 12 to 24 h. The extent of the lung injury seen at thoracotomy or autopsy or on CT scan is usually much greater than suspected from chest x-rays.

Treatment   Treatment of pulmonary contusions primarily involves maintenance of adequate ventilation. Chest physiotherapy, intercostal nerve blocks, epidural analgesia, and nasotracheal suction are used as needed to ensure that the patient takes deep breaths and coughs adequately. If ventilatory assistance is required, ventilation with IMV and positive end-expiratory pressure (PEEP) usually provides much better ventilation-perfusion matching, better venous returns, and quicker weaning than does standard controlled ventilation. An important determinant of the need for mechanical ventilation is the volume of contused lung. Patients with less than 18 percent of total lung volume (about one lobe) do not require such support, whereas patients with more than 28 percent of total lung volume involved in the contusion predictably require such support. Premorbid health status and associated injuries can, of course, affect the threshold for mechanical ventilation in either direction. The point is that the "gray area" is quite narrow—a reflection of the progressive nature of the injury.

Patients who have a severe unilateral lung injury and are responding poorly to conventional mechanical ventilation may benefit from synchronous independent lung ventilation (SILV) provided through a double-lumen endobronchial catheter. This technique helps prevent overinflation of the normal lung and underinflation of the damaged, poorly compliant lung. [10]

In severe pulmonary contusion, ordinary mechanical ventilation may be insufficient to reverse the hypoxemia. The first maneuver should be to place the good lung "down" by turning the patient to the decubitus position. This simple maneuver can improve ventilation/perfusion matching. While administration of nitric oxide gas is still considered experimental therapy at the time of this writing, it has proven to be a superb adjunct in many patients with contusion because the gas reaches only ventilated alveoli and exerts its vasodilator effects in precisely those ventilated alveoli. Failing these two maneuvers, consideration should be given to chemical paralysis and institution either of pressure-controlled inverse-ratio ventilation or high-frequency oscillation. Both modes cause hemodynamic changes that require experience and invasive monitoring to manage effectively.

HEMOTHORAX   **Etiology**   Hemothorax requiring a thoracotomy is most frequently caused by bleeding from lung injuries. However, the compressing effect of the shed blood, the high concentration of thromboplastin in the lungs, and the low pulmonary arterial pressure combine to help reduce bleeding from torn lung parenchyma, so that a thoracotomy is needed only in about 5 to 15 percent of patients admitted with chest trauma. The other causes of severe and/or continuing intrathoracic bleeding include damage to the great vessels of the chest or intercostal or internal mammary arteries.

Pathophysiology   If there is more than 300 to 500 mL of blood in the pleural cavity, it should be removed as completely and rapidly as possible. Large clots can act as a local anticoagulant by releasing fibrinolysins and fibrinogenolysins from their surface. A large hemothorax also restricts ventilation and venous return. Bleeding from multiple small intrathoracic vessels often stops fairly rapidly after the hemothorax is completely evacuated.

Diagnosis   A hemothorax should be suspected following trauma if the breath sounds are reduced and the chest is dull to percussion on the involved side. Fluid collections greater than 200 to 300 mL can usually be seen on good upright or decubitus roentgenograms of the chest. However, if the patient is supine, more than 1000 mL of blood may easily be missed because it may only produce a mild to moderate diffuse haziness on that side. Ultrasound use in trauma to detect hemothorax has not been well studied and techniques for such detection are currently being evaluated. Even so, plain chest x-rays give much more additional information.

Treatment   THORACENTESIS   A very small, stable hemothorax does not always have to be removed, but it should be carefully observed. If the hemothorax seems large enough to drain, we have avoided needle aspiration and have relied on chest tubes. Needle aspiration of a hemothorax is usually incomplete and may cause a pneumothorax or infection of the hemothorax.

CHEST TUBES   **TECHNIQUE** Chest tubes for treatment of traumatic pneumothorax or hemothorax are usually inserted in the anterior axillary line just behind the lateral edge of the pectoralis major muscle. For a pneumothorax we tend to direct the tube as high and anteriorly as possible without the tip pressing on the mediastinum. For

a hemothorax, the tube is usually inserted at the level of the nipple and directed posteriorly and laterally.

Once the insertion site is selected, the area around it is painted liberally with an iodophor preparation and then widely draped with a fenestrated sheet. A 22-gauge needle is used to liberally infiltrate the skin, subcutaneous tissue, and intercostal muscles down to the parietal pleura with 1% lidocaine (Xylocaine) with adrenalin, keeping the total amount of lidocaine used below 0.5 mL/kg (5 mg/kg).

A transverse incision 2 to 3 cm in length is then made and extended down to the intercostal muscles. The skin incision for the chest tube should be at least 1 to 2 cm below the interspace through which the tube will be placed. A large clamp is then inserted through the intercostal muscles in the next higher intercostal space, with care taken to prevent the tip of the clamp from penetrating the lung (Fig. 251-1*A*). The resulting oblique tunnel through the subcutaneous tissue and intercostal muscles usually closes promptly after the chest tube is removed, thereby reducing the chances of recurrent pneumothorax.
FIG. 251-1A. The clamp is inserted through the incision and is tunneled up to the next intercostal space. (From Roberts JR, Hedges JR: *Clinical Procedures in Emergency Medicine,* 2d ed. Philadelphia: Saunders, 1991, with permission.)

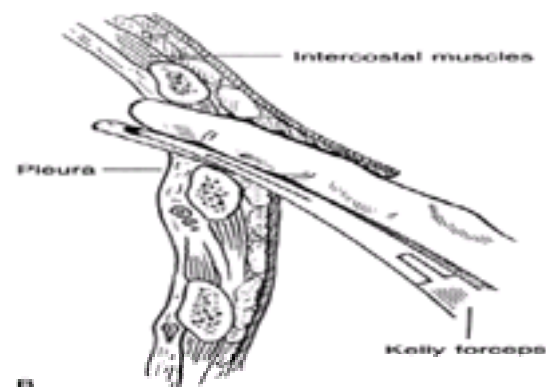
Once the clamp is pushed through the internal intercostal fascia, it is opened to enlarge the hole to approximately 1.5 to 2 cm. A finger is inserted along the top of the clamp through the hole to verify the position within the thorax and to make sure the lung is not stuck to the chest wall (Fig. 251-1 *B*). This is particularly important if a chest x-ray has not been taken or if the x-ray does not clearly show that the lung is away from the chest wall.


FIG. 251-1B. Using the finger as a guide, one places the tip into the pleural cavity. The pleura is punctured just above the rib to avoid intercostal vessels and nerves. (From Roberts JR, Hedges JR: *Clinical Procedures in Emergency Medicine,* 2d ed. Philadelphia: Saunders, 1991, with permission.)

For a simple pneumothorax, a 24F or 28F chest tube can be inserted. For a hemothorax, a 32F to 40F chest tube is preferred. When in doubt, the larger tube should be chosen for trauma situations. Smaller tubes may not drain blood adequately. The chest tube is grasped at its tip with the clamp and directed through the hole into the pleural space and advanced in the appropriate direction (Fig. 251-1*C*). The tube is advanced until the last side hole is 2.5 to 5 cm (1 to 2 in.) inside the chest wall. The tube is secured in place with a long, heavy suture (2–0 or 1–0) of nonabsorbable material placed in a U fashion around the tube. The suture is tied so as to pull the soft tissues snugly around the tube and provide an airtight seal. The tails of the suture can be wrapped around the tube in opposite directions approximately half a dozen times and then tied to secure the tube to the chest wall.
FIG. 251-1C. The tube is grasped with the curved clamp, with the tube tip protruding from the jaws. (From Roberts JR, Hedges JR: *Clinical Procedures in Emergency Medicine,* 2d ed. Philadelphia: Saunders, 1991, with permission.)

The open end of the tube is attached to a combination fluid-collection water-seal suction device, such as the Pleur-evac, with 20- to 30-cmH $_2$O suction (Fig. 251-2). If a significant hemothorax is known to be present or if a large amount of blood starts to drain immediately, consideration should be given to collection of blood in a heparinized autotransfusion device so that it can be returned to the patient either directly or after washing the red blood cells in saline.
FIG. 251-2. Chest drainage. *A.* Suction control. S-1, atmospheric vent. Use this opening for filling the suction control chamber. This is also the vent to atmosphere. S-2, self-sealing diaphragm on face of unit. Use an 18- or higher-gauge needle, attached to a syringe, to remove fluid from this chamber. S-3, suction control pressure scale. When suction is applied and bubbling occurs, the approximate level of suction imposed is determined by the original fluid level. S-4, suction tubing for connection to suction source. If suction is not required, tubing should remain uncapped and unclamped, to allow air to exit and minimize possibility of tension pneumothorax. *B.* Water-seal chamber. The water-seal chamber serves three purposes: (1) acts as a one-way valve to allow air to exit from the pleural space; (2) serves as a manometer, measuring the amount of negativity in the patient's chest cavity; (3) allows for observation of the degree of air leak. W-1, water-seal pressure scale (to determine negativity in patient's chest cavity). Without suction, the pressure in the chest cavity is read directly by the fluid level in the calibrated water-seal pressure scale. With suction, add the reading from the suction control chamber setting to the reading of the water-seal pressure scale (e.g., −20 suction plus −10 water seal = −30 cmH₂O patient negativity). Patency of the patient's thoracic catheter can be observed as oscillation in the water-seal chamber. The water level rises and falls as the patient breathes. Oscillations may not be present when suction is operative, the lung is fully expanded, or the tubing is blocked or kinked. W-2, positive-pressure relief valve opens with increases in positive pressure, preventing pressure accumulation. W-3, high-negativity float valve preserves the water seal in the presence of high negativity. W-4, filtered high-negativity relief valve is provided to vent excessive negativity. W-5, self-sealing diaphragm is provided in the front of the unit to adjust the water level in the water-seal chamber. *C.* The major collection chamber is calibrated in 2-mL increments up to 200 mL. Over 200 mL, calibrations are in 5-mL increments. Fluids overflow from one section to the next. The capacity of the major collection chamber is 2000 mL. C-2, the minor collection chamber. Its collection capacity is 100 mL. C-3, self-sealing diaphragms are provided on the back of the unit for taking laboratory samples of patient drainage. (Adapted from instructions for use of the Pleur-evac, Deknatel, Inc., Fall River, MA.)

After it appears that the chest tube is correctly situated and working properly, a sterile occlusive dressing is placed over the incision and additional layers of tape are used to secure the tube to the chest wall, so that it will not be accidentally pulled out.

The intrathoracic position of the chest tube and its last hole and the amount of air or fluid remaining in the pleural cavity should be checked with a chest x-ray as soon as possible after the tube is inserted. If there is a significant air leak, the chest films are best done as portables at the patient's bedside so as not to risk the development of a tension pneumothorax while the patient is off suction en route to the x-ray department.

If the patient is sent to the radiology department for x-rays, the chest tube should not be clamped because any continuing air leakage can rapidly collapse the lung and/or cause a tension pneumothorax. While the tube is unclamped, the water-seal bottle should be kept 1 to 2 ft lower than the patient's chest.

Serial chest auscultation, chest x-rays, and careful recording of the volume of blood loss and the amount of air leakage are important guides to the functioning of chest tubes. If a chest tube becomes blocked and a significant pneumothorax or hemothorax is still present, the tube should be replaced. This can often be done easily through the same incision. Irrigating an occluded chest tube or passing a Fogarty catheter through it in an effort to reestablish its patency seldom works well and almost certainly increases the risk of infection. If the chest tube is functional and well placed but a decubitus film shows a shift of some of the pleural fluid, the hemothorax is partially clotted; another chest tube placed with ultrasound guidance may be helpful. If a significant hemothorax persists, early evacuation of the clotted blood via thoracoscopy can prevent atelectasis.

If a chest tube is inserted because of a pneumothorax, it is left in place on suction for at least 24 h after all air leaks have stopped. If inserted for bleeding, it is left in place until the drainage is serous and less than 100 mL/24 h. However, if the patient is on a ventilator, many physicians would prefer to keep the chest tubes in case a new pneumothorax suddenly develops.

When the tube is to be removed, the patient is asked to take a deep breath and bear down, as in a Valsalva maneuver. While intrathoracic pressure and lung volume are at their maximum, the tube is quickly pulled out and petrolatum (Vaseline) gauze is immediately applied as an airtight dressing over the chest tube site. It is important that the patient be in full inspiration when the tube is pulled. The involuntary reflex while the tube is being pulled is a quick inspiratory effort because of the pleural pain. This may rapidly suck in several hundred milliliters of air just as the tube is being removed, necessitating reinsertion of another tube. Some surgeons put only one throw in their initial chest tube suture so that the ends can be unwound from the chest tube and then tied down to provide an airtight seal of the chest tube hole.

Following removal of the chest tube, a chest x-ray should be obtained to rule out a recurrent pneumothorax. Another chest x-ray should be obtained 12 to 24 h later to confirm continued complete expansion of the lungs.

Although there continues to be controversy about the need for prophylactic antibiotics in patients requiring a chest tube for a traumatic hemothorax and/or pneumothorax, a recent review by Wilson of the six available double-blind prospective studies showed a clear reduction in the incidence of pneumonia and/or empyema when antibiotics were given until the chest tubes were removed.[11] Studies suggest that giving antibiotics for just 24 h is adequate,[12] and one study suggests that only one dose of antibiotic need be given when thorecostomy tubes are required following penetrating trauma.[13]

AUTOTRANSFUSION   In patients with massive bleeding into a body cavity, proper collection and autotransfusion of the shed blood may reduce the need for bank blood and its associated risks. Intrathoracic bleeding is generally ideal for this technique, because there is usually no contamination of the blood by bile or intestinal contents.

To use shed blood for autotransfusion, one adds citrate or heparin to it as it is removed (to keep it from clotting) and collects it in a special sterile container. The red blood cells are then usually washed with saline. Autotransfused blood can greatly reduce many of the risks of blood transfusion, but, in emergency situations, attempts at autotransfusion can be time-consuming and difficult. The suction used for collecting blood for autotransfusion is also not as efficient as the regular suction for keeping the operative field clear. As a consequence, if adequate type-specific blood is readily available, many centers make little effort to use autotransfusions. Furthermore, using more than five units of autotransfused blood may contribute to a tendency to a coagulopathy. If the cells are washed in a cell saver, more autotransfused blood can be given safely, but there is still some concern about the development of a coagulopathy. Generally it is easier and much faster to use bank blood unless (1) the bleeding is massive and not rapidly controllable by surgery, (2) the blood type is rare, and/or (3) there is difficulty with the cross-matching.

THORACOTOMY   Most patients with intrathoracic bleeding can be treated adequately by intravenous administration of fluids and evacuation of the hemothorax with a chest tube. Fewer than 5 percent will require operative management. Massive hemothorax mandates operation. (See earlier discussion.) Selection of management approach must be made by a qualified surgeon in the context of available resources.

Occasionally, when the chest tube is initially inserted, blood emerges at an alarmingly rapid rate. If the patient's condition improves as the blood is being removed, continuing drainage of the blood and observation of the patient are in order. However, if the patient's vital signs deteriorate as the blood is being removed, loss of the tamponading effect of the hemothorax has probably allowed serious bleeding from the lung to recur. Consequently, the patient should be taken directly to surgery.

PNEUMOTHORAX   **Pathophysiology**   Collections of air or blood within the pleural cavity reduce vital capacity and increase intrathoracic pressure, thereby decreasing minute ventilation and venous return to the heart. During inspiration, the negative intrapleural pressure increases the tendency for air or blood to leak into the pleural cavity through any wound in the lung or chest wall. If there is any obstruction of the upper airway or if the patient has chronic obstructive lung disease, additional air may be forced into the pleural cavity during expiration, increasing the likelihood of tension pneumothorax with intrapleural pressures exceeding atmospheric pressure.

Diagnosis   Failure to obtain a chest x-ray soon after admission and again in 4 to 8 h may result in missing significant intrathoracic injuries. The presence of a chest injury is usually readily apparent from the history and physical examination; however, accurate assessment of the damage, especially to intrathoracic organs, often requires serial chest x-rays and/or a CT scan.

A pneumothorax is not likely to cause severe symptoms unless it (1) is a tension pneumothorax, (2) occupies more than 40 percent of one hemithorax, or (3) occurs in a patient with shock or preexisting cardiopulmonary disease. If there is a suspicion of a pneumothorax but it is not clearly seen on the first chest roentgenogram, repeat films during expiration may be helpful. Apical-lordotic films may allow better visualization of an apical pneumothorax. Occasionally, a pneumothorax after a stab wound is delayed for more than 12 h. Consequently, serial chest x-rays every 6 h for 12 to 24 h are indicated in selected patients. In a recent study of 4106 patients

with initially asymptomatic stab wounds of the chest, Ordog et al found that 12 percent of the patients required a tube thoracostomy for a delayed hemothorax or pneumothorax.[14] Current accepted practice is to observe the patient and repeat the film in 6 h. If no pneumothorax is noted on the repeat film, and there are no other concerns, the patient can be discharged.

One should assume that a tension pneumothorax is present and begin treatment without waiting for a chest x-ray if the patient has (1) severe respiratory distress, (2) decreased breath sounds and hyperresonance on one side of the chest, (3) distended neck veins, and (4) deviation of the trachea away from the involved side. Insertion of a large needle into the involved side through the second intercostal space in the midclavicular line may help confirm the diagnosis and provide temporary relief while a chest tube is inserted.

A small pneumothorax (less than 1.0 cm wide and confined to the upper one-third of the chest) that is unchanged on two chest roentgenograms taken 4 to 6 h apart in an otherwise healthy individual can usually be treated by observation alone. However, in most instances after trauma, a chest tube or small catheter should be inserted as a precautionary measure, especially if the patient cannot continue to be observed closely.

Occasionally a small pneumothorax is not apparent on chest x-rays but is seen on a CT scan of the chest or abdomen. This is referred to as an *occult pneumothorax.* Chest tube drainage of an occult pneumothorax is not required unless the patient is going to be on a ventilator. [15,16]

If only a pneumothorax is present, a small- to moderate-sized (24F to 28F) chest tube may be inserted anteriorly in the second intercostal space in the midclavicular line. However, a high midaxillary tube is generally preferable. Although some physicians insert chest tubes over trocars because it is less painful, especially if the lung is well away from the chest wall, we believe it is safer to avoid the trocar and insert chest tubes using a large hemostat. Catheter aspiration of a simple pneumothorax (CASP) is most suitable for the treatment of pneumothoraces caused by needles or catheters.

Complications In general, a small- or moderate-sized pneumothorax does not cause problems unless there is a continuing air leak or the patient has other trauma or preexisting cardiopulmonary disease. Also, a continuing air leak does not usually result in complications if the lung is completely expanded. However, if a combination of a pneumothorax and continued air leak is allowed to exist for more than 24 to 48 h, the incidence of empyema and bronchopleural fistula is greatly increased.

The most frequent reasons for failure to evacuate a pneumothorax rapidly and to completely expand the lungs are (1) improper connections or leaks in the external tubing or water-seal collection apparatus, (2) improper position of the chest tube(s), (3) occlusion of bronchi by secretions or a foreign body, (4) a tear of one of the large bronchi, or (5) a large tear of the lung parenchyma. If a pneumothorax persists in spite of one or two well-placed chest tubes and there is a large leak, emergency bronchoscopy should be performed to clear the bronchi and identify any damage to the tracheobronchial tree that may need repair. Continued large air leakage and failure of the lung to expand adequately in spite of these measures is an indication for early thoracotomy to control the air leak.

PNEUMOMEDIASTINUM   Subcutaneous emphysema in the neck should make one look closely for a pneumomediastinum. The diagnosis of pneumomediastinum should also be suspected from the presence of a crunching sound (Hamman sign) over the heart during systole. The diagnosis is usually readily apparent on CT scans, but it can easily be missed on chest x-rays. Traumatic pneumomediastinum is of itself usually asymptomatic, but one must look closely for an injury to the larynx, trachea, major bronchi, pharynx, or esophagus.

PULMONARY HEMATOMAS   Pulmonary hematomas are parenchymal tears filled with blood. These generally resolve spontaneously over a few weeks; however, if they become infected, they can form lung abscesses that may be very difficult to manage. These hematomas are more likely to become infected if a thoracotomy is performed, if there is prolonged chest tube drainage of the pleural cavity, and/or if prolonged ventilatory assistance is required.

PULMONARY LACERATIONS WITH HEMOPNEUMOTHORAX   Major hemorrhage from lacerations of the lung following blunt trauma are usually caused by the sharp ends of fractured ribs. Occasionally, they may be caused by tearing of the lung at pleural adhesions during rapid deceleration injuries. Rarely, the adhesions themselves are quite vascular, and a torn adhesion will bleed enough to cause shock.

SYSTEMIC AIR EMBOLISM   In patients with penetrating chest wounds, and particularly those with hemoptysis, positive-pressure ventilation must be used with great care. High ventilatory pressures, especially over 50 cmH$_2$O, may force air from an injured bronchus into an adjacent injured vessel, producing systemic air emboli. This probably accounts for many of the severe dysrhythmias or central nervous system (CNS) changes that occur when patients with penetrating chest wounds are intubated and ventilated. One should be particularly concerned about causing systemic air emboli if the patient has hemoptysis.

If systemic air embolism occurs, the head should be lowered, and an immediate thoracotomy should be performed to clamp the injured area of lung and then aspirate air from the heart and ascending aorta. Open cardiac massage with clamping of the ascending aorta may help push air through the coronary arteries. Cardiopulmonary bypass should be instituted promptly if available.

INTRABRONCHIAL BLEEDING   Intrabronchial bleeding is poorly tolerated and can rapidly cause death from severe hypoxemia by flooding dependent alveoli. Patients with intrabronchial blood tend to die from "drowning" rather than from hypovolemia.

In patients with hemoptysis due to trauma, the uninvolved lung should be kept as free of blood as possible and nasotracheal suction and bronchoscopy used as often as necessary. If the bleeding is severe, a double-lumen endotracheal (Carlen) tube can sometimes be used to confine the bleeding to one lung. If a Carlen or similar split-function tube is not available or cannot be inserted, one may insert an endotracheal tube over a flexible bronchoscope into the bleeding main-stem bronchus. The balloon on the endotracheal tube can then be inflated as needed. If the bleeding is from the intubated lung, the endotracheal tube prevents blood from passing into the other lung, and ventilation of the other lung may then be maintained either spontaneously or via a mask or another endotracheal tube.

In some instances, the bleeding can only be controlled by occluding the involved bronchus with a Fogarty balloon catheter or by packing it with gauze until the bleeding site can be controlled surgically.

ASPIRATION   Aspiration of gastric contents is quite common after severe trauma, especially if the patient is unconscious. If it is recognized promptly, immediate bronchoscopy should be performed to remove any residual food particles. Immediate irrigation of the tracheobronchial tree with buffered saline or a bicarbonate solution may also help reduce the severity of the chemical pneumonitis, but the value of such irrigation is controversial.

Radiologic changes are usually delayed for more than 12 to 24 h. If an opaque foreign body is aspirated into the tracheobronchial tree, it is usually readily diagnosed on x-ray. However, radiolucent foreign bodies are easily missed. Inspiratory and expiratory chest films may help diagnosis of a one-way valve effect due to a foreign body by demonstrating failure of one lung to empty properly during expiration. Occasionally, a foreign body can remain lodged in various bronchi, causing repeated pulmonary infections or hemoptysis for years before being discovered. Persistent or recurrent cough, atelectasis, or pneumonia after trauma should be indications for bronchoscopy and/or bronchography.

Tracheobronchial Injury

LOWER TRACHEA AND MAJOR BRONCHI   Most injuries to major bronchi are due to rapid deceleration and shearing of more mobile bronchi from relatively fixed proximal structures. However, forced expiration against a closed glottis and/or compression against the vertebral column may cause bursting of these structures.

Numerous reports have emphasized that the most common presenting signs and symptoms are dyspnea, hemoptysis, subcutaneous emphysema, Hamman sign, and sternal tenderness. A large pneumothorax, pneumomediastinum, deep cervical emphysema, and an endotracheal tube balloon with a round appearance on chest roentgenograms may suggest tracheobronchial injury; however, approximately 10 percent are almost completely asymptomatic.

Most tracheobronchial injuries occur within 2 cm of the carina or at the origin of lobar bronchi. On bronchoscopy, the usual bronchial injury seen is a transverse tear in a main bronchus or a disruption at the origin of an upper lobe bronchus. The characteristic injury in the trachea is a vertical tear in the membranous portion near its attachment to the tracheal cartilages.

Even if the lung expands and the air leak stops, lacerations of the bronchi involving more than a third of the circumference should be repaired because they tend to

eventually cause severe bronchial stenosis with repeated pulmonary infections or complete atelectasis. Untreated tracheal tears may result in severe mediastinitis.

The majority of airway injuries can be corrected using standard techniques. With complex ruptures, cardiopulmonary bypass can provide safety during correction of the lesion and may encourage repair of the involved lung rather than its resection.

Those patients who survive a tracheal transection generally have their injury in the cervical trachea and have no associated injuries. Intrathoracic tracheal transection is usually associated with two or more major injuries and is almost invariably fatal. Concurrent esophageal injuries occur in almost 25 percent of penetrating tracheobronchial injuries and are easily missed unless esophagoscopy or contrast studies are also performed.

CERVICAL TRACHEAL INJURIES   Injuries to the cervical trachea from blunt trauma usually occur at the junction of the trachea and cricoid cartilage. This is most frequently caused when the anterior neck strikes the dashboard in an automobile accident. Evidence of trauma to the neck with subcutaneous emphysema should arouse suspicion of this injury. Inspiratory stridor usually indicates a 70 to 80 percent upper airway obstruction. However, cricotracheal separation is often only suspected when an endotracheal tube or bronchoscope cannot be inserted past the cricoid cartilage.

If the patient has a laceration of the trachea that is small and high, it may be managed simply by performing a tracheostomy below the injury. All lacerations of the trachea should be repaired.

Diaphragmatic Injury

ETIOLOGY   In urban centers, diaphragmatic injuries are caused most frequently by penetrating trauma, particularly gunshot wounds of the lower chest or upper abdomen. Rupture due to blunt trauma is much less frequent and occurs in only 4 to 5 percent of patients hospitalized with chest trauma. If there is a fracture of the pelvis, the incidence increases to about 8 to 10 percent.

Because of the protective effect of the liver on the right and the possible increased weakness of the left posterolateral diaphragm, most series report that 80 to 90 percent of the diaphragmatic injuries following blunt trauma occur in that area. However, in the series of Brown and Richardson, [17] the incidence of right- and left-sided diaphragmatic rupture was almost equal.

NATURAL HISTORY   Since 60 to 70 percent of normal ventilation depends on proper function of the diaphragm, trauma to this structure can cause serious ventilatory problems. However, the initial signs and symptoms are often masked by other injuries. Unless the diaphragmatic lesion is large, symptoms due to abdominal viscera in the thoracic cavity usually occur rather late. Over time, sometimes even years, a large amount of viscera can gradually work up into the chest through small diaphragmatic tears. The intrathoracic bowel may then become obstructed or strangulated or cause severe compression of the adjacent lung, a phenomenon we have referred to as *tension enterothorax.*

DIAGNOSIS   With penetrating trauma, the diagnosis of diaphragmatic injury is often made only intraoperatively. However, if the entrance wound is in the abdomen and there is evidence of an intrathoracic injury or foreign body, one can assume that the missile or knife has traversed the diaphragm. In the series just mentioned, 59 percent of the patients with diaphragmatic injuries had diagnostic chest x-rays. However, eight of nine peritoneal lavages done in these patients were negative. In the only positive lavage, the lavage fluid drained out through a previously placed chest tube.

With blunt trauma, any abnormality of the diaphragm or lower lung fields on chest x-ray should arouse suspicion of a diaphragmatic tear. Occasionally a nasogastric tube is seen to go into the abdomen and then back up into the chest because the stomach has passed through a diaphragmatic tear.

Techniques for diagnosing the less obvious diaphragmatic injuries include (1) peritoneal lavage with a chest tube in place; (2) upper gastrointestinal (GI) series, looking for displacement of viscera into the chest; (3) pneumoperitoneum with carbon dioxide; (4) CT scan with contrast; and (5) intraperitoneal technetium sulfur colloid. However, up to 50 percent of diaphragmatic injuries are diagnosed only during a thoracotomy or laparotomy.

Subtle diaphragmetic injuries can be difficult to diagnose, particularly on the right. Axial CT scans that are virtually tangent to areas at risk are difficult to interpret unless there is herniation of abdominal contents through the defect. The advent of laparoscopy has provided a new, useful tool for identifying the smaller injuries, and this may well be the diagnostic mode of choice for patients who have no other indications for laparotomy. Caution should be exercised, since insufflated gas can leak from the abdomen across a violated diaphragm and cause acute cardiorespiratory embarrassment.

THERAPY   Laparotomy is necessary to repair the diaphragm. Thoracotomy may be necessary for associated chest injury, resuscitation, delayed repair of the diaphragm, or management of thoracic complications. Recently there have been several reports of repair using thoracoscopy techniques.

HEART

Penetrating Injury to the Heart

The many factors affecting survival from penetrating injury to the heart include the weapon used, the size of the myocardial injury, the injured cardiac chamber, coronary artery damage, the presence of tamponade, associated injuries, and the time taken to reach the hospital. Every patient with penetrating chest injury anywhere near the heart and shock on admission should be considered as having a cardiac injury until proven otherwise. The converse is not true, since about one-third of patients who arrive in an ED alive and are subsequently proven to have a penetrating cardiac wound have near-normal vital signs.

With early aggressive resuscitation and surgery, up to one-third of patients arriving in a trauma center in extremis with a cardiac injury can be saved. In patients brought to the operating room with signs of life and a recordable blood pressure, the survival rate should exceed 70 percent for gunshot wounds and 85 percent for stab wounds.

Prognosis in penetrating cardiac injury correlates with cardiovascular status on presentation. Those patients who reach the ED with near-normal vital signs typically have good outcomes, while few who lose signs of life during transport or on arrival to the ED survive with intact neurologic function. Patients who have no signs of life "in the field" are not candidates for resuscitative efforts.

PATHOPHYSIOLOGY   Penetrating wounds of the heart are usually rapidly fatal, generally because of massive hemorrhage; fewer than one-fourth of the patients with this injury reach the hospital alive. Patients surviving more than 15 to 30 min usually have either a small wound or some component of pericardial tamponade. In a sense, pericardial tamponade is a two-edged sword; although it may prolong life by reducing the initial blood loss, the tamponade itself can be fatal by interfering with diastolic filling of the heart.

DIAGNOSIS   **Clinical Features**   All patients in shock with a penetrating wound of the chest between the midclavicular line on the right and the anterior axillary line on the left should be considered to have a cardiac injury until proven otherwise. If the only problem is tamponade and the patient is not hypovolemic, Beck's triad may be present. This consists of distended neck veins, hypotension, and muffled heart tones. The last is the least reliable sign; even with a large acute pericardial tamponade, which seldom is more than 200 mL, the heart tones are usually fairly clear.

Since patients with penetrating heart wounds are usually hypotensive, the neck veins will generally not distend until the blood volume is at least partially restored. On the other hand, chest injuries can cause the patient to breathe abnormally or strain, thereby causing neck vein distention even in the absence of tamponade. Other causes of Beck's triad include tension pneumothorax, myocardial dysfunction, and systemic air embolism.

Tamponade may also cause two Kussmaul signs. One is increased distention of neck veins during inspiration and the other is pulsus paradoxus. Paradoxical pulse is characterized by a drop in systolic blood pressure of more than 10 to 15 mmHg during normal spontaneous inspiration. The amount of paradox may be increased by hypovolemia.

Invasive Monitoring   While the obstruction to cardiac venous return is usually evident on physical examination and by the finding of distended neck veins, occasionally a central venous catheter may be required to confirm the elevated central venous pressure in the setting of hypoperfusion. Patients in extremis should

undergo diagnostic pericardiocentesis in lieu of central venous pressure following insertion of a central venous catheter.

X-Rays   The pericardium is noncompliant. Whereas an obviously globular cardiac silhouette may suggest tamponade as the cause of hypoperfusion, the converse is not true: most patients with tamponade have very ordinary-appearing cardiac silhouettes.

Electrocardiography   Electrocardiography (ECG) changes following cardiac injury are usually nonspecific. ST-T wave changes may indicate pericardial irritation or may reflect associated ischemia or hypoxia.

Echocardiography   Transthoracic echocardiography (TTE) performed by both emergency physicians and trauma surgeons has been shown to be successful in the detection of pericardial fluid.[18,19 and 20] Accordingly, TTE is now frequently used in penetrating chest trauma for the evaluation of potential cardiac tamponade. It has been shown that TTE performed in the ED results in more rapid diagnosis, faster time to surgical intervention, as well as improved survival and neurologic outcome.[19] The presence of a hemothorax may limit the ability of TTE to detect occult cardiac injuries;[21] however, there are methods to distinguish hemothorax from pericardial fluid by using different views.

Echocardiography can identify pericardial fluid and may help localize missile fragments in the pericardium. While TTE remains a mainstay of rapid assessment and diagnosis, emergency physicians practicing in trauma centers will periodically encounter critically ill patients for whom the diagnosis of cardiac injury must be excluded while a series of other injuries are being addressed. In experienced hands, transesophageal echocardiography (TEE) is an efficient diagnostic tool, particularly if the patient is already intubated and ventilated and the probe can be inserted quickly.

Pericardiocentesis   ACCURACY   There is an increasing tendency to avoid the use of pericardiocentesis as a diagnostic procedure in acutely injured patients with possible tamponade. In Demetriades' series, the incidence of false-negative pericardiocentesis was 80 percent and the incidence of false-positives was 33 percent.[13] In addition to its inaccuracy, attempts at pericardiocentesis may injure the heart or cause dangerous delays in needed surgery.

TECHNIQUE   The paraxiphoid approach is commonly used. An 18-gauge, 10-cm spinal needle is attached to a stopcock and then to a 20-mL syringe. The pericardiocentesis should be done with continuous ECG monitoring if possible. The ECG monitoring is more sensitive if one attaches the V lead of the ECG to the metal pericardiocentesis needle using an insulated wire with alligator clips on both ends.

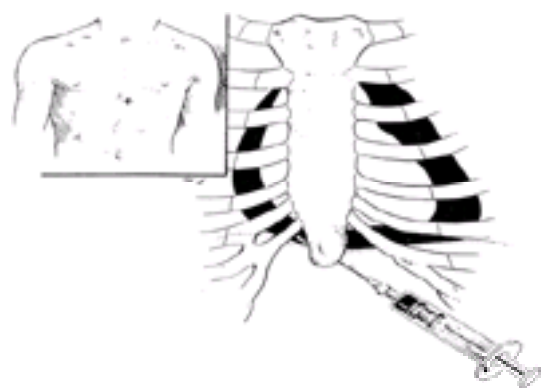
The needle is passed upward and backward at an angle of 45° for 4 to 5 cm and advanced slowly until the point seems to enter a cavity (Fig. 251-3). Most authors direct the needle toward the left scapula tip; however, directing the needle toward the right scapula is more likely to parallel the right border of the heart and is less likely to penetrate the right ventricle.


FIG. 251-3. The paraxiphoid technique for pericardiocentesis is usually performed with the needle directed toward the left shoulder or left scapula tip.   *However,* if one aims toward the tip of the right scapula, the needle tends to go parallel to the lateral border of the right heart and is less apt to penetrate the coronary artery or myocardium. [From Wilson RF: Injury to the heart and great vessels, in Henning RS (ed): *Critical Care Cardiology.* New York: Churchill Livingstone, 1989, with permission.]

One should aspirate every 1 to 2 mm as the needle is advanced. One can insert a stylet or inject 0.5 to 1.0 mL of saline solution at intervals to be certain that the needle is not plugged. The needle is then carefully advanced until blood is obtained, cardiac pulsations are felt, or the ECG shows an abrupt change.

Generally, a large portion of the blood in the pericardial cavity is clotted. Consequently, one can usually remove only a few milliliters of blood without manipulating the needle. If 20 mL of blood can be drawn out easily and rapidly, it usually indicates that the blood is being aspirated from the right ventricle.

If an immediate thoracotomy is not possible in a patient with a positive pericardiocentesis, a plastic catheter (inserted over a needle or Seldinger wire) can be left in place for continuous drainage of intrapericardial blood until the cardiac wound can be surgically repaired.

COMPLICATIONS   The pericardiocentesis needle can perforate the right ventricle as a coronary artery and cause tamponade as a consequence of the procedure itself. Dysrhythmias may also occur. A falsely negative pericardiocentesis may delay needed surgery.

Subxiphoid Pericardial Windows   If the patient has been hemodynamically stable and echocardiography is either not available or equivocal, an alternative method for diagnosing pericardial tamponade is a subxiphoid pericardial window. Although this can occasionally be performed under local anesthesia in the ED in a cooperative patient, it is best done in the operating room under general anesthesia. If blood is found in the pericardium, the incision can be extended up as a median sternotomy to repair the cardiac wound.

TREATMENT   **Fluid Replacement**   It is essential that patients with penetrating wounds of the chest have two or more large intravenous lines in place, with at least one line in a leg vein in the event that the superior vena cava or one of its major branches is injured. It is particularly important to have an adequate or increased blood volume if hypovolemia or tamponade is present. If tamponade is present with an elevated central venous pressure, one should generally not be reluctant to administer further fluid and blood to improve venous return to the heart while moving the patient to an operating room.

Pericardiocentesis   Pericardiocentesis can be both diagnostic and therapeutic. Patients who are in shock and may have a cardiac injury should have an emergency thoracotomy as soon as possible. If it is not possible to perform an emergency thoracotomy promptly, continuing pericardiocentesis to relieve the suspected tamponade should be attempted.

Removal of as little as 5 to 10 mL of blood from the pericardial sac may increase stroke volume by 25 to 50 percent, with a dramatic improvement in cardiac output and blood pressure. In patients who have small puncture wounds of the heart, pericardiocentesis may be curative, and thoracotomy may not be required as long as the vital signs remain stable for at least 24 to 48 h after the procedure.

Thoracotomy   Occasionally, a highly selected, stable patient with a small penetrating cardiac injury, as by a needle or ice pick, may be successfully treated without surgery. However, all patients with hemodynamic instability and a suspected injury to the heart should have emergency thoracotomy.

INCISION   For penetrating wounds over the precordium thought to involve the heart, an anterolateral thoracotomy is performed in the left fifth intercostal space, which is one interspace below the male nipple (Fig. 251-4). The incision should be as long as possible, extending from just lateral to the sternum to a point high in the axilla. In females, the breast is displaced upward, and the incision is made through the breast crease. The incision is extended through the intercostal muscle into the pleural cavity, with care taken not to injure the underlying lung or heart. A rib spreader is then inserted and opened widely so that two hands can fit inside the chest (Fig. 251-5). Cutting the intercostal cartilages above and below the incision may help increase the exposure. Not infrequently the internal mammary vessels, which lie

about 0.5 to 1.0 cm lateral to the sternum, are cut; if so, they must be clamped and tied or suture-ligated.
FIG. 251-4. Emergency thoracotomy to treat a stab wound of the heart or to perform open cardiac massage is usually done through an anterolateral thoracotomy approach. The incision extends along the fifth intercostal space with the skin incision placed in the inframammary crease. It extends from just lateral to the sternum to the midaxillary line. (From Geller ER: *Shock and Resuscitation.* New York: McGraw-Hill, 1993, with permission.)
FIG. 251-5. If the descending thoracic aorta is to be cross-clamped, it is best done under direct vision. To accomplish this, the anterior thoracotomy must be large and the incision opened as widely as possible. The left lung is pulled up anteriorly as far as possible by an assistant standing at the right side of the table. The pleura and fascia anterior to the aorta are thin, but the tissue between the aorta and the vertebral column is often rather tough and must be incised to get around the aorta properly. A straight clamp is often easier to put around the aorta than a curved clamp and is less likely to rupture the intercostal vessels. (From Geller ER: *Shock and Resuscitation.* New York: McGraw-Hill, 1993, with permission.)

When the injury is to the right of the sternum, a right thoracotomy is initially performed to control any bleeding sites, but strong consideration should be given to extending the incision across the sternum as a bilateral thoracotomy so as to be able to also control the descending aorta and, if needed, massage the heart directly. The sternum can be divided with a rib cutter. A bilateral anterolateral thoracotomy allows wide exposure of both sides of the heart and the proximal great vessels. In patients with a cardiac arrest, there is usually minimal bleeding from the thoracotomy incision until the circulation is restored. However, once circulation is restored, incisional bleeding may become quite severe, especially from the internal mammary arteries, which should be suture-ligated.

In hemodynamically stable patients with penetrating anterior chest trauma, a midsternotomy provides superior exposure for the organs most apt to be injured. [22] They feel that an anterolateral or lateral thoracotomy should be reserved for hemodynamically unstable patients, or if posterior mediastinal injury is suspected or aortic cross-clamping is apt to be needed.

PERICARDIOTOMY   Even when the pericardial sac is not distended with blood, it can be difficult to grasp the pericardium with a forceps. It may be necessary at times to "hook" the pericardium with one blade of a scissors and then grab it with a forceps or clamp. Another technique is to very carefully incise the pericardium near the apex of the heart with a small-bladed knife to produce a hole just big enough to allow the tip of one blade of a scissors. If a scalpel is used to open the pericardial sac, inadvertent injury to the underlying myocardium or left anterior descending coronary artery can easily occur.

The pericardial sac should then be opened from the diaphragm below to the great vessels above with a scissors in a longitudinal direction 1 to 2 cm anterior to the left (or right) phrenic nerve. If the pericardial sac is still tight around the heart, a transverse cut of the anterior pericardium just above the central diaphragm may greatly help with exposure. The liquid blood and clots in the pericardial sac should then be manually evacuated and cardiac massage initiated if needed.

CLAMPING THE DESCENDING AORTA   The second maneuver in the patient with severe hypotension or a cardiac arrest is compression or clamping of the descending thoracic aorta to help improve coronary and cerebral arterial flow. Since more than 60 percent of the cardiac output goes through the descending thoracic aorta, cross-clamping of this vessel can increase blood flow to the coronary and cerebral arteries two- to threefold.

To expose the descending aorta, an assistant on the right side of the patient lifts the left lung anteriorly, almost out of the hemithorax, so that the aorta can be seen from the left side of the table. The pleura and fascia in front of the aorta are easily opened, but the tougher posterior tissue between the aorta and the vertebral bodies often has to be incised sharply.

After the aorta has been exposed, a finger or a vascular clamp can be hooked around it. In this way, clamping is performed under direct vision, and the chances of intercostal or esophageal injuries are reduced. To be sure that the clamp is applied properly, one should feel pulsations from the spontaneous heartbeat or cardiac massage above the clamp but none below. If a nasogastric tube is not in place and there is little or no blood pressure, it is possible that the esophagus was mistaken for the aorta. After the clamp is applied, the time is noted, and the left lung is allowed to drop back into the thorax.

CLAMPING INJURED LUNG   If there is an obvious associated lung injury, it should be controlled with a vascular clamp or a lung clamp to prevent systemic air embolism and stop the bleeding and air leak until more definitive control can be accomplished. If there is a large central lung injury, one should put a clamp across the hilum. If the hilar clamp does not control the bleeding because the injury is too close to the heart, one may have to clamp the pulmonary vessels inside the pericardium.

EXAMINING THE HEART   If the bleeding site(s) is (are) not obvious, one should first carefully examine the right ventricle and right atrium, which are the chambers most apt to be injured. If an injury is still not seen, the heart can be swung out laterally and anteriorly into the left hemithorax to allow better examination of the remainder of the heart. When examining the posterior heart, one should be very careful because lifting the heart straight up increases the possibility of entry of air into a left-sided or posterior cardiac perforation, and this could result in sudden fatal coronary or cerebral air embolism.

CONTROLLING CARDIAC WOUNDS   Most atrial wounds can be controlled by the application of a Satinsky vascular clamp and then sewn with a running 3–0 or 4–0 polypropylene suture. Traditionally, wounds of the ventricles can generally be tamponaded by the operator's finger while pledgeted horizontal mattress sutures of 2–0 silk or Prolene are passed under the finger and tied by an assistant. However, given the uncontrolled setting and poor visualization, this procedure can only be considered of the highest risk for needle-stick injury and potential exposure to blood-borne infections. Thus, other techniques described below should be used. When a wound lies next to a major coronary artery, mattress sutures are placed beneath the artery so as to avoid ligation or compression of the vessel. Cardiac stapling can also be highly effective in the initial management of simple penetrating cardiac wounds.

For handling more difficult cardiac wounds, several other techniques are available. The insertion of a 5- or 30-mL balloon Foley catheter into a large or inaccessible

(posterior) defect may allow for control of hemorrhage until a purse-string suture can be applied around the hole. Use of such a catheter also allows one to infuse fluids very rapidly, directly into the heart.

Wide horizontal mattress sutures placed on either side of a large defect and pulled together can also be used to control hemorrhage until cardiopulmonary bypass can be instituted. If cardiopulmonary bypass is not readily available, occlusion of the superior vena cava and inferior vena cava by vascular tapes or clamps can allow quick repair of large defects without causing exsanguinating hemorrhage. Before restarting the heart, if the caval occlusion technique is used, all air is evacuated from the various cardiac chambers by allowing bleeding through the injury prior to tying the final suture and then inserting large needles into the apex of the right and left ventricles while the heart is cautiously massaged.

CARDIAC MASSAGE   Once cardiorrhaphy had been completed, internal cardiac massage can be performed as needed by compressing the heart between the palms of two hands or between one palm and the sternum. Warm—preferably 40 to 42.2°C (104 to 108°F)—saline solution poured over the heart may help prevent ventricular fibrillation. If ventricular fibrillation occurs, defibrillation with internal paddles, starting at 20 to 40 W/s should be performed. Lidocaine (1 mg/kg), correction of severe acidosis or alkalosis, and intravenous infusions of 1 to 2 g of MgSO$_4$ may help prevent recurrent ventricular fibrillation.

AIR EMBOLISM   If severe dysrhythmia or cardiac arrest develops during endotracheal intubation or while the chest is being opened, aspiration of the cardiac chambers for air should be performed immediately. Systemic air embolism is most frequently diagnosed by seeing air bubbles in the coronary arteries. This serious complication is seldom mentioned in the literature but is seen in about 20 percent of patients with penetrating truncal trauma who have a cardiac arrest in the ED after endotracheal intubation. Patients rarely survive this complication.

CONTINUED CARE   Once the heart develops a satisfactory rhythm, the descending thoracic aorta is gradually declamped as infusions of fluid and blood are administered, with care taken to keep the systolic blood pressure above 90 to 100 mmHg. One should also avoid systolic blood pressures greater than 160 to 180 mmHg because they may tear open cardiac repairs, excessively dilate the left ventricle, and/or cause intracerebral bleeding. The use of vigorous inotropes, such as epinephrine, should be particularly avoided at this point, as they may cause sudden, severe hypertension and can also increase the risk of recurrent ventricular fibrillation.

After the cardiac wounds and all bleeding vessels are controlled and an adequate cardiac output has been obtained, all clot is washed out of the pericardial and pleural cavities. One must look closely to make sure that the internal mammary arteries are intact or carefully suture-ligated. If the heart is edematous or dilated, the pericardium can be left open. Occasionally, the sternum cannot even be closed. In such instances, the skin can usually be stapled. The sternum can then be closed after several days when the cardiac edema and dilatation have resolved.

CORONARY ARTERY INJURIES   Ligation of the cut ends is the treatment of choice for lacerations of small coronary vessels. Torn proximal coronary arteries may also be ligated if there is no evidence of cardiovascular dysfunction. However, such patients must be observed closely. If a large proximal coronary artery laceration results in dysrhythmias, myocardial infarction, or impaired hemodynamic function, an aortocoronary revascularization with a saphenous vein graft should be performed under cardiopulmonary bypass.

Blunt Injury to the Heart

ETIOLOGY AND MECHANISMS OF INJURY   The most common cause of blunt cardiac trauma is a high-speed motor vehicle accident. However, myocardial injury has been documented in accidents involving vehicles going less than 20 mph. Other causes include direct blows to the chest, industrial crush injuries, falls from heights, blast injuries, and athletic trauma.

The heart is suspended relatively freely within the chest cavity from the great vessels, and this mobility plus its location between the sternum and the thoracic vertebrae make it susceptible to injury as a result of several mechanisms: (1) sudden horizontal acceleration and/or deceleration, causing the heart to impact against the sternum and vertebrae; (2) a compression between the sternum and vertebrae following a direct forceful blow to the chest; (3) a sudden increase in intrathoracic and intracardiac pressures, causing disruption of the myocardium or cardiac valves; (4) a "hydraulic ram effect," with compression of the abdomen forcibly displacing abdominal viscera against the heart with sudden great force; and (5) strenuous or prolonged cardiac massage, particularly if done through the intact chest wall.

TYPES OF INJURIES   Blunt trauma to the heart can cause a wide spectrum of injuries, including (1) rupture of an outer chamber wall, with resulting death from tamponade or bleeding; (2) septal rupture; (3) valvular injuries, of which injury to the aortic valve is the most common; (4) direct myocardial injury (contusion); (5) laceration or thrombosis of coronary arteries; and (6) pericardial injury.

Some authors have stressed the differences between myocardial concussion and myocardial contusion. With myocardial concussion, there is no anatomic cellular injury, but there is some dysfunction, as demonstrated by abnormal wall motion studies. With contusion, there is an anatomic injury, as demonstrated either by elevated CPK-MB isoenzymes or by direct visualization at surgery of autopsy. Because these are difficult to distinguish, the term *blunt myocardial injury* (BMI) is often used (see below).

DIAGNOSTIC PROBLEMS   Blunt cardiac trauma can be very difficult to detect at times. The victim may have experienced severe multiple-system trauma, and the presence of a cardiac injury may be overshadowed by other, more obvious injuries. In addition, the forces that produce blunt cardiac trauma may cause little or no external evidence of injury. Therefore, a history of moderate to severe chest or upper abdominal injury, even without abnormalities on physical examination, should make one suspect cardiac injury (Table 251-4).

History
   High-speed motor vehicle accident
   Crushed steering wheel
   Angina-like chest pain
Physical examination
   Tachycardia out of proportion to other findings
   Any dysrhythmia
   Any part of Beck triad
   Evidence of severe anterior chest injury
   Any evidence of heart failure
Radiography
   Fractured sternum or first two ribs
   Widened pericardial silhouette
Laboratory
   Elevated CPK-MB levels
ECG
   Dysrhythmias or conduction disturbance
   Elevated ST segments
Other studies
   Impaired motion of anterior heart on two-dimensional echocardiogram or
      radionuclide angiography
   PA catheter monitoring showing elevated PAWP, low cardiac output,
      and/or poor response to fluid

TABLE 251-4   Clues to Diagnosis of Blunt Cardiac Injury

BLUNT MYOCARDIAL INJURY   **Terminology**   There has been great confusion regarding the appropriate appellation for cardiac injuries related to blunt trauma. The terms *cardiac* (or *myocardial*) *contusion, cardiac* (or *myocardial*) *concussion, blunt myocardial injury,* and *blunt cardiac injury* have all been proposed. Certainly there is a spectrum of injuries to the heart for which the term *blunt cardiac injury* would be appropriate, if not very specific. *Myocardial concussion,* sometimes referred to as *commotio cordis,* suggests no obvious gross or microscopic pathology to explain the phenomenon. However, sudden death from dysrhythmia can occur. The initiating mechanism is usually from a sudden direct force to the chest, while an individual is participating in certain sports (e.g., karate, hockey, etc.).[23] The term *myocardial contusion,* although somewhat out of favor currently, may in fact have a pathologic definition (see below). The term *blunt myocardial injury* (BMI), a more encompassing term although not universally accepted, has come into vogue, since *myocardial contusion* rarely exists in the strictest sense but is often associated with other injuries (e.g., coronary artery thrombosis, infarction related to hypotension). Also, the underlying pathologic definition is less important than determining the cardiac risk profile of patients with blunt chest trauma.

Pathologic Changes   The pathologic changes seen in the myocardium typically include subendocardial hemorrhage and a much larger area of focal myocardial edema, interstitial hemorrhage, and myocytolysis with infiltrates of polymorphonuclear leukocytes. The areas most frequently involved are (1) the anterior right

ventricular wall, (2) the anterior interventricular septum, and (3) the anterior-apical left ventricle.

Additional myocardial injury may occur if there are concomitant intimal tears or compression from adjacent hemorrhage and edema. Indeed, some feel that much of the myocardial injury seen is due to redistribution of coronary blood flow. Very occasionally, transient hypotension may cause complete occlusion of a previously diseased coronary artery.

Usually there is complete clinical recovery with minimal residual scarring within 3 to 6 weeks of a myocardial contusion. However, in rare cases with severe transmural injury, a ventricular aneurysm may develop.

Physiologic Changes   In addition to rhythm and conduction disturbances, some reduction in cardiac output can be found in most victims studied. The degree of cardiac depression is directly related to the mass of contused myocardium. Screening tests, such as the ECG and CPK-MB isoenzymes, usually do not accurately indicate the severity of the injury, nor are they predictive of major morbidity or mortality.

Although there seems to be a great concern about making the diagnosis, most patients with myocardial contusions have relatively little problem. However, occasionally there is a problem with an dysrhythmia, especially premature ventricular contractions (PVCs), atrial fibrillation, or a conduction defect, or there is clinical evidence of heart failure. Such problems are most apt to occur in patients with: (1) preexisting cardiac disease, (2) prolonged general anesthetics, or (3) hypotension because of other injuries.

Diagnosis   Methods to diagnose myocardial injury have long been controversial. The variation in sensitivity reported for the various diagnostic tests has two origins. First, the tests require subjective interpretation. Second, there is no "gold standard" for comparison. Overall, significant BMI is an unlikely injury. A recent meta-analysis of studies of blunt cardiac trauma revealed that less than 3 percent of over 2200 patients in 25 prospective studies developed a cardiac complication (defined as requiring treatment or intervention). Most of these were ECG abnormalities (ventricular ectopy, superventricular dysrhythmias, symptomatic bradycardia). The most frequent cardiac rhythm finding, sinus tachycardia, was not considered, as it never required any specific treatment. ECG abnormalities requiring treatment were independently associated with a cardiac complications. [24]

Since diagnostic criteria (and even terminology) have not enjoyed universal or even general agreement, the focus has appropriately become predicting the likelihood of adverse events.

CLINICAL FEATURES   Any patient involved in a motor vehicle accident involving speeds exceeding 35 mph and having any chest symptoms or signs should be suspected of having a BMI. Rarely, a patient with BMI will have angina-like pain that is not relieved by nitroglycerin.

Tachycardia that is out of proportion to the degree of trauma or blood loss may be the first sign of a BMI. Occasionally, an irregular rhythm due to atrial fibrillation or multiple premature atrial or ventricular contractions may be noted. Differentiation from an acute myocardial infarction in older individuals may be difficult in the ED.

RADIOLOGIC EXAMINATION   The chest x-ray has its greatest value in the recognition of associated injuries. The closest x-ray correlates of BMI are pulmonary contusion or fractures of the first two ribs, the clavicles, or the sternum. Sternal fractures were thought to have been of importance, but, as noted above, when isolated, they are rarely associated with injury. [7,8]

Acute cardiac decompensation may be diagnosed by x-ray evidence of acute pulmonary edema (if the left ventricle is involved) associated with a normal-sized heart. Cardiac tamponade usually does not cause an enlarged cardiac silhouette, but a widened azygos vein is suggestive of this diagnosis.

ELECTROCARDIOGRAPHY   As with other tests, the potential value of the ECG is controversial. Suggestions have ranged from a single ED-based ECG to 72 h of continuous ECG monitoring. A recent study of 71 patients with blunt chest trauma (not requiring admission to an intensive care unit) revealed that the initial ECG was predictive of subsequent clinically significant ECG events. Still, an initially normal ECG does not exclude the development of a clinically significant cardiac event, since, most abnormalities will develop within 24 h. [25] The most frequent ECG abnormality is sinus tachycardia, although this finding does not suggest increased risk in and of itself. Significant ECG findings include injury pattern, tachydysrhythmias, ST-T wave abnormalities, and ectopy—particularly premature ventricular contractions.

One reasonable approach is to obtain an initial 12-lead ECG. If it is normal, then the patient must be monitored for 4 to 6 h. If there are no untoward events, patients can be safely discharged. [26] (Some authorities advocate no further monitoring.) If the ECG is abnormal but there is no hemodynamic instability, the patient should be admitted to a monitored setting, with the 12-lead ECG repeated in 24 h. Some authorities suggest an intervening ECG at 6 and 12 h. Hemodynamic instability suggests an aggressive diagnostic approach (see below). If, at any time, the ECG is abnormal (or changed) or if there is ectopy or dysrhythmia, cardiac monitoring should be continued and a cardiology consult obtained.

CARDIAC ENZYMES   Initially there was considerable controversy regarding the value of CPK-MB determination. Its certainly appeared that CPK-MB determinations were of questionable value and likely only to confuse, as they appeared to be of insufficient specificity and sensitivity. [27] Further, elevated MB fractions in this setting do not correlate with the clinical course.

Determination of cardiac troponins has shown promise [28] (Fig. 251-6), has been advocated as a laboratory criterion, and has even been proposed as the "gold standard" for the diagnosis of BMI. These determinations have been shown to have greater specificity for myocardial injury than CK-MB or myoglobin. However, the issue at this time appears no clearer than it was for CK-MB. A recent study found that troponin T (TT) had a specificity of 91 percent in predicting clinically significant ECG changes among those with blunt thoracic trauma, but the sensitivity was only 27 percent. [25] The authors concluded that TT determinations were useful. Using different criteria for the diagnosis of "myocardial contusion" (rather than untoward events), another study found very similar sensitivity (31 percent) and specificity (91 percent), minimally better than CK-MB. [29] The authors of the latter study conclude that TT has no important diagnostic value. More recent work suggests the sequential TT and troponin I (TI) may improve predictability for adverse events and need for intensive monitoring. There is intensive work in this area, but—as with other diagnostic tests—lack of agreement on definition or other end points; in the case of troponin, appropriate cutoff values and the type of assay used will continue to veil its potential usefulness.
FIG. 251-6. Highest value of MBCK found *(peak)*, peak MBCK to total CK ratio, and highest value of cTnI. *Open circles* indicate patients without cardiac contusion; *solid circles* indicate those with contusion. *Heavy horizontal lines* indicate upper reference limits for each parameter. (From Adams et al, [28] reprinted with permission.)

ECHOCARDIOGRAPHY   A recent detailed review concludes that echocardiography does not appear to be useful as a primary screening modality in the identification of patients likely to develop complications from myocardial injury. [30] It may well be the most sensitive test, but observed wall motion abnormalities often resolve and are usually clinically insignificant. However, patients who do develop cardiac complications may benefit from echocardiographic evaluation. Thus, the current recommendation is to use echocardiography in selected patients who demonstrate cardiac dysrhythmias or dysfunction. [31] While myocardial wall motion abnormalities

may be present in stable patients with blunt chest trauma, this finding alone does not seem to predict the likelihood of a complication.

OTHER DIAGNOSTIC TESTS Technetium-labeled pyrophosphate scanning, thallium single-photon-emission computed tomography, and radionuclide angiography have all been controversially discussed in the literature. They do not appear to have any greater front-line diagnostic value than the diagnostic adjuncts already discussed.

Summary of Diagnostic Approach There is no consistent standard of care to advocate at this time. Certainly the trend toward identifying patients who require intensive monitoring or who are at higher risk for adverse events is better than trying to arrive at a diagnosis (BMI) that has poor clinical correlation. Certainly all patients should have a CXR. Any abnormalities found will help to stratify patients for risk and allow consideration of other diagnoses. All patients should have a 12-lead ECG and be initially monitored. A conservative practice would be to monitor all patients with significant chest wall trauma for up to 24 h, although, based on the current literature, 4- to 6-h of cardiac monitoring would be acceptable in patients who have been hemodynamically stable throughout. Patients with abnormal ECGs merit continued monitoring, serial 12-lead ECGs, and consideration for echocardiography. It is difficult to recommend outright the routine use of cardiac enzymes for screening purposes, although one cannot be faulted for considering cardiac troponin determination, particularly for delayed diagnosis. The reader is advised to stay abreast of this rapidly developing modality.

Patients with hemodynamic compromise at any time should not only be monitored in an intensive care unit setting, but also warrant echocardiography and a cardiac consultation for further diagnostic and therapeutic options.

Treatment Although some patients will require treatment of heart failure or rhythm or conduction disturbances, specific treatment interventions are seldom required. In general, blunt cardiac injuries cause death very rarely, as noted elsewhere, [24] and the incidence of clinically significant dysrhythmias or other cardiac complications is generally greatly overestimated.

Supplemental oxygen should be administered as needed to maintain the arterial P$_{O_2}$ above 80 mmHg, and analgesics should be given as needed to reduce excessive pain. Coronary vasodilators should not be used unless the patient has suspected preexisting coronary artery disease. Cardiac dysrhythmias should be diagnosed early and treated appropriately. Prophylactic treatment of dysrhythmias is not indicated. Low cardiac output or hypotension should be treated with fluids or inotropic agents as indicated.

In the absence of dysrhythmias or hemodynamic instability, patients with BMI can safely undergo surgical procedures if the pulmonary artery wedge pressure and cardiac output are closely monitored.

If the patient remains in a low-output state despite adequate fluid resuscitation, inotropic support, and correction of any mechanical problems such as tamponade, use of an intraaortic balloon counterpulsation device should be considered.

There is some question as to whether patients with a myocardial contusion and an intramural thrombus seen on two-dimensional echocardiography should have prophylactic anticoagulation if not otherwise contraindicated. In limited studies, patients with echocardiographically proven right ventricular thrombi did not develop subsequent systemic or pulmonary embolization. Furthermore, anticoagulation is contraindicated in most cases of multiple trauma because of the potential for severe hemorrhage.

OTHER BLUNT CARDIAC INJURIES Cardiac rupture is the most frequent finding at autopsy in patients dying at the scene, and up to 90 percent with this injury die at the scene. Among those who reach the hospital, a few arrive seemingly stable. Most of these patients will deteriorate suddenly and resuscitation will most likely be unsuccessful. The diagnosis is suggested when shock is out of proportion to the degree of recognized injury despite attempts at hemorrhage control and volume repletion. Immediate thoracotomy and surgical repair is the only hope for a successful outcome.

Septal defects are rare but may be evident when a systolic murmur is heard and an infarct pattern is seen on the ECG. An ultrasound exam may also prove helpful. The diagnosis can be suspected when hypoxemia is severe with a normal CXR. Patients with atrial septal defects are unlikely to survive.

Rupture of the aortic valve is the most common valvular lesion found in patients who survive nonpenetrating cardiac injury. Patients with bioprosthetic heart valves are particularly likely to have traumatic valve injury. The next most frequent blunt valvular injury is laceration of a papillary muscle or the chordae tendineae of the mitral valve. The prognosis for rupture of a mitral papillary muscle or a mitral valve leaflet is grave, and death usually occurs within a few days after injury.

Direct injury to the coronary arteries from blunt chest trauma occurs very rarely, but if it causes pericardial tamponade or intrathoracic bleeding, immediate operation is required. Coronary artery thrombosis is also rare but has been reported. Coronary artery spasm does not appear to occur.

The incidence of major cardiac injury from blunt trauma resulting in cardiac tamponade or acute hemopericardium at autopsy has been reported to be about 6 percent. Hemopericardium or pericardial effusion with or without frank tamponade can occur without any evidence of blunt cardiac injury. This may develop acutely or may be delayed for more than a week. As with other causes of pericardial effusion, the rate of fluid accumulation is the main determinant of its hemodynamic consequences. In some instances, only echocardiography or autopsy provides the diagnosis. Small posttraumatic pericardial effusions can be seen with many cardiac injuries following blunt chest trauma but are usually of little or no consequence. They generally remain asymptomatic and resolve without any therapy. In rare instances, a patient may develop late constrictive pericarditis, occasionally with extensive calcification of the pericardium.

FOLLOW-UP It is important that patients with proven or suspected cardiac injury be closely observed, not only throughout their hospital stay but also later, for undiagnosed injuries or complications. One should look particularly for posttraumatic pericarditis, ventricular septal defect, valvular defects, and ventricular aneurysms.

POSTPERICARDIOTOMY SYNDROME **Etiology and Pathogenesis** The cause of the postpericardiotomy syndrome (PPCS) is still largely unknown, but it may be a delayed hypersensitivity reaction to the presence of damaged myocardium in the pericardial cavity. This damaged tissue can act as a foreign protein, inducing the production of autoantibodies against similar tissues. In fact, antimyocardial antibodies can be measured, and their serum concentration varies with the severity of the symptoms. Autogenous blood and lipids in the pericardium can also set up an inflammatory response that may be a contributing factor.

Diagnosis PPCS should be suspected in individuals who develop chest paint, fever, and pleural or pericardial effusions 2 to 4 weeks after cardiac trauma (or heart surgery). Patients may also have friction rubs, arthralgia, and pulmonary infiltrates. The blood count often shows a leukocytosis, and the ECG will often show ST-T wave changes consistent with pericarditis.

Treatment Treatment is primarily symptomatic. Salicylates and rest can often reduce symptoms dramatically within 12 to 24 h, but glucocorticoids are occasionally required. Rarely, drainage of pleural or pericardial fluid may be required to relieve symptoms or rule out other problems.

GREAT VESSELS OF THE CHEST

Penetrating Trauma

Of the patients who reach the hospital with penetrating chest wounds and require admission, only 5 to 15 percent require a thoracotomy, but up to 25 percent of the patients having such surgery have an injury to a great vessel. The survival rate with stab wounds is generally much higher than with gunshot wounds. Small knife wounds are often rapidly sealed off by surrounding tissue, especially vascular adventitia. This limits the amount of blood loss, particularly after hypotension develops. If the knife stays in place, it may temporarily seal the involved vessel.

The factors that determine the amount of tissue destruction caused by a bullet are discussed in Chap. 256.

TYPES OF VASCULAR INJURIES Simple lacerations of the great arteries of the chest can cause exsanguination, tamponade, hemothorax, or air embolism. Other vascular injuries include AV fistulas and false aneurysms, which may not be apparent for days or even months. As time goes on, AV fistulas tend to increase in size.

Eventually, if more than 25 percent of the cardiac output goes through an AV fistula, high-output cardiac failure is likely to develop.

Pulmonary AV fistulas after penetrating chest trauma are said to be extremely rare because of the small pressure differential that usually exists between the pulmonary arteries and veins. However, if the patient develops hypoxemia out of proportion to the apparent lung injury and has a persisting pulmonary density, one should suspect this problem.

DIAGNOSIS   History   History is particularly important in establishing the goals of care when a patient arrives without signs of life. Unless the patient had signs of life "in the field" or in the ED, resuscitative efforts are not indicated. Witnessed traumatic arrest following penetrating thoracic injury requires immediate suspicion and intervention for tension pneumothorax and cardiac tamponade followed by emergent thoracotomy if the percutaneous maneuvers fail to substantially improve the perfusion. The contrast between declaring death and proceeding with truly emergent resuscitative maneuvers is obvious, and the decision is based on history alone.

The size of a knife, its depth, and the angle of penetration may indicate the vessels or organs most likely to be injured. If there are two skin wounds, it is helpful to know whether they represent two entrance wounds or an exit and an entrance wound. In some instances, a bullet that entered the chest without exiting is not evident on chest or abdominal x-rays because it is in lateral subcutaneous tissues or has entered a major vessel and has embolized. It is also extremely important to know, if possible, the caliber of the bullet and whether it was a high-velocity missile (>1000 ft/s).

Physical Examination   Close inspection including lifting the skin edge with a forceps may be useful to determine the general trajectory. Under no circumstances should the wound be deeply probed to determine depth.

A large upper mediastinal hematoma may cause an acute superior vena caval syndrome, tracheal compression, and/or respiratory distress. Occasionally, a decreased upper extremity pulse may be noted. Unfortunately patients with injuries to major vessels at the thoracic inlet may have none of the usual diagnostic signs of significant vascular injury.

One should auscultate the entire chest for bruits after a penetrating injury. A systolic bruit, particularly over the back or upper chest, should make one suspect a false aneurysm involving one of the great vessels. A continuous bruit suggests an AV fistula. A millwheel murmur, thought to be due to the churning of air in the heart, may be diagnostic of air embolism. Loss of a peripheral pulse caused by an embolization of a bullet from a thoracic vascular injury is rarely but occasionally seen.

Radiography   PLAIN RADIOGRAPHS   Evidence of cervical or supraclavicular swelling or widening of the upper mediastinal silhouette or chest x-ray is often present in patients with injury to brachiocephalic vessels. A "fuzzy" foreign body (bullet) can be an important radiologic sign, and one should not assume that is is due to poor radiologic technique. Because foreign bodies tend to pulsate when they lie next to major vessels, their margins may appear indistinct on chest films. Therefore, a fuzzy foreign body contiguous with clear mediastinal structures on chest films can be an important x-ray clue to a vascular injury. Even if an angiogram is normal, a fuzzy foreign body should still be considered an indication for surgery.

COMPUTED TOMOGRAPHY SCAN   CT scans are rarely performed immediately for penetrating wounds of the chest because of the usually precarious condition of the patient. However, in a stable patient, a CT scan can identify localized hematomas or collections of blood that may not be apparent on routine x-rays. If a persistent "mass" is adjacent to a great vessel and does not move with position changes by the patient, one should assume that a contained hematoma is present. Intravenous contrast provides additional help for demonstrating a vascular defect or false aneurysm on the CT scan. CT scans can be particularly helpful for suspected thoracic aorta trauma or dissection, and false-negative studies without an adjacent hematoma are very unusual if the CT scan has been performed and interpreted properly. Nevertheless, CT scans should be used primarily for screening for great vessel injuries rather than for definitive diagnosis.

ARTERIOGRAM   Arteriograms may be particularly helpful in identifying major intrathoracic vascular injuries within contained hematomas, especially those resulting from penetrating wounds of the lower neck. Indeed, before exploring penetrating injuries of the thoracic inlet in hemodynamically stable patients, one should obtain a preoperative arteriogram to visualize the arch of the aorta and its major branches. Aortography is still considered by many to be the definitive study for examining injury to the aorta.

VENOGRAMS   Venograms to identify major vascular injuries in the chest are seldom performed. A patient who is actively bleeding from a major venous injury is usually explored emergently because of unstable vital signs or continued blood loss through chest tubes. However, once a venous injury stops bleeding, the hemorrhage generally does not recur and does not require a thoracotomy.

CONTRAST SWALLOWS   A contrast swallow may be performed on a stable patient if there is concern about an associated esophageal injury. Gastrogratin is used first but may miss up to half of esophageal leaks. Barium swallows have fewer false-negatives but can cause a worse mediastinitis if a perforation is present.

Endoscopy   With penetrating wounds of the chest or lower neck in hemodynamically stable patients, it may be prudent to perform bronchoscopy and esophagoscopy to rule out an injury to the aerodigestive tract. In some patients with "hemoptysis," the source may not be clear; such bleeding may result from injury to lung parenchyma, trachea, or a major bronchus. In other instances, it may be unclear whether mediastinal air is caused by an esophageal, pulmonary, or tracheobronchial injury.

Ultrasound   There is much controversy on how to evaluate hemodynamically stable patients with transmediastinal gunshot wounds. Such injuries often result in either prompt surgical exploration or an extensive evaluation to rule out injury to the heart, great vessels, esophagus, or tracheobronchial tree. Recently, however, transesophageal echocardiography has been noted to be of great diagnostic help, particularly if the aortogram demonstrates an equivocal injury. (See discussion under "Blunt Trauma to Great Vessels," below.)

TREATMENT   **Initial Resuscitation**   The standard ABCs (airway, breathing, circulation) of initial resuscitation should be followed aggressively if the patient is in shock. One of the problems occasionally seen with injuries to vessels in the thoracic outlet is massive mediastinal hematoma formation with resulting tracheal compression. Consequently, early endotracheal intubation should be performed. Tracheostomy should be avoided in patients with injuries at the thoracic inlet, at least initially, because of the possibility of precipitating massive bleeding from an otherwise controlled hematoma.

If the patient is in severe shock (systolic blood pressure <60 mmHg), surgery should be performed promptly and aggressive fluid replacement should not be employed until the major bleeding sites are controlled. With mild to moderate shock (systolic blood pressure = 60 to 88 mmHg), one should infuse 2000 to 3000 mL of balanced electrolyte solution in 10 to 15 min. If the shock is persistent, the patient is rushed to the operating room. If the patient is about to have a cardiac arrest in the ED, an immediate resuscitative thoracotomy should be performed there to control bleeding, provide internal cardiac massage, and cross-clamp the descending thoracic aorta as needed.

If rapid control of the bleeding sites and cross-clamping of the descending thoracic aortic arch do not raise the systolic blood pressure to at least 90 mmHg within 5 min, terminal cardiovascular failure is present; almost all of these patients will die in the operating room. Even if large doses of epinephrine or dopamine combined with aortic cross-clamping can raise the systolic blood pressure over 90 mmHg, death is still almost invariably the outcome.

Even if the patient's vital signs are relatively stable, one should probably perform a thoracotomy for continued bleeding if (1) a total of more than 1500 mL of blood is lost from the chest within the first 4 to 8 h and the patient is still bleeding, (2) the drainage of blood from the chest tubes continues to exceed 200 to 300 mL/h, or (3) the chest continues to be more than half full of blood on x-ray after the chest tubes are inserted and functioning well.

Bullets entering large systemic veins or the right heart can embolize to the lungs, whereas bullets entering the pulmonary veins or left heart can embolize to major systemic arteries. Some of these emboli cause no symptoms or signs and cannot be found except with multiple x-rays. Fluoroscopy in the operating room can be important in tracing these bullets, especially in the central veins or heart, because they can change position rapidly during the surgery itself.

Blunt Trauma to the Great Vessels of the Chest

INCIDENCE   Approximately 80 to 90 percent of patients with blunt trauma to thoracic great vessels, particularly the aorta, die at the scene, and up to 50 percent of the remaining patients die within 24 h if not promptly treated. The frequency of these injuries appears to be increasing and is primarily related to the use of high-speed automobiles. Each year at least 5000 to 8000 individuals in the United States suffer traumatic rupture of the thoracic aorta or one of the other great arteries in the

chest. Over 80 percent of the cases are due to automobile accidents.

MECHANISM OF INJURY   The mechanical factors responsible for traumatic rupture of the thoracic aorta and its major branches are probably somewhat different for each anatomic area. For the descending aorta at the level of the isthmus, three mechanical factors thought to contribute to rupture are shearing stress, bending stress, and torsion stress. The difference in deceleration between the mobile aortic arch and the relatively immobile descending aorta puts the aortic isthmus under tension, and the resultant shearing stress can lead to rupture or tears opposite the site of fixation. Bending stress is produced as the heart exerts downward traction on the aortic arch, resulting in the hyperflexion of the blood-filled aortic arch on a transverse fulcrum created by the hilar structures of the left lung. Torsion stress occurs when anteroposterior compression of the chest with resultant displacement of the heart to the left is combined with an intravascular pressure wave transmitted to the aorta. These three forces can combine to produce maximum stress to the inner surface of the aorta at the ligamentum arteriosum, which is its point of greatest fixation.

The aortic injury tends to progress from the intima out toward the adventitia. The adventitia, which has the lowest elastic limit, seems to withstand these stresses better than the intima or media.

Rupture of the innominate or left subclavian artery at their origins probably results primarily from the interaction of two forces. One is a compression force that displaces the heart into the left chest and places the brachiocephalic vessels under tension at their attachment to the aortic arch. The other force occurs when hyperextension of the neck with rotation of the head to one side places the contralateral subclavian arteries under tension. Subclavian artery injuries can also occur just over the first rib, and injuries at that site are usually caused by direct trauma and/or excessive stretching.

PATHOLOGIC CHANGES   Blunt aortic tears usually extend partially or completely around the vessel in a transverse or spiral direction. Preexisting disease, such as atherosclerosis or medial necrosis, does not appear to predispose to traumatic rupture. When the aortic tear involves all layers of the aortic wall, death by exsanguination is usually almost instantaneous. If the aortic tear does not involve the adventitia, and the parietal pleura and the surrounding mediastinal tissues remain intact, a false aneurysm often forms. The false aneurysm tends to expand, particularly if the patient is hypertensive, and about 50 percent of these, if untreated, will rupture within 24 h. However, some posttraumatic aortic false aneurysm remain intact and may not be detected for 20 years or longer. Although a lacerated subclavian artery occasionally forms a false aneurysm, it usually just occludes and does not require surgery.

It should be emphasized that the small hemothorax that is often present with blunt trauma to the aorta does not result from the aortic injury itself but rather from tears to adjacent small mediastinal vessels or other structures. In the same manner, although the widened mediastinum may be partly due to the aortic pseudoaneurysm, much of it is actually caused by bleeding from small mediastinal vessels.

NATURAL HISTORY   Of the patients who reach a hospital and survive for 1 h, about half die within 24 h, and three-quarters die within 7 days. Of the remainder, most die within the next 1 to 3 months.

Many of the early deaths are caused by associated injuries, but even when the aortic injury is an isolated problem, diagnosis and repair should usually be accomplished on an urgent basis. All too often the patient dies of exsanguination before a definitive repair can be effected. Keeping the systolic blood pressure <120 mmHg and prevention of Valsalva maneuvers may avoid many of the early deaths.

LOCATION   At least 90 percent of blunt aortic injuries in patients who reach the hospital alive occur in the isthmus of the aorta, between the left subclavian artery and the ligamentum arteriosum. The next most common sites involved are the innominate or left subclavian artery at their origin or a subclavian artery over the first rib. Patients do not usually survive injury to the ascending aorta, but this injury may be seen in up to one-third of the individuals who die at the scene of an accident, especially with vertical deceleration from falls from great heights or plane crashes. Tears in the lower aorta below the ligamentum arteriosum are quite uncommon but tend to occur adjacent to severely comminuted fractures of vertebral bodies.

DIAGNOSIS   **History**   The single most important factor in establishing the diagnosis of acute traumatic rupture of the aorta (TRA) is a high index of suspicion because of the nature of the trauma (Table 251-5). Even if there is no external evidence of chest injury, one should still be acutely aware of the possibility of this injury in anyone who has sustained an accident characterized by sudden severe deceleration or a high-speed impact from the side.

High-speed deceleration injury or side impact
Multiple rib fractures or flail chest
Pulse deficits
Hypertension
Systolic murmur over back
Hoarseness without laryngeal injury
Superior vena caval syndrome

TABLE 251-5   Clinical Factors Suggesting Possible Traumatic Rupture of the Aorta

Patients with TRA usually complain primarily of their associated injuries and generally have no symptoms related to the aortic injury itself. The most common complaint that may be due to the aortic injury itself is retrosternal or interscapular pain from "stretching" or dissection of the adventitia of the aorta. Recurrence or exacerbation of the pain, particularly if associated with a rise in blood pressure (which may be due to excess fluid administration or inadequate pain control), may herald an impending rupture of the pseudoaneurysm. Less frequent symptoms, due primarily to pressure from the associated hematoma, include dysphagia, stridor, dyspnea, or hoarseness.

Physical Examination   In many reports, at least one-third of the patients with blunt trauma to the aorta have no external evidence of thoracic injury at the time of the initial physical examination.

Physical findings that suggest aortic injury include (1) an acute onset of upper extremity hypertension, (2) difference in pulse amplitude between the upper and lower extremities, and (3) the presence of a harsh systolic murmur over the precordium or posterior interscapular area. Upper extremity hypertension has occurred in 31 to 43 percent of the patients reported in the literature and has been attributed to compression of the aortic lumen by a periaortic hematoma. However, the hypertension may also be secondary to stretching or stimulation of special receptors located in the vicinity of the aortic isthmus.

If the torn intima and media form a flap that acts as a "ball valve," partial or complete aortic obstruction can occur. With partial obstruction, an "acute coarctation syndrome" can develop, with hypertension in the upper extremities and weak pulses or hypotension in the lower extremities. A systolic murmur, thought to be caused by turbulent blood flow across the area of transection, is found in fewer than 30 percent of the patients with acute aortic rupture. If complete aortic obstruction occurs, anuria and paraplegia can develop almost immediately. Other, less frequently encountered physical findings include hoarseness, voice change, superior vena cava syndrome, swelling at the base of the neck, and paraplegia.

Plain Chest X-Ray   The results of a study by Gundry and colleagues[32] are shown in Table 251-6. These data confirm prior reports that a widened mediastinum visualized on an upright chest radiograph is the most sensitive and specific finding in patients subsequently shown to have traumatic rupture of the aorta (TRA). While secondary signs—including esophageal deviation, obscuration of the aortic knob, and loss of the paraspinal stripe—may suggest TRA or great vessel injury, these secondary signs are less predictive.

Radiographic or Clinical Finding	Correlation with TRA	Sensitivity	Specificity	Accuracy
Widened mediastinum (under 45 years old)	$r = 0.061$	0.85	0.12	0.34
Widened mediastinum (all ages)	$r = 0.081$	0.86	0.12	0.42
Hemar	$r = 0.062$	0.32	0.86	0.34
Pneumothorax/pulmonary contusion	$r = 0.07$	0.32	0.67	0.51
Elevations	$r = 0.12$	0.25	0.08	0.11
1st/2nd rib fracture	$r = 0.09$	0.06	0.73	0.46

*All other clinical and radiographic criteria were less useful in detecting TRA.
†Sensitivity = TP/(TP + FN); Specificity = TN/(TN + FP); Accuracy = (TP + TN)/All tests.

TABLE 251-6 Reliability of Selected Clinical and Radiographic Criteria in the Detection of Traumatic Rupture of the Aorta*†

One of the main reasons that many unnecessary aortograms are preformed is a technically poor chest x-ray. The upper mediastinum tends to appear wider than normal if the chest x-ray is taken (1) anteroposteriorly (AP) rather than posteroanteriorly (PA), (2) with the patient less than $3\frac{1}{4}$ ft (100 cm) from the origin of the x-ray beam, (3) with the patient lying flat, or (4) with poor inspiration. The optimal chest x-ray is an upright PA chest x-ray taken at a distance of 6 ft (about 2 m) with the patient leaning forward about 10 to 15°.

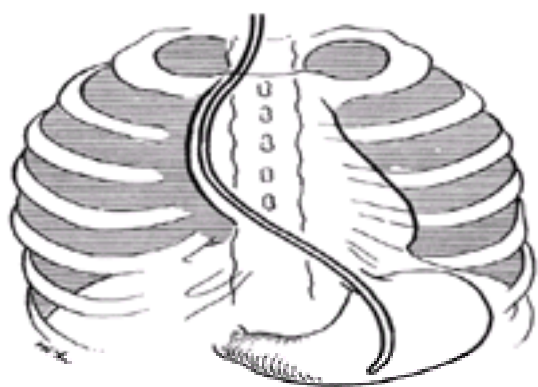
The most accurate radiographic sign of TRA is usually deviation of the esophagus more than 1 to 2 cm to the right of the spinous process of T4 (Fig. 251-7). Patients in whom the esophagus is deviated less than 1.0 cm from the midline are unlikely to have a TRA. A nasogastric tube in a normal position virtually excludes TRA.


FIG. 251-7. Deviation of the esophagus (nasogastric tube) to the right is generally a very accurate sign of traumatic rupture of the aorta. If the distance from the nasogastric tube to the spinous process of the fourth thoracic vertebra is greater than 2.0 cm, it is almost 100 percent indicative of a torn descending thoracic aorta.

Blurring or obscuration of the aortic knob or descending aorta is almost as accurate an indication of TRA. Studies have shown that patients with a normal aortic contour and no evidence of deviation of the trachea or nasogastric tube to the right on the chest x-ray do not have TRA.

Other chest x-ray signs include displacement of the left main stem bronchus more than 40° below the horizontal, obliteration of the usual clear space between the aortic knob and the left pulmonary artery (apical cap), widening of the right paratracheal stripe, and displacement of the right paraspinous interface (Fig. 251-8).
FIG. 251-8. Mediastinal hematomas, indicated by the blackened areas, may widen and displace the paratracheal stripe separating the right side of the tracheal air column from the medial border of the right lung by more than 5 mm. Mediastinal hematomas may also displace the right and left paraspinal lines in the lower thorax rather widely from the lateral edges of the thoracic spine. The paraspinal lines are not readily seen on most x-rays because of overlying structures.

The paratracheal stripe is a linear structure just to the right of the tracheal air column (Fig. 251-8). It extends from the thoracic inlet to the proximal right bronchus and normally measures less than 5 mm in thickness at a level 2 cm above the azygos vein. If the paratracheal stripe is more than 5 mm wide and/or is deviated to the right, this may be another sign of mediastinal hemorrhage.

The paraspinal lines lie between the pleura and the lung, projected away from the lateral margin of the thoracic spine. The right paraspinal line is usually not visible on routine chest x-rays, but if it is seen and if it is displaced to the right in the absence of spinal or sternal fractures, it may be of some diagnostic value.

The left paraspinal line may be distinguished from the image of the descending aorta by the fact that it is not continuous with the aortic knob. When displaced more than one-half the distance from the spine to the left margin of the descending aorta without spinal or sternal fractures, it is highly specific.

It often takes great force to fracture the first or second ribs or sternum, especially in young patients. Consequently, such fractures tend to be associated with an increased incidence of major intrathoracic injuries; however, it is now very controversial whether fractures of the first or second ribs are associated with a significantly increased incidence of TRA.

One should not assume that a TRA has been ruled out if the initial chest x-ray is normal. In up to one-third of patients with TRA, widening of the mediastinum and other characteristic changes may not be apparent on the chest x-ray until several hours after the injury. Two-thirds of patients above 65 years of age with TRA may not show mediastinal widening. Consequently, serial chest films should be taken in any patient with severe chest trauma at 6- to 12-h intervals during the first day and then daily for at least the next 3 days. Indeed, the circumstances of the trauma in such individuals should be the main indication for ordering an aortogram.

Transesophageal Ultrasound   Although aortography is the "gold standard" for the diagnosis of traumatic disruption of aorta (TDA), it is positive in only about 10% of patients in whom injuries are suspected based on plain films. Further, it is an invasive procedure that requires 1 to 2 h. Unlike aortography, CT, or magnetic resonance imaging (MRI), transesophageal echocardiography (TEE) can be safely performed in hemodynamically unstable patients. [33]

The thoracic aorta is not readily imaged by TTE. However, with the advent of new-generation TEE transducers, the entire thoracic aorta can be imaged. TEE visualizes the aortic isthmus and descending aorta very well and allows assessment of the pericardial cavity (hemopericardium, tamponade), valve function (and potential rupture), pulmonary veins (potential avulsion), and regional wall motion abnormalities.

One study that examined the role of both aortography and TEE found 100 percent sensitivity and specificity, respectively, with higher accuracy for TEE than aortography.[34] In this study, there were no complications from TEE, which was performed in less than 30 min on average, as compared with aortography, which required over 75 min on average. Other studies have found the sensitivity and specificity of TEE (in the hands of cardiologists) to be as low as 63 and 84 percent respectively.[35] The differences in the various studies are likely attributable to local factors such as patient population, limited study enrollment, and operator experience. TEE in this setting may be performed by cardiologists, surgeons, and radiologists. Because of the variability of findings using this relatively new diagnostic modality, the exact role of TEE for aortic imaging in both blunt and penetrating chest injuries remains to be defined.

The complication rate from TEE is very low, with esophageal perforation (perhaps the most feared complication) being on the order of 2 to 3 per 10,000.

CT Scans   CT scans, particularly helical (spiral) CT scans, are increasingly used as screening tools to evaluate patients with blunt chest trauma who are thought to be at risk for aortic and great vessel injury. Reports in the literature are contradictory regarding the sensitivity, specificity, and safety of this technique, which may well reflect the rapidly evolving technology as much as variation in technique and interpretation. The following comments apply to situations where technically adequate images can be obtained using a late-generation helical-capable CT scanner. Primitive CT scanners cannot be recommended for screening for aortic injury.

CT scanning is not a substitute for plain radiography or aortography. When a patient with an appropriate mechanism of injury (rapid deceleration) also has a chest radiograph suspicious for an aortic or great vessel injury, aortography should be the next step. However, there is a group of patients with an equivocal history and an equivocal radiograph. These patients may be screened to exclude an aortic injury using CT scans *provided that certain conditions are met.* The first and most important condition is that the patient is not thought to be at risk for great vessel injuries, since *injuries to the great vessels are commonly missed by axial CT.* The second condition is that the patient should be hemodynamically stable and capable of tolerating two dye loads, the first in CT and the second if aortography is required. We generally obtain a "dry" (noncontrast) view of the thoracic aorta first. If there is evidence of mediastinal hematoma on this initial study, we proceed to angiography. If the study appears normal, a CT "angiogram" is obtained using rapid infusion and helical scanning to collect images through the aortic arch and isthmus. If this study is entirely normal, we consider the aorta "cleared." Abnormalities require an aortogram. This special use of CT has found its widest application in our practice with obese patients who cannot tolerate an erect chest x-ray owing to skeletal instability. We reiterate that CT scanning is not a substitute for the proven methods of chest x-ray and aortography, and the use of CT should probably be limited to screening under specific circumstances. Difficulties in demonstrating injuries near or involving the great vessels should allow information about a "high-probability" mechanism of injury to prevail and thus justify proceeding with aortography even in the face of a "negative" CT.

Magnetic Resonance Imaging   MRI is a technically seductive method for investigating injuries to the aorta and great vessels. MRI has certainly emerged as the preferred tool for the evaluation of dissecting aneurysms of the thoracic aorta. However, even current-generation MRI instruments require long intervals in quiet patients who lie in an isolated room free of metallic objects to obtain satisfactory images—a requirement that is often difficult to meet in patients who are suspected of harboring major vascular injuries. For these reasons, the role of MRI in the evaluaton of blunt thoracic injuries remains indeterminate. As scan times become faster, the other limitations become less onerous.

Aortography   If an aortic rupture is suspected on clinical or radiologic grounds, an aortogram should be performed. While waiting for the aortogram or surgery, it is important to ensure that the systolic blood pressure is kept below 120 mmHg. It is also important to protect the patient from excessive gagging or straining.

The most common finding on aortogram is a pseudoaneurysm of the isthmus of the aorta. A slight pouching out of the inferior or inner border of isthmus, sometimes referred to as a pseudodiverticulum, is normal but may be confused with a traumatic pseudoaneurysm. Bulging of the aorta laterally is a more reliable indicator of TRA. A linear filling defect caused by torn intima and media is the best evidence that a TRA is present.

A patient who is in shock from a suspected TRA or who has a rapidly expanding mediastinal hematoma should be taken directly to the operating room without undergoing aortography. It should be remembered that occasional false-negatives occur with aortography.

Although it is often thought that there is relatively little risk to angiography, local complications with conventional angiography may occur in up to 23 percent of cases, and systemic complications may occur in up to 9 percent.[36] Although the rates of amputation (0.1 percent) or death (0.3 percent) resulting from transfemoral studies is relatively low, if they occur in an individual with a negative study, the indications for the aortogram are apt to be questioned. Death has also occurred in at least two instances when the angiographic catheter was manipulated through the aorta at the level of a tear. If angiography is done in a hospital where relatively few cases are done each year, the incidence of complications can be increased up to 32-fold.

Intraarterial Digital Subtraction Angiography   In an effort to improve the speed and accuracy of angiography and reduce the dose of contrast material, intraarterial digital subtraction angiography (IA-DSA) has been investigated. Studies have shown IA-DSA to be up to 100 percent accurate, as indicated by the results of surgery, conventional arteriography, serial chest x-rays, and clinical follow-up. The method is 50 percent faster than conventional aortography, and it can significantly reduce x-ray film costs. The use of smaller-caliber catheters for the intraaortic injection and a decrease in radiographic contrast media requirements also make this method safer than conventional arteriography.

TREATMENT   Although it is essential to resuscitate severely injured patients aggressively and to correct hypotension and hypoxemia rapidly the patient with a TRA should not be allowed to develop a systolic blood pressure over 120 mmHg or to perform a Valsalva maneuver. Endotracheal intubation can likewise cause gagging and coughing. Therefore these patients should not be intubated "awake." In addition to the standard paralytic and sedative drugs administered during rapid-sequence intubation, preemptive intravenous administration of lidocaine (1 mg/kg) to attenuate the vascular and bronchial responses prior to laryngoscopy may be advisable in patients with suspected or proven TRA. Fluid administration should be watched carefully, and administration of sedatives, analgesics, vasodilators, or even beta-adrenergic blockers may be required to keep the patient's systolic blood pressure at safe levels.

It is often important to insert a nasogastric tube in patients with multiple injuries, but it is essential that the patient with a suspected TRA not perform a vigorous Valsalva maneuver. Sudden gagging or bearing down can cause intraaortic pressure to rise abruptly to well over 200 mmHg and complete the rupture of a partially torn aorta. Similar precautions must be undertaken when inserting an endotracheal tube.

Since the initial report of a successful repair of an acute traumatic thoracic aortic disruption in 1958, [37] emergency operation has become the accepted standard for treatment. However, in selected cases, delays in surgical intervention may be warranted and safe. Such delay should be considered if (1) the patient is stable but the conditions for surgery are not ideal, or (2) the patient represents an extremely high operative risk because of associated injuries or preexisting medical conditions.

In a few centers with extensive experience with thoracic aortic surgery, the aortic repair may be preferentially performed by a rapid "clamp and sew" technique without an external shunt or cardiopulmonary bypass. Under these circumstances, an intravenous infusion of an alpha and beta blocker may be used to keep the systolic blood pressure in the upper portion of the body less than 150 mmHg so as to diminish the chances of intracerebral hemorrhage or left heart failure while the aorta is clamped. The operation must be rapid and precise, because clamping of the descending aorta for more than 30 min without perfusion of the distal aorta greatly increases the risk of damage to the spinal cord and abdominal viscera.

Because it allows increased time for a meticulous, unhurried repair and reduces the risk of ischemic damage to the spinal cord and abdominal viscera, repair of traumatic rupture of the thoracic aorta is often performed under partial cardiopulmonary bypass. If the patient's condition is stable, transfer to a hospital where cardiopulmonary bypass is available is wise, just in case problems develop during the repair.

Special Considerations in Less Frequent Great Vessel Injuries

ASCENDING AORTA   **Incidence**   Very few patients with ascending aortic injury survive long enough for the diagnosis to be established and repair to be carried out. These injuries are frequently associated with cardiac rupture or severe myocardial contusion, and the aortic tears are multiple in up to 15 to 20 percent. Most victims

have been hit by or thrown from moving vehicles or have fallen from great heights.

Diagnosis   Since most ascending aortic tears occur within the pericardium, if there is a small complete tear, there is often evidence of both shock and pericardial tamponade. The chest x-ray findings often show a widened superior mediastinum with or without obscuration of the aortic knob. Aortography is generally required for the diagnosis to be established. The aortogram usually shows a pseudoaneurysm with an intimal tear seen as an irregular filling defect within the lumen. If there is an associated valvular injury, aortic insufficiency of varying severity will usually also be seen.

Thoracic aortic injuries distal to the isthmus should be suspected with severe chest trauma in which a lower thoracic vertebra is severely crushed.

DESCENDING AORTA   Injuries to the descending aorta are uncommon. The presentations include paraplegia (owing to injuries to vessels supplying the spinal cord), mesenteric ischemia, anuria, or lower extremity ischemia. Angiography is typically required for diagnosis, and cardiopulmonary bypass may be required for surgical management. The more distal the injury, the better the anticipated outcome—assuming that the patient does not exsanguinate prior to surgical repair. Immediate surgery is indicated.

OTHER GREAT VESSEL INJURIES   **Innominate Artery**   INCIDENCE   In patients reaching the hospital alive, blunt injuries of the innominate artery are second in frequency only to rupture of the aorta at the isthmus. Associated injuries, such as rib fractures, flail chest, hemopneumothorax, fractured extremities, head injuries, facial fractures, and abdominal injuries, are found in more than 75 percent of these patients.

DIAGNOSIS   Making a diagnosis of blunt injury to the innominate artery can be very difficult because there are no characteristic physical findings except for some diminution of the right radial or brachial pulse, which occurs in about 50 percent of the patients. Signs and symptoms of distal ischemia are uncommon. Occasionally, a systolic murmur may draw attention to a possible lesion in this area.

The chest x-ray findings are somewhat similar to those seen with TRA, but the mediastinal hematoma tends to be higher and the trachea and esophagus may be pushed to the left. Aortography must generally be performed for the diagnosis to be established. Associated injuries in other brachycephalic vessels or the aorta are found in about 10 percent of patients.

Subclavian Artery   ETIOLOGY   Although a subclavian artery is occasionally avulsed at its origin because of sudden deceleration, direct trauma to the distal artery with intimal damage and occlusion associated with fractures of the first rib or clavicle are more likely. Shoulder restraints that are loose may be a major factor in causing this injury.

DIAGNOSIS   The most important sign of a subclavian occlusion is absence of a radial pulse. In the patient with only a partial laceration and no occlusion, the radial pulse may be preserved. Other physical findings that are highly suggestive of subclavian artery rupture are a pulsatile mass or a bruit in the root of the neck. Occasionally a patient may develop an acute subclavian steal syndrome if the subclavian artery occludes proximal to the origin of the vertebral artery.

Up to 60 percent of patients with blunt injury to the subclavian artery, especially from motor vehicle accidents, will also have some damage to the brachial plexus. Consequently, a complete neurologic examination preoperatively is important in these patients. A Horner's syndrome often indicates avulsion of nerve roots from the spinal cord.

The chest x-ray with subclavian artery injuries may show the presence of a widened superior mediastinum without obscuration of the aortic knob. The angiogram usually shows occlusion, but a pseudoaneurysm is occasionally found. Blunt subclavian artery injuries are associated with other major vascular injuries in about 10 percent of patients.

TREATMENT   The treatment of acute subclavian artery injury is usually immediate repair. However, in certain high-risk patients who are doing poorly, occlusion by an interventional radiologist may be the treatment of choice. If the artery is already occluded, observation may be all that is required. The collateral circulation to the distal portions of the vessel is usually very good. However, if there has been severe blunt trauma to the shoulder girdle, many of the collateral vessels may be damaged, resulting in critical ischemia of the hand or upper extremity gangrene in about 30 percent.

ESOPHAGEAL AND THORACIC DUCT INJURIES

Esophageal Injuries

MECHANICAL TRAUMA   Lacerations of the esophagus occur most frequently during endoscopic biopsy or dilatation of a narrowed or obstructed esophagus. The esophagus can also be injured by swallowed foreign bodies. Injury to the thoracic esophagus is seen only rarely in patients who reach the hospital alive.

If esophageal injury is suspected, an esophagogram should be obtained. The initial study should be performed using water-soluble contrast, since extravasation of barium into the mediastinum can complicate mediastinitis. However, a negative water-soluble contrast study should always be confirmed with a barium study owing to the former's relatively high false-negative rate.

Flexible esophagoscopy is being performed increasingly for diagnosis but may miss more than 20 percent of injuries, even if combined with an esophagogram. Some prefer rigid esophagoscopy in combination with bronchoscopy to rule out associated tracheobronchial injuries.

If treatment is delayed beyond 24 h, primary closure of a torn esophagus is usually not advisable because local edema, tissue necrosis, and infection make secure suturing and primary healing unlikely. If mediastinitis develops, it may be rapidly fatal unless the site is drained early and completely. Even if an esophageal repair is not attempted, continuous complete drainage of the stomach (preferably with a gastrostomy tube) and the adjacent mediastinum (with chest tubes) is important and may be necessary for up to several weeks.

In spite of all our technical and nutritional advances in recent years, the mortality rate for esophageal injuries ranges from 5 to 25 percent for those treated definitively within 12 h and 25 to 66 percent for those treated after 24 h.

Thoracic Duct Injuries

Most injuries to the thoracic duct in the chest result in a chylothorax. Because the thoracic duct in the chest tends to be slightly to the right of the midline, injuries to it usually cause a chylothorax on the right. Initially, the chyle may just accumulate in the mediastinum as a chyloma, but eventually, usually within 7 to 13 days, it will cause an increasing pleural effusion, especially after the patient begins to eat. Thoracic duct leakage in the chest can result in the loss of 1500 to 2500 mL/day of fluid with fat globules (demonstrated by Sudan III) and/or chylomicrons (demonstrated by lipoprotein electrophoresis) with minimal cholesterol.

Keeping the patient from eating and providing adequate drainage of the pleural cavity with a chest tube for several days usually results in spontaneous closure of the fistula. If the fistula persists and is large, nasogastric suction can help reduce the amount of chyle draining, and intravenous hyperalimentation can help prevent the protein malnutrition that can rapidly develop in these patients. If the patient is allowed to eat, a strict no-fat diet or a diet in which fat is given only as medium-chain triglycerides is preferred. If the drainage is greater than 1500 mL/day and leads to metabolic and nutritional problems or persists for more than 14 days, surgery to ligate the duct is generally indicated.

252 ABDOMINAL INJURIES

Thomas M. Scalea
Sharon A. Boswell

The evaluation of patients with abdominal injury cannot occur in a vacuum. It must be part of the systematic trauma evaluation designed to identify immediately life-threatening injuries and treat them first. Injuries that are potentially life-threatening can then be diagnosed in rank priority, allowing for the formation of a definitive plan of care.

Abdominal evaluation presents special challenges. There are five body cavities in which patients may be injured and sequester a significant volume of blood: the thorax, the abdomen, the retroperitoneum, muscle compartments, and "the street." A chest x-ray can easily diagnose intrathoracic blood loss. A pelvic film will diagnose pelvic fractures, the presence of which correlates strongly with retroperitoneal bleeding. External blood loss must be estimated based on prehospital provider information. The abdomen is a large body cavity, and patients can easily lose virtually their entire blood volume into it. There are no radiographic markers, and physical examination can be imprecise in the diagnosis of intraabdominal injury. Patients with missed injuries may not become symptomatic for 7 to 10 days postinjury, long after they are discharged home.

The management of intraabdominal injury continues to evolve. There are now many more injuries treated nonoperatively than there were 5 or 10 years ago. There continues to be debate as to which patients are safe for nonoperative management. Successful implementation of this strategy is contingent on accurate diagnostics and appropriate clinical follow-up.

The purpose of this chapter is to discuss the various issues concerning abdominal trauma. Clearly no one chapter can provide an indepth discussion of the multiplicity of issues concerning the evaluation and treatment of injury to the abdomen. It is our hope that we will be able to delineate these issues and provide the framework for clinical decision making when treating an injured patient.

PATHOPHYSIOLOGY OF INJURY

This year nearly 40 million people will be seen in this nation's emergency departments as a result of nonintentional injury. Over 2.5 million will remain hospitalized. In 1996 the number of deaths from nonintentional injury increased for the fourth consecutive year to 93,874. This trend is expected to continue.

The most common case of death and disability from nonintentional injury worldwide is the motor vehicle crash. In 1996 deaths from motor vehicle-related incidents in the United States alone rose to 43,300, and nearly 21 million people suffered disabling injury. Forty-one percent of these crashes were alcohol-related.

Falls, the second leading cause of accidental death in the United States, were responsible for 8,436,000 emergency department visits in 1994 and continue to account for more than 20 percent of all injury-related hospital admissions.

Increasing urban violence in the United States presumably has led to the continuously rising incidence of penetrating trauma. While penetrating trauma can be self-inflicted or accidental, more than 55 percent of these fatalities are caused by violence. In 1994 gunshot wounds and stabbing injuries accounted for 4,123,000 (10 percent) of all emergency department visits in the United States.

Abdominal trauma generally is divided into two types: blunt and penetrating. This is somewhat simplistic, and a skilled clinician must make more subtle differentiations within these injury patterns. Patients can suffer both blunt and penetrating trauma simultaneously. Patients involved in motor vehicle crashes may be impaled on objects at the time of impact. In addition, people who are shot or stabbed may be assaulted at the same time.

Blunt Trauma

Blunt trauma is the most common mechanism of injury seen in the United States. The injury pattern is often diffuse; thus all parts of the abdomen are at risk for injury. The biomechanics of blunt injury involve a compression or crushing by energy transmission directly to the patient. If the compressive, sheering, or stretching forces exceed the tolerance limits of the tissue or organ, the tissues are disrupted. This may result in injury to solid viscera such as the liver or spleen or rupture of hollow viscera such as the gastrointestinal tract.

Injury also can result from the movement of organs within the body. Some organs are rigidly fixed, whereas others are more motile. Injury is particularly common in areas of transition where one part is fixed and the other is free to move with some velocity. Typical examples in the abdomen include mesenteric or small bowel injuries, particularly at the ligament of Treitz or at the junction of the distal small bowel and right colon.

Falls from a height produce a unique pattern of injury. The degree of injury is a function of the distance, the surface on which the victim lands, and whether the fall has been broken by objects. Interestingly, intraabdominal injuries are very uncommon in patients who have fallen from a height. When they occur, they usually involve hollow visceral rupture and almost never cause hypotension.[1] Retroperitoneal injuries, however, are quite common because force is usually transmitted upward along the axial skeleton.

Pedestrians struck by cars may have unique patterns of injury because they are completely unprotected and all force is applied directly to the patient's body. Motorcyclists or bicyclists generally are poorly protected with the exception of a helmet. Their injuries are also compounded by the fact that motorcycles can travel at a great rate of speed.

Penetrating Trauma

Stab wounds are relatively straightforward. The wounding blade directly injures tissue as it passes through the body. Unfortunately, the penetrating object produces a hole no larger than the blade. External examination of the size of the wound may grossly underestimate the degree of internal damage. In addition, the trajectory of the blade is not apparent by external examination. Any stab wound located in the lower chest, pelvis, flank, or back must be presumed to have an abdominal injury until proven otherwise.

Gunshot wounds injure in several different ways. Bullets may directly injure organs. They also may do so secondarily from missiles such as bone or bullet fragments or from energy transmission from the bullet. Some bullets are designed to expand or break apart once they enter a victim. These tend to cause much more tissue destruction than a bullet that remains intact.

Entrance and exit wounds can approximate the missile trajectory. Plain radiographs help to localize the foreign body, allowing prediction of organs at risk. Unfortunately, bullets may not travel in a straight line. Thus all structures in any proximity to the presumed trajectory must be considered injured until proven otherwise (see Chap. 256, "Wound Ballistics").

DIAGNOSING ABDOMINAL INJURY

Solid Visceral Injuries

The organs of the abdomen involve a variety of both hollow and solid viscera that produce symptoms differently. Clearly, injuries to these viscera can, and often do, occur in concert with one another. Solid visceral injuries produce symptoms in a variety of ways. Substantial blood loss will produce alterations in vital signs, and patients often will present with or rapidly develop hypotension.[2] Some patients develop tachycardia, skin changes, and mental confusion with progressive blood loss.[2] These signs are tremendously nonspecific. Young patients may lose 60 percent of their total circulating blood volume and remain relatively asymptomatic.[3] Thus the assumption that a stable patient does not have an intraabdominal injury is hazardous. Abdominal tenderness, distension, and/or tympany may not be present until patients have nearly exsanguinated into their abdomen. In addition, it may be difficult to determine whether initial abdominal findings reflect hemoperitoneum or simply the patient's body habitus. Some patients develop exquisite abdominal tenderness early after development of hemoperitoneum. Others, however, remain asymptomatic for many hours or days. Thus, relying on physical examination to make the determination of hemoperitoneum will lead to an unacceptable rate of missed injuries.

Hollow Visceral Injuries

Hollow visceral injuries produce symptoms by the combination of blood loss and peritoneal contamination. Perforation of the stomach, small bowel, or colon is almost always accompanied by some blood loss such as from a concomitant mesenteric injury. Blood loss from the mesentery can be substantial. Gastrointestinal contamination will produce physical findings over a period of time. This assumes that the patient is awake and alert enough to complain of pain and demonstrate tenderness. Patients with closed head injuries or those who are significantly intoxicated may not demonstrate physical findings for hours or days after admission. In addition, patients with substantial injuries elsewhere may be distracted from their abdominal pain for a number of hours.

Gastrointestinal injuries may take as long as 6 to 8 h to manifest clear findings on physical examination. Gastric injuries produce abdominal symptomatology by chemical irritation when acidic contents are spilled into the abdominal cavity. This often occurs early in the treatment course but may take more time if patients are on H_2 blockers. The fluid within the small bowel and colon produce symptomatology by virtue of its bacterial content. Thus peritonitis is suppurative. Inflammation may take some hours to develop. The duodenum, on the other hand, is located within the retroperitoneum. If duodenal injuries are contained, there may be few early symptoms. Thus duodenal injuries represent a special subset of hollow visceral injuries that require more complete investigation, including the maintenance of a high index of suspicion.

The bladder is a hollow viscus whose fluid is not an irritant. Urine can be in the peritoneal cavity for days before producing symptoms. Retroperitoneal bladder injuries will produce virtually no symptoms. The bladder wall is tremendously well vascularized. Thus almost all patients with bladder injuries have significant hematuria. Intraperitoneal bladder rupture usually produces fluid in the abdomen. The amount of fluid will depend on the amount of urine in the bladder at the time of impact. If the bladder injury is contained within the retroperitoneum, there will be no free fluid. Physical examination will rarely diagnose a bladder injury. More sophisticated diagnostic testing is necessary to make this diagnosis.

Retroperitoneal Injuries

The diagnosis of retroperitoneal injuries can be extremely complicated. As with intraabdominal injuries, symptomatology and physical findings may be subtle or completely absent at the time of patient presentation. Occasionally, retroperitoneal injuries do produce symptomatology such as abdominal pain, even if they are relatively insignificant, such as a small retroperitoneal hematoma. Even computed tomography (CT) may miss retroperitoneal injuries initially.

Duodenal injuries also can be asymptomatic at the time of presentation. Duodenal wall hematomas can produce relative gastric outlet obstruction with abdominal pain, nausea, and vomiting (Fig. 252-1). Duodenal ruptures usually are contained within the retroperitoneum. They may present with abdominal pain, fever, and tenderness, although all of these may take hours or even days to become clinically obvious. Mechanism of injury should alert the clinician. Duodenal ruptures often occur from rapid increases in intraluminal pressure when both the pylorus and the proximal small bowel develop spasm. This is most often associated with high-speed vertical or horizontal decelerating trauma. Thus all such patients require some evaluation of the duodenum.
FIG. 252-1. Duodenal injury. CT scan demonstrating duodenal hematoma. Note the partial obstruction of the duodenum with an intramural hematoma. The injury resolved with nasogastric decompression and a short period of intravenous nutrition.

Pancreatic injuries also can be extremely subtle. They often accompany rapid decelerating injury. Pancreatic transection usually occurs in the midbody as the pancreas is displaced against the vertebral column. Thus unrestrained drivers who hit the steering column or bicyclists who hit the handlebars are at risk for pancreatic injury. Falls from height also can cause pancreatic injury.

The diagnosis of pancreatic injury can be elusive because many of these patients have very little in the way of symptoms at the time of presentation. Unfortunately, there are no biochemical or radiographic markers pathognomonic for the diagnosis. Elevations in serum amylase are nonspecific and not particularly useful. CT scanning may be normal initially. Relatively small pancreatic injuries can go on to become symptomatic days later. This is probably a result of leakage of pancreatic enzymes from the injured organ. Peripancreatic fluid develops and is activated, and a form of autodigestion occurs. Thus small pancreatic injuries ultimately may become larger and more symptomatic. These also can become superinfected with bacteria, producing a retroperitoneal abscess.

Urologic injuries often present with hematuria. Both the kidney and the bladder are well-vascularized organs, and even relatively minor injuries can produce an

impressive amount of blood in the urine. Unfortunately, there are some injuries that may produce no hematuria. Ureteral injuries are common after penetrating trauma but also have been reported with blunt trauma, particularly vertical decelerating injuries. These injuries often present without hematuria. In addition, major renal hilar injuries such as vascular thrombosis and extraparenchymal vascular injury may have no hematuria at all (Fig. 252-2).
FIG. 252-2. Blunt renal artery injury. CT scan demonstrates lack of enhancement of the left kidney. There is no evidence of perinephric hematoma or other sources of retroperitoneal blood loss. The patient underwent renal artery revascularization with a successful outcome.

Diaphragmatic Injuries

Diaphragmatic injuries are particularly difficult to diagnose. A plain film of the chest demonstrating viscera in the chest or a nasogastric tube coiled in the thorax will definitively diagnose a diaphragm injury. More often, chest x-ray findings are far more subtle or completely absent. Diagnostic peritoneal lavage (DPL) can be helpful, particularly if the DPL fluid exits via a concomitantly placed chest tube or if follow-up chest x-ray demonstrates a new pleural effusion. Helical CT and magnetic resonance imaging (MRI) can both be helpful in determining the presence or absence of a diaphragmatic injury. [4] Occasionally, blind surgical exploration or a less invasive technique such as laparoscopy or thoracoscopy may be necessary to make the diagnosis of diaphragmatic injury.

ABDOMINAL EVALUATION AFTER BLUNT TRAUMA

A multiplicity of diagnostic modalities is available to evaluate the abdomen. These diagnostics are applied radically differently depending on whether the patient has sustained blunt or penetrating trauma. No test is foolproof, and each must be used in conjunction with an assessment of the patient's stability as well as associated injuries and physical findings. All too often the discussion surrounding evaluation of the abdomen centers on what diagnostic test should be used. Clinicians often fail to take into account several key issues such as the limitations of the diagnostic test and whether the patient needs abdominal evaluation at all.

Who Needs Evaluation?

All patients undergo physical examination as part of the primary and secondary surveys. Physical examination is often inadequate to make the diagnosis of intraabdominal injury. On the other hand, application of expensive diagnostic testing or prolonged observation in every patient is clearly not possible. Conversely, a missed injury may result in long-term disability or death. Clearly, any patient with abdominal pain or other physical findings requires further evaluation. The mechanism of injury and other prehospital details also provide important information to guide the clinician.

The abdomen extends through the pelvis and rises to approximately the fourth intercostal space during deep exhalation. Patients with evidence of lower chest or pelvic injury require abdominal evaluation. In addition, patients involved in high-speed collisions or collisions where there has been substantial deformity to the vehicle probably should undergo abdominal evaluation regardless of physiologic status or physical findings. This is particularly true if the patient was unrestrained. Motor vehicle crashes with fatalities or those in which there were other substantial injuries also should make the clinician suspicious of abdominal injury even in seemingly asymptomatic patients.

Abdominal evaluation is mandated in all patients who sustain unprotected injury. Patients who are unable tolerate a missed injury or delayed diagnosis should undergo early abdominal evaluation even if the indications seem somewhat soft. The elderly or those with chronic cardiovascular or pulmonary disease should undergo prompt evaluation, since a delayed diagnosis certainly will increase their morbidity and mortality. Lastly, patients with distracting injuries such as long bone injuries should undergo abdominal evaluation because such patients clearly have sustained sufficient force to produce injury, and a concomitant abdominal injury is certainly possible.

There is debate as to whether all patients with a decreased sensorium require abdominal evaluation. Closed head injury or the presence of alcohol and other intoxicants limits a patient's ability to complain of pain or demonstrate physical findings such as subtle tenderness. In addition, small injuries may progress while patients are under observation. Ethanol may reduce the amount of blood loss necessary to produce shock. In general, we prefer to be aggressive and evaluate the abdomen in most patients with head injuries and decreased levels of consciousness.

Techniques of Evaluation

In the past, abdominal diagnostics were designed merely to document that an abdominal injury existed. Organ-specific diagnosis was made at the time of surgery, since virtually all patients with intraabdominal injury underwent exploratory laparotomy. A large number of patients are now managed nonoperatively. Table 252-1 details the available diagnostic testing used for blunt abdominal trauma. Some specific comments, however, are important.

Techniques	Easy	Rapid	Sensitive	Specific	Retroperitoneum	Expensive	Repeatable	Invasive	Transportation from ED
Physical Examination	Yes	Yes	No	No	No	No	Yes	No	No
DPL	Yes	Yes	Yes	Not usual	No	No	No	Yes	No
FAST	Yes	Yes	Yes	Not usual	No	No	Yes	No	No
CT	No	No	Yes	Yes	Yes	Yes	Yes	IV contrast	Yes

TABLE 252-1 Diagnostic Testing

The vast majority of patients who undergo abdominal evaluation are found to have no injury. Thus it makes sense to use a rapid, inexpensive screening test that reliably excludes injury in most patients. More sophisticated and expensive testing can then be reserved for patients who are proven to have some intraabdominal injury. The choice of diagnostics largely depends on local interest and expertise. For instance, a community hospital that has a limited volume of injured patients may chose to observe patients. On the other hand, large municipal hospitals that are often inundated with injured patients cannot reliably provide serial examinations.

Exploratory laparotomy has the advantage of rapidly diagnosing intraabdominal injuries. While injuries certainly can be missed at the time of laparotomy, this is

relatively rare. Blind exploration, however, is an inefficient way to make the diagnosis of abdominal injury most of the time with an excessive rate of nontherapeutic operations. On the other hand, it is occasionally appropriate.

Physical Examination

The abdomen should be examined for outward signs of injury such as abrasions or contusions to the abdominal wall. This should include the flank, back, and lower chest, as well as the anterior abdominal wall.

Physical examination is insensitive, as discussed earlier. In addition, injuries suspected on physical examination may be insignificant and require no therapy. Overall, if care depends on information gathered only by physical examination, care may be inappropriate up to 50 percent of the time.

Comprehensive serial physical examinations may be an acceptable method for identifying intraabdominal injury. These must be performed by the same senior-level clinician and should span a period of time of at least 16 to 24 h. The patient must be reliable and not have a condition where sensorium is altered. While there is little science describing this technique, we believe that physical examination must be performed at least every 30 minutes for the first 4 h and then hourly for an additional 4 to 6 h and every 2 to 4 h for the remainder of the 24-h observation period. This should be accompanied by frequent hematocrit determinations and measurement of serial vital signs. While this may be a rational technique in patients in a 23-h observation unit or in relatively quiet emergency departments that do not see a large volume of trauma, it is almost never applicable in high-volume centers that commonly see a multiplicity of injuries.

Plain Radiographs

Plain radiographs have an extremely limited use in the initial evaluation of patients with blunt abdominal trauma. They are incapable of making the diagnosis of hemoperitoneum. Even patients with hollow visceral injury often have normal radiographs. Occasionally, a chest x-ray will show free air under the diaphragm, and this will prompt laparotomy. However, universal use of plain films of the abdomen is not a cost-effective way of evaluating patients with blunt trauma.

Pelvic films, on the other hand, are standard in the evaluation process. Patients with pelvic fractures must be assumed to have high-energy injury mandating abdominal evaluation. Patients with pelvic fractures can have retroperitoneal blood loss. Thus abdominal evaluation must be rapid to avoid confusing retroperitoneal from intraabdominal blood loss. In addition, patients with thoracolumbar spine fractures have a mechanism that mandates abdominal evaluation. Thus any patient with pain or tenderness in the back must have radiographs to exclude a spine fracture. More sophisticated plain imaging such as intravenous pyelography (IVP) is occasionally useful. In patients who are hemodynamically stable, CT is far superior and has eliminated the use of IVPs. Retrograde urethrography is useful in males with pelvic fractures to exclude urethral injury.

Screening Examinations for Abdominal Injury

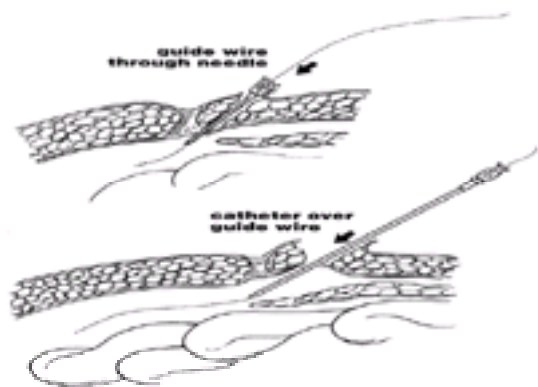
Both diagnostic peritoneal lavage (DPL) and ultrasonic abdominal evaluation are good screening tests for the presence of hemoperitoneum after blunt trauma. Both examinations are similar in that they identify the presence or absence of blood in the abdomen but can make no determination as to the etiology of the hemoperitoneum. DPL is rapid, safe, and inexpensive. There is approximately a 1 percent incidence of major complication. DPL can be performed using either an open or a closed technique (Fig. 252-3 and Fig. 252-4). We generally prefer closed percutaneous DPL because the complication rate is no different from the longer, more cumbersome open technique. A positive tap is defined as the aspiration of 10 cc of free-flowing blood. If the tap is negative, 1 L of saline is instilled into the abdomen and the abdomen is drained by gravity. It is not clear how much return is necessary to have the test be reliable. Some authors recommend that 250 cc of return is necessary.[5] One hundred thousand red blood cells per cubic centimeter is considered a positive lavage in blunt trauma. Thus only 25 cc of blood must accumulate in the abdomen (assuming complete mixing) for DPL to be positive.


FIG. 252-3. Closed diagnostic peritoneal lavage (DPL). Closed percutaneous DPL is an effective manner of evaluating the abdomen for hemoperitoneum. A needle is inserted two finger breaths below the umbilicus after infiltration with local lidocaine with epinephrine. A guide wire can be then inserted into the abdomen and the peritoneal lavage catheter inserted over the guide wire. One liter of fluid is instilled and the abdomen is then drained.
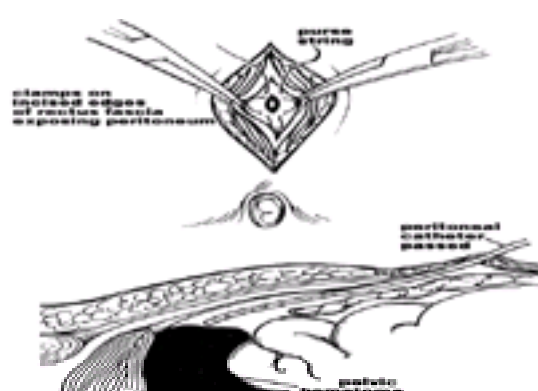

FIG. 252-4. Open diagnostic peritoneal lavage. Open diagnostic peritoneal lavage is a surgical procedure requiring some expertise. An incision is made under local anesthetic and can be performed in an infraumbilical or supraumbilical location. Patients with pelvic fractures must have their DPL performed open and above the umbilicus. An incision is made through the skin and subcutaneous tissue under local anesthesia. The fascia is opened and a purse-string suture placed in the peritoneum. The peritoneum is then opened within the purse-string suture and the catheter passed into the peritoneal cavity. Fluid is infused and returned as with a closed DPL.

Laparotomy based solely on a positive DPL for red blood cells results in a nontherapeutic procedure approximately 30 percent of the time.[6] Minimal injury to the liver or spleen or trivial mesenteric injuries can easily produce a hemoperitoneum sufficient to render DPL positive. Five hundred white cells per cubic centimeter had been suggested as another limit for positivity. More recently, white cell count DPL effluent has been criticized as being nonspecific.[7] We have abandoned the use of white cells as criteria for positive DPL. In addition, biochemical assays such as liver function tests or amylase determination are occasionally done in DPL effluent. None of these is an effective screen for intraabdominal or retroperitoneal injury. Decision on laparotomy should be made based on the patient's hemodynamic stability and associated injuries in concert with the results of the DPL. A patient with a positive DPL who is stable and does not exhibit signs of peritonitis is a candidate for nonoperative management.

Focused assessment with sonography for trauma (FAST) is a rapidly evolving technique to screen for intraabdominal injury. Like DPL, it can determine the presence or absence of hemoperitoneum. FAST is clearly operator-dependent, and considerable expertise is necessary to use FAST safely as a screening test for abdominal

injury. FAST is extremely rapid and can be performed in under 1 minute by a skilled operator. Like DPL, FAST is nonspecific and is ineffective for imaging the retroperitoneum.

The number of cubic centimeters of intraabdominal fluid necessary for a positive FAST remains a subject of interest. Clearly, more skilled operators will be able to detect smaller amounts of fluid. Many people believe that several hundred cubic centimeters are necessary to be clearly visible using ultrasound. [8] Like DPL, FAST cannot determine the etiology of the fluid.

FAST is generally performed in four areas: perisplenic, perihepatic, pelvic, and pericardial, the so-called four P's. No matter which organ is injured, the perihepatic view is most commonly positive. Blood pools in Morison's pouch, the most dependent portion of the abdomen. FAST offers a view of the pericardium that can be extremely helpful. Pericardial tamponade is rare in patients with blunt injury.

The utility of FAST to determine the need for laparotomy is at best questionable. Several authors have described scoring systems for FAST. McKinney and colleagues have encouraging data that suggest that their scoring system is accurate in determining the need for laparotomy. [9] Unlike DPL, FAST can be done easily in a serial fashion.

Clearly, FAST has limitations. Its ability to detect small amounts of fluid is questionable even in very skilled hands. Thus a small bowel injury with a small amount of fluid may not be detected by the initial FAST. In addition, there are no data that suggest that a single FAST is capable of absolutely excluding intraabdominal injury. While the data on this are somewhat sketchy, a recent international consensus conference on the use of ultrasound for trauma concluded that prudent evaluation would involve a minimum of two ultrasound examinations performed at least 6 h apart. [10] This would need to be supplemented with serial physical examinations and laboratory evaluations to avoid missing an intraabdominal injury.

ORGAN-SPECIFIC DIAGNOSIS

At this juncture, only CT scanning can make the diagnosis of organ-specific injury in the abdomen. CT scanning images both the intraabdominal content and the retroperitoneum. Thus it is the diagnostic test of choice to investigate the duodenum and pancreas. In addition, it has almost completely supplanted use of the intravenous pyelogram (IVP) in the evaluation of urologic injuries. It is a more complete examination than IVP and assesses the status of the renal vasculature. It can diagnose urinary extravasation and images the ureters most of the time. It can quantitate the amount of blood in the abdomen and can image the individual organs with precision.

The disadvantages of CT are the expense and time required to perform the examination. In many centers, the CT scanner may be located some distance away from the emergency department, mandating transport of patients out of a monitored setting. This may limit the utility, particularly in critically ill patients. An additional disadvantage is the oral contrast material, which often produces nausea and vomiting or must be administered while the spine remains immobilized, and the intravenous contrast material, which has a small incidence of allergic reactions. Some have advocated that oral contrast is unnecessary for abdominal CT during the initial assessment. [11] While some institutions have adopted this practice or apply it only to selective patients, omission of oral contrast in the CT evaluation of blunt abdominal trauma requires further study before it is likely to gain widespread acceptance.

There are some patients who require CT scanning despite a normal ultrasound exam. Chiu and colleagues have demonstrated that up to 28 percent of all patients with specific physical findings or injury complexes may have intraabdominal solid visceral injury without hemoperitoneum. [12] These findings include abrasions or tenderness in the lower chest, abdomen, or pelvis. Other findings mandating CT are the presence of pelvic fractures or thoracolumbar spine fractures. Ultrasound may still have a role in the triage of these patients. Patients with a positive ultrasound should have CT scans performed urgently. Those with a normal ultrasound can have their CT scan performed in a less urgent fashion.

The increased resolution of helical CT allows for the identification of even very subtle injuries, although standard CT is almost always sufficient. CT scans should be performed with intravenous contrast agents in order to differentiate normal parenchyma from blood. Oral contrast agents are extremely helpful in detailing loops of bowel from the mesentery. Rectal contrast agents are virtually never needed for blunt trauma.

EVALUATION OF THE ABDOMEN AFTER PENETRATING TRAUMA

Stab Wounds

Mandatory exploration, a policy used in many trauma centers in the 1960s and early 1970s, has largely been abandoned. Mandatory exploration yields unacceptably high rates of nontherapeutic laparotomy. This is a particular concern because Feliciano and Renz have documented over 40 percent complication rates for nontherapeutic laparotomy in patients with penetrating abdominal injury. [13]

There are several diagnostic modalities available for the evaluation of patients with stab wounds to the anterior abdomen. Those most commonly employed are physical examination, DPL, and local wound exploration.

Physical examination may fail for all the reasons stated in the aforementioned discussion on use of physical examination in patients with blunt trauma. Accurate physical examination may be difficult if patients are intoxicated with either drugs or alcohol. Furthermore, retroperitoneal injury or tenderness from concomitant blunt trauma may produce abdominal tenderness in the absence of intraabdominal injury. Thus a single physical examination may be misleading much of the time. Serial physical examinations, on the other hand, have been shown to be accurate in the evaluation of patients with stab wounds to the abdomen. [14] This must be considered with all the provisos mentioned in the discussion on blunt trauma.

Closed percutaneous DPL, as described earlier, is an excellent technique to evaluate patients with anterior abdominal stab wounds. It is performed exactly as described previously for patients with blunt trauma. There is some controversy as to which level of red cells constitutes a positive DPL when used for stab wounds. There is a linear relationship between lavage count and rates of nontherapeutic laparotomy and missed injuries. Thus the lower the threshold for a positive lavage cell count, the higher is the rate of nontherapeutic laparotomy, but the lower is the rate of missed injury. If the threshold for a positive lavage count is set higher, there are fewer nontherapeutic laparotomies but more missed injuries. Most centers set between 10,000 and 20,000 red blood cells/μL as a threshold for laparotomy in patients with stab wounds. The accuracy increases from approximately 78 to 90 percent as the threshold for positivity decreases. Any patient who undergoes DPL must be observed in the hospital for at least 12 to 24 h.

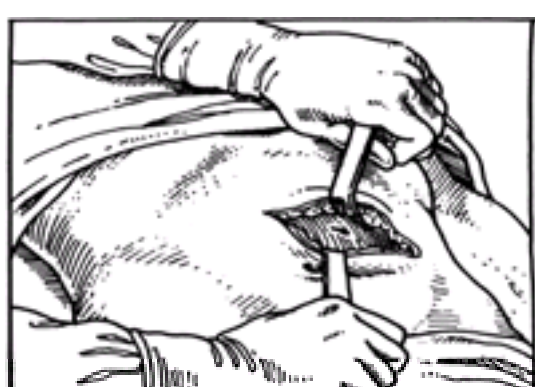
Local wound exploration is a superb way to evaluate the abdomen after a stab wound (Fig. 252-5). It is important to remember that this is a surgical procedure and must be regarded as such. This requires good lighting, proper instruments, and an acceptable level of local anesthesia. Often this must be supplemented with intravenous conscious sedation. Digital probing of the wound or radiographic trajectograms with contrast material should be mentioned only to be condemned. These are completely inaccurate and lead to a very high rate of both nontherapeutic laparotomy and missed injuries.


FIG. 252-5. Local wound exploration. Local wound exploration is the appropriate way to evaluate the abdomen after a stab wound. This is a surgical procedure requiring expertise, proper instrumentation, and lights. It is an appropriate diagnostic technique only for patients with anterior abdominal stab wounds. The stab wound

is widened and explored down to the level of the fascia. A determination can be made whether the anterior fascia and/or posterior fascia has been violated.

If local wound exploration demonstrates no violation of the anterior fascia, the patient can be discharged home safely. If local wound exploration demonstrates clear violation of the fascia, several options are available. It is entirely reasonable to explore these patients because the rate of nontherapeutic laparotomy will be relatively low. On the other hand, if one wishes to absolutely limit the number of nontherapeutic laparotomies, positive local wound explorations can be followed by DPL. If DPL fluid exits the wound or is positive by cell count, the patient should then undergo laparotomy.

Perhaps it is most important to realize the limitations of local wound exploration. It is often difficult to follow the trajectory of a stab wound. If the clinician is not completely comfortable that this has been a technically satisfactory procedure, one must abandon the use of the local wound exploration in that patient and use another form of evaluation. Our preference would be to use DPL if the local wound exploration is not considered technically satisfactory.

Gunshot Wounds

A major concern with anterior abdominal gunshot wounds is to determine whether the missile traversed the peritoneal cavity. All patients with transabdominal gunshot wounds require exploration because virtually all of them will have intraabdominal pathology requiring surgery. Most often this can be determined by estimating trajectory. While it can be difficult to determine whether a hole is an exit wound or an entrance wound, a hole both in the anterior and posterior abdomen clearly defines a transabdominal trajectory. In the event of a single entrance, a plain film of the chest, pelvis, and/or abdomen often can determine trajectory. A lateral film may be necessary to help determine the trajectory precisely. A missile in a location that defines a transabdominal pathway mandates exploration.

Occasionally, in the case of tangential injuries or multiple gunshot wounds, it may be impossible to clearly estimate trajectory. Several options exist. It often may be safest to simply explore the patient. While the rate of nontherapeutic laparotomy may be relatively high, surgical exploration at least ensures that a potentially life-threatening injury will not be missed. The second option is to very carefully observe the patient with frequent physical examinations and laboratory values. The last option is to perform a peritoneal lavage. There are virtually no data that determine the correct threshold for red or white blood cell positivity in patients with gunshot wounds. The only purpose is to determine whether the missile traversed the abdominal cavity. Thus we generally set the threshold very low and explore patients if there is even a pink tinge to the effluent or the red blood cell count is 5000/cc.

THERAPY FOR ABDOMINAL INJURY

Laparotomy

Laparotomy is the "gold standard" therapy for intraabdominal injuries. As mentioned previously, it is definitive and rarely misses an injury. It allows for complete evaluation of virtually all structures within the abdomen and the retroperitoneum at a single point in time. Laparotomy may be exploratory in nature or may be performed to treat a diagnosed injury.

Indications for surgical abdominal exploration vary from institution to institution depending on location, expertise, and interest. Table 252-2 describes generally accepted indications for exploratory laparotomy. Certainly all patients with hypotension, abdominal wall disruption, or peritonitis mandate surgical exploration. In addition, the presence of extraluminal, intraabdominal, or retroperitoneal air either on plain film or CT should prompt surgical exploration. Finally, organ-specific diagnosis on CT often will mandate exploration. Examples include pancreatic injury, duodenal injury, renal injury with urinary extravasation outside Gerota's fascia, or a small bowel or colon injury.

TABLE 252-2 Indications for Laparotomy

Some patients have the diagnosis of injury made but are hemodynamically stable with a normal physical examination. This would include patients with a positive DPL or FAST or patients with a CT-diagnosed splenic or hepatic injury. Clearly, some of these patients may be managed nonoperatively. The ability to do so will involve readily available ancillary diagnostic testing such as CT scanning and angiography. This is discussed in more detail below. In smaller centers or community hospitals this may not be realistic. These patients are then best served by surgical exploration. In tertiary care centers some of these patients can be managed nonoperatively.

Special mention must be made of patients with fluid seen on CT scan without a clear source. Some will have hemoperitoneum from a trivial liver or splenic injury that is simply missed on CT. Unfortunately, others will have mesenteric injuries and/or small bowel injuries. Again, in many centers the safest course is to simply explore to avoid late diagnosis of gastrointestinal perforation or ischemia. In tertiary care centers some can be managed nonoperatively by means of careful observation and/or ancillary diagnostics.

The diagnostic dilemma is much less in patients with penetrating trauma. Diagnostic evaluation is undertaken only to infer the presence of abdominal injury. Specific organ injury is diagnosed at the time of surgical exploration. In stab wounds, the presence of hemoperitoneum or suspicion of gastrointestinal injury by physical examination should prompt exploratory laparotomy. A positive local wound exploration is a relative indication for operation. Any patient with a proven transabdominal trajectory following a gunshot wound requires laparotomy.

Some patients with penetrating trauma can be managed nonoperatively. For the most part, this involves patients with injury to the flank and back section. Only 9 percent of such patients who present hemodynamically stable have injuries mandating surgery.[15] Diagnostic adjuncts involve contrast-enhanced CT enema using oral, intravenous, and rectal contrast agents (Fig. 252-6). Perivascular hematomas can be investigated further with angiography. Endoscopy of the colon also may provide useful information.
FIG. 252-6. Contrast enhanced CT enema. CT scan with oral, rectal, and intravenous contrast should be performed for asymptomatic patients with injury of flank and back. CT demonstrates a thickened left colon with contrast extravasation.

NONOPERATIVE MANAGEMENT OF BLUNT TRAUMA

There is no question that many injuries previously thought to require surgery may now be managed nonoperatively. The evolution of this technique has been greatly advanced by the evolution of CT. CT makes the diagnosis of solid visceral injury and often can rule out other injuries requiring surgery. Solid visceral injuries can be graded as to severity.

Unfortunately, CT grading may not agree with intraoperative observation.[16] In addition, CT grading does not always predict the success of nonoperative therapy.[17] This may be true for several reasons. CT provides a good description of the status of the internal parenchyma but does not provide three-dimensional injury anatomy. Operative grading, on the other hand, provides an excellent three-dimensional view of the organ but may underestimate internal damage. In addition, a traditional CT cannot provide information as to the integrity of the parenchymal vasculature. It is a single snapshot in time that cannot diagnose ongoing blood loss.

Organ-specific properties may affect the success or failure rate of nonoperative management. As patients age, the capsule of the spleen and liver weakens. Parenchymal changes may occur as well. Thus nonoperative management of even very severe injuries is the norm in children. Failure rates are much higher in adults. In addition, as patients age, the consequences of rebleeding become more substantial. Thus many tramatologists are less willing to attempt nonoperative management in elderly patients.

Over the last several years, several technologic advances have increased the sophistication of nonoperative management. The increased resolution of helical CT often identifies vascular injuries such as pseudoaneurysms or AV fistulas. Helical CT also can identify contrast material extravasation, indicating active bleeding. The role of angiography and nonoperative hemostasis has expanded greatly in nonoperative management of solid visceral injuries. Angiography has the ability to diagnose intraparenchymal vascular injury and evaluate the possibility of ongoing blood loss. Patients without vascular injury usually can be managed nonoperatively. In patients in whom vascular injury is diagnosed, percutaneous transcatheter embolization with either stainless steel coils or Gelfoam pledgets can arrest hemorrhage with a high degree of reliability.

Nonoperative Management of Hepatic Injury

Nonoperative management of hepatic injury has become the norm. Several recent large series have documented successful nonoperative treatment in 90 percent of patients who are hemodynamically stable at presentation.[18] Liver injuries are most commonly classified according to the system described by the American Association for the Surgery of Trauma (AAST) (Table 252-3). Unfortunately, most patients in these large series have had relatively low-grade injuries. Complications of nonoperative management of hepatic injuries include delayed bleeding, bile leak, intraabdominal sepsis, and missed intraabdominal injuries. These are relatively rare and occurred in only 5 percent of the largest series of nonoperative management of liver injuries.[18] However, the vast majority of complications occurred in higher-grade injuries.

TABLE 252-3   American Association for the Surgery of Trauma (AAST) Liver Injury Scale

In the past, the failure of nonoperative management, either bleeding or bile leak, required operative management. More recently, it has become clear that many of these complications can be managed nonoperatively as well. Angiography with selective embolization is an effective means of treating even delayed blood loss from hepatic injuries. Percutaneous drainage can treat "bilomas" and can be used for hepatic abscesses. Endoscopic retrograde cholangiopancreatography (ERCP) with or without biliary stenting can be extremely helpful in decompressing clots from the biliary tree and definitively treating intraparenchymal hepatic ductal injury. Recently, Carrillo and colleagues reviewed 135 patients managed nonoperatively.[19] Thirty-two patients developed complications requiring intervention, with most of these patients having higher-grade injuries. A combination of the aforementioned techniques was successful in managing these complications nonoperatively 85 percent of the time.

Finally, nonoperative techniques can be combined with operation. Laparotomy and temporary packing to control hepatic injury ("damage control") are now commonplace. This can be followed by angiographic embolization to control arterial injuries deep within the substance of the liver. Other techniques can then be used once the patient has stabilized.

Nonoperative Management of Splenic Injury

Although nonoperative management of splenic injuries is the norm in children, its use in adults has been far less successful. Failure rates have been reported to be as high as 20 to 30 percent. This relatively high failure rate has prompted some authors to advocate limiting nonoperative management to patients under 55 years of age and those with a CT injury grade no higher than 3 (Table 252-4).

TABLE 252-4   American Association for the Surgery of Trauma (AAST) Spleen Injury Scale (1994 Revision)

The addition of angiography to the treatment algorithm has radically changed the nature of nonoperative management for splenic injury. First reported by Sclafani and colleagues from Kings County Hospital, sequential DPL, CT, and angiography was used as a management algorithm in the care of patients with blunt trauma. [16] Stable patients with a positive DPL underwent CT. All patients with CT-diagnosed splenic injury were then treated angiographically. All vascular injuries identified at the time of angiography were treated with proximal coil embolization. Proximal embolization, similarly to splenic artery ligation, decreases the pressure head to the spleen, allowing for spontaneous hemostasis. Splenic viability and immune function are preserved by collateral vessels via the pancreatic branches of the splenic artery, the short gastric vessels, and collaterals from the superior mesenteric artery. In a series of approximately 150 patients, splenic salvage was 95 percent when this algorithm was used. Most important, a negative splenic arteriogram predicted successful nonoperative management 100 percent of the time.

The group from Memphis recently reported on 524 consecutive patients with blunt trauma. [20] Nonoperative management was attempted in 344 patients. Ninety-four percent were managed successfully nonoperatively, which represented 60 percent of the total splenic injuries. The indication for angiography was the presence of a pseudoaneurysm seen on helical CT. They used subselective embolization as opposed to proximal coil embolization. Only one patient developed clinically significant splenic infarction despite the subselective embolization. Importantly, nearly three-quarters of the patients had a pseudoaneurysm seen at the time of follow-up CT scan that was not seen at the time of initial scanning. The authors stressed the importance of follow-up CT even in asymptomatic patients.

It would seem that an initial helical CT scan, while valuable, is not definitive and that injuries evolve. In both series, higher-grade injuries had an increased likelihood of having a vascular injury identified. However, in the Brooklyn series, 12 percent of patients with grade 1 injuries had vascular injuries identified and embolized at the time of angiography. [16] Thus simple CT grading may not be sufficient to predict the success of nonoperative therapy. It would seem that careful follow-up is mandatory for all patients in whom nonoperative management is attempted. Follow-up CT scan has the potential to identify the progression, if any, of injury. In addition, it appears to reliably identify pseudoaneurysms not seen at the time of initial scanning. Alternatively, early, liberal use of angiography should help to identify patients with vascular injuries. Either of these techniques appears to radically decrease the incidence of delayed splenic rupture. This often presents at 7 to 10 days in patients who were stable initially following the diagnosis of splenic injury.

In fact, the term *delayed splenic rupture* is probably a misnomer. Instead, this more correctly is misdiagnosis of splenic vascular injury at the time of initial presentation, almost certainly small injuries such as pseudoaneurysms or AV fistulas. Over 7 to 10 days they expand and ultimately rupture, producing blood loss and corresponding symptoms. The term pulsating splenic hemorrhage more correctly describes this entity.

Neither of these series had a large proportion of high-grade splenic injuries contained within them. Recently, the group at the Shock Trauma Center prospectively evaluated a series of 73 patients. [21] All patients diagnosed with splenic injuries underwent early angiography. There was a large proportion of CT grade 3 and 4 injuries contained within this series. The presence of a vascular abnormality correlated with grading. The higher the grade, the more likely the patient was to have vascular injury at the time of angiography. Patients with high-grade injuries tended to have more severe injuries and often had multiple injuries. These were treated with a combination of proximal coil and subselective embolotechniques (Fig. 252-7). Nonoperative management was successful 88 percent of the time, and the splenic salvage rate was 94 percent in this series.

FIG. 252-7. Nonoperative management of splenic injuries. **A.** FAST in this 21-year-old female with blunt abdominal trauma clearly demonstrates hemoperitoneum. **B.** The patient remains hemodynamically stable and CT scan demonstrates a grade 4 splenic injury.

Nonoperative management for splenic injuries is certainly a safe and effective technique. However, this must involve a committed team of emergency physicians, surgeons, and invasive radiologists in order to safely manage patients with high-grade injuries nonoperatively. Coil embolization is a safe technique and an effective method of hemostasis. These innovative techniques should be performed in a tertiary care center under strict protocol in order to be managed safely.

253 PENETRATING TRAUMA TO THE FLANK AND BUTTOCK

Alasdair K. T. Conn

Penetrating injuries to the flank and buttock challenge the physician because of the possibility of missed injuries to retroperitoneal structures. Gunshot and stab wounds in these areas must be carefully evaluated to determine whether there is retroperitoneal injury with intraperitoneal or vascular injury that might mandate immediate surgical intervention. Evaluation is difficult; the retroperitoneal structures are well protected by dense layers of musculature and the spine. There is significant risk of missed injury and delay in diagnosis. Fortunately, an increased armamentarium of diagnostic testing assists in timely diagnosis and allows for selective conservative management. The choice of management, conservative or operative, is determined based upon the emergency evaluation, making the emergency physician's input essential to a correct decision and a clinically successful outcome. Penetrating injuries to the buttock are relatively uncommon and some trauma centers report as few as three to five patients with this type of injury per year. Trauma centers in urban settings have reported 50 to 80 patients per year. With appropriate management the mortality is low, but case reports indicate that there is a potential for a missed injury to the bowel or major vessels, especially with shotgun or high velocity gunshot wounds, unless the clinician is vigilant in the emergency evaluation. This chapter outlines the evaluation of patients who present to the Emergency Department (ED) with penetrating trauma to the flank and to the buttock.

PENETRATING TRAUMA TO THE FLANK

Pathophysiology

The flank is the area between the anterior and posterior axillary lines, superiorly bordered by the sixth rib and inferiorly bordered by the iliac crest. Although a penetrating wound to the flank can produce intraperitoneal injury with the associated physical findings of peritonitis or hemoperitoneum with shock, it is possible that a penetrating flank wound only injures the retroperitoneal organs. A delay in diagnosis of duodenal, colonic, rectal, renal, pancreatic or major vascular injuries may result in the late appearance of septic or hemorrhagic shock.

The path of a gunshot or stab wound to the flank may track superiorly. Bullets may ricochet off the bony structures of the spine and produce a unique bullet path and injury pattern. Other intra-abdominal organs may be injured, such as the stomach or pancreas, the diaphragm, and intrathoracic organs. Inferior tracking will jeopardize the lower GI tract and colon. Treatment of these specific organ injuries is covered elsewhere in this text (see Chap. 251).

Clinical Features

Patients with penetrating trauma to the flank should be resuscitated and evaluated according to standard resuscitative protocols. Initial resuscitative efforts should be directed towards the primary survey (see Chap. 243). Information regarding the mechanism of injury, how much time has passed since the traumatic event, and the nature of the weapon should be obtained and recorded. In the case of a gunshot wound, the nature of the gun (shotgun, handgun, BB gun) and the range between the gun and the patient at time of the gun's discharge should be ascertained and noted in the emergency record. Following stabilization, an attempt should be made to find an exit wound, and a bullet path reconstructed. Baseline laboratory and radiologic data, including a hemogram, chest radiograph, urinalysis, and rectal exam with testing for occult blood, should be performed on all patients. In the presence of peritonitis, intravenous fluid and broad-spectrum antibiotics should be administered and urgent surgical consultation obtained. A suitable regime of antibiotics is ampicillin, gentamycin, and metronidazole initiated in the emergency department. Most patients are stable and will require additional diagnostic modalities.

Diagnosis

PORTABLE ULTRASOUND   In a patient with a penetrating wound to the flank, portable ultrasonography can be utilized to determine if there is fluid in the abdominal cavity. In the absence of a preexisting medical condition (such as cirrhosis with ascites), such information may be invaluable. Although the sensitivity and specificity varies with the type of equipment used and the experience of the operator, fluid collections of 600 cc should easily be detected by the emergency physician. [1] For a patient with a gunshot wound this may be sufficient to recommend an operative approach. For a patient with a stab wound, even if hemodynamically stable, this indicates a significant intra-abdominal injury. Operative intervention is sometimes delayed pending further adjunctive diagnostic measures.

WOUND EXPLORATION   Although local wound exploration under adequate local anesthesia using sterile technique is of value in anterior abdominal wounds, it is only of limited value in wounds of the flank. If local exploration demonstrates that the injury does not penetrate beyond fascia or muscle, the wound may be safely closed and the patient discharged from the ED with appropriate follow-up instructions. With deeper penetrating injuries, it is difficult to determine the extent of injury with local wound exploration. More information can usually be obtained by CT scanning. Deep wound exploration often leads to further hemorrhage and tissue damage and is of limited value. It is difficult, if not impossible, to ascertain the exact depth of a stab wound from deep wound exploration.

DIAGNOSTIC PERITONEAL LAVAGE   Appropriately performed, diagnostic peritoneal lavage (DPL) is highly accurate in determining the presence of intraperitoneal injury; it does not detect the presence of a retroperitoneal injury. (For details of the technique, see Chap. 252.) The criteria of what constitutes a positive diagnostic lavage in penetrating trauma are different from the criteria for blunt trauma. The exact criteria vary from hospital to hospital, but a guide is a red cell count of >10,000/mm^3 as an indication to perform an exploratory laparotomy. Lavage fluid may also be analyzed for bowel content, white cells, or enzymes such as amylase; although criteria for what constitutes a positive lavage vary from center to center. In some hospitals, enzymatic assay and examination for bowel content have been abandoned. Others still advocate its use to ascertain if a bowel or pancreatic injury has occurred. In most institutions, the use of diagnostic peritoneal lavage for a stable patient has been replaced by CT scanning. In an unstable patient, DPL can be performed (especially if portable ultrasound is not immediately available) to rapidly detect the presence (or absence) of hemoperitoneum.

COMPUTED TOMOGRAPHY (CT)   In many centers, computed tomography has become the diagnostic modality of choice in patients who present hemodynamically stable following a flank penetrating trauma. [2,3] Double (oral gastrografin and intravenous contrast) or triple (oral, intravenous, and rectal contrast) are used; rectal contrast should be used if there is even a remote likelihood of a rectal or sigmoid injury. Cooperation with the radiologist is essential as fine "cuts" through the site of injury may be required to delineate the injury tract. Particular attention should be paid to the presence of intraperitoneal fluid and any edema of the bowel wall. The latter may represent bowel perforation, although no leak is visible by leakage of the contrast. [4]

The majority of patients with identified injury will be found to have retroperitoneal hematoma, without bowel or solid organ damage. Rarely, a hematoma around one of the major blood vessels or the pancreas is evident, requiring further diagnostic testing such as angiography, venography, or endoscopic retrograde cholangiopancreatogram (ERCP). Occasionally, a gunshot wound may be observed to pass extraperitoneally, but concerns about blast effect may lead to the decision to perform laparoscopy.

Treatment

The treatment of penetrating trauma to the flank remains somewhat controversial, although there is a tendency toward more conservative management. Some patients

present with signs and symptoms that mandate immediate exploratory celiotomy.

Although in the past, celiotomy was more liberally utilized, it should be reserved for those patients who present with these conditions:

- Hemorrhagic shock
- Peritonitis
- Evisceration
- Transabdominal missile path
- Intraperitoneal free air

At the time of surgery, all intraperitoneal and retroperitoneal organ structures should be evaluated according to standard operative procedures.

Although some surgeons still advocate mandatory exploratory laparotomy in an effort to detect all injuries early, most surgeons now advocate selective management with early CT scanning, which allows many injuries to be managed by close observation. Using this conservative approach, celiotomy rates have been decreasing from 100 percent to approximately 30 percent with the incidence of positive laparotomy rising from 15 percent to approximately 80 percent, without increases in untoward outcome.[5] Using this approach, the risks associated with the "negative laparotomy" (early: hemorrhage and infection; and late: complications small bowel obstruction) as well as added expense are avoided. Many recent reviews support this selective management approach.

Exploratory laparotomy is most commonly performed for flank gunshot wounds. Many flank stab wounds can be safely managed conservatively. In the case of high-velocity gunshot wounds, blast effect must be considered. Depending on the exact location and type of injury, consideration of the blast effect may lead to exploratory laparotomy if there is concern as to the bowel, bladder, or vascular integrity; or laparoscopy may be used to determine the extent of intraperitoneal injury. An experienced surgeon should perform laparoscopy, as bowel injuries may be difficult to detect.

With CT, the exact depth of a stab wound can often be determined. Decision algorithms based upon low-risk patients' flank stab wounds (penetration superficial to the deep fascia) or high-risk (penetration beyond the deep fascia) have been developed and appear to be clinically justified. [6] Hemodynamically stable patients with stab wounds to the flank can be risk-stratified based upon these contrast-enhanced computer tomography findings. Low-risk patients may be discharged immediately from the Emergency Department. High-risk patients require surgical consultation and should be admitted to the hospital, but in many cases a discharge decision can be made within 24 h.

PENETRATING BUTTOCK INJURIES

Pathophysiology

Penetrating trauma to the buttock may be either from gunshot wounds or stab wounds. Gunshot wounds have the greatest potential for injury; as the thick musculature and fat over the buttocks normally protects the gastrointestinal, genitourinary, and neurological systems from injury in all except the deepest penetrating trauma from stab wounds. With gunshot wounds, the risk of intraperitoneal injury is much higher and may necessitate immediate exploratory celiotomy. Injured systems requiring operative intervention are the lower GI tract, the lower GU tract, and, rarely, a vascular injury. A delay in diagnosis of colonic or rectal injury will contribute to increased mortality and morbidity. From the civilian trauma literature, approximately 30 percent of patients who present with gunshot wounds require surgery. Factors associated with surgical intervention include findings of peritonitis; a positive finding at sigmoidoscopy; gross blood in the urine; entrance wound above the level of the greater trochanters; and a transpelvic (as opposed to extrapelvic) bullet course. [7,8 and 9] Stab wounds to the buttock infrequently require laparotomy.

Clinical Features

Initial approaches to trauma resuscitation should be followed as noted earlier. Attention should be paid to the abdominal examination. If there is indication of peritonitis or of a gunshot with a transabdominal missile path, emergent surgical consultation should be obtained and preparations made for an exploratory laparotomy. Baseline hemogram, urinalysis, and rectal examination should be performed on all patients. If there is any concern of injury to the rectum because of blood being noted on rectal examination or because of the trajectory of the bullet, proctosigmoidoscopy should be performed. [10] Cystography should be performed on patients when there is blood on urinalysis or the proximity of the wound to the GI tract is a concern. Vascular injury to gluteal or internal iliac arteries has been reported from gluteal-penetrating wounds and may lead to exsanguinating external hemorrhage. [11] An intrapelvic injury may also cause injury to the internal iliac vessels with hypovolemic shock; this will require early operative intervention. In all patients, the peripheral pulses in lower extremity should be examined looking for decreased pulses or pallor as evidence of a proximal injury. Neurologic examination of the lower extremities to document any injury to the sciatic or femoral nerve should also be performed on all patients. Buttock wounds rarely cause damage to the sciatic plexus or femoral plexus. Injury could include transsection, partial transsection, or stretch injury secondary to the trauma. The presence of any symptomatic signs requires appropriate consultation.

Diagnosis

The signs of peritonitis, intrapelvic or transabdominal missile path, and intraperitoneal free air warrant immediate celiotomy. Proctosigmoidoscopy can be a great aid in the diagnosis of a rectal injury, and should be performed in the ED. To evaluate the lower GU tract, a cystourethrogram should be performed. This can be performed either as a separate study or in conjunction with CT scanning, with rectal and intravenous contrast and clamping the urethra catheter to obtain a CT cystogram. If the CT scan demonstrates a pelvic hematoma, angiography or venography may be indicated to document a significant vascular injury. Also, appropriate consultation should be obtained. Local wound exploration is of limited value in penetrating buttock injuries. For those patients who present with peritonitis, or if there is a concern of a rectal injury, broad spectrum intravenous antibiotics should be initiated in the ED. Operative therapy for rectal injuries should be directed at proximal colostomy, presacral drainage, and distal washout. Genitourinary tract injuries are repaired with appropriate drainage and often a suprapubic cystostomy.

254 GENITOURINARY TRAUMA

Gabor D. Kelen

EPIDEMIOLOGY

Injuries to the genitourinary system occur in about 2 to 5 percent of adult trauma victims. The vast majority of these injuries are due to blunt trauma. Accurate overall estimates for children are not available, but it appears that about 10 percent of pediatric patients with blunt abdominal trauma have renal system injury. [1,2] More than 80 perecnt of those with injuries to the kidney have other concurrent injuries, about a third of them life threatening. Approximately 80 percent of the urogenital injuries involve the kidney, and about 10 percent involve the bladder. Significant ureteral injuries are relatively rare and are usually associated with penetrating trauma. Significant urethral injuries most often occur in males and are usually associated with pelvic fracture. Patients with anatomic anomalies, including tumor and hydronephrosis, appear more susceptible to injury.

CLINICAL APPROACH

The overall approach to trauma is discussed in Chap. 243. Only issues specific to genitourinary trauma are discussed here.

Renal system injuries rarely require immediate intervention. Investigation of renal injuries should not supercede evaluation of more life-threatening injuries. For example, with a pelvic fracture, determining the need for pelvic angiography is more important than determining whether a urethral injury exists. The patient may well die from a sheared major artery, whereas an injured urethra will never require immediate attention. The retrograde introduction of dye will render subsequent pelvic angiography very difficult, if not impossible.

During the detailed secondary survey, a concerted effort should be made to closely inspect the perineum. Blood on the underwear is an important finding. In both male and female patients, the folds of the buttocks should be spread in search of perineal lacerations, which often denote an open pelvic fracture. Such lacerations should not be probed lest a clot be disrupted and exsanguinating hemorrhage result. During the rectal examination, sphincter tone, the position of the prostate gland, and presence of any blood should be noted. If the prostate is riding high or feels boggy, there has been a disruption of the membranous urethra. Next, the scrotum is palpated and inspected for ecchymoses, laceration, and testicular disruption. Simultaneously, the length of the penis is palpated to inspect for blood at the meatus. In females, the labia are inspected for lacerations and hematomas. If there is any evidence of likelihood of trauma in this area, a bimanual vaginal examination is required. If there is blood in the vagina, a speculum examination is necessary to rule out vaginal laceration.

During the secondary survey, the trauma series x-rays are obtained and often include an anteroposterior view of the pelvis. The presence of a pelvic fracture has important implications in the workup of genitourinary injuries.

Generally, no urinary catheter should be introduced until the urine can be evaluated for hematuria. However, the placement of a urinary catheter for monitoring of urine output may be required in severely injured patients who cannot void. If there is doubt and placement of a catheter is urgent, a suprapubic approach may be the most prudent. In menstruating women, a specimen obtained with a catheter is likely to offer more accurate urinalysis than a spontaneously voided specimen.

The standard serologic and blood specimen results are generally not helpful in determining the presence or degree of renal injury in the acute setting.

BLUNT TRAUMA

Detection of Specific Injuries

The need to determine the existence of specific injuries is based on the clinical elements obtained in the history, physical examination, and plain films, and to some extent the age of the patient. Table 254-1 lists some key elements that should prompt the consideration of further evaluation of renal tract injury. The approach to evaluation is dependent on the following: blunt versus penetrating trauma, the presence of hematuria and whether it is gross or microscopic, associated injuries, mechanism of injury, hemodynamic stability, and age of the patient. [3] Each of these factors affects the approach somewhat. Renal injuries require staging for appropriate management (Table 254-2). [4] Staging is usually accomplished through use of an imaging modality, but sometimes exploration is required (see below).

Acceleration or deceleration injury (renal pedical)
Lower rib fractures (kidney)
Fracture lower thoracic or upper lumbar spine
Pelvic fracture (urethra)
Abdominal trauma
Flank ecchymosis, tenderness, mass (kidney)
Straddle injuries (urethra)
Penetrating trauma (in vicinity of any part of the renal system)
Penile scrotal or perineal hematoma (urethra)
Gross hematuria
Microscopic hematuria in certain circumstances (see text)
Abnormally positioned prostate (posterior urethra)
Blood at penile meatus (urethra)

TABLE 254-1   Key Clinical Findings Associated with Renal System Injury

Grade	Injury
I	Contusion (microscopic or gross hematuria, with normal uro-logic study results)
	Subcapsular, nonexpanding hematoma without laceration
II	Parenchymal laceration <1.0 cm depth limited to cortex, no extravasation
	Nonexpanding hematoma, confined to retroperitoneum
III	Parenchymal laceration >1 cm depth with extravasation or col-lecting system rupture
IV	Laceration extending through to collecting system
	Vascular pedicle injury, hemorrhage contained
V	Shattered kidney
	Avulsed hilum (devascularized kidney)

TABLE 254-2 Grading of Renal Injuries[4]

MEATAL BLOOD   Blood at the meatus is associated with urethral injuries. Urethral injuries are almost exclusively seen in males. Posterior urethral injuries are commonly associated with pelvic fractures. A superiorly displaced prostate indicates disruption of the posterior urethra. Anterior urethral injuries are associated with straddle injuries and instrumentation.

When meatal blood is noted, a urinary catheter should not be placed in order to prevent the conversion of a partial urethral laceration into a complete transection. A retrograde urethrogram is virtually mandatory in this setting.

HEMATURIA   For the purposes of trauma, microscopic hematuria is defined as more than five red blood cells (RBCs) per high-power field (hpf). A 10-mL specimen must be centrifuged for 5 min at 2000 revolutions for an accurate assessment. Gross hematuria is, of course, readily visible blood. Reddish urine does not necessarily indicate hematuria; several medications and toxic substances may cause discoloration (Table 254-3). Also, results of a dipstick evaluation may be erroneous, since myoglobin, a frequent finding in major trauma, reacts with the reagent.

Black	Brown	Red
Cresols	Benzene	Ampicillin
Levodopa	Carbon tetrachloride	Aniline
Methocarbamol	Chloroquine	Anthocyanin (beets, blackberries)
Phenazopyridine	Cresols	Betaine (fresh beets)
Phenol	Dinitrophenol	Deferoxamine
Quinine	Fava beans	Ibuprofen
	Hydroquinone	Lead (chronic)
	Lead	Lycopene (tomatoes, watermelon)
	Levodopa	Mercury
	Mercury	Myoglobin
	Methemoglobinemia	Naphthalene
	Methocarbamol	Phenolphthalein (in laxatives)
	Metronidazole	Phenothiazines
	Naphthalene	Phenytoin
	Nitridazole	Porphyrins
	Nitrofurantoin	Quinines
	Phenacetin	Rifampin
	Phenols	
	Phenothiazine	
	Phenytoin	
	Primaquine	
	Quinines	
	Sulfonamides	

TABLE 254-3 Substances and Medications Associated with Urinary Discoloration

The initially voided urine may provide clues as to the location of injury. When possible, at least two specimens (initial stream and terminal stream) should be obtained. Initial hematuria suggests injury to the distal system (i.e., urethra or prostate). Terminal hematuria suggests bladder neck injury. Continuous hematuria suggests upper renal system (bladder, ureter, or kidney) injury.

Many studies have demonstrated that, in adult patients with blunt trauma, the degree of hematuria does not correspond to the degree of injury. Gross hematuria may be seen with relatively minor renal contusions, whereas microscopic hematuria (or even no hematuria) may be seen in renovascular injuries. However, in the absence of significant hemodynamic compromise, isolated microscopic hematuria is unlikely to represent significant blunt injury. While there is no clinically validated or generally accepted upper limit of microscopic hematuria beyond which imaging is done, many physicians image patients where the degree of microscopic hematuria is ³50 RBCs/hpf. A review of several major studies addressing this question concluded that isolated microscopic hematuria indicates significant injury in about 1 in 500 patients with such a finding.[3] Thus, the current consensus is that adult patients with isolated microscopic hematuria do not require further imaging studies. There are three exceptions. When the mechanism of trauma involves rapid deceleration, renal pedicle injuries may ensue but can present with minimal (or even no) hematuria. Also, hematuria in a patient with even transient hypotension should not be considered an isolated finding. Finally, microscopic hematuria may be a significant finding in children, as detailed later in the text.

All patients in whom microscopic hematuria is found with concurrent nonrenal injures and those with hemodynamic instability should have a diagnostic imaging study, as discussed below. In such patients, computed tomography (CT) is often impractical. A "one-shot" intravenous pyelogram (IVP) can be obtained in the operating room.

Gross hematuria may occur from injury virtually anywhere in the renal tract. The finding of gross hematuria mandates a diagnostic imaging study that is chosen based on other findings (Table 254-4). For example, in the presence of pelvic fractures, gross hematuria should raise the possibility of bladder or urethral injury. Almost 95 percent of bladder injuries are associated with gross hematuria.

Imaging Study	Suspected Injury
Retrograde urethrogram or cystogram	Urethral injury
CT (with IV contrast)	Renal injury (staging)
	Ureteral injury
Cystogram, plain film (retrograde)	Bladder injury
CT cystogram (retrograde)	Bladder injury
"One-shot" IVP	Unstable patients taken to operating room
IVP	Alternative to CT in unstable patients
	Ureteral injury
Angiogram or venogram	Pedicle injuries, venous disruption
Retrograde pyelogram	Renal pelvis disruption

TABLE 254-4 Selection of Diagnostic Imaging for Suspected Renal System Injury

Special Considerations

RAPID DECELERATION FORCES   Rapid deceleration injuries may result in renal pedicle and vascular injuries. Such injuries result in high mortality rates, but fortunately they are quite rare, occurring in less than 1 percent of blunt renal trauma. However, hematuria, the clue to renal injury, may not be present. Accordingly, patients whose mechanism of injury is from forces of rapid deceleration should have a renovascular imaging study. Since pedicle injuries virtually always occur in

association with other significant injuries, [5] other indications for radiographic evaluation are likely. Many such patients have other indications for surgical exploration.

PEDIATRIC BLUNT TRAUMA   Hematuria following blunt trauma may have different significance in the pediatric population. [6,7] Unlike the situation in adults, the degree of hematuria does seem to correlate with the degree of injury. [5] Many advocate that pediatric patients with any degree of hematuria, even if hemodynamically stable, should undergo imaging studies. [8,9] However, pediatric patients with less than 50 RBCs/hpf do not appear to have significant injuries. [5] Thus, it appears appropriate to perform imaging studies on only those patients with significant hematuria, as defined above. [3] Other standards for imaging studies for pediatric patients remain similar to those for adults.

Choice of Radiographic Study for Evaluation and Staging of Renal System Injury

The following should be considered when ordering studies in the trauma patient: (1) intravenous contrast agents can cause false-positive scan results for blood; (2) the total quantity of contrast required may limit the number of contrast studies, especially with shock; (3) hypotensive patients are at risk for developing contrast-induced acute renal failure; (4) abdominal CT reveals more information but requires a hemodynamically stable condition; and (5) an intraoperative IVP during an emergency laparotomy is needed to determine the status of the contralateral kidney.

A guideline for the selection of diagnostic imaging modalities is shown in Table 254-4.

PLAIN FILM   Plain films are helpful in determining likelihood of renal trauma when abnormalities such as lower rib fractures, lower thoracic and upper lumbar spinal fractures, and pelvic fractures are seen. Loss of the psoas shadow or scoliosis may suggest injury. However, plain films are inappropriate for evaluating the renal tract.

COMPUTED TOMOGRAPHY   Indications for imaging the kidneys following blunt trauma include gross hematuria, hematuria with multiple injuries or hemodynamic instability, and mechanisms that include rapid deceleration. When renal injury is suspected, CT is considered superior to other imaging modalities, including sonography, angiography, or IVP. CT is most likely to allow appropriate staging of renal injury (Table 254-2) and has several advantages. CT is a noninvasive modality with superior imaging detail that allows detection of even minor injuries and minimal extravasation, estimation of extent of hematoma, and simultaneous evaluation of other organs. The major disadvantage is that it can be performed only in a stable patient. Other disadvantages are cost and the difficulty in detecting vascular, particularly venous, injury. In children with hematuria, CT is the radiographic study of choice in evaluating renal injuries because a significant nonrenal intraabdominal injury is more likely than a renal injury.

Certain considerations should be kept in mind. Routine abdominal CT evaluation often stops at the iliac crests. In situations where renal system trauma is under consideration, the examination should be extended to the pelvis. Also, contrast enhancement is usually indicated for appropriate evaluation. Both oral and intravenous contrast material is often given when other intraabdominal trauma is under consideration. However, if enhanced CT is required to image the kidneys and collecting system appropriately, gastrointestinal contrast studies may need to be delayed to allow accurate interpretation.

MAGNETIC RESONANCE IMAGING   Magnetic resonance imaging (MRI) is generally not a first-line imaging modality. However, its accuracy appears to be similar to that of CT. It may prove useful in stable patients who have dye allergy.

ANGIOGRAPHY   Angiography has largely been replaced by CT. It still has a role when vascular injury is suspected and remains the gold standard for detecting renal venous injury. Arteriography may be indicated in selected patients when no renal function is evident on IVP or CT. Other indications include penetrating trauma where vascular injury is high, and when embolization is considered for persistent or delayed hemorrhage. It should be kept in mind that the kidney can tolerate only 4 to 6 h of warm ischemia. Arteriographic confirmation may cause an undue delay.

ULTRASOUND   Ultrasound examination of the right upper quadrant (Morrison pouch) and the left upper quadrant (splenorenal recess) is part of the Focused Assessment for the Sonographic Examination of the Trauma Patient (FAST) examination (see Chap. 243 and Chap. 295) but has little accepted role to date in the initial detection (or exclusion) of significant renal injury in the United States. Certain conditions, such as patient position and fractured ribs, make such examinations difficult to perform. Furthermore, sonography reveals nothing about renal function. In Europe, however, ultrasound is used as a technique of choice for the initial imaging modality in some centers. [10]

RADIONUCLIDE IMAGING   Radionuclide imaging has a very limited role now, given the superiority of CT. It may still be useful in patients with iodinated dye allergy in whom technetium-99m glucoheptonate can be safely used.

INTRAVENOUS PYELOGRAM   Formal IVP with or without tomograms can be used in stable patients if CT is unavailable. However, it is not the ideal study in the trauma setting, given the need for quality imaging. If used, the dose of contrast material needs to be greater than the standard 1 mL/kg to account for hemodilution for intravenous fluid administration and possible impaired renal perfusion. The recommendation is 2 mL/kg up to 150 mL of 60% iodinated contrast. In patients with a history of allergy, a nonionic agent, such as iohexol, can be used. Alternatively, noncontrast CT, radionuclide imaging, or MRI may offer satisfactory results.

IVP remains the mainstay of diagnosing ureteral injuries, although it is not infallable. [11] Extravasation of die is the classic finding, although on occasion there is absence or delay of contrast in the distal collecting system. However, many are now using spiral CT to diagnose ureteral injuries, since it offers the advantage of viewing the entire retroperitoneal space and has the ability to detect urinomas.

A "one-shot" IVP can be obtained in unstable patients in the emergency department or operating room. This technique entails injecting 2 mL/kg intravenous contrast material about 5 min before the film is taken. However, if the patient's blood pressure is 70 mmHg or less, the kidneys may not concentrate the contrast material and are more susceptible to injury by it.

CYSTOGRAPHY   For suspected bladder injuries, plain-film cystogram is classically used. About 300 to 500 mL (5 mL/kg in children) of contrast media is instilled retrograde into the bladder under gravity from 2 ft (60 cm) above the patient. At a height of 2 ft, the intravesical pressure generated approximates the physiologic voiding pressure. Unless adequate bladder pressure is generated, the cystogram may be falsely negative. Ideally, the procedure is performed under fluoroscopy to avoid filling the peritoneal cavity with contrast material in the event of a tear. A film of the distended bladder is taken, and a postdrainage view is obtained to note any extravasation not evident on the initial film. Some authorities suggest that the bladder be "washed out" with saline solution prior to obtaining the post–"wash-out" view.

Allowing intravenous contrast material to flow into the bladder following intravenous injection is not considered an appropriate technique, [12] although some continue to advocate clamping a urinary catheter to allow antegrade filling of the bladder. [13] A CT cystogram may be preferred in a patient who requires intravenous contrast-enhanced CT imaging for other indications. [14] However, contrast material must still be injected retrograde. [15] Postvoiding scans are generally not required, since CT allows full imaging of the retrovesicular space.

A prospective investigation studying indications for cystography in blunt trauma with hematuria or pelvic fracture concluded that it was appropriate and cost effective to restrict this procedure to patients with gross hematuria only. [16] The authors contend that patients with pelvic fracture and microscopic hematuria do not routinely require cystography.

Urethral injuries are also investigated by retrograde cystography. An unlubricated urinary catheter is placed about 2 to 3 cm into the navicular fossa of the distal urethra, and the balloon is inflated with 1 to 3 mL water. Approximately 20 to 30 mL of contrast material is injected. An oblique view is obtained. The entire length of the urethra is seen on the plain film when the x-ray is taken as the last 10 mL of the contrast solution is injected. Occasionally, a patient may be transferred from another facility with an indwelling urethral catheter in place. A retrograde urethrogram can still be performed without removing the catheter, by injecting contrast solution into the urethra through a small feeding tube placed adjacent to the urethral catheter.

Urethral injuries should not be investigated in cases of pelvic trauma until it is certain that pelvic angiography or embolization is not required. Also, if the prostate gland was grossly displaced on rectal examination, the urethra is transected, and a retrograde study is not needed, at least not during the initial evaluation.

CONTRAST STUDIES   When both upper and lower tract injuries are suspected, imaging needs to be approached with particular attention to order. While the most serious potential injury should guide the order of obtaining images, oral contrast material should generally not be given before an IVP or cystogram because

gastrointestinal contrast may obscure important findings. Patients with potential bladder injuries may require a retrograde urethrogram to evaluate possible urethral disruption first. If injury is noted, cystography can be accomplished by suprapubic puncture.

IMAGING CONSIDERATIONS FOR OTHER CONDITIONS   A perinephric hematoma may initially be difficult to distinguish from a urinoma. A delayed CT image may demonstrate contrast, indicating a urinoma. Patients with such perinephric collections can be followed with ultrasound studies. A nuclear ^{99m}Tc renal scan can also detect a persistent urine leak.

Significant adrenal injuries are relatively rare. Adrenal hematomas may be found in up to 3 percent of patients with blunt abdominal trauma. They are usually associated with other significant thoracic and abdominal injuries. Adrenal hematomas can be followed by CT or sonography and usually resolve over a few months. Long-term sequelae are unlikely.

PENETRATING TRAUMA

About 10 percent of patients with renal injury related to stab wounds may not manifest hematuria. Thus, appropriate evaluation depends on clinical suspicion, the weapon involved, and patient characteristics. Generally, all stable patients with penetrating trauma with the potential of renal system injury should undergo imaging studies. Hematuria, microscopic or gross, does not correlate with injury from penetrating trauma.[17] The choice of imaging depends on the vicinity of the trauma. Thus, its presence alone mandates further evaluation.

Ureteral injuries are usually a result of bullet wounds. Again, hematuria is not a reliable finding in this setting. Imaging is required for penetrating injuries near ureters. Contusions from secondary energy forces related to bullets cannot be detected by imaging. They may come to light during surgical exploration.

Penetrating bladder injuries are usually accompanied by gross hematuria. As with other penetrating trauma, in the absence of hematuria, the need to perform imaging studies is driven by clinical concern.

Choice of Diagnostic Imaging for Penetrating Renal Trauma

CT with intravenous contrast material remains the primary imaging modality for penetrating trauma to the kidneys. It usually shows appropriate detail of injury to inform management decisions. At least one study has shown its utility for staging even penetrating injuries, allowing nonoperative management in selected patients (i.e., those with minor injury).[18] As with blunt trauma, sonography has no accepted role for detection or staging of renal injury in the United States at this time.

Ureteral injuries can be assessed by IVP or CT with contrast. Extravasation indicates injury. CT has the added advantage of being able to evaluate the extent of extravasation and other intraabdominal injuries. As with blunt trauma, cystography (plain film or CT) is required to evaluate penetrating injuries of the bladder. Unstable patients who require emergency laparotomy can undergo a "one-shot" IVP while in the operating room.

SPECIFIC INJURIES

Kidney Injuries

The kidneys are well protected in the retroperitoneal location surrounded by bulky musculature, fascia, and lower ribs. Considerable force is generally necessary to cause significant renal injury. Fractured ribs, vertebral transverse process fractures, flank bruises or hematomas, and hematuria may indicate injury. Contusions account for most (92 percent) renal injuries, with renal lacerations (5 percent), renal pedicle injuries (2 percent), and renal ruptures or shattered kidneys (1 percent) accounting for the rest.

RENAL CONTUSION   Renal contusion accounts for over 90 percent of renal injuries. This relatively minor injury includes renal parenchymal ecchymosis, minor lacerations, and subcapsular hematomas with an intact renal capsule. Radiographically, results of the IVP are usually normal, and the CT may reveal edema with microextravasation of contrast material within the renal parenchyma. Subcapsular hematoma appears as a flattened portion of the renal cortex compressed by the hematoma under the renal capsule.

RENAL LACERATION   Renal lacerations are classified as either minor cortical lacerations that do not involve the medulla or collecting system, or major renal lacerations that extend deep into the corticomedullary junction or collecting system (Table 254-2). The resulting perirenal hematoma may fill the perirenal space before it is tamponaded by the Gerota fascia. Renal lacerations account for approximately 5 percent of renal injuries. Radiographic studies demonstrate disruption of the renal outline, a perirenal hematoma, and possibly extravasation of contrast material adjacent to the kidney.

RENAL PEDICLE INJURY   Renal pedicle injuries include lacerations and thrombosis of the renal artery, renal vein, and their branches. Renal pedicle injuries make up 2 percent of all renal injuries. These injuries result from high-velocity deceleration injuries and penetrating trauma. In blunt trauma, the most common renal pedicle injury is thrombosis of the renal artery, which follows tearing of the intima with intact adventitial and medial layers. There is bruising surrounding the renal artery, but no perirenal hematoma is found in renal pedicle lacerations. When the renal artery is occluded or divided, the IVP shows nonfunction, and the arteriogram reveals renal artery occlusion or bleeding. In such injuries, CT demonstrates a nonenhanced kidney with minimal peripheral enhancement from the renal capsular vessels ("rim sign"). Renal vein thrombosis results in delayed renal function and parenchymal swelling in the absence of ureteral obstruction.

RENAL RUPTURE   Renal ruptures, or shattered kidneys, account for 1 percent of renal injuries. A large expanding perirenal hematoma accompanies renal rupture, and the patient becomes clinically unstable from continued bleeding. Radiographic studies reveal multiple deep lacerations, devitalized kidney fragments, and extravasation of contrast.

RENAL PELVIS RUPTURE   Ruptures of the renal pelvis result in extravasation of urine into the perirenal space and along the psoas muscle. Renal pelvis ruptures are rare and are often associated with congenital renal anomalies. Radiographic studies reveal a normally functioning kidney, filling of the calyceal system, and extravasation of contrast without visualization of the ureter. Renal pelvis ruptures are often misdiagnosed as small renal lacerations. If the diagnosis is delayed, the patient may develop high fever, increased abdominal pain, and tenderness as the extravasation of urine continues into the retroperitoneal space. Sepsis may ensue. The diagnosis of renal pelvis rupture is confirmed by retrograde pyelogram.

Ureteral Injuries

Ureteral injuries are the rarest of all genitourinary injuries and are usually the result of penetrating trauma (Fig. 254-1). Blunt trauma, however, can induce a rupture at or just below the ureteropelvic junction as a result of hyperextension of the spine with the distal ureter fixed at the trigone of the bladder. Blast effects from gunshot wounds may cause microvascular thrombosis in the ureteral wall, delayed ureteral necrosis, and urinary fistula formation. Diagnosis is sometimes delayed. If the ureter is completely transected, hematuria may be absent.[11] IVP is likely to miss such injuries.[11] Enhanced CT or a retrograde pyelogram may be required for detection.

FIG. 254-1. Rare ureteral injury from a gunshot wound, with extravasation of contrast material on retrograde pyelogram.

Bladder Injuries

The bladder is an intraabdominal organ in children but is situated deep in the bony pelvis in adults. It is protected from all but the most severe injuries to the abdomen and pelvis. Bladder injuries are the second most common injury to the genitourinary tract after renal injuries and are usually associated with blunt trauma and pelvic fracture. Penetrating bladder injuries are often associated with injuries to other abdominal and pelvic organs.

BLADDER CONTUSION   Bladder contusion is bruising of the bladder wall and resultant hematuria. A cystogram demonstrates an intact bladder outline. With a fractured pelvis, a large hematoma often results inside the bony pelvis, causing displacement of the bladder superiorly and laterally (Fig. 254-2). This finding can serve as an indicator of pelvic hemorrhage. Large bladder hematomas also alter the architecture of the bladder, which takes on the shape of an inverted pear, hence the term "pear-shaped" bladder. Hematomas are best detected by CT.
FIG. 254-2. Bladder contusion and displacement from pelvic hematoma.

BLADDER RUPTURE   There are two types of bladder injuries.[19] Intraperitoneal bladder rupture is usually a burst injury of a full bladder resulting in a 1-in laceration in the dome posteriorly, the only portion of the dome covered by the peritoneum. In this type of injury, urine is spilled into the peritoneal cavity. Extraperitoneal bladder rupture is more common. The rupture is usually located at the bladder neck. Associated pelvic ring fractures predominate. The classic triad includes abdominal pain and tenderness, hematuria (usually gross), and inability to void. If the rupture is intraperitoneal, there may be peritonitis. Kehr sign (pain referred to the shoulder), suggesting blood or urine irritating the diaphragm, may be a clue. Patients in whom bladder injury is suspected but who are unable to void spontaneously should have a retrograde or suprapubic catheter placed. Retrograde catheter placement should be avoided until urtheral disruption has been ruled out.

Bladder injuries are best diagnosed by cystogram or CT cystogram (see above). Gross extravasation indicates rupture. Intraperitoneal rupture is demonstrated by extravasation of contrast material in the cul-de-sac posterior to the bladder, along the paracolic gutters, and between the loops of intestine above the bladder. In extraperitoneal bladder rupture, the cystogram shows flamelike extravasation of contrast material streaking into the perivesical tissues. The washout film (not necessary with CT cystogram) is helpful when the extravasation is predominantly behind the bladder and obscured by contrast material in the full-bladder film of the cystogram. An irregular outline of an intact bladder may indicate contusion, hematoma, or an incomplete tear. Cystoscopy is not considered useful in this setting due to the gross hematuria and clot formation.[3]

Urethral Injuries

Urethral injuries in males occur in the posterior (prostatomembranous) urethra and in the anterior (bulbous and penile) urethra. Posterior urethral injuries are associated with pelvic fractures. Digital rectal and perineal examinations reveal the presence of a perineal hematoma or high-riding detached prostate, which is associated with complete posterior urethral disruption. Anterior urethral injuries result from direct blows to the urethra (e.g., fall-astride injuries, straddle injuries, or kicks) or from instrumentation, and in conjunction with a penile fracture. Examination reveals the classic "butterfly" perineal hematoma, limited by the attachments of the fascia lata.

In anterior urethral contusions, there is blood at the external urinary meatus, but the retrograde urethrogram findings are normal. In partial anterior urethral lacerations, the retrograde urethrogram reveals contrast extravasation at the site of injury and contrast material outlining the urethra proximal to the site of injury (Fig. 254-3). In complete anterior urethral lacerations, the retrograde urethrogram reveals contrast extravasation at the site of injury without contrast proximal to the site of injury.

FIG. 254-3. Partial urethral laceration, with contrast extravasation at the site of injury and outlining the prostatic urethra and bladder.

Female urethral injuries should be suspected in extensive pelvic fractures. Eighty percent of female urethral injuries present with vaginal bleeding. Careful vaginal and endoscopic examination should be undertaken, even when the patient has menstrual bleeding or an indwelling tampon. Delayed diagnosis has resulted in labial edema, necrotizing fasciitis, and sepsis.

MANAGEMENT OF RENAL SYSTEM INJURIES

General management of trauma in the emergency department is discussed in Chapter 243. Only aspects specifically related to genitourinary system trauma are discussed here.

Patients with isolated microscopic hematuria (5 to 50 RBCs/hpf) in whom imaging was not indicated may be discharged from the emergency department. Strenuous activity should be proscribed. Follow-up urinalysis should be obtained in 1 to 2 weeks.

Kidney

Grade I and II renal injuries (Table 254-2) are usually managed nonoperatively. If there are no other medical considerations, such patients can be treated similarly to those with isolated hematuria. Renal contusions almost always resolve without sequelae unless there is a preexisting renal lesion, such as hydronephrosis, cyst, or tumor. Almost all minor lacerations heal without sequelae with conservative management.

Patients with grade III and IV injuries should be admitted to the hospital. Most of these patients will have other compelling reasons to be admitted or be taken to the operating room. Many stable adult patients with clearly delineated grade III and even grade IV injuries can still be managed nonoperatively. [20,21] Many centers attempt nonoperative management for all stable children unless the renal injury is particularly severe or the child fails conservative therapy. [8,22] Exploration itself is not without consequence, since it may accentuate considerable hemorrhage. Neither the volume of blood replacement nor the degree of extravasation is an indication for exploration in itself. [3] However, if exploration is undertaken for the evaluation of other injuries, repair of renal injuries is usually undertaken. If conservative management is attempted, frequent reassessment is required, and there should be a low threshold for ordering reimaging studies. Conservative management includes bed rest, hydration, serial hematocrit determinations, monitoring of vital signs, and serial urine specimens to assess the degree of hematuria. Patients with gross hematuria remain at bed rest until the gross hematuria resolves and remain at limited activity until microscopic hematuria resolves.

Indications for operative management are listed in Table 254-5. [3] Renal rupture is usually explored and nephrectomy usually required. Most, but not all, penetrating injuries are explored. The only widely accepted absolute indication for surgical exploration of a renal injury is persistent retroperitoneal bleeding with hemodynamic instability. As noted, CT may allow adequate staging even for penetrating injuries. [18] If the patient has other injuries warranting abdominal exploration, an intraoperative IVP may assist in determining the necessity for retroperitoneal exploration while also giving information regarding function of the contralateral kidney.

Uncontrolled renal hemorrhage
Penetrating injuries
Inadequate staging
Multiple kidney lacerations
Shattered (ruptured) kidney
Avulsed major renal vessel
Pulsatile or expanding hematoma found on abdominal exploration
Vascular injuries*
Extensive extravasation

*Only those found early (see the text).

TABLE 254-5   Indications for Operative Exploration or Intervention in Renal Injury [3]

Renal pedicle injuries are usually associated with multiple life-threatening injuries, and the safest surgical option is nephrectomy. In a stable patient with an isolated renal pedicle injury, repair should be undertaken within 12 h of the injury if a viable kidney is to result. Thrombosis of segmental arteries is treated conservatively.

Surgical exploration consists of preliminary vascular control, debridement, and surgical repair. Early control of the renal vessels decreases the nephrectomy rate in potentially salvageable kidneys. Nephrectomy, however, may be necessary in unstable patients.

Ureter

Ureteral injuries are managed intraoperatively. Unfortunately, not all ureteral injuries are found at the time of injury. Delayed presentations include infection, including sepsis, and urinoma formation. Contusions are missed by imaging studies, but, if noted at the time of exploration, can be managed expectantly or with placement of an internal stent.

Bladder

Incomplete bladder lacerations can be managed by catheter placement and observation. Contusions require no specific intervention. Intraperitoneal rupture and penetrating injuries require operative intervention. Extraperitoneal bladder ruptures are treated with urethral catheter drainage alone. In such cases, the catheter remains indwelling for 10 to 14 days, and the cystogram is repeated to verify healing before the urethral catheter is removed. Rarely, persistent urinary extravasation is seen, with a bony fragment remaining in the bladder wall or a pelvic fixation impinging upon the bladder.

Urethra

Anterior contusion heals with conservative management, with or without a urethral catheter, depending on whether the patient can void. Partial anterior urethral lacerations are managed with an indwelling urethral catheter (placed coaxially over a guide wire under fluoroscopic control) or with a suprapubic cystostomy. Complete lacerations of the anterior urethra are repaired surgically with debridement and end-to-end anastomosis over a urethral catheter.

Surgical repair is usually deferred for posterior urethral injuries. Suprapubic cystostomy is favored by most for bladder drainage. Partial posterior urethral lacerations are managed with a urethral catheter placed coaxially over a guide wire under fluoroscopic control or with a suprapubic catheter. In complete posterior urethral lacerations, the management remains controversial. The injury is managed with primary realignment of the lacerated urethra or with suprapubic cystostomy alone. Stricture formation occurs with both techniques. However, the subsequent urethral stricture in patients with primary realignment tends to be less extensive. The advantage of suprapubic cystostomy alone, especially in an unstable patient, is its simplicity. The impotence and incontinence rates are thought to be related to the extent of injury and are the same for both techniques.

In women, a layer repair of the urethral and associated vaginal injuries is performed over a urethral catheter. The voiding phase of the repeat cystogram is essential in confirming complete urethral healing.

The Full-Bladder Dilemma

Emergency physicians in nontrauma centers may encounter patients with a urethral injury precluding bladder catheterization but with a full urinary bladder. Such a patient may have to be transferred many miles to reach a center with a urologic service. Spontaneous or conscious bladder contraction may ensue, with spillage of urine into the perivesicle space, increasing the risk of infection. Guide-wire-aided placement of a temporary suprapubic catheter into the bladder can alleviate this problem. A large-bore Seldinger-technique central venous catheter or cavity drainage catheter may provide temporary relief. The exploring needle is inserted perpendicularly about two finger breadths above the symphysis pubis. The guide wire is inserted when urine returns. The catheter selected should be long enough to coil within the bladder so that it remains in the lumen of the bladder when it is empty. Because the bladder may be displaced by a large hematoma or extravasated urine, it is advisable to inject a few milliliters of contrast material into the bladder while obtaining an x-ray to confirm that the catheter is actually in the bladder.

GENITAL INJURIES

Testicular and Scrotal Injuries

The mobility of the testicle, cremaster muscle contraction, and the tough capsule of the testis (tunica albuginea) are responsible for the infrequent rate of injury to the testis. A direct blow to the testis impinging it against the symphysis pubis is the primary cause of blunt testicular injury. Blunt testicular injuries are either contusions or ruptures. Rarely, traumatic dislocation of the testicle to the inguinal canal has been reported. In testicular contusions or ruptures, the tunica vaginalis sac fills with

blood (hematocele) and appears as a large, blue, tender scrotal mass. Penetrating injuries to the scrotum through the tunica vaginalis require exploration. Bilateral testicular injuries are often seen in penetrating trauma. Testicular ultrasound studies with colored Doppler studies can help delineate the extent of testicular trauma and are quite reliable in diagnosing ruptured testes.

Early exploration, evacuation of blood clots, and repair of testicular rupture tend to result in an earlier return to normal activity, decreased hematoma infection, and less testicular atrophy than does conservative management. Testicular salvage following penetrating trauma is on the order of 35 percent. [23]

Scrotal skin avulsion is managed by housing the testicle in the remaining scrotal skin even though the reconstruction places the skin under tension. Usually the scrotum returns to nearly normal size within a few months. In complete scrotal skin loss, the testicles are placed in pouches in the inner thighs.

Injuries to the Penis

Self-inflicted injuries of the penis include vacuum cleaner injuries and blade injuries. Vacuum cleaners cause extensive injury to the glans penis and some loss of the urethra, requiring debridement of devitalized tissue and reconstruction. Blade injuries range from superficial lacerations to complete amputation. Amputation of the penis is managed by reimplantation or local repair. Reimplantation is preferable if the distal penis is in satisfactory condition, and the ischemia time is less than 12 to 18 h. Loss of penile skin by avulsion injury or burns is managed by split-thickness skin grafts after the denuded penis is clean and uninfected. The avulsed skin should not be reapplied, for it invariably becomes necrotic and infected and must be subsequently removed.

Traumatic rupture of the corpus cavernosum of the penis or fracture of the penis occurs when the erect penis impacts forcibly on a hard object (sexual partner's pubis or the floor), receives a direct blow, or is subjected to abnormal bending. A cracking sound is heard, followed by penile pain, immediate detumescence, rapid swelling, discoloration, and distention. Urethral injuries may accompany penile ruptures. Penile ruptures are managed by immediate surgical evacuation of blood clot and repair of the torn tunica albuginea of the corpus cavernosum and urethra.

Zipper injury to the penis is caused when the penile skin is trapped in the trouser zipper. Mineral oil and lidocaine infiltration are useful in freeing the penile skin from the zipper. Otherwise, wire-cutting or bone-cutting pliers are used to divide the median bar (or diamond) of the zipper, which causes the zipper to fall apart, freeing the penile skin.

Contusions of the perineum or penis, which can result from straddle or toilet seat injuries, are treated conservatively with cold packs, rest, and elevation. If the patient is unable to void, catheter drainage is elected.

Allan Kumar

Emergent management of penetrating extremity injuries is an evolving and controversial subject. Recent advances in surgical technique enable arterial repair with an extremely low rate of postoperative thrombosis, making the recognition and rapid treatment of arterial injury of paramount importance. Associated injury to soft tissue, nerve, and bony structures are now the primary determinants of limb salvage. Emergency physicians play a crucial role in the management of penetrating extremity injuries by identifying injuries early and promptly initiating care crucial to limb rescue. Unnecessary delays in treatment can lead to irreversible limb ischemia and subsequent limb loss.

EPIDEMIOLOGY

In the past 10 years, there has been a surge in the number of violent crimes associated with firearm usage. Gun-related assaults, robberies, and murders have risen by 59 percent since 1987. Penetrating trauma accounts for up to 82 percent of all vascular injuries to the extremities. Gunshot and shotgun wounds account for nearly 65 percent of penetrating vascular extremity injuries, and stab wounds account for approximately 15 percent. Of patients presenting with gunshot wounds, 20 to 40 percent have extremity involvement, either isolated or in combination with other injuries. In 1950, a patient with a penetrating extremity injury with vascular involvement had a 50 percent chance of leaving the hospital with an amputated limb. With recent advances in emergency care, vascular surgery, invasive radiology, and the science of thrombosis, penetrating extremity injury results in amputation in fewer than 5 percent. [1] Despite this improved diagnosis, there is still a 15 to 40 percent long-term morbidity due to other complications, such as nerve damage, fractures, wound infections, open joint injuries, and compartment syndromes. [2]

PATHOPHYSIOLOGY

Gunshot and stab wounds account for the largest percentage of penetrating extremity injuries. Gunshot and blast injuries often present a diagnostic and management dilemma. A basic understanding of wound ballistics will enable astute clinicians to better plan the clinical management of patients who sustain a gunshot wound to the extremity. Diagnostic and treatment modalities as well as outcome differ with the type and severity of the injury. Although the damage from a stab wound can be relatively predictable with a good knowledge of clinical anatomy, the tissue damage inflicted by a missile or blast depends on a variety of factors (see Chap. 256, "Wound Ballistics"). The notion that projectile velocity alone determines the extent of damage is false. Wound profiles depend on variables that include the projectile's shape, construction, composition, angle of impact, flight characteristics in tissue (yawing, or turning sideways in relation to line of flight), velocity, and mass. [3] An example would be a shotgun blast. At close range, a shotgun creates a more severe wound than a high-velocity M-16 assault rifle would at the same range because of the increased total mass and fragmentation of the shotgun load. The impact of a missile on tissue also creates indirect damage due to pressure waves accelerating radially away from the point of penetration, thereby displacing tissue. This phenomenon, termed *temporary cavity,* can cause significant additional damage. [4] The severity of injury due to the temporary cavity varies inversely with the elasticity and density of the surrounding tissue. As an example, muscle and fat are relatively more elastic and therefore far less susceptible than bone or liver to this type of indirect damage. A third proposed mechanism of damage is termed shock wave: a sound wave traveling in front of the bullet is generated by the missile impact onto tissue. This theory has not been proven in multiple studies, and the nature of the subsequent damage is not well defined. Overall, tissue damage is usually proportional to the amount of fracture comminution and displacement, blood loss within the limb, and nerve or vascular injury. The wide variety of handguns available on the market and the availability of military-surplus weapons, as well as the inaccuracy of the information given to treating physicians about weapon and bullet type by the injured and their associates, make clinical findings and diagnostic modalities the best guides in determining management.

DIAGNOSIS AND MANAGEMENT

After the initial trauma resuscitation and primary and secondary surveys are complete, specific points of the victim's past medical history should be examined: preexisting vascular and neuromuscular deficits, and the events surrounding the injury, such as the type of gun and number of shots. An extremely careful and thorough physical examination is imperative to identify significant injuries rapidly and to determine whether immediate surgical intervention is necessary or which, if any, diagnostic studies are indicated. This may be challenging in the presence of other serious trauma or distracting injuries.

The presentation of penetrating vascular injury varies widely. Prompt recognition of arterial injury is one of the fundamental goals of management. The presence and volume of the distal pulses in the affected extremity should be noted and compared with the unaffected limb. Ankle-brachial indices (ABIs) should be calculated on the affected and unaffected limbs (method described below). The color, temperature, and capillary refill time are important clinical indicators of more subtle injury to underlying vessels. Examination should also look for signs of compartment syndrome. Capillary refill alone is an unpredictable marker of vascular injury but may be useful in conjunction with other modalities. Only a small minority of patients (fewer than 6 percent) will present with classic "hard" signs of arterial injury (Table 255-1). These patients require expeditious operative management or, under certain circumstances, angiography (Fig. 255-1). A surgeon should be involved in the management of these patients as soon as possible. Patients with "soft" signs (Table 255-1) of arterial vascular trauma can usually be managed without surgical intervention on an inpatient surgical service. [5] Controversy surrounds the management of the patient with a wound in proximity to a major vascular structure but without clinical evidence of arterial injury. Historically, patients with these types of injuries were all surgically explored, which yielded a large number of negative exploratory surgeries, and thus angiography became popular. Angiography based on proximity alone yields abnormalities in 10 to 20 percent of the cases, with less than 2 percent requiring surgical intervention. Current practice regarding penetrating injuries in proximity to major vessels without any signs of vascular injury is to observe patients with clinically silent arterial injury. The natural course in these cases is likely benign, and these patients can be safely observed with serial examinations.

Hard signs
  Absent or diminished distal pulses
  Obvious arterial bleeding
  Large expanding or pulsatile hematoma
  Audible bruit
  Palpable thrill
  Distal ischemia (pain, pallor, paralysis, paresthesias, coolness)

Soft signs
  Small, stable hematoma
  Injury to anatomically related nerve
  Unexplained hypotension
  History of hemorrhage no longer present
  Proximity of injury to major vascular structures
  Complex fracture

TABLE 255-1   Clinical Manifestations of Extremity Vascular Trauma

FIG. 255-1. Algorithm for the evaluation of an injured extremity for vascular trauma. (Adapted from Frykberg: Advances in diagnosis and treatment of extremity trauma. *Surg Clin North Am* 75:207, 1995.

Duplex ultrasound has become a popular modality in the management of proximity injuries without evidence of arterial injury. Recent advances in duplex ultrasonography have shown highly accurate rates of detecting occult arterial injury (vide infra). Some clinicians use duplex ultrasound to distinguish between patients who require observation and those who can safely be discharged home.

Although venous trauma can bleed profusely, management by either ligation or reanastomosis often yields similar results. [6] Asymptomatic venous injury rarely results in long-term morbidity. During the initial trauma resuscitation, attempts should not be made to clamp or ligate bleeding vessels in an attempt to control bleeding. Nerves are bundled with vascular structures and can be easily damaged by blind clamping or ligation. Profuse bleeding should be initially controlled with direct pressure.

Although arterial injury is the most dramatic result of penetrating extremity injury and represents the most immediate life threat, injuries to major nerves are the most likely to lead long-term disability. Fortunately, 70 percent of peripheral nerve injuries noted during the initial examination recover completely within 6 months of the initial injury. A neuromuscular exam of the extremities should indicate both muscular and sensory function (Table 255-2) and check for evidence of compartment syndrome. Patients with suspected nerve, orthopedic, or vascular injury or compartment syndrome should be immediately evaluated by surgical subspecialists.

TABLE 255-2   Clinical Examination of the Nerves of the Extremities

The size and shape of the wounds, and soft tissue and obvious bony deformities, should be noted and thoroughly examined. Pain on palpation or movement of an extremity is suspicious for an underlying fracture. Penetrating trauma near a joint should be evaluated thoroughly for damage to the joint capsule, as associated long-term morbidity is significant. Radiologic evidence of air in a joint is evidence of joint penetration. Patients with obvious bony or joint capsule injury should be evaluated by an orthopedic surgeon. The majority of orthopedic surgeons will undertake arthroscopic exploration and "wash out" an involved major joint. Joint sepsis and destruction, rapid chondrolysis, and loss of anatomic contours can lead to long-term morbidity in the form of posttraumatic degenerative arthritis and decreased or total loss of flexibility. Metal fragments left in the joint space may dissolve in the synovial fluid, resulting in lead toxicity. Patients with penetrating injury proximal to, or overlying, a major joint without obvious joint penetration and without fracture can be splinted and discharged with 24-h orthopedic follow-up. Most orthopedic authors recommend discharging these patients on oral antibiotics, although the rationale has not been clearly established. Bony fractures as a result of penetrating injury are treated as open fractures. The injury is surgically debrided and the patient admitted for intravenous antibiotics.

DIAGNOSTIC MODALITIES

Radiographic Studies

Plain films, including anteroposterior and lateral views, of the involved extremities should be obtained in all cases. Oblique views may also offer additional information. It is important that the joints above and below the suspected injury site are imaged. Five general types of fracture patterns are created from bullets (Fig. 255-2). A drill hole pattern from penetration of cancellous bone is often seen in sites such as the proximal humerus, pelvis, and distal femur. These fractures have less comminution than those in cortical bone, because cancellous bone is more porous and less dense. Unicortical fractures of the metaphysis on long bones are often seen with bullet impact on a tangential plane. The majority of gunshot fractures of the diaphysis are comminuted, and the degree of comminution depends on the amount of energy transfer from the penetrating missile. Spiral fractures distant from the site of impact on the bone can occur if the bone is under a degree of torsional stress. There have also been reports of simple fractures of long bones caused by indirect damage from the temporary cavity. It is also important to note whether a joint has been penetrated, because this complication changes patient management. In the case of shotgun or blast injury, it is important to image the extremity distal to the injury in order to detect any pellets that may have embolized (Fig. 255-3 and Fig. 255-4).
FIG. 255-2. Types of fracture patterns created with bullets: drill hole, unicortical, distant spiral, comminuted. The fifth type seen is a simple fracture.

FIG. 255-3. Gunshot wound to the shoulder and axilla.
FIG. 255-4. Actual embolization of shotgun pellet, illustrating importance of obtaining images of the extremity distal to such injuries.

Computed tomography, although rarely useful in the acute diagnosis and treatment of extremity trauma, is considered helpful in selected cases before definitive orthopedic care. It can help diagnose bony pathology and determine if intraarticular fractures, fragments, or foreign bodies are present. Magnetic resonance imaging, once thought to be a promising tool in the assessment of extremity trauma, is not readily available in many institutions, is time consuming, and often is of low yield.

Angiography can be used to delineate the extent, nature, and location of vascular injuries with special situations such as shotgun wounds, multiple or severe fractures, chronic vascular disease, thoracic outlet wounds, or extensive soft tissue injury. The widespread availability and accuracy of angiography led to it become the gold standard in the evaluation of patients with wounds in proximity to major neurovascular bundles. Arteriography for the evaluation of proximity injuries in patients without hard signs of injury reveals normal results in 80 to 90 percent, with a complication rate of 1 to 2 percent from the procedure. Recent studies have shown that occult vascular injuries can exist, without hard clinical findings, in up to 23 percent of patients. Among these, however, fewer than 2 percent have surgically important lesions. Still, with observation and a careful examination, positive findings will eventually be more evident and the wounds subsequently repaired without increased morbidity.[7,8,9 and 10] The algorithm presented in Figure 255-1 outlines the approach to vascular injuries. In the presence of hard signs of vascular injury on clinical examination, immediate surgery is indicated in some conditions, without a preoperative angiogram. However, certain injuries are still best evaluated by angiography prior to surgical intervention. The need for angiography in patients with soft signs of vascular injury is still a matter of some debate among surgeons and radiologists. However, current practice in most centers is to observe patients with soft signs and conduct serial examinations. Angiography and surgery are delayed until there is clinical evidence of arterial injury.

Digital subtraction angiography has also been used in evaluation of vascular trauma with accuracy similar to standard techniques but is less reliable in detecting intimal disruption. The test requires a cooperative patient, because it is extremely sensitive to motion artifact.[5]

Ankle Brachial Indices

Doppler devices are used to determine ABIs or wrist brachial indices. Diagnostic accuracy has been reported to be as high as 95 percent, but sensitivity and specificity vary depending on whether the classification of abnormal is set at a ratio of 1.0 or 0.9.[10,11] This test does not reliably detect nonocclusive arterial disease, such as intimal flaps and pseudoaneurysms. It can augment the clinical examination by objectively confirming the subjective impression of a diminished pulse in a patient under observation. To perform accurate ABIs, it is important to place the patient in supine position and measure the systolic blood pressure in all four extremities. To measure an ankle systolic pressure, a standard adult blood pressure cuff should be snugly wrapped around the ankle just above the malleoli. While using the Doppler flowmeter to monitor the signal from the posterior of the anterior tibial artery, distal to the cuff, inflate the cuff to a pressure approximately 30 mmHg above the systolic pressure to occlude flow temporarily. As the cuff is slowly deflated (2 to 5 mmHg/s), the pressure at which the Doppler flow signal is heard should be noted and recorded as the ankle systolic pressure. To assure accuracy, the upper extremity systolic blood pressure should be measured by using a Doppler flowmeter, as well. An ABI is then calculated by dividing the ankle systolic blood pressure by the greater of the two systolic upper extremity blood pressures. An ABI of greater than 1.0 is normal. An ABI of 0.5 to 0.9 is indicative of injury to a single arterial segment. An ABI of less than 0.5 is indicative of severe arterial injury or injury to multiple arterial segments. A difference of greater than 20 mmHg between the upper extremity blood pressures is indicative of upper extremity arterial injury. Underlying conditions, such as preexisting peripheral vascular disease or severe hypothermia, can also affect the accuracy of the ABI.

Duplex Ultrasonography

Duplex ultrasonography has a diagnostic accuracy of 96 to 98 percent and can image extremity vessels with as much resolution as contrast angiography. Advantages over angiography include an increased safety profile and rapid results. However, it is highly operator dependent and has not been tested in patients with severely injured extremities with open wounds or fractures, large hematomas, bulky dressings, or traction devices.[1,5,12]

DISPOSITION

Patients with hard signs of arterial injury are not a diagnostic dilemma. These patients require surgical intervention or, at the very least, expedient surgical evaluation and angiography. Patients with soft signs of arterial injury require inpatient observation. Patients with penetrating extremity injury, no signs of arterial injury, no bony or nervous injury, minimal soft tissue defect, and no signs of developing compartment syndrome can be safely discharged home with close follow-up after a period of observation and serial examinations. There is no consensus on the ideal observation time, but the current literature describes times from 3 to 12 h. Wound exploration in the emergency department should be reserved for those patients with suspected foreign bodies in the wound, for ligamentous involvement, or for control of minor venous bleeding. Wound exploration to control arterial or major venous bleeding should be done in the operating room. The general principles of wound management, including tetanus prophylaxis, apply here. Although controversial, there is no proven role for prophylactic antibiotics unless a wound is contaminated or patients have an underlying preexisting condition that would predispose them to infection.

EPIDEMIOLOGY

Violence involving firearms is a significant problem in the United States. Handguns are used in the overwhelming majority of cases because they are easy to carry and conceal. Many criminals now use semiautomatic handguns that carry up to 15 cartridges in their clips. Funds produced in the lucrative illegal drug trade enable drug traffickers to switch from cheap revolvers (Saturday night specials) to expensive modern high-technology semiautomatic pistols. Law enforcement has followed suit in this "arms race." It is not surprising that multiple gunshot wounds are becoming more common.[1] A higher percentage of patients wounded by semiautomatic pistols are dead at the scene, increasing from 5 percent in 1985 to 34 percent in 1990 in Philadelphia County.[1] In that study, the percentage of firearm homicide victims with criminal records increased from 43 percent in 1985 to 67 percent in 1990. Of all the 1990 Philadelphia firearm homicide victims, 61 percent were intoxicated at the time they were killed, and 39 percent were using cocaine at the time of death compared with 9 percent in 1985.

Between 1983 and 1992, a total of 37 million handguns, rifles, and shotguns were produced in the United States. These were added to the pool of existing firearms. This figure does not include guns imported into the United States during the same period. In 1992, a total of 3 million handguns, rifles, and shotguns were produced in the United States, and 2.85 million more were imported.[2]

When tracing the ownership history of a firearm for a crime investigation, the record often stops at the point of the gun's first private sale. Except where expressly outlawed by individual states, anyone who owns a firearm is free to sell it without demanding identification and without keeping any record of the sale. The Brady law does not apply. Like most federal gun-sale laws it regulates only the transactions of federally licensed gun dealers.

Each day in the United States, there are 65 murders.[3] At least 68 percent of these are committed with firearms. Many of these murders and much of the urban gun violence result from disputes between criminals, so criminals are often the victims. The medical literature regarding the epidemiology of firearm-involved trauma is often misleading and sometimes outright false.[4,5]

GENERAL CONCEPTS

The medical literature is full of erroneous articles classifying gunshot wounds based on bullet velocity. Other bullet and tissue characteristics are at least as important as velocity.[6,7 and 8] Bullet *mass,* which is related to diameter and length, is a major determinant of how deeply the bullet will penetrate tissue. Bullet *construction* (such as whether the bullet is solid lead with no bullet jacket, is partially jacketed, or has a full metal jacket) is a primary determinant of whether the bullet will deform or fragment. Bullet shape and center of mass (which determine how soon it will yaw in its path through tissue), the *thickness of the body part wounded* (determining whether the bullet has a long enough path through tissue to deform or yaw) (Fig. 256-1), *tissue type* struck (e.g., femur versus lung), tissue elasticity, density, specific gravity, and internal cohesiveness [which determine how well the tissue will withstand tissue stretch (temporary cavitation) forces] are all important, in addition to bullet *velocity,* in determining the nature of the wound produced. The amount of kinetic energy "deposited" or "retained" in a victim wounded by a projectile is not a reliable predictor of wound severity,[9] and muzzle energy is not a reliable indicator of bullet performance.
FIG. 256-1. A. The photograph shows a .22 long rifle round (*left*) and an M16 round (*right*). **B** and **C.** These are the wound profiles of the same .22 long rifle (B) and .224 caliber M-193 round of the M16A1 rifle (C). [Full metal case (FMC) is a synonym of full metal jacket (FMJ), the type of bullet used in the military.] This figure shows that caliber (bullet diameter in decimals of an inch or in millimeters) is only one indicator of wounding potential and not a very good one. Because of much higher velocity [3094 ft/s (943 m/s), as opposed to 1122 ft/s (342 m/s) for the .22 long rifle bullet], because it fragments in tissue, and because of greater bullet mass, the M16 bullet has the potential to cause a much more severe wound if the anatomic part struck is sufficiently thick. Note that, in the gelatin block, both the permanent cavity and the temporary cavity caused by the M16 bullet are much larger than those of the .22 long rifle bullet. As is usual for a non-deforming bullet, the temporary and permanent cavities caused by the .22 long rifle bullet are largest when the bullet has a 90° yaw. (From Hollerman et al (p 686),[4] with permission.)

An understanding of wound ballistics enables physicians to evaluate and treat missile wounds without repeating the errors of conventional "wisdom." Based on common misconceptions about wound ballistics, many papers have suggested harmful and unnecessary treatment for gunshot wounds. An example of such an unnecessary and harmful recommendation is that for mandatory surgical excision of the tissue surrounding the bullet track (the path of the projectile through tissue) whenever an extremity wound is caused by a high-velocity bullet. This is based on the belief that these tissues will become necrotic. Clinical experience and research show this to be false.[10]

WOUNDING POTENTIAL

Every moving bullet has a maximum wounding potential determined by its mass and velocity. Bullets of equal wounding potential may produce wounds of very

different severity, depending on bullet shape, internal and external construction, and which tissues they traverse.

Bullets with equal wounding potential often do not produce similar wounds. A heavier, slower bullet crushes more tissue but induces less temporary cavitation; most of the wounding potential of a lighter, faster bullet is likely to be used up forming a larger temporary cavity, but this bullet leaves a smaller permanent cavity (crushes less tissue).[9,12] The heavier, slower bullet causes a more severe wound in elastic tissue than the lighter, faster bullet, which uses up much of its wounding potential producing tissue stretch (temporary cavitation). This tissue stretch may be absorbed with little or no ill effect by elastic tissue such as lung or muscle. In less elastic tissue such as liver or brain, the temporary cavity produced by the lighter, faster bullet can produce a more severe wound. Penetration depth will be less with the lighter, faster bullet, and critical structures such as the heart may not be reached.

MECHANISMS OF WOUNDING

Both missile and tissue characteristics determine the nature of the wound. Missile characteristics are partly inherent (mass, shape, and construction) and are partly conferred by the weapon (longitudinal and rotational velocity). Tissue characteristics (elasticity, density, and anatomic relationships) also strongly affect the nature of the wound. The severity of a bullet wound is influenced by the bullet's orientation during its flight through tissue and by whether the bullet fragments[9] deform (into the typical mushroom shape of expanding hollow-point or soft-point bullets).

Two major mechanisms of wounding occur: the *crushing* of the tissue struck by the projectile (forming the permanent cavity), and the radial *stretching* of the projectile path walls (forming a temporary cavity) (Fig. 256-1). In addition, a sonic pressure wave precedes the projectile through tissue. The sonic pressure wave plays no part in wounding.[11]

Crushing of Tissue

A missile crushes the tissue it strikes, thereby creating a permanent wound channel (permanent cavity). If the bullet is traveling with its pointed end forward and its long axis parallel to the longitudinal axis of flight (0° of yaw, the angle between the long axis of the bullet and its path of flight), it crushes a tube of tissue no greater than its approximate diameter. When the bullet yaws to 90°, the entire long axis of the bullet strikes tissue. The amount of tissue crushed may be three times greater than at 0° of yaw.

When striking soft tissue with sufficient velocity, soft-point and hollow-point bullets deform into a mushroom shape. This increases surface area and the amount of tissue crushed. For most big-game hunting, such bullets are mandated by law. This is to increase the probability of prompt lethality, rather than the creation of a disabling but nonlethal wound causing an animal prolonged suffering. If the mushroomed diameter is 2.5 times greater than the initial diameter of the bullet, the area of tissue crushed by the bullet is 6.25 times greater than the amount that would have been crushed by the undeformed bullet.

Bullet fragmentation also increases the volume of tissue crushed.[8] After bullet fragmentation, bullet surface area is increased and much more tissue is crushed. For large handgun (e.g., .44 magnum) and rifle bullets, the striking of bone is one of the causes of early bullet fragmentation.

Comminuted fracture may be created by rifle and large handgun bullets striking bone. Bone fragments can become secondary missiles, crushing tissue. Many handgun bullets are unable to fragment bone significantly. When a large bone is struck, it is likely that the bullet will expend its wounding potential in the victim and will not exit.

Bullet fragments and secondary missiles, such as bone fragments, teeth, or coins, propelled by contact with the bullet are likely to increase the severity of the wound. Multiple perforations weaken tissue and create focal points for stress (stress risers). Tissue tears are particularly likely to occur at stress risers during temporary cavitation stretch.[9]

Unjacketed lead bullets cannot be driven faster than about 2000 ft/sec (610 m/s) without some of the lead stripping off in the barrel. This is avoided if a jacket made of a harder metal (such as copper or a copper alloy) is used to surround the lead. The jacket of a military bullet completely covers the bullet tip (a full metal jacket). Civilians often use hollow-point or soft-point bullets. Hollow-point bullets have a hole in the jacket at the bullet tip, and soft-point bullets have some of the lead core of the bullet exposed at the bullet tip. These constructions weaken the bullet tip, causing it to flatten on impact. This flattening often greatly exceeds bullet diameter, resulting in a mushroom-shaped projectile.

The hollow-point and soft-point bullets used by civilians are often more damaging to tissue than are military bullets fired from rounds otherwise configured identically.[6,9 and 13] Because of this, wounds produced by civilian hunting rifles, shotguns, and large-caliber handguns are usually more severe than wounds produced by military-rifle bullets of the same mass and velocity.[13]

Hollow-point and soft-point bullets either deform into a mushroom shape or stay undeformed. Up to one-third of hollow-point and soft-point handgun bullets fail to deform into a mushroom shape, usually due to insufficient bullet velocity or an excessively stiff or thick bullet jacket that prevents deformation.

When the tip of a hollow-point bullet is plugged with material such as clothing or drywall, bullet expansion into a mushroom shape in tissue is usually delayed and sometimes prevented. This causes deeper penetration of tissue, sometimes causing a perforating wound (having both and entrance and an exit). This may result in the injury of bystanders. Some recent handgun bullets have designs attempting to overcome this problem.

Projectiles penetrate more deeply as projectile velocity is increased, but only up to the point where velocity becomes sufficiently high to deform the projectile. Penetration decreases markedly from that point on. The greater the bullet diameter expansion from mushrooming, the less is the depth of penetration.[14]

There is a critical range of velocity for each handgun hollow-point and soft-point bullet, within which the bullet may perform as expected. Below this velocity range the bullet will have insufficient velocity to mushroom on impact, and at velocities above this range the bullet may fragment after impact, resulting in many light bullet pieces crushing tissue at a superficial depth.

Military full metal jacket bullets do not flatten at the bullet tip, i.e., they do not mushroom. Sometimes they can break and fragment as a result of yawing to 90°. The stress on the bullet as its long axis strikes tissue causes the sides of the bullet to flatten as if it had been squeezed in a vise. If the bullet breaks, it will usually do so at the cannelure, a circular groove around the bullet where it is crimped into the cartridge case. Although the M-193 military bullet of the M16 rifle fragments in soft tissue wounds with a characteristic pattern depending on range,[15] most other full metal jacket military bullets, such as those fired from the AK-47, AK-74, and the NATO 7.62-mm rifle (US version), do not fragment unless they strike a large bone.

If a bullet is jacketed, the bullet jacket usually cannot be distinguished from the lead core on standard radiographs, because the entire bullet is metallic density. Occasionally, as the bullet deforms or fragments, the bullet jacket separates from the bullet and is visible on a radiograph.

In extremity wounds, when a radiograph reveals an undeformed bullet lying in the soft tissues and no fracture is present, tissue disruption is usually minor. If a major vessel or nerve is divided, however, even a simple wound can have a severe effect.

Wounding is like real estate: location is the most important factor. A bullet of low wounding potential can cause a severe wound if it passes through a vital structure such as the spinal cord.

Temporary Cavitation (Tissue Stretch)

Fired from an appropriate and well-designed weapon, a bullet flies in air with its nose pointed forward; it yaws only 1° to 3°. Yaw occurs around the bullet's center of mass. In pointed rifle bullets, the center of mass is behind the midpoint of the bullet's long axis. Although the bullet's most naturally stable in-flight orientation would be with its heaviest part (its base) forward, for aerodynamically efficient flight it must fly point forward.

During flight, a bullet is stabilized against yaw by the spin imparted to it by the spiral grooves (rifling) in the gun barrel. The longer (and heavier) the bullet in relation

to its diameter, the more rapidly it must be rotated to avoid significant yaw in flight. A gun barrel intended to fire a heavier bullet has rifling that makes a full turn in fewer inches of barrel length than the rifling in a barrel intended for a shorter, lighter bullet of the same caliber. This will cause a faster rate of bullet spin.

A gun with a shorter barrel will generally produce a bullet of lower velocity than would a weapon with a longer barrel when firing the same round. With shorter barrel length, the expanding gasses of the burning gunpowder have less time to accelerate the bullet before they are discharged into the atmosphere. A .22 long rifle round fired in a rifle will produce a bullet with up to 300 ft/s more velocity than would the same round fired in a handgun.

Although the bullet's spin is adequate to stabilize it against yaw in its flight through air, it is not adequate to stabilize it in its path through tissue, because of the higher density of the medium. If it does not deform, a pointed bullet eventually yaws to a base-forward position (180° of yaw). Expanding bullets lose the physical stimulus to yaw because, after mushrooming, their heaviest part is forward.

As a bullet passes through 90° of yaw or after it deforms into a mushroom shape, it is crushing its maximal amount of tissue (unless it fragments, which will crush more). It is slowed down rapidly, as its wounding potential is used up. The bullet creates a splash-type force in tissue, which spreads out radially. This force creates the temporary cavity. This aspect of the wounding process is analogous to the splash of a diver entering the water.

If a diver enters the water very straight and point forward (similar to a bullet at 0° of yaw), the splash may be minimal. If the diver does a belly flop (similar to a bullet at 90° of yaw), a large splash is induced. In tissue, this splash, the temporary cavity, produces localized blunt trauma. [9]

The maximal size of the temporary cavity occurs several milliseconds after the bullet has passed through the tissue. Because forces follow paths of least resistance, temporary cavitation is likely to be asymmetric and spread out through tissue planes.

The temporary cavity caused by common handgun bullets is generally too small to be a significant wounding factor in all but the most sensitive tissues (brain and liver). Center-fire rifle bullets and large handgun bullets (e.g., .44 magnum), often induce a large temporary cavity [10- to 25-cm (4- to 10-in) diameter] in tissue. This can be a significant wounding factor, depending on the characteristics of the tissue in which it forms.

Near-water-density, less elastic tissue (such as brain, liver, or spleen), fluid-filled organs (including the heart, bladder, and gastrointestinal tract), and dense tissue (such as bone) may be damaged severely when a large temporary cavity displaces them or forms within them. More elastic tissue (such as skeletal muscle) and lower-density elastic tissue (such as lung) are less affected by the formation of a temporary cavity. [16,17] Because of these tissue differences, transmitted blunt trauma from temporary cavitation caused by a bullet traveling 800 to 950 m/s can cause a more severe pulmonary contusion when the bullet traverses the chest wall musculature than the pulmonary contusion it would have caused if passing through the lung. [17]

Although the formation of a large temporary cavity often has devastating effects in the brain or liver, its effect in wounds of the extremities has frequently been exaggerated.[18] Fracture of large bones not hit by the bullet and tearing of major vessels or nerves by the temporary cavity are often mentioned in the literature but are rare in clinical experience. This includes a systematic review of 1400 rifle wounds sustained in the Vietnam conflict and analyzed in the Wound Data and Munitions Effectiveness Team (WDMET) study (R.F. Bellamy, personal communication). Most of the permanent damage done in wounds of the extremities is the result of structures being hit by the intact bullet, bullet fragments, or secondary missiles. As in all blunt trauma, shear forces develop and tear structures at points where one side is fixed and the other side is free to move. The temporary cavity is no exception. In the unlikely event that the blunt trauma caused by the temporary cavity tears a vessel wall, this is particularly likely to occur at the vessel origin.

BALLISTIC PROPERTIES AND THE WOUND PRODUCED

Animal experiments using military-rifle bullets[9] have clearly disproved the assertion that all tissue exposed to temporary cavitation is destroyed. Not only does the 14-cm diameter temporary cavity produced by the AK-74 not destroy a great amount of muscle, but the sizable stellate exit wound it causes in the uncomplicated thigh wound ensures excellent wound drainage, which assists healing. [9,16] A history that the wound was caused by a high-velocity bullet does not mandate radical excision of the wound path.[16,18]

The characteristics of the wounded tissue, the thickness of the body part, the point in the path of the bullet at which deformation into a mushroom shape, yaw or fragmentation occurs, and other factors strongly influence the wound produced.

Experiments with ballistic gelatin (which reproduces the projectile deformation and penetration depth of living animal muscle) have shown that most full metal jacketed rifle bullets yaw significantly only at tissue depths greater than the diameter of human extremities.

In the first 12 cm (the average thickness of an adult human thigh) of a soft tissue wound path, there is often little or no difference between the wounding effect of low- and high-velocity bullets when the high-velocity bullet is of the military full metal jacket type. This is particularly true of the relatively heavier military-rifle bullets such as those fired by the AK-47 and NATO 7.62-mm (USA version) rifle. A wound of an extremity caused by an AK-47 bullet that does not hit bone is often similar to a handgun bullet wound. No matter how high its velocity, if a non-deforming, heavy bullet does not break, fragment, or hit a large bone, it may exit an extremity with much of its wounding potential unspent. These same bullets are often lethal in chest or abdominal wounds because the trunk is thicker than an extremity and allows the bullet a sufficiently long path through tissue to yaw. Maximal temporary cavitation induced by the AK-47 bullet usually occurs at a tissue depth of 28 cm, much greater than the diameter of a human extremity.

A soft-point or hollow-point bullet fired from a civilian center-fire rifle deforms soon after entering tissue and produces a much more severe extremity wound than will a military full metal jacket bullet that does not break and fragment.

The more recently developed, smaller-caliber, AK-74 fires a bullet that is lighter than the AK-47 bullet and yaws earlier. [19] Its maximal temporary cavity occurs at a tissue depth of 11 cm. Extremity wounds from the AK-74 can be expected to be more severe than those from the AK-47.[19] The lighter, smaller AK-74 round allows a soldier to carry many more rounds of ammunition. This was the primary motivation for development of the M16 and the AK-74.

Caliber

Caliber (bullet diameter in decimals of an inch or in millimeters) is only one indicator of wounding potential but not a very good one (Fig. 256-1). Caliber indicates bullet diameter, but not bullet length, and therefore does not disclose bullet mass. Caliber also is independent of bullet velocity and bullet construction.

Unfortunately, commonly used weapon and bullet designations are often misleading. As an example, the .38 special and the .357 magnum use bullets that have the same diameter [.357 in. (9.07 mm)] (Table 256-1). The longer cartridge case of the magnum can hold more powder, giving the bullet higher velocity and greater wounding potential.

TABLE 256-1   Cartridge Case Name and Actual Bullet Diameter Used

Gunshot Fractures

Handgun wounds of the extremities yield characteristic fracture patterns. Frequently seen are divot fractures of cortical bone, drill-hole fractures, butterfly fractures, and double butterfly fractures.[8] Nondisplaced fracture lines sometimes radiate from these defects. These usually heal well. The bullet hole itself can act as a stress riser. Spiral fractures extending proximally or distally from the bullet hole may result from the dissipation of stress forces at the bullet hole. Occasionally, remote spiral fractures at some distance proximal or distal to the bony gunshot wound also occur, probably because of the presence of stress risers, such as vascular channels in the bone, and the fact that the bone was under load and often torsional stress at the time of impact.[20]

In gunshot fractures from rifles and large handguns, a greater extent of comminution may be seen. These fractures often have complications because of the soft tissue damage these bullets cause.[8] The vascular compromise associated with these comminuted gunshot fractures increases the likelihood of delayed union or nonunion of the fracture. Wound infections are more common in this group. Early fasciotomy to prevent compartment syndrome is important, when needed.

At some hospitals, outpatient treatment is being used successfully for extremity fractures caused by handguns, if no significant neurologic or vascular compromise has occurred.[21]

Trunk Wounds

Bullets are not sterilized by the heat of firing. They can carry bacteria from the body surface or body organs, such as a perforated colon, deep into the wound.

In trunk wounds, an analysis of the bullet path is mandatory to determine whether a laparotomy is needed. Two radiographs in planes separated by 90°, computed tomography (CT), clinical examination, and peritoneal lavage are all useful. Abdominal CT is more accurate if performed before peritoneal lavage. If peritoneal penetration by a bullet is suspected, laparotomy is indicated.[22] The morbidity and mortality rates of an exploratory laparotomy that shows no significant intraabdominal injury are low compared with those of missed intestinal injury. CT is useful, especially when an exclusively body wall or retroperitoneal path is suspected. CT has largely replaced excretory urography as the preferred means of evaluating the urinary tract after penetrating trauma.

Any bullet wound below the nipple line should raise the question of whether the diaphragm or abdomen has been penetrated. CT sometimes can be used to make this determination. Laparotomy is required if peritoneal penetration cannot be excluded.[22]

Whenever a gunshot wound traverses the midline of the neck or the width of the mediastinum, perforation of the esophagus should be suspected. Esophageal evaluation should not be overlooked after angiographic evaluation of the neck or chest.

Head Wounds

In skull wounds, as elsewhere in bone gunshot fractures, inward beveling of the calvarial defect at the bullet entrance and outward beveling of the skull at the exit wound are typical.[23] This is due partly to the geometry of the skull and partly to the bullet-bone interaction. Characteristic fracture patterns of the skull can be used to identify entrance and exit wounds.[23] When there is a cranial exit wound, skull fractures propagate across the calvarium faster than the bullet travels through the brain, producing characteristic patterns of fracture. These fracture patterns sometimes allow differentiation of entrance and exit wounds.[23] Radial fractures often spread out in a star pattern from the entrance and to a lesser extent from the exit holes in the skull. Concentric heaving fractures may occur, connecting the arcs of the radial fractures around both the entrance and exit holes, if sufficient temporary cavitation forces are generated inside the brain to cause significant outwardly directed tissue splash forces inside the skull, pushing out the calvarium.[23] Because a fracture will not cross a preexisting fracture line, the temporal sequence of the occurrence of the fractures can sometimes be determined from the pattern of the fractures.

Brain, whose tissue properties include near-water density, very little elasticity, and poor tissue cohesiveness, is extremely sensitive to temporary cavitation forces. When disrupted by such forces, severe brain injury often results. In addition to the relative lack of elasticity of brain tissue, its enclosure in the rigid cranial vault magnifies brain disruption by temporary cavitation forces.

Pellet Wounds

Compared with a pointed rifle bullet, spherical pellets slow rapidly in its flight through air or tissue. In tissue, the entire wounding potential of a shot pellet at its entrance velocity is likely to be delivered to the target, often with no exit wound. At close range (less than 3 m), shotgun pellets remain tightly clustered. Therefore, shot pellet size makes little difference, as the entire load of the pellets functions as a unit, with a velocity virtually equal to muzzle velocity. Shotgun wounds at ranges of less than 5 m consist of multiple parallel wound channels. This grossly disrupts the blood supply to tissue between the wound channels.

The most severe civilian firearm wounds typically seen are those inflicted by a shotgun from close range. After a close-range or contact shotgun wound to the trunk, external examination of the patient, particularly after adequate volume resuscitation, often does not disclose the severity of the internal injuries present.

Major neural injury after shotgun wounding of the extremities may be more important than fracture or major vascular injury in determining the final outcome.[24]

During surgical exploration of a close-range shotgun wound, it is important to search for wadding, casing debris, plastic shot cup, and surface materials carried into the wound (e.g., clothing, glass, or wood). Many of these are radiolucent.[8]

Diagnosing long-range injury on the basis of the pattern of pellet spread is sometimes problematic. When shotgun pellets are tightly clustered or widely spread out, close-range injury or long-range injury (respectively) is usually suspected. However, in close-range injuries, the *"billiard ball" effect* may cause considerable pellet spread.[25] When the tightly clustered group of shot at close range contacts the skin, the pellets at the front of the group are slowed. The pellets behind them in the group strike the pellets in front with an effect like a billiard ball break. This causes much more pellet spread in tissue than would be expected at close range. On radiographs, particularly in trunk wounds, this effect can simulate the pellet spread of a longer-range injury.[25] This pitfall can be avoided if the skin physical examination is correlated with the radiologic findings. If there is only one entrance wound hole, it is a close-range injury. If the distribution of the multiple skin entrance wounds is the same as the pellet spread on the radiograph, the injury occurred at longer range.

Recently manufactured BB guns and air guns that fire small pellets have considerably higher muzzle velocity [600 ft/s (183 m/s) or more] than older guns of this type. Penetrating injuries from these weapons are sometimes fatal. These air guns should not be considered toys. It is possible for someone to have been shot with a BB pellet that has penetrated the scalp, skull, and brain and think only a scalp wound is present.[26]

ASSESSMENT OF MISSILE TYPE AND LOCATION IN THE BODY

As in all of radiology, localization requires two views at 90°, or a tomographic image. CT of the head and body is often useful for analysis of bullet path.[8]

The CT digital scout radiograph, which can be used for missile localization, usually can be taken in anteroposterior and lateral projections without moving the patient. The ability to manipulate the display window and center enables visualization of bullets seen through dense structures, such as the shoulders and pelvis.

Assessment of Missile Type

On a radiograph, assessment of missile caliber is difficult because of magnification and missile deformation. If an undeformed bullet is seen in two views at 90°, and its degree of magnification is known, the approximate caliber of the bullet can be determined. Some bullets are difficult to distinguish because the diameter is similar to others (Table 256-1). Sometimes deformed bullets can be accurately characterized radiologically for intact bullet caliber and weight. [27]

Many radiographs show only fragments of the bullet and do not enable determination of the type of weapon and projectile that caused the wound. However, certain bullets deform or fragment in a characteristic pattern (such as the M16 military bullet, the Winchester Black Talon or SXT handgun bullets, and the .357 magnum 125-grain Remington semijacketed soft-point bullet) that can be used to identify them. Deformation of large lead shotgun pellets (e.g., 00 buckshot) after contact with bone can cause these to be confused with deformed bullet fragments.

MISSILE EMBOLIZATION

It always must be ascertained that the path from the entrance wound is consistent with the bullet's current location, because a bullet may have reached its present location by embolization. Arterial and venous embolization of bullets and shotgun pellets, as well as bullet movement within the subarachnoid space in the head and spine, have been reported. It is generally accepted that a missile freely floating within a cardiac chamber should be removed to prevent embolization. [28] Missiles clearly embedded in chamber walls are relatively safe. [28] Missile size does not seem to be especially important, as all sizes can produce morbidity after embolization. Two-dimensional echocardiography is useful in determining whether a missile is embedded in a chamber wall. [28] CT (particularly high-speed CT) and magnetic resonance imaging for nonmagnetic missiles also have a role. On chest radiographs, blurring of the margins of a pericardiac missile or fragment is a reason to suspect that the missile is in or next to the heart. [25]

Whenever a bullet is not found on radiographs of the body part predicted based on the entrance wound, the bullet's location is not known, and there is no exit wound, additional radiographs or fluoroscopy to find the bullet are mandatory. Immediately before surgery for missile removal, repeat radiographic confirmation of the exact location of the missile is usually indicated.

Interventional radiologic techniques are useful in bullet removal, including the removal of intravascular and intrarenal bullets. Significant deformation of an intravascular bullet is a relative contraindication to retrieval using a transarterial catheter because of potential damage to the intima. Arthroscopy sometimes can be used for removing bullets from joints, especially the knee.

Most bullets follow straight paths through the body, but sometimes, even in the absence of embolization, a bullet, particularly a handgun bullet, will not. It may ricochet off body structures, especially bone, or may follow fascial or tissue planes. Bullets traveling less than 1100 ft/s (335 m/s) are the ones most likely to be deflected by anatomic structures or to follow tissue planes. Bullet shape also influences the tendency to be deflected.

Far more common than bullet displacement by embolization from where it came to rest in the body at the end of its path is bullet movement due to the effect of gravity on a bullet that ends up free in the pleural space or peritoneal cavity.

LEAD FRAGMENTS AND LEAD POISONING

Lead fragments in soft tissue usually become encapsulated with fibrous tissue and do not cause problems. Bullet-induced lead poisoning is most common with intraarticular, disk space, and bursal locations of bullet fragments because of the solubility of lead is synovial fluid. [29,30] Lead fragments in the brain are usually relatively benign unless they are copper plated (as are many civilian .22 caliber bullets). [31] Copper-plated lead pellets produced a sterile abscess or granuloma in the brain of cats surgically implanted with missiles of this type. [31] This can be associated with downward migration of the missile, resorption of copper from the surface of the missile, progressive neurologic deficit, and sometimes the death of the cat. These findings were absent in cats whose brains were implanted with uncoated lead pellets.

Intraarticular fragments should be removed to avoid both the mechanical trauma and the destructive synovitis lead can cause. [29] Significant damage to the articular cartilage visible at surgery may be present as a result of lead synovitis, when radiographs remain normal except for bullet fragments. [29] If large fragments are present in the joint, they can cause severe mechanical trauma during motion. This motion can lead to further lead fragmentation.

Whether lead poisoning occurs depends largely on the surface area of the retained lead particles and their location in the body. [30] Sometimes the onset of clinical lead poisoning can be quite rapid, but usually it takes years.

Patients with retained lead pellets or lead bullet fragments should be advised that, on rare occasions, a fragment might erode into a bursa or joint space and cause lead poisoning. They should be assured that lead poisoning poses a threat *only if unrecognized and untreated.* They should be cautioned to inform their physician of the retained lead any time they seek treatment for problems such as headache, abdominal pain, personality change, or bizarre neurologic symptoms. Once the possibility of lead poisoning is considered, it can be easily confirmed or ruled out simply by determining the blood lead level.

EVIDENTIARY CONCERNS

Physicians must be aware of the importance of preserving evidence in patients being resuscitated after penetrating trauma. Do not cut through bullet holes or knife holes in clothing when removing it. Do not incise through skin wounds unless absolutely necessary. To preserve powder marks, do not scrub wounds unless necessary. Emergency departments must have a protocol for collecting clothing and other evidence so that it can be documented that it was always under surveillance or otherwise kept in such a way that tampering could not occur. Do not describe wounds as entry or exit wounds; instead, describe the appearance of wounds in detail, without interpretation. Describe the location, size, and shape of all gunshot wounds. Include the presence or absence of a soot ring, or skin or subcutaneous tissue tattooing with gunpowder, or the presence of subcutaneous gas (such as from a contact wound with injection into the subcutaneous tissues of gases from burning gunpowder). When a bullet or fragment is encountered, do not pick it up with a metallic clamp, so ballistic markings can be interpreted without the possibility that marks were made later with a surgical instrument. Prehospital personnel should receive similar instruction relative to preserving evidence at the scene. The history of the episode can be useful if the number of shots fired or the position of the victim relative to the assailant was observed.

The sharp bullet jacket edges that some soft-point and hollow-point handgun bullets have when they are deformed into a mushroom shape should be avoided. Infectious diseases such as hepatitis and HIV can pass from the victim to the health-care provider as a result of skin punctures from these sharp edges.

Some emergency medicine residency programs now include a course in forensic medicine. [32]

257 FORENSICS

John E. Smialek

State laws and standard medical practices obligate physician/health care providers in the emergency departments (EDs) to serve as an interface between patients and the state within the context of the legal and justice systems. To comply with these additional responsibilities, physicians must be aware of legal obligations and must be able to recognize patterns of injury. Observations must be appropriately documented and evidence must be processed in a manner consistent with legal standards.

Each ED should provide its physicians with a standard protocol for responding to state-imposed legal responsibilities such as reporting requirements. As an example, all states impose an obligation to report certain types of injuries to state social services or law enforcement agencies. Generally, these reporting requirements are centered around the vulnerable patients such as children, the elderly, and other victims of domestic violence. Reporting laws for other types of injuries vary from state to state. There may be obligations to report gunshot wounds, knife wounds, assaults and burns.

The physician must also take a proper history from the patient and other reporting witnesses, which must include a statement regarding the origin of the injury. These statements must be documented verbatim for several reasons. Firstly, they may be self-serving and the explanation may change upon subsequent reflection. Secondly, such statements are of legal significance and are admissible in subsequent legal proceedings where they will be analyzed in minute detail.

In addition to obtaining this initial history, the physician must also provide a physical examination of the injury and documentation of that examination before the injury is altered by healing or medical treatment. The physical examination should be supplemented by other diagnostic and documentary tools, such as x-ray. The legal significance of injury assessment also warrants documentation of the injury by photograph. Therefore, an autofocus, Polaroid, or digital camera should be standard equipment in every ED. The newer digital cameras may also suffice but may be more prone to accusations of computer alteration.

PATTERNS OF INJURY

Classification

Injuries may be classified in a variety of ways. Mode of production is one method that includes blunt force, sharp force, missile, heat, electricity, and chemicals. Injuries may also be categorized according to the circumstances in which they were inflicted. Such circumstances are accidental, suicidal or homicidal. Wounds may also be characterized as surgical or ritual, depending on the setting in which these wounds are sustained. However, the most useful classification is based on the components of the injury pattern. Injuries consist of one or a combination of several of the following types of tissue damage:

1. Abrasion
2. Bruise (ecchymosis)
3. Contusion
4. Laceration/tear
5. Stab/cut
6. Bite
7. Burn
8. Missile penetration
9. Strangulation

Abrasion

An *abrasion* is the damage inflicted on the superficial layers of the skin (epidermis) by friction or pressure. An abrasion may be sustained by sliding on a rough carpet, producing what is commonly called a *rug burn*. A much more extreme version of an abrasion is the injury produced when a pedestrian is knocked to the pavement by an automobile, sustaining extensive friction injuries to the skin on various parts of the body. These injuries are commonly called *road burn* or *road rash*. While abrasions may be lacking in specific detail to allow an instrument of causation to be identified, some abrasion patterns may be very specific. These may include the abrasions resulting from a rope used as a ligature around the neck or extremities and rubbed against the skin, called *ligature marks*. Abrasions can also be caused by the irregular surface of the shoe sole or by an electrical cord used as a whip (Fig. 257-1).

FIG. 257-1. Abrasion caused by electric cord.

Bruise (Ecchymosis)

An *external bruise* represents bleeding beneath the skin. If sufficient bleeding occurs to create a lump, this is called a *hematoma*. Such injuries result from direct force applied to the skin surface, resulting in the tearing of subcutaneous blood vessels. The pattern of bleeding may be circular, surrounding a central bleeding point where the blow has stretched and torn a blood vessel wall. When multiple blood vessels are torn because of the use of a specific instrument, the bleeding pattern may

conform to the outline of that instrument. For example, a blow inflicted with a human fist can produce multiple circular bruises in a pattern that conforms to the tips of the knuckles (Fig. 257-2). Similarly, pressure from fingertips such as occurs when someone grabs another by the arm may produce around of circular oval bruises. In contrast, a strike with a police baton can produce parallel linear bruises conforming to the diameter of the baton (Fig. 257-3).
FIG. 257-2. Bruise pattern from knuckles.
FIG. 257-3. Parallel linear bruises from police baton.

Contusion

When sufficient force is applied to the surface of the body, the combination of friction or pressure and tearing of underlying blood vessels produces a bruise with an overlying abrasion. The term commonly used for this injury pattern is *contusion*, although some individuals use it interchangeably with bruise. Contusions as well as bruises have different appearances, depending on the pigmentation of the person's skin and the age of the injury. A bruise or contusion that is dark red or purple with well-defined margins is consistent with having been inflicted less than 48 h prior to examination. In contrast, a bruise or contusion that is yellow or brown or whose margins have begun to fade is certainly older than 48 h.

Laceration/Tear

A *laceration* is a tear of the skin. Depending on the amount of force used, the tear may be confined to the dermis or may extend through the full thickness of the skin. An example of an injury confined to the dermis is overstretching (Fig. 257-4). A full-thickness laceration extends into the subcutaneous tissue. When the injury is examined, *bridging* by intact blood vessels may be evident (Fig. 257-5). The resilience of elastic walled structures, such as arteries, allows them to maintain their integrity despite a blunt-force impact that tears the adjacent skin.

FIG. 257-4. "Overstretching" type laceration confined to the dermis.

FIG. 257-5. Full thickness laceration with "bridging by intact blood vessels.

Because a laceration is usually the result of a crushing force, the margins of the laceration will show the effects of the pressure crushing the epidermal layer or skin surface. Depending on the instrument causing the injury, a specific imprint may be evident when the margins of the laceration are reapposed. A laceration can also be called a tear but should never be called a cut, which implies the application of something other than blunt force. A common type of laceration occurs in protuberant areas of the body such as the elbow, knee, or eyebrow, where a fall against a hard surface such as a floor or pavement may result in the crushing of the skin against the underlying bone. Because the crushed skin margins may be nonviable, simple suturing of such a laceration without debridement will not result in healing by first

intention.

Since lacerations often result from contact with a foreign object, residue from this object may be left within the wound. Recognition and recovery of particles of concrete, brick, or sand may be very helpful in the determination of whether an injury resulted from impact with an object such as a rock or the butt of a handgun (Fig. 257-6). This information should be included in the description of the injury.
FIG. 257-6. Revealing pattern suggesting that injury was caused by butt of a handgun.

Stab/Cut

A *stab* or *cut* is an injury inflicted on the skin by contact with a sharp object. Knife blades, shards of glass, and fragments of metal can penetrate the skin and leave a cutting pattern that will vary depending on the movement of the injured party and the object causing the injury. The sharp edge of these objects severs structures in the skin, leaving no evidence of bridging such as that seen in lacerations. Depending on the shape of the sharp object, the cut edges will be abraded accordingly while the ends of the wound may be squared or pointed (Fig. 257-7). Unique abrasions found around a stab wound may represent the effect of the hilt of a knife blade striking the skin (Fig. 257-7). Examination of the stab-wound track may reveal particles of the offending weapon, and such particles should be retained as evidence to assist in the identification of a weapon. The location of specific stabs or cutting wounds may suggest the manner in which they were inflicted. For example, cuts or stabs on the inner (volar) side of the wrist or forearm are consistent with efforts of individuals trying to protect themselves from an assailant by raising their arm in front of their body in a defensive posture. These are called *defense wounds* by forensic pathologists.
FIG. 257-7. Abrasion and bruise around periphery of stab wound suggesting cause is blunt trauma from hilt of a knife blade.

To properly evaluate the wound characteristics of cutting or stabbing wounds, the wound edges must be reapposed. The reapposition counteracts the effect of elastofibroretraction and allows the physician to observe the wound as it occurred. It also enables the physician to identify abraded margins as well as patterns of squared ends or pointed ends. A *squared end* results from the noncutting or blunt edge of a knife blade, whereas a *pointed end* results from contact with the sharp edge of a blade. The physician should use transparent tape to hold the edges of the wound together while the wound is photographed. This practice can be extremely valuable in the comparison of the wound with a suspected weapon (Fig. 257-8).
FIG. 257-8. Transparent tape applied over wound may aid in reconstruction and identification or verification of weapon.

Another example of a patterned abrasion injury is the one caused by fragments of automobile glass. These characteristic wound patterns in human skin can enable the physician to identify whether the glass causing the injury is from a windshield or side auto window. The side window consists of tempered glass that breaks into 5-mm cubes, causing right-angle cuts to the left side of the face of the driver of the vehicle sustaining a driver-side impact. They may also be found on the right side of the face of passenger of a vehicle sustaining a passenger-side impact (Fig. 257-9A). Recognizing these patterns and their location can be useful in establishing who was driving the vehicle at the time of the collision. Cuts from windshield glass are distinguishable from side impact injuries. Windshield glass, which consists of thin layers of laminated glass, breaks into tiny splinters that produce superficial, parallel, linear cuts (Fig. 257-9B).
FIG. 257-9A. Right angle lacerations from side window glass of car made of tempered glass that brakes into 5 mm cubes.
FIG. 257-9B. Linear lacerations and abrasions from windshield glass that brakes into tiny splinters.

Bite

Contact between human mouth and/or teeth and skin will leave evidence of the amount of force used in the contact as well as material (saliva) and/or teeth marks that can lead to the identification of the biter. Love bites or hickeys (suction injuries) result when there is extended oral contact with the skin of a partner involving sucking or biting. Hickeys are typically seen on the neck but may occur on any part of the body and usually exhibit no evidence of damage to the subepidermal layers, although discoloration from tissue fluid leakage may occur. On the other hand, *love bites*, and bites inflicted during a struggle, usually damage the dermis, leaving a partial or complete pattern of the dentition of the biter (Fig. 257-10). Not only can this bite pattern be used for comparison with the dental pattern of the suspect, but the recognition of the bite mark sustained during an attack should alert a physician to protect the skin surrounded by the bite pattern so that it can be swabbed to obtain saliva containing DNA material. A DNA profile can be compared with that of a suspect, providing almost 100 percent accuracy of identification. The most severe form of human bite is one that extends through the dermis into the subcutaneous tissue and results in the loss of blood. Thus, one can grade bite marks as first degree (mild), second degree (moderate), or third degree (severe). Using this grading system, a love bite would be considered in the mild category, whereas one similar to that occurring during a recent notorious boxing match as third degree (severe).
FIG. 257-10. Human bite revealing pattern of dentition.

Burn

Injuries of the skin resulting from contact with electrical energy, extreme heat, heated objects, or certain chemicals often exhibit characteristic patterns. For example, immersion of a child's buttock in 140°F (60°C) water will result in second-degree burns to the immersed skin. The resulting burn pattern will show a characteristic line of demarcation that represents the amount of skin immersed in the hot water (Fig. 257-11). Similarly, contact of the skin with electrical current can result in a central area of necrosis characteristically seen as black, charred tissue surrounded by a pale zone with a bright red peripheral margin.
FIG. 257-11. Characteristic line of demarcation secondary immersion burn injury seen in abuse.

Tremendous electrical force contained in a lightning strike may produce relatively little in the way of external evidence and may include only singeing of hair or slight charring of skin where contact occurs. An arborization or fernlike pattern of redness may be seen on the skin of fatally injured victims. A possible result of contact with a lightning strike is magnetization of certain metal articles on the victim's body.

Missile Penetration

The entrance wound of a skin penetration caused by a high-speed missile (such as a bullet) or a low-speed missile (such as an arrow) is circular, oval, or triangular, with a circumferential rim of abrasion. This abrasion pattern, produced by the friction sustained by the skin margins in contact with the missile, enables a physician to identify which hole is the exit and which is the entrance in a through-and-through gunshot wound. The outer skin edges of an exit wound do not come in contact with the missile and therefore do not sustain friction damage and do not exhibit this rim of abrasion. However, if a person is wearing tight clothing or the skin is resting against a hard, firm surface when the missile exits, the skin around the exit wound may be abraded from contact with this material. This produces a pattern called a *shored exit wound* (Fig. 257-12).
FIG. 257-12. Characteristic "shored exit wound," an abrasion pattern resulting from missile exit when skin is resting against a hard surface.

The presence of gunpowder residue surrounding a gunshot wound of the skin is a critical finding that needs to be described and documented with photographs before cleansing. The description of the distribution of the gunpowder residue, whether it consists of black smudging (soot) or stippling by particles of gunpowder, should include measurements with photographs. Wound photographs should always have a measurement scale in the field (Fig. 257-2). Clothing soiled with gunpowder residue must be protected and retained for collection by law-enforcement agencies for analysis in the crime lab. This type of evidence is used for determining the distance between the muzzle of the weapon firing the bullet and the injured party. Establishing this distance provides one parameter for evaluating the validity of accounts given by each of the parties as to the circumstances of the shooting. For example, one person may allege that there was a struggle and the gun was fired in self-defense, while the other person may say he or she was shot without threatening the shooter in any way.

Identification of the site of the entrance and exit of a gunshot wound path is an important step in the reconstruction of the shooting incident. When these incidents are not fatal, legal action often results, leading to a dispute over the accuracy of accounts given by each of the two parties: the injured party and the shooter.

Physicians without forensic training should avoid giving any opinion regarding a wound being an entrance or exit, or whether it was caused by firing at close range or a distance, or whether any type of activity or movement occurred during the shooting or what type of ammunition was used. Rather, physicians should document in as much detail as possible the information set out above for evaluation by those expert in this area.

Strangulation

Attempts to injure or kill a person by strangulation using one's hands, a ligature, or forearm, in a choke hold, may result in skin damage to the neck. For example, in manual strangulation, multiple bruises and scratches typical of contact with hands and fingernails will be seen on a victim's neck. On the other hand, if a ligature is forcefully wrapped around a victim's neck, a band of abrasion approximating the diameter of the ligature will be seen on the skin. Pinpoint hemorrhages, or petechiae, which are dramatically evident in the translucent conjunctival lining of the eyes, are important evidence of strangulation. These hemorrhages, which are the result of ruptured capillaries, occur when the buildup in pressure occurring when venous return from the head and face is obstructed. Since a period of 4 min is required for compression of the blood supply of the brain to result in irreversible neuronal damage and death, it is not surprising that so many attackers let go of their victim before death has occurred. If other force such as shooting, stabbing, or beating is not used, a victim may survive strangulation and appear in the ED, with evidence of neck injury and petechial hemorrhages in the eyes. Such victims should be examined for evidence of sexual assault, and vaginal swabs should be taken for identification with semen and DNA analysis.

The foregoing categories of injuries represent those most commonly seen in a trauma unit or a medical examiner office. However, readers who wish to become more familiar with the variety and details of injury are referred to several informative forensic medicine texts available in the medical library.

MEDICAL RECORDS

When an injury becomes the subject of a legal proceeding, the medical record documenting that injury and its subsequent treatment becomes a central part of the court deliberations, which may include obtaining testimony from the physician that created that record. The defendant or the accused is entitled to cross-examine that physician to establish or refute the validity of the medical information presented to the court. Physicians must recognize the legal responsibility that society places on them and be prepared to provide competent, professional testimony when required. The proper documentation of injuries includes the description of the details previously specified under *wound pattern*. The use of anatomic diagrams, together with photographs, makes the record more representative of the injuries as a physician saw them and more understandable by the lay members of a court. These items (charts, diagrams, and cameras) should be essential equipment in an ED, and photographs should become part of the permanent medical record.

PRESERVATION AND COLLECTION OF EVIDENCE

Preservation of blood samples, missiles, and debris found in wounds may be extremely valuable in identifying a particular weapon and tying this weapon to an assailant. However, this evidence is useful only if a proper chain of custody has been established. In handling such evidence, EDs should follow a protocol developed in consultation with the local law-enforcement agency. The use of a simple envelope that enables a physician to identify the patient, the date the evidence was recovered, where it was recovered from, and to whom it was given, and signed by the physician is adequate for establishing the chain of custody. Use of an appropriate receipt form documenting the transfer of this evidence should be an essential part of the medical record.

REPORT OF DEATH

This chapter has been confined to those issues relevant to the assessment of living patients. However, another important responsibility of the emergency physicians is that of notifying the local law-enforcement agency or medical examiner or coroner of a death that constitutes a medical examiner or coroner case.

Statutory language identifies those deaths that require an investigation by a medical examiner/coroner of the circumstances of the death. This enables one to determine whether an autopsy is necessary, which can then be carried out under the same statutory authority. Such deaths are generally those of individuals who die suddenly while not under the immediate care of a physician and any death associated with some type of injury, and usually include a category of any suspicious or unusual death. It should be emphasized that the length of time a patient has been in hospital, or the age of an injury associated with the underlying cause of death, is not a factor in determining whether the death should be reported to the medical examiner/coroner.

For example, the death of a person who sustained paraplegia from a gunshot wound of the back remains a medical examiner case despite the many medical procedures and complications that result from such an injury—even when many years have passed and the victim has died of a complication of paraplegia, such as a chronic urinary tract infection. The evidence of gunshot injury together wtih the medical treatment and any other intervening events leading up to the eventual death need to be assessed by the medical examiner/coroner. If a chain of events exists, leading from the gunshot wound to the immediate cause of death, then the manner

of death would be determined to be homicide.

INTRODUCTION

Injuries account for about one-fourth of emergency department (ED) visits and they are the most common cause of death for Americans ages 1 to 44.[1] Because injuries disproportionately affect the young, they account for more years of potential life lost before age 65 than all causes of cancer and heart disease *combined.*

Epidemiological research shows that injuries, like diseases, tend to affect identifiable groups, follow an often predictable chain of events, and therefore are preventable. After an injury occurs, morbidity can be minimized by providing optimal acute care and subsequent rehabilitation. This combination of strategies—prevention, acute care, and rehabilitation—is called *injury control.*

A PUBLIC HEALTH APPROACH

William Haddon developed the classic approach to injury control by identifying the three principal factors of injury (host, vehicle, and environment) and subdividing each factor by the three temporal phases of an injury event: pre-event; the event itself; and the postevent phase. This resulted in a "phase-factor" matrix of nine discrete cells.[2] Examining these cells can suggest various strategies to prevent or control injuries. Since its introduction in 1972, the Haddon matrix has proven to be an invaluable tool for injury control.

Haddon outlined 10 generic injury-control strategies that can be utilized to break the chain of injury causation (Table 258-1).[3] Examining this list to identify promising approaches to injury control is known as *options analysis.* Certain options lend themselves more easily to one class of injuries than others. The best injury control option is not always the most obvious. Often a combination of approaches is superior to any single strategy.

TABLE 258-1   Options Analysis: Strategies with Examples, for Injury Control

The Injury Control Model

More than a century after yellow fever was controlled by targeting the vector of transmission, Haddon's work demonstrated that many injuries can be controlled by broadening our traditional emphasis on acute care and rehabilitation to include *preventive* efforts. Injury control draws on the expertise of many disciplines, including epidemiology, prevention, biomechanics, acute care, rehabilitation, law, and public administration. Prevention is attempted whenever practical. When prevention is not enough, acute care can minimize further damage from major trauma. After the victim is stabilized, long-term outcomes can be enhanced by optimal rehabilitation.

Haddon's approach was first applied to great effect in the control of deaths and injuries due to car crashes. Prior to his work, the Federal government poured millions of dollars into costly and largely ineffective media campaigns directed to the driver. Little progress occurred until the National Highway Traffic Safety Administration mandated changes in the design of motor vehicles, as well as the creation of safer roadways and driving environment. (See "Engineering" below.)[4]

These efforts produced one of the greatest public health achievements of this century. While the number of vehicle miles traveled in the United States has risen annually, today's crash fatality rate is less than one-third that of 1950. If the United States had not launched and maintained its highway traffic safety initiative, the annual toll of motor vehicle crash-related deaths, injuries, and costs would be thousands of lives and billions of dollars higher than it is today.

PREVENTION STRATEGIES

Active and Passive Countermeasures

Active countermeasures require the conscious cooperation of the individual. Examples include manual safety belts, motorcycle helmets, and child safety seats. *Passive* countermeasures, on the other hand, require little or no cooperation. Examples include air bags, automatic sprinkler systems, and spring-loaded kill switches on lawn mowers. In general, the less a countermeasure relies on user initiative, the more likely it will provide protection when needed. When used, manual safety belts reduce the risk of death in a car crash by 45 to 55 percent. However, they are effective only when buckled by the user. In contrast, air bags deploy in serious crashes virtually 100 percent of the time.

Education

Education is generally the first approach taken to encourage the public to accept an active countermeasure of proven efficacy. Implicit in its approach is the belief that once people are taught what to do, they will change their behavior and reduce their risk of injury. Driver's education programs, child pedestrian training, and bicycle helmet campaigns are examples of this strategy.

Although these campaigns are popular and attract large numbers of volunteers, they rarely result in sustained behavior change. One study evaluated the impact of a $78 million federal "alcohol safety action program." Although it was launched in dozens of communities around the United States, subsequent evaluation revealed that the program did not reduce the rate of alcohol-related fatalities in the target population. [5]

Robertson and colleagues evaluated a saturation advertising campaign promoting safety belts in one city served by two cable systems. One system aired over 1000 high-quality promotional spots; the other aired none. Subsequent observation revealed no difference in rates of safety belt use among subscribers of either system. [6]

Not all public education efforts have yielded such discouraging results. A large-scale community action campaign promoting bicycle helmet use in Seattle, Washington produced sharp increases in helmet sales. Observed rates of helmet use among school-aged children increased from 5.5 percent in 1986 to 40.2 percent in 1992. More importantly, head injuries that came to medical attention decreased by approximately two-thirds in this age group. [7]

The impact of many public education campaigns is blunted by *attenuation of effect.* No matter how powerful, pervasive, and repetitive a safety message may be, there are always some who never encounter it. Among those who see or hear the message, some actively reject it. Some are not sufficiently motivated to change their behavior. Among those changing their behavior, some relapse into old habits over time. Others fail to follow the message on a consistent basis. Finally, not everyone who adopts a protective strategy escapes injury.

Educational interventions may be enhanced by incorporating theoretical models that include important determinants of individual behavior. [8] These include a number of personal, community, and political factors. The PRECEDE health promotion model has been used with some success in planning injury prevention programs. [9] PRECEDE is an acronym for *predisposing, reinforcing,* and *enabling causes* in *educational diagnosis* and *evaluation.* Predisposing factors are characteristics of a patient, consumer, or community that motivate behavior. Reinforcing factors are rewards or punishments that are anticipated or follow as a consequence of these behaviors. Enabling factors are environmental characteristics that facilitate or hinder injury-prevention behaviors. This framework has been successfully used to assess educational needs and select appropriate strategies to encourage car seat-belt use and prevent motor vehicle injuries. [10]

Enforcement

Unfortunately, young males (the group that experiences the highest rates of serious injury) often resist behavioral change. When voluntary acceptance of a countermeasure of proven effectiveness is poor, compliance can be increased by making the countermeasure compulsory. The impact of "mandatory use" laws can be impressive. A study of Michigan's child safety seat law revealed that injuries declined 25 percent after passage of the law. [11] The 55-mph speed limit was estimated to have saved 2000 to 4000 lives annually. Raising the minimum age to purchase alcohol in 26 states decreased nighttime fatal crashes by an average of 13 percent. [12] After Victoria, Australia enacted legislation to make bicycle helmet use compulsory for all cyclists, rates of helmet use rose from 31 to 75 percent. During the same period, the number of insurance claims from bicyclists killed or injured after sustaining a head injury decreased by 70 percent. [13]

Community education and visible enforcement are needed to obtain maximal benefit from mandatory use laws. In Elmira, New York, an enforcement and publicity campaign promoting the state's seat belt law boosted compliance rates from 49 to 77 percent. Four months later, the rate of use sagged to 66 percent, but rebounded to 80 percent during a reminder campaign. [14]

Mandatory use laws are effective, but they are difficult to enact. People are quite willing to support measures limiting the ability of others to injure them but resist measures intended to protect them from their own actions. Speed limits, drunk driving laws, and measures to ban the carrying of weapons on commercial aircraft enjoy broad-based support, but mandatory seat belt laws, motorcycle helmet laws, and gun control are less popular. Mandatory use laws often engender spirited resistance from a vocal minority that view these laws as an infringement of "personal freedom."

Political backlash can block legislation or lead to the repeal of a successful law. Despite overwhelming evidence that motorcycle helmet laws save lives, 26 states repealed their statutes when federal incentives were relaxed in 1976. In these states, motorcycle crash fatality rates increased 40 percent. [15]

Opponents of mandatory use laws argue that individuals should be permitted to ignore sound safety policies if the level of risk is acceptable to them. Unfortunately, the circle of harm extends far beyond the victim. Motorcyclists and bicyclists who ride without a helmet face an increased risk of serious head injury or death. When such individuals are killed or disabled in a crash, families and loved ones lose companionship, dependents lose their principal source of financial support, employers lose productivity, and society is required to cover the expense of care. All of us, either directly or indirectly, bear the costs of preventable injury.

Engineering

Many injuries can be prevented by building safer vehicles and modifying the physical environment in which injuries occur. The cost to develop and implement passive countermeasures usually exceeds the cost of education campaigns. However, engineering is usually more effective because it does not require millions of users to permanently and consistently change their behavior.

Consider these examples. In contrast to the disappointing results of driver's education, federal standards for motor vehicle construction saved an estimated 37,000 lives between 1975 and 1978 alone. These standards addressed such issues as passenger restraint systems, windshields, fuel tank integrity, and the flammability of interior fabric. Introduction of air bags cut the nation's toll of deaths and injuries due to car crashes still further.

Construction of the interstate highway system saved lives as well. Modifications to the driving environment, such as banked curves, divided lanes of traffic, controlled ramps for ingress and egress, elimination of crossing streams of traffic, and the positioning of energy-absorbing pilings in front of fixed obstructions, cut the interstate highway death rate to less than half that for other roads.

These lessons can be applied to other hazardous products. Cigarettes cause more than half of U.S. fatalities due to house fires. Most occur when the smoker falls asleep in bed or leaves a burning cigarette on the arm of a sofa or chair. Television, radio, and print advertisements warning of the dangers of smoking in bed have had little no impact on this problem. Smoke detectors save lives by warning of an impending catastrophe in time to permit the occupants to evacuate the house, but they require a concerted effort to encourage people to install and maintain them.

Passive engineering of the home environment by installing sprinkler systems could be a very effective strategy. Unfortunately, residential sprinkler systems are expensive and often cannot be retrofitted into older homes. However, the cigarette itself could be modified to diminish its potential to ignite furniture or bedding.

Laws requiring products to be designed to diminish their potential to cause harm can be highly effective. Unfortunately, such laws are difficult to enact. Manufacturers often oppose such regulations because they fear it will raise the price of the products and discourage sales. In addition to the issue of personal freedom, concerns are often raised about cost, government interference, and reduced competitiveness with nonregulated manufacturers. If efforts to regulate a hazardous product fail, product liability lawsuits may force a needed change in product design.

PRACTICE OF INJURY CONTROL

Step 1: Define the Problem

Population-based data on the incidence and impact of injury are essential to define the scope of the problem and mobilize the resources necessary to achieve change. Public health surveillance is needed to monitor patterns and trends, and to evaluate the impact of countermeasures.

Several sources of information can be used for this purpose. Vital records or death certificates are useful to document the impact of injuries on overall rates of

mortality, but they do not provide information about nonfatal injuries. Hospital discharge data and trauma registries can provide essential information about cases of major trauma, but population-based data are needed to calculate rates of injury. Furthermore, hospital admission statistics and trauma registry data do not capture patients who are treated and released from the ED.

Although injuries that are managed on an outpatient basis are generally assumed to be minor, they can result in significant long-term disability. This is particularly true of head, back, and hand injuries. Patients visiting an ED for injury have an increased risk for recurrent injury, especially if their index visit is related to alcohol abuse or violence.

Assignment of external cause of injury codes ("E-codes") to every injury-related emergency department visit can substantially enhance community-based surveillance efforts. Several states mandate E-coding of all hospital admissions, but only one requires hospitals to E-code ED visits.

Step 2: Identify Causes and Risk Factors

Descriptive studies are usually conducted to determine *who* is injured, *what* kinds of injuries are involved, and *where, when,* and, *why* those injuries occur. These data provide essential clues to injury causation, and often generate hypotheses that can be investigated with analytical methods.

In some cases, the link between a risk factor and injury is so strong that no additional research is needed. For example, studies of automobile injury show that 50 percent of all fatal crashes and 60 percent of all fatal single-vehicle crashes involve alcohol. [16] In most cases, however, it is necessary to compare the rate of injury among those *with* a risk factor to the rate of injury in an otherwise similar group *without* a risk factor. Cohort, quasiexperimental, or experimental designs may be needed to reach a definitive conclusion. When the outcome of interest is rare, and exposure to the risk factor(s) of interest can be shown to precede the injury, case-control studies may be employed. Meticulous attention to methodology is essential to generate valid results and control for the effects of confounding variables.

Step 3: Develop and Test Interventions

Once the magnitude of the problem and its associated risk factors are identified, a variety of countermeasures may be considered for implementation. Careful attention must be given to the characteristics of the target population, the feasibility of the countermeasure(s), their acceptability to the target population, and cost. Pilot intervention programs are often helpful to test various strategies. The most promising program can then be selected for more widespread implementation.

Community education programs are often tried first because they are relatively easy to initiate, attract motivated volunteers, and are invaluable for raising public awareness. They can also help build public support for legislative changes at a later time. It is essential to take the views and values of the community into consideration at every step of the process. Citizen involvement is crucial to any program's success.

Most programs set milestones and predefined measures of success. For example, a campaign to prevent deaths and injuries in residential fires may identify selected measures of *structure* (staff hired, office space, cooperative agreements reached), *process* (number of pamphlets distributed, number of home visits made, total smoke detectors installed), or *outcome* (reductions in the rate of fire deaths, or a decline in hospital admissions due to burns and smoke inhalation).

It is not always feasible to demonstrate major impacts on rates of morbidity or mortality with small-scale demonstration projects. When this is the case, surrogate measures may be used to demonstrate program impact. For example, preintervention rates of smoke detector use in a target neighborhood can be compared with rates noted after an educational campaign. Telephone surveys can seek evidence of changes in knowledge, attitudes, and self-reported behavior. Self-reports do not guarantee long-term behavior change, but they confirm that a program is reaching the target group.

Step 4: Implement Effective Interventions and Evaluate Their Impact

Once a program is initiated on a large-scale basis, evaluation data should be collected to demonstrate its impact. Measures of cost-effectiveness (e.g., dollars spent per life saved or injury prevented) are particularly important. It is easy to tabulate the cost of a prevention program, but it is harder to document the savings from "tragedies that didn't happen." Program support tends to wane over time, especially when no group or organization has an economic interest in seeing it continued. During more difficult economic times, prevention programs are often the first to go. Without documented evidence of impact, worthy programs can wither and die.

THE ROLE OF THE EMERGENCY PHYSICIAN IN INJURY CONTROL

Patient Education

Injury-control measures need not be implemented on a grand scale to make a difference. Emergency physicians can incorporate injury prevention into their clinical practice. [17] The impact of these bedside interventions can be substantial.

Special efforts should be made to correct factors that precipitated the injury or contributed to its severity. Otherwise, a patient is likely to return with a more serious injury in the future. A child sustaining a minor head injury while bike riding should be told to wear his bicycle helmet. The unbelted adult who sustained minor injuries in a low-velocity motor vehicle crash deserves a short lecture on the importance of safety belts.

However, any ED encounter is a "teachable moment." [18] Because emergency physicians are more likely to provide acute care to injured patients than any other physician group, they should have a special stake in preventing and controlling injuries. The mother who brings her child to the ED for evaluation of a severe otitis can leave the department with information about the importance of child safety seats, bicycle helmets, and four-sided fencing around her swimming pool. Emergency physicians have the opportunity to motivate patients to change high-risk behaviors and modify their home environment to decrease injury risk. Unfortunately, the ability to influence behavior from these brief emergency setting encounters have not been well studied.

Data Collection and Program Evaluation

If current trends towards capitated care continue, the ED will become a pivotal arena for prevention efforts and health resource utilization. Until now, the financial incentives of health care have encouraged hospitalization and provision of services. The move towards capitated payment will substantially increase the incentive to prevent, rather than treat illness and injuries. As the portal of entry for 40 percent of U.S. inpatients and virtually all admissions, the emergency department can play a key role in monitoring system performance, identifying high-risk groups, reducing the need for expensive inpatient care, and evaluating the impact of prevention programs.

Research

Emergency physicians are ideally positioned to conduct injury surveillance and evaluate countermeasures and should take the lead in community-based epidemiologic research. Research on pediatric injuries, alcohol-related trauma, drunk driving enforcement, firearm-related injuries, intimate violence, residential fires, and the biomechanics of trauma are important areas for emerging research.

Advocacy

Sometimes, evaluation data indicate that a countermeasure is effective but rarely used. When education is not enough to motivate behavioral change, legislation may have a major impact, particularly when coupled with ongoing education efforts and visible enforcement. For example, states with mandatory motorcycle helmet laws report compliance rates as high as 98 percent.

Coalition building is essential to assemble a broad base of support. Physician leadership is essential to the success of these efforts. The testimonies of health care providers, surviving family members, and disabled individuals are needed to give the statistics an emotional context. Information on the economic impact of injuries and the cost-effectiveness of countermeasures is also helpful.

It is also important to train the next generation of injury control experts. Research suggests that many medical students lack a fundamental understanding of the

principles and practice of injury control.[19] Academic emergency physicians can play an important role by emphasizing the importance of injury control to their students and trainees.

CLINICAL PHYSIOLOGY OF FRACTURES

The ability to properly assess and treat acutely injured patients in the emergency department depends largely on an understanding of the way fractures are created and how they heal. Practical knowledge of fracture physiology may provide the index of suspicion needed to diagnose an injury that might otherwise be missed. It may also help prevent or minimize complications and may form the basis for advising the patient regarding the outlook for ultimate recovery of function.

How Fractures Occur

Although fractures are sometimes described in terms of the external mechanism by which they are created, they may also be thought of simply in terms of the physiologic processes involved.

"TYPICAL" FRACTURES   Most fractures are the result of significant trauma to healthy bone. The bony cortex may be disrupted by a variety of forces, including a direct blow, axial loading, angular (bending) forces, torque (twisting) stress, or a combination of these.

PATHOLOGIC FRACTURES   Fractures that occur from relatively minor trauma to diseased or otherwise abnormal bone are termed pathologic fractures. This implies that a preexisting pathologic process has weakened the bone and rendered it susceptible to fracture by forces that, under normal circumstances, would not disrupt the cortex. Common examples of such injuries are fractures through metastatic lytic lesions, fractures through benign bone cysts (as in the humerus of Little League pitchers), and—perhaps most common—vertebral compression fractures in patients with advanced osteoporosis. Numerous other disease processes may render patients susceptible to pathologic fracture.

Because these injuries are often not associated with a history of significant trauma, pathologic fractures may go undetected unless there is a preexisting index of suspicion based on the knowledge that such injuries can occur.

STRESS FRACTURES   In some cases, bone may undergo a "fatigue" fracture from repetitive forces applied before the bone and its supporting tissues have had adequate time to accommodate to such forces. An example is the insidious occurrence of a metatarsal shaft fracture in unconditioned foot soldiers (the so-called march fracture). The physiologic principle of stress fracture can be easily envisioned by anyone who has "cut" an aluminum finger splint to the desired length by bending it back and forth. The pliable metal—too hard to cut with an ordinary scissors—ultimately gives way in the face of repeated stresses requiring relatively little force.

The processes that render bone susceptible to stress fracture are not generally agreed upon. The important point is that diagnosis depends on a familiarity with the entity, because *x-rays are typically negative* early in the patient's course. Early diagnosis may be purely clinical, based on the history and physical findings. Days or weeks may pass before the fracture line or new bone formation becomes visible on x-ray, ultimately confirming the suspicions of the physician who, having made the correct presumptive diagnosis, will have treated the patient appropriately from the outset.

SALTER (EPIPHYSEAL) FRACTURES   Fractures involving the physis—the cartilaginous epiphyseal plate near the ends of the long bones of growing children—are called Salter fractures after Salter and Harris, the physicians who devised the most popular method of classifying these injuries. [1] The supply of new bone material needed for the elongation of bones during growth is provided by specialized cells within the physis. When growth is completed, the physis is transformed into bone, ultimately fusing with the surrounding bone and disappearing as a distinct entity. By definition, Salter fractures cannot occur in fully grown adults.

Any damage to the epiphyseal plate during a child's growth may destroy part or all of its ability to produce new bone substance, resulting in aborted or deformed growth of the bone thereafter. The potential for growth disturbance from an epiphyseal injury is related to the number of years the child has yet to grow (the older the child, the less time remains for deformity to develop) and to the pattern of the fracture line through the epiphyseal area. Classification of Salter fractures and their clinical implications are discussed later in this chapter.

Fracture Healing

The physiology of fracture healing constitutes the basis for many decisions in the emergency department. The judgment as to whether an angulated fracture requires reduction or can be left to heal as is, the choice of treatment modality in relation to the patient's age, and the prognosis for regaining function or being left with residual deformity all require familiarity with the short- and long-term aspects of the healing process.

Fracture healing can be described in terms of three phases—the inflammatory, reparative, and remodeling— each of which gradually blends into the next. [2]

When a fracture occurs, the microscopic vessels crossing the fracture line are severed, depriving the damaged bone ends of their blood supply. In the ensuing hours and days, the bone ends necrose, triggering a classic inflammatory response. This early phase is brief but creates the tissue environment for the most predominant aspect of fracture healing: the reparative phase.

Soon, granulation tissue begins to infiltrate the area. Within this tissue are specialized cells capable of forming collagen, cartilage, and bone, the ingredients of callus, which gradually surrounds the fractured ends and stabilizes them. With time, the callus becomes more densely mineralized.

Meanwhile, the necrotic edges of the fragments are removed by osteoclasts, cells whose specific function is to resorb bone. That is why some "hairline" fractures do not appear on x-ray until days after injury. Initially invisible, the diagnostic fracture line appears only after necrotic bone has been resorbed from the area.

The final phase of bone healing, the remodeling phase, is the longest, often lasting years. Remodeling is the tendency of bone to gradually regain its original shape and contour. During this phase, the superfluous portions of callus are resorbed, and new bone is laid down along natural lines of stress. These internal layers, easily visible in x-rays of normal bone, are the bony trabeculae. Formation of trabecular bone is a physiologically efficient process, providing maximum strength relative to the amount of bone material used.

The anticipated success of remodeling is related to a number of factors. Young children have a greater capacity for remodeling than adults do. Accordingly, their potential for residual deformity is less, other circumstances being equal. Remodeling is also related to the magnitude and direction of unreduced angulation and to the fracture's location along the bone. Specific predictors of satisfactory remodeling include youth, proximity of the fracture to the end of the bone (but not involving the epiphyseal plate), and direction of angulation coinciding with the plane of natural joint motion.

Clinical decisions regarding the aggressiveness of fracture reduction are directly linked to a knowledge of this physiology. Angulation near the end of a long bone, for example, is more acceptable than angulation near the midshaft. Dorsal or volar angulation at the wrist has a better prognosis than ulnar or radial angulation because the natural plane of wrist motion is dorsal-volar. Mild angulation in a 2-year-old may be left to remodel on its own, whereas the same angulation in an adult may require correction.

ORTHOPEDIC EMERGENCIES

Some types of musculoskeletal trauma deserve special mention because a delay in their diagnosis or treatment can increase the chance of significant complications or a negative outcome.

Open Fracture

An open fracture (compound in older terminology) is a fracture associated with overlying soft tissue injury, creating communication between the fracture site and the external surface of the body. Although open fracture may initially convey the image of grossly exposed bone, the term is equally applicable to a simple puncture wound extending to the depth of an underlying fracture. Such puncture wounds may be created by external forces or by a sharp bone fragment transiently protruding through the skin before receding back beneath the surface.

The most dreaded complication of open fracture is osteomyelitis. Once established, osteomyelitis may result in months or years of pain, disability, medical therapy, surgical procedures, and ultimately amputation. Although osteomyelitis may be unavoidable in some cases, it becomes less likely when treatment is prompt and meticulous.

Open fractures are sometimes classified by severity, based on the length of the overlying laceration, extent of tissue damage, kinetic energy of the injuring force, and evidence or likelihood of significant contamination. Irrespective of these factors, any open fracture should be promptly and carefully treated. Elements in the care of open fractures are described later in this chapter.

Dislocation and Subluxation

A joint is dislocated when the articular surfaces of the bones that normally meet at the joint are completely out of contact with one another. This is distinct from subluxation, a condition in which the articular surfaces are only partially out of contact.

The urgency of treating dislocated joints is based on several factors. One is the potential for neurologic or circulatory compromise. The neurovascular bundle passing close to the affected joint is typically "kinked" around the deformity associated with the dislocation. Persistence of this condition can result in a neurologic or vascular deficit that may be temporary if the deformity is reduced promptly but irreversible if treatment is delayed.

Another consideration is that, the longer a joint has been dislocated, the more difficult it may be to reduce and the more likely it is to be unstable after reduction. This is probably due at least in part to edema, muscle spasm, and other tissue changes that increase over time.

Dislocation of the hip carries its own particular urgency in addition to those mentioned above: the danger of avascular necrosis of the femoral head. Avascular necrosis occurs because much of the blood supply to the femoral head is delivered through vessels that emerge from the acetabulum. When the joint is dislocated, circulation to the femoral head is disrupted. At some point, the vascular insult becomes irreversible, and bony necrosis is the ultimate result. Although aseptic necrosis may occur despite the physician's best efforts, its likelihood increases with the time delay until reduction.

Neurovascular Deficit

Naturally, any injury associated with neurologic or vascular compromise—such as may result from a severely deformed fracture—should be addressed as soon as possible. The longer a deficit goes untreated, the longer it is likely to persist and the greater the possibility that it will be irreversible. In some cases, simply reducing a deformity by means of longitudinal traction may restore circulation or nerve function, allowing the remainder of the patient's evaluation and treatment to proceed at a calmer pace.

PREHOSPITAL CARE

With the growing sophistication of emergency medical service (EMS) programs in many areas of the United States, important aspects of early care are no longer overlooked.

Preliminary Splinting

Effective splinting of the injured extremity is crucial for several reasons: (1) it reduces the patient's pain; (2) it reduces damage to nerves and vessels by preventing them from being repeatedly ground between the fragments or being stretched by increased angulation at the fracture site; (3) it reduces the chance of inadvertently converting a closed fracture to an open one as a sharp bone fragment pokes its way through the skin (considered a mishap of severe consequence, because of the potential for the disastrous complication of osteomyelitis), and (4) it facilitates patient transport and the taking of x-rays, by reducing the pain and manipulation associated with moving the patient from ground to ambulance to emergency department stretcher to x-ray table.

PREHOSPITAL SPLINTING DEVICES   Many splinting devices are available to EMS systems. For injuries of the wrist or forearm, a foam-padded intravenous board can be wrapped in place, supplemented by a sling. The sling is important because optimal immobilization includes the joint above and the joint below the fracture. The sling keeps the elbow (the joint above) at rest.

For suspected injuries to the elbow or humerus, a sling-and-swathe arrangement works well. This involves applying a sling and then binding the affected arm to the thorax with a gauze wrap. An exception to this principle is immobilization of patients with suspected anterior dislocation of the shoulder. Such patients are unable to adduct the forearm against the thorax, and forcibly binding it there is painful and not recommended. A simple sling is adequate. (Anterior dislocation is unlikely if the patient prefers to keep the arm tightly bound against the thorax and abdomen.)

Injuries to the ankle can be immobilized in a pillow or well-padded cardboard splint. If fracture of the tibial shaft or knee is suspected, the device should extend well above the knee (to immobilize the joint above as well as the joint below).

Some injuries warrant specialized splints, such as winch-mechanism traction devices for femoral shaft fractures. Although such devices do not immobilize the hip (the joint above), the added element of traction makes this unnecessary. If a traction device is unavailable, the hip needs to be immobilized. This can be accomplished with military antishock trousers (MAST) with all compartments inflated or, less elegantly, by binding the legs together, then binding the patient to a backboard from ankles to thorax.

Other types of splints exist, but their use is controversial. Inflatable plastic splints, for example, are acceptable for injuries to the ankle or wrist, but are often used inappropriately for fractures of the humerus or femur. Because these devices normally do not extend above the elbow or knee, they provide inadequate immobilization for such injuries. Also, overinflation of plastic splints can seriously impair circulation. (If the splint cannot be dented by moderate thumb pressure, it is probably overinflated.) Inflatable splints should not be applied over clothing because underlying wrinkles in the clothing may cause pressure sores in swollen and vulnerable tissue.

Also controversial are nonmalleable aluminum splints because they are based on the "one size fits all" principle, which some physicians regard as "this size fits none." If used, aluminum splints should be very well padded because their hard surface may cause pressure sores. Like any splint, they should immobilize the joint above and the joint below the fracture if they are used for long-bone injuries. For example, an above-knee splint is needed for fracture of the tibial shaft. Aluminum splints should be removed as soon as possible, once a fracture is diagnosed or ruled out. If a fracture is confirmed, the splint should be replaced with another type of immobilization dressing before the patient leaves the emergency department.

Reducing Deformity in the Field

Many EMS programs do not recommend prehospital reduction of deformity of an injured extremity. If the deformity is near a joint (suggesting the possibility of dislocation), this is certainly good advice. Injudicious manipulation may convert a pure dislocation to a fracture-dislocation. Even if a fracture already exists, there will be no way to prove it was not caused by the manipulation.

A circumstance in which prehospital reduction of obvious fractures along the shaft of a long bone can be justified is the absence of a distal pulse. Minutes count in such cases. If reduction is attempted, it should be performed by means of longitudinal traction.

In the absence of a common standard, the indications for reduction of deformity by prehospital personnel ultimately remain at the discretion of the supervising EMS program.

EMERGENCY DEPARTMENT EVALUATION AND DIFFERENTIAL DIAGNOSIS

The importance of a careful history and physical examination cannot be overstated. Orthopedic diagnosis is sometimes thought of as being as simple as taking an x-ray where the patient says the pain is. This philosophy is probably responsible more than any other factor for physicians' missing significant injuries.

Although x-ray is of course an important adjunct, it is not the ultimate diagnostic resource, for the following reasons. The pain of a fracture or even a dislocation may be referred to another area. For example, patients with disruption of the sternoclavicular joint or fracture of the humeral shaft may present complaining of shoulder pain. If the x-ray is based solely on where the patient reports subjective discomfort, then the injury might not even be included on the film. The area x-rayed should be determined not only by the patient's chief complaint, but also by systematic palpation, looking for subtle deformity or significant point tenderness.

Some fractures or dislocations are apparent only on special x-ray views, which are not part of the standard series for that body part. Such special views will never be ordered unless the physician has already formulated a presumptive differential diagnosis before x-ray, based on the history and physical findings.

Some injuries may not be radiologically apparent on the first day regardless of what views are taken. Common examples of such injuries are fracture of the scaphoid (carpal navicular), nondisplaced fracture of the radial head, and stress fracture of a metatarsal. The classic radiologic signs accompanying such injuries, such as the fat-pad sign of the elbow, are not always conveniently present, but suggestive history and findings commonly are. In such cases, the diagnosis of fracture may have to be purely clinical until 7 to 10 days after injury, when enough bony resorption has occurred at the fracture site to reveal a lucency on x-ray. A bone scan may suggest the fracture even sooner, but on the day of injury, there may be no readily available test capable of demonstrating the pathology. Only the physician's clinical impression, arrived at through a systematic history and physical examination, will result in proper and timely treatment of a radiologically undemonstrable fracture.

History

The value of history taking in the case of orthopedic injuries is often underestimated. In fact, knowing the precise mechanism of injury or listening carefully to the patient's symptoms can be the key to diagnosing fractures or dislocations. For example, a history of shoulder injury combined with the complaint of dysphagia may be the only clue to the existence of posterior sternoclavicular dislocation. This entity, which causes pressure on the mediastinal structures, can often be demonstrated only by computed tomography (CT) scan and is associated with severe complications if treatment is delayed. Another example is a history of landing flat on the feet from a significant height, which should prompt the physician to consider fracture of one or both calcanei, as well as lumbar vertebral compression fracture.

History is often the only means of correctly assessing and treating young children who "just won't use the arm." Such children, who present with a seemingly paralyzed arm ("pseudoparalysis") after being pulled or yanked, may be incorrectly diagnosed as having a brachial plexus injury, when in fact the history and presentation are classic for subluxed radial head, an entity *not discernible on x-ray* and easily and quickly remedied by a proper reduction maneuver.

A careful history may enable the physician to diagnose posterior dislocation of the shoulder, another entity commonly missed on routine films. If the patient has (1) experienced a direct blow to the front of the shoulder, (2) landed forward on an outstretched arm, or (3) had a seizure or undergone violent muscle contraction for any other reason (e.g., contact with high-voltage current) and now complains of excruciating shoulder pain and severely limited motion, the diagnosis of posterior dislocation should be entertained. If the implications of the history are not appreciated, then the specific x-ray views needed to demonstrate the injury may never be ordered.

Table 259-1 provides further examples of mechanisms that might lead the clinician to suspect, or presumptively treat for, specific injuries. This is by no means a definitive or exhaustive list. Some of the mechanisms described may produce injuries other than those mentioned. Conversely, the injuries may be produced by mechanisms besides those listed.

TABLE 259-1   Mechanisms Associated with Particular Orthopedic Injuries

Some musculoskeletal injuries or conditions may not necessarily be associated with a history of trauma. Occult fracture of the hip in an osteoporotic individual, occult stress fracture of a metatarsal in someone who has recently done an unusual amount of walking, and slipped capital femoral epiphysis in a preteenager or young adolescent, are all examples of injuries whose symptoms may be gradual and insidious in onset, unrelated to an isolated traumatic event. Tenderness to palpation or pain on weight-bearing or range-of-motion suggests the possibility of an occult or easily missed fracture. Depending on the index of suspicion, further studies, such as bone scan or magnetic resonance imaging (MRI), may be indicated to rule out significant pathologic conditions before the patient is allowed to resume weight-bearing.

History taking should not necessarily be limited to orthopedic issues. Depending on the situation, a general medical history should be obtained, since it may have implications for further workup, the potential for complications, or ultimate prognosis for recovery of function. For example, relevant items may include a history of heart disease, anticoagulant medication, falling due to syncope or transient hemiparesis rather than simply stumbling, or an unsteady baseline gait that cannot withstand further impairment.

Physical Examination

Essential components of the examination for musculoskeletal trauma are (1) inspection for swelling, discoloration, or deformity; (2) assessment of active and passive range of motion of the joints proximal and distal to the injury; (3) palpation for tenderness or subtle deformity; and (4) verification of neurovascular status.

INSPECTION AND RANGE OF MOTION   Gross deformity along the shaft of a long bone is of course pathognomonic for fracture. The presence of most dislocations or fractures near a joint can be inferred by deformity at the joint, loss of range of motion, and severe pain at rest. An exception is posterior dislocation of the shoulder, which, while intensely painful, may not be accompanied by obvious deformity. Chapter 263 has a more complete discussion of this entity.

PALPATION   When gross deformity is not present, presumptive orthopedic diagnosis depends strongly on the findings noted on palpation. Palpation will disclose areas of bony step-off, as well as the precise location of point tenderness. If films are ordered before performing this phase of the examination, the wrong area may be x-rayed, because pain is commonly referred to a location distant from the injury site.

The palpation examination should be done systematically and consistently from one patient to the next. The area palpated should extend well beyond the location of the patient's subjective pain. For example, when an injured patient complains of shoulder pain, palpation should begin at the sternoclavicular joint and then proceed along the extent of the clavicle, onto the acromioclavicular joint, onto the humeral head, and along the entire humeral shaft. In addition, the scapula should be palpated for tenderness and the posterior aspect of the shoulder palpated for any unnatural prominence that might suggest a posterior dislocation. Injury to any of these areas may be reported by the patient as pain in the shoulder. Only a meticulous palpation examination may protect the physician from being misled by referred pain and missing a crucial diagnosis.

NEUROVASCULAR ASSESSMENT   When injury involves an extremity, as opposed to the vertebral column, sensorimotor testing should be performed on the basis of *peripheral nerve* function, rather than nerve root and dermatomal distribution. In the upper extremity, the radial, median, and ulnar nerves should be tested. When the shoulder is anteriorly dislocated, two additional nerves—the axillary (supplying sensation to the lateral aspect of the shoulder) and the musculocutaneous (supplying sensation to the extensor aspect of the forearm)—should be checked as well. In the lower extremity, examination of the saphenous (sensory only), peroneal, and tibial nerves should be performed. Neurologic deficit, although not necessarily immediately reversible, is important to document early, particularly before the patient has undergone any significant manipulation or reduction maneuvers.

Assessment of vascular status should also be performed early. The sooner circulatory compromise is identified and addressed, the greater the chance of avoiding tissue infarction and necrosis. Such injuries as dislocation of the knee (tibiofemoral joint), fracture-dislocation of the ankle, and displaced supracondylar fracture of the elbow in children are commonly associated with vascular occlusion or disruption, with resulting circulatory impairment.

RADIOLOGIC EVALUATION

The area x-rayed and the particular views ordered should be based on the history and physical examination, rather than simply on where the patient reports subjective pain. The joint above and the joint below a fracture should be included on the films because injury at the proximal or distal joint may coexist with long-bone fractures.

Injuries that may require special views to be visualized include acromioclavicular separation, fracture of the scaphoid, posterior shoulder dislocation, and sternoclavicular dislocation. That is why formulation of a presumptive diagnosis *prior to* x-ray is crucial. The physician may never order the specialized views needed to demonstrate a particular injury unless he or she has already anticipated the injury by virtue of the history and physical examination.

Children who have sustained trauma at or near a joint may need comparison studies of the opposite extremity to differentiate fracture lines from normal epiphyseal plates or ossifying growth centers. This is particularly true for the pediatric elbow, which typically exhibits six separate ossification centers sequentially as the child grows.

Although the physician may be tempted to base diagnostic and treatment decisions on the radiologist's written report, this is not advisable for at least two reasons. First, a report of negative findings does not rule out significant injury. Fractures of the radial head, scaphoid, or metatarsal shaft, for example, may initially be undetectable on x-ray, even when special views are taken. Second, the terminology used by radiologists to describe malposition of fracture fragments or disrupted joints is often different from the terminology used by orthopedists. Because the emergency physician will often be conferring with an orthopedist regarding the initial management of a patient, and because this interaction commonly involves describing the radiologic appearance of a patient's injury, it is important that the two physicians "speak the same language." This might not be achieved by simply relaying the radiologist's written description.

Describing Radiographs

When orthopedic consultation is indicated, proper management of the patient may rest on the emergency physician's accurate description of the x-ray. Often the narrative will influence the orthopedist's decision regarding the need for hospital admission and whether surgical versus nonsurgical management is warranted. In essence, the emergency physician should be able to transmit a virtual copy of the x-ray by means of verbal description.

There are various ways of classifying or categorizing fractures. The method presented here is intended to be the most practical from the standpoint of effective communication with a consultant who is not physically present.[3]

OPEN VERSUS CLOSED   Although not a radiologic finding per se, this aspect of an injury is among the most important and should be conveyed to the orthopedist before any other. The implications of open fracture are of such significance that this factor alone may determine the patient's immediate care or ultimate disposition.

LOCATION OF THE FRACTURE   Typical reference points used by orthopedists to describe the location of a fracture along the shaft of a long bone are the midshaft, the junction of the proximal and middle thirds, and the junction of the middle and distal thirds. Any fracture more proximal or distal than this may be localized in terms of its distance, in centimeters, from the bone end.

When a proximal or distal fracture extends into the adjacent joint, it is termed intraarticular. Intraarticular fractures have special significance because disruption of the joint surface may warrant surgery to restore the joint's contour and prevent subsequent traumatic arthritis. This feature of a fracture line, if present, constitutes important information.

Anatomic bony reference points should be cited when applicable. A fracture just above the condyles of the distal humerus or femur, for example, is most precisely called a *supracondylar* fracture. A fracture running from the greater to the lesser trochanter of the proximal femur is an *intertrochanteric* hip fracture, whereas a fracture just below the trochanters is *subtrochanteric,* and a fracture just above is said to involve the femoral *neck.* The area at or proximal to the coronoid process of the ulna is the *olecranon* and should be referred to as such, rather than simply the proximal ulna. Other bony landmarks include the radial head (proximal), radial styloid (distal), and greater tuberosity of the humerus. Numerous additional examples exist.

ORIENTATION OF THE FRACTURE LINE   The most common orientations of fracture lines are illustrated in Fig. 259-1. Torus and greenstick fractures are seen almost exclusively in young children, whose bones are more pliable than those of adults. Note the segmental fracture, which is commonly described incorrectly as a comminuted fracture. To an orthopedist, the term *comminuted* implies splintering or shattering. A single large free-floating segment of bone between two well-defined fracture lines is a *segmental fracture.*

FIG. 259-1. Fracture line orientation. **A.** Transverse. **B.** Oblique. **C.** Spiral. **D.** Comminuted. **E.** Segmental. **F.** Torus. **G.** Greenstick.

DISPLACEMENT AND SEPARATION   *Displacement* refers to the position of the fracture fragments as nonconcentric or offset from each other. It is expressed in terms of direct measurement (4-mm displacement) or in terms of the percent of the width of the bone (e.g., 50 percent displacement or complete displacement). The direction of displacement is based on the position of the distal fragment in relation to the proximal.

Displacement should not be confused with separation, which is the distance two fragments have been pulled apart. Figure 259-2 illustrates principles of displacement and separation.
FIG. 259-2. Fracture displacement and separation. **A.** No displacement, slight separation. **B.** Fifty percent dorsal displacement. **C.** Complete dorsal displacement. **D.** Nondisplaced, no separation. **E.** A 4-mm separation.

SHORTENING   Shortening is the amount by which the bone's length has been reduced and is expressed in millimeters or centimeters. Shortening can occur by impaction (telescoping of the fragments into one another) or by the overlap of two completely displaced fragments (Fig. 259-3). The latter is referred to by some orthopedists as overriding. Because an x-ray affords no depth perception, a fracture that appears impacted on one view must also be visualized at an angle 90° from the first to differentiate it from a fracture whose ends are completely displaced and overriding.
FIG. 259-3. Shortening at fracture site. **A.** Complete displacement with overriding. **B.** Impaction. In both cases, the width of the shaded area represents the amount of shortening.

Depending on the location of the fracture and the age of the patient, shortening may have long-range functional implications and may have to be corrected by closed manipulation or by surgery.

ANGULATION   Angulation is expressed in terms of two parameters: direction and amount (Fig. 259-4). Quantifying the angulation is relatively simple. The physician need only estimate the amount of "unbending" (expressed in degrees) that would be required to make the fragments parallel.
FIG. 259-4. Fracture angulation. All figures depict 30° dorsal angulation. **A.** and **B.** Direction is based on the apex of the angle drawn below the figures. **C.** Direction is based on the direction of the terminal fragment.

Describing the direction of angulation is more difficult because the terminology is less consistent among clinicians. Generally, when a fracture is near the midshaft of a long bone, the direction of angulation is the direction of the *apex* of the angle formed by the two fragments. Figure 259-4A and Figure 259-4B both represent 30° of dorsal angulation. When a fracture is located near the end of a bone, however, angulation is described in terms of the direction the *terminal fragment* is deviated. Figure 259-4C also represents 30° of dorsal angulation, even though the apex of the angle formed by the fragments is pointing in the opposite direction from that in the preceding figures. If there is a possibility of ambiguity in the description, specifying the *direction of deviation of the distal fragment* can usually resolve it.

Depending on the anatomic area involved, direction of angulation may be expressed as radial or ulnar, dorsal or volar, anterior or posterior, or lateral or medial.

ROTATIONAL DEFORMITY   Rotational deformity—the extent to which the distal fracture fragment is twisted on its own axis relative to the proximal fragment—is generally not measurable on x-ray and sometimes not even radiologically apparent. This element of fracture description depends on physical examination. Its detection is particularly important in the phalanges of the fingers, where, if rotational deformity goes unrecognized and uncorrected, the affected finger will always be malaligned when the hand is closed.

FRACTURE COMBINED WITH DISLOCATION OR SUBLUXATION   Injuries near a joint may involve dislocation or subluxation in combination with a proximate fracture. An example is fracture of one or more ankle malleoli, together with partial or complete displacement of the talus from beneath the tibia. Fracture-dislocations are significant injuries, often requiring surgical intervention. If, in describing the injury, the physician emphasizes the fracture component but expresses the dislocation or subluxation component as mere displacement, then the full severity may not be appreciated by the orthopedist. Such injuries should be described as fracture-dislocations or fracture-subluxations.

SALTER FRACTURES   The physiology of Salter fractures—fractures involving the epiphyseal plate at the end of the long bone of a growing child—has already been discussed. Salter fractures are classified into five types, based on the pattern of the fracture line. Because the type generally correlates with the potential for future growth disturbance (and, consequently, with the aggressiveness of treatment required), the ability to classify such injuries based on their x-ray appearance is important.

Perhaps the easiest way to remember the Salter classification system is to think of these injuries not in terms of where the fracture line runs, but in terms of what has been broken off. Figure 259-5 illustrates the anatomy involved. Table 259-2 describes the five types of Salter fractures, which are illustrated in Fig. 259-6. The potential for growth disturbance is least for type I and increases with the classification number, the worst prognosis being associated with type V injuries.
FIG. 259-5. Epiphyseal anatomy.

Salter Type	What Is Broken Off
I	The entire epiphysis
II	The entire epiphysis with a portion of the metaphysis
III	A portion of the epiphysis
IV	A portion of the epiphysis with a portion of the metaphysis
V	Nothing "broken off;" compression injury of the epiphyseal plate

TABLE 259-2   Description of Salter Fractures
FIG. 259-6. Epiphyseal fractures based on Salter-Harris classification.

Type I and type V Salter fractures may be radiologically undetectable. Type I injuries usually involve little or no separation of the epiphysis from the rest of the bone, and the lucent fracture line is not visible along the equally lucent epiphyseal plate. If the epiphysis and plate slip transversely along the end of the shaft, the abnormal position will be seen on x-ray, but slippage does not always occur. Diagnosis of acute Salter I fractures is usually clinical, based on the presence of swelling and tenderness in the region of the physis.

Type V injuries may be evident only retrospectively, when growth disturbance first begins to appear. At time of initial presentation, however, a history of a significant axial loading force, coupled with significant tenderness in the area of the epiphyseal plate, should suggest the possibility of a type V injury. Such children should be immobilized and referred for orthopedic follow-up.

TREATMENT IN THE EMERGENCY DEPARTMENT

Control of Pain and Swelling

Measures to reduce swelling should be initiated early. Severe swelling not only intensifies the patient's discomfort but may also delay the application of a long-term definitive immobilization dressing and may make the skin more susceptible to pressure sores. Although sometimes regarded as trivial modalities, the application of cold and elevation are both effective in keeping swelling to a minimum or at least preventing its progression. When cold is applied, the skin should be protected from direct contact with ice-cold temperatures.

Parenteral analgesics should be administered as necessary. If the patient is relatively comfortable at rest, medication may not be required. Analgesics have virtually no effect on the pain of movement or manipulation unless combined with hypnotics or other central nervous system active agents. Jewelry, watches, or rings that can cause compression as an extremity swells should be removed if there is suspicion or confirmation of proximal injury.

Keeping the Patient NPO

Any patient who may be a candidate for prompt surgical fixation, manipulation, or any other procedure under general anesthesia or conscious sedation should be kept NPO from the moment of arrival until the need for, and timing of, such a procedure has been ascertained. This seemingly obvious point is commonly overlooked, particularly in a busy emergency department, where the process of clinical evaluation may be prolonged and hunger may develop in the interim.

Reducing Fracture Deformity

The long-term purpose of reducing significant deformity associated with fractures is, of course, restoration of normal appearance and function of the extremity. However, there are also short-term reasons for reducing deformity early in the patient's course, including (1) alleviating pain, (2) relieving the tension on nerves or vessels that may be stretched as they pass over the deformity, (3) eliminating or significantly minimizing the possibility of inadvertently converting a closed fracture to an open one when the skin is tented by a sharp bony fragment, and (4) restoring circulation to a pulseless distal extremity.

After the patient has been sedated, deformity at or near the midshaft of a long bone is usually easy to reduce with gradual, steady longitudinal traction. Any rotational deformity should be corrected only after the angular component has been addressed and should be performed while traction is maintained. If reduction is performed as a definitive procedure prior to immobilization, attention to rotational deformity is particularly important because of its profound effect on ultimate function. As discussed earlier, rotational deformity is much easier to appreciate by examining the patient than by examining the x-ray.

The nearer the deformity is to a joint, the more difficult it may be to correct and the more specialized the reduction maneuver may have to be. Who performs the procedure, the emergency physician or the orthopedist, is determined by a variety of circumstances, some of which may be specific to the particular practice environment. When deformity is associated with circulatory deficit, a true emergency exists, and the anticipated delay until reduction should be considered.

Reducing Dislocations

The techniques used to reduce specific dislocations are discussed in subsequent chapters. In general, prereduction x-rays are advisable unless circulation is threatened and prompt radiologic evaluation is not available. X-rays are needed because dislocations and fracture-dislocations may have the same clinical appearance on physical examination, but the techniques used to treat them may be markedly different. An example is simple anterior dislocation of the shoulder, as opposed to the same injury associated with complete fracture through the humeral neck. If the fracture is identified at the outset, the patient will be spared the pain of prolonged unsuccessful reduction attempts, and no question will arise as to exactly when the fracture might have occurred. Even "pure" dislocations may be associated with minute fracture fragments. A prereduction film will usually furnish proof of the preexistence of such fragments.

Of course, there are circumstances in which the potential benefits of a prereduction film may be outweighed by the associated expenditure of time and money. For example, a prereduction film may be omitted in a patient with a history of multiple recurrent dislocations of the shoulder, who presents with history, signs, and symptoms typical of another recurrence.

The importance of postreduction films is another consideration. Occasionally a joint may feel as though it has been reduced, when in fact it has not. Even when a maneuver is successful, the joint may redislocate after the patient leaves the emergency department. There is no way to prove that the joint was in anatomic position at the time of discharge, without a postreduction film. The obtaining of postreduction films is, of course, a matter of judgment and ultimately at the clinician's discretion.

Initial Management of Open Fractures

Open fractures, which may be complicated by subsequent osteomyelitis, warrant prompt and meticulous attention. The most important elements in the treatment of open fractures, aside from tetanus prophylaxis that applies generally to any wound, are irrigation, débridement, and antibiotics provided as soon as is practical. Although irrigation and debridement are commonly performed in the operating room, antibiotics may be administered in the emergency department.

Early administration of antibiotics can help reduce the incidence of infection in open fractures.[4,5] The longer the interval between the time of injury and the initiation of antibiotic therapy, the less likely that such therapy will be of benefit. Exactly what constitutes the ideal antibiotic is controversial. An accepted combination is a first-generation cephalosporin plus an aminoglycoside, but this is by no means the only regimen in use. Aerobic and anaerobic wound cultures can be obtained before antibiotics are administered.

Antibiotics by themselves are no substitute for irrigation and debridement, both of which have been well demonstrated to be crucial to reducing the incidence of osteomyelitis in open fractures by reducing bacterial contamination and the potential for bacterial colonization.[6,7] Irrigation should be extensive to (1) make the area more visible for inspection for foreign material, (2) float out nonviable tissue or at least float it into the field of vision so it can be removed, and (3) float out contaminated blood clots and bits of tissue. Pulsatile pumps may increase the effectiveness of irrigation, provided the stream is not too forceful. Excessive force will simply pack debris farther into the recesses of the wound.

Debridement of minor wounds that overlie a fracture may sometimes be performed in the emergency department. When tissue damage is moderate or severe, formal debridement and irrigation are commonly performed in the operating room.

ORTHOPEDIC CONSULTATION IN THE EMERGENCY DEPARTMENT

In many cases, such as hip fracture or both-bone fracture of the forearm, the need for hospital admission and/or orthopedic consultation in the emergency department is obvious. In some situations, however, differences of opinion may exist among emergency physicians, as well as among orthopedists, as to whether the patient needs to be seen by an orthopedist in the emergency department, or whether the patient may be treated in preliminary fashion and referred for subsequent definitive orthopedic management. Even patients with injuries that may ultimately require surgical repair, such as an unstable ankle fracture, may sometimes be immobilized and discharged for prompt orthopedic follow-up.

Some entities or situations that may warrant orthopedic consultation while the patient is still in the emergency department are discussed below.

Compartment Syndrome

The physiology and potentially catastrophic consequences of compartment syndrome are described later in this chapter. In cases of known or suspected compartment syndrome, orthopedic consultation should be obtained promptly. Emergency surgical intervention may be required to try to avert permanent tissue damage and muscle contracture.

Irreducible Dislocation

The emergency physician may sometimes be unable to reduce a dislocation, even with the aid of nerve block or pharmacologic sedation. While technique is certainly a factor, there may be other reasons closed reduction cannot be accomplished, such as the interposition of soft tissues or the presence of associated fractures. Orthopedic consultation should be sought in such cases. Timely reduction, which may sometimes only be achieved surgically, can help minimize the complications (and shorten the pain) resulting from a dislocated joint.

Circulatory Compromise

Circulatory deficit resulting from musculoskeletal injury warrants prompt orthopedic consulation. Even if circulation has been restored by the emergency physician through the correction of deformity, the orthopedist may wish to investigate the integrity of the involved vessels, and should at least be contacted in order to discuss the case.

Open Fracture

As mentioned earlier, some open fractures need to be treated aggressively in the operating room. Other types, such as those involving the phalanges, may often be irrigated in the emergency department and referred for follow-up. If there is any question, a discussion with an orthopedist can result in a mutually agreeable plan of care.

Injuries Requiring Surgical Repair

While some musculoskeletal injuries require operative intervention as soon as possible, others may be treated on a delayed basis. In many cases, orthopedists differ in their preferred approach to the timing of surgery. Orthopedic consultation, at least by telephone, is indicated in cases of musculoskeletal injury that the emergency physician believes may need operative fixation or repair. The orthopedist may then exercise his or her choice to admit the patient right away, or to see the patient in timely follow-up and schedule surgery at that time.

IMMOBILIZATION TECHNIQUES

Immobilization is indicated not only for fractures but also for dislocated joints that have been reduced. When a joint becomes dislocated, the ligaments that had provided it with stability are disrupted, and the joint is susceptible to redislocation until healing has occurred.

Whether plaster or fiberglass is used in the dressing depends on a number of factors, including the emergency physician's preference, the philosophy of the orthopedic community, the needs of the patient, and the hospital's resources. Fiberglass has the advantages of being lightweight, fast setting, and resistant to damage by moisture (although most splint dressings contain additional bandaging materials that need to be kept dry). Ultimately, the physician should use the material he or she is most comfortable with and can use most skillfully with best results.

Principles of Splinting

With the exception of the specific chemical substance involved, references to plaster in the following description are equally applicable to fiberglass.

The chemical reaction that causes plaster of paris (calcium sulfate) to crystallize, or set, is initiated by contact with water. The higher the water temperature, the faster the hardening process. However, the setting of plaster is an exothermic chemical reaction, which liberates heat. The faster plaster sets, the more heat it generates. This means, the maximum temperature to which the patient's skin is exposed will be the *additive* result of the water temperature plus the heat released by the plaster. For this reason, severe burns can result when plaster has been immersed in hot water, even though the temperature of the water itself was not sufficient to cause such burns. Although there is no universally prescribed ideal water temperature, a safe practice is to make the water slightly warmer than room temperature. If steam is visible, the water is almost certainly too hot.

To avoid irritation and minimize the potential for pressure sores, plaster dressings need to include several layers of padding between the plaster and the skin. When longitudinal splints are used, the padding need not be circumferential. Longitudinal padding will effectively protect the skin as long as it slightly exceeds the width and length of the splint. The best way to ensure this is to fashion the dry splint first and then measure the padding over it.

The length of a splint should be sufficient to provide ample leverage to immobilize the injured joint. To immobilize the elbow, for example, a splint should begin distal to the wrist and extend high up the lateral arm, to the level of the humeral neck. To effectively immobilize the ankle, a splint should extend from beneath the metatarsal heads to high calf. If the fracture is located along the midshaft of the distal extremity rather than at a joint, the splint should be long enough to immobilize the joint above and the joint below the fracture.

Splints may be fashioned from the plaster rolls normally used for casting or from prepadded material supplied on a continuous roll, which can be cut to length. When using common plaster rolls, determine the necessary length of the splint by measuring out a single layer along the extremity. Then, on a flat surface, unroll the plaster back and forth over itself to make a multilayered splint. For an adult, the splint should be at least 12 layers thick. Even more layers should be used for children, who typically remain as active as possible and have little regard for protecting the dressing.

When the dry splint has been prepared, measure out several layers of padding over it, making the padding longer and wider than the plaster. After setting the padding aside, grip each end of the splint and immerse it in water, keeping it submerged until bubbling stops (indicating the water has been fully absorbed into the interstices of the material). Then withdraw the splint and strip out the excess water by sliding the thumb and index finger along the length of the plaster on each side. (Be sure to use a stripping motion, rather than crumpling the dressing to wring out the excess water, or much of the plaster will be wrung out as well.)

The next step, frequently overlooked, is to lay the splint on a flat surface and massage the layers into one another so that they fuse. This creates a strong dressing that is solid on cross section. A splint whose separate layers are still visible on cross section is much weaker.

The padding should now be laid over the plaster and the dressing applied to the extremity, with the padded surface against the skin. An assistant can hold the splint against the extremity while it is wrapped in place with gauze bandage. Make sure the assistant uses the palms, rather than fingertips, when holding the plaster. Hardened finger dents can cause irritation or even pressure sores. If a compressive effect is desired, an elastic bandage may be wrapped over the gauze. (If an elastic bandage is wrapped directly onto plaster without an intervening layer of gauze, it will set into the plaster and lose its compressive function.)

While the plaster is setting, the physician may need to maintain the affected joint in a particular position. Again, the palms, rather than the fingers, should be used.

Once the setting process is well underway, if the position of a joint is changed, the dressing will crack and become functionally useless. If the joint has gradually migrated from the desired position, the physician must decide either to accept the current position or remove the dressing and start over. There is no need to feel self-conscious about the latter course. Patients generally appreciate a desire for perfection by their physician.

Types of Immobilization Dressings

The more common immobilization dressings used in the emergency department are discussed below.

SHOULDER IMMOBILIZER   This is a removable, Velcro-fastened device that keeps the arm in "sling position" but allows less mobility than a sling (Fig. 259-7). A wide band wraps around the thorax. Two cuffs are attached to the thoracic piece, one on the lateral side, which grasps the upper arm, keeping it adducted against the thorax, and one anterior, which grasps the wrist, keeping the forearm against the abdomen. This dressing is suitable for fractures about the shoulder girdle, including clavicle and well-positioned humeral neck fractures, as well as for reduced anterior shoulder dislocations.

FIG. 259-7. Shoulder immobilizer.

The shoulder immobilizer is also commonly used for acromioclavicular separations, although the ideal dressing for this injury is one that exerts upward pressure on the elbow and downward pressure on the clavicle. Commercial versions of such dressings exist, but they are cumbersome to apply and uncomfortable to wear, leading to non-compliance. A shoulder immobilizer (or sling and swathe) is an acceptable alternative dressing.

CLAVICLE STRAP (FIGURE-OF-EIGHT BANDAGE)   The purpose of an immobilization dressing for clavicular fractures is to maintain support and minimize pain. The figure-of-eight bandage or strap (Fig. 259-8) has long been considered the "appropriate" immobilization device, but more recent studies have shown it to be no more effective than a simple sling or shoulder immobilizer in terms of providing comfort and achieving alignment of the fragments. [8] Generally, anatomic alignment can be maintained only by surgical fixation, but this is a controversial modality because of its association with a significant frequency of non-union and other complications. In any event, manipulation and realignment of the fragments are usually unnecessary unless there is compromise to the subclavian neurovascular structures, entrapment of tissue, or the likelihood of penetration of the skin by a sharp fragment. While untreated malalignment may result in a permanent "bump" at the fracture site after healing (of which the patient should be forewarned at the initial visit), this should not prevent the ultimate return of normal function.

FIG. 259-8. Clavicle strap.

Another consideration is that, in contrast to a simple sling, a clavicle strap may be awkward to apply, may require frequent readjustment, may cause problems related to pressure on the brachial plexus, and is often uncomfortable. Finally, some studies suggest that, depending on the location of the fracture, a figure-of-eight may actually *increase* the displacement of the fragments. Nevertheless, for the sake of completeness, a description of this still-common dressing is included here.

The clavicle strap (figure-of-eight dressing) consists of padded straps that pass down the anterior aspect of both shoulders and under the axillae. The right and left halves of the dressing meet in back, where they are attached to clips centered between the scapulae. The straps, whose tension is adjustable, exert backward pressure on each shoulder.

Patients or their parents should be cautioned to watch for paresthesias or swelling in the hands or fingers. Such symptoms suggest that the dressing is too tight, and it should be removed until symptoms disappear. The strap may then be reapplied more loosely.

LONG-ARM ULNAR GUTTER SPLINT   This is a plaster splint that maintains the elbow in flexion, usually at 90° (Fig. 259-9). The upper extremity is placed in sling position (elbow flexed and palm facing the abdomen). The splint begins on the ulnar surface of the hand at the metacarpal heads and extends along the ulnar surface of the forearm, past the apex of the elbow, to a spot high on the lateral surface of the upper arm just opposite and below the axillary crease. It should be supplemented with a sling.

FIG. 259-9. Long-arm ulnar gutter splint.

The most common error associated with fashioning this dressing is insufficient length. If the splint is not carried far enough above the elbow, it will not be able to exert enough leverage to prevent motion of the joint.

The long-arm ulnar gutter is useful for injuries about the elbow, including radial head fractures, nondisplaced supracondylar humeral fractures, and reduced dislocation of the elbow.

SUGAR-TONG SPLINT   This is a plaster splint that prevents motion of the wrist and elbow, including pronation-supination (Fig. 259-10). The upper extremity is placed in sling position, as described above. The splint begins on the extensor aspect of the hand at the level of the metacarpal heads and extends along the extensor aspect of the forearm, around the elbow and humeral condyles onto the flexor aspect of the forearm, and ultimately to the palmar aspect of the hand, ending at the level of the metacarpal heads. It is wrapped in place with gauze and often topped off with a compression bandage. It should be supplemented with a sling.

FIG. 259-10. Sugar-tong splint.

Proper length of the sugar-tong dressing is important. Too short a splint will fail to immobilize the wrist. If the dressing is too long, it will impair motion of the metacarpophalangeal joints, leaving them stiff and making the fingers more susceptible to swelling due to immobility.

The sugar-tong splint is appropriate for fractures about the wrist or distal forearm. Some orthopedists use it as a definitive dressing after reduction of wrist fractures.

"COCK-UP" WRIST SPLINT (TO BE AVOIDED)   The "cock-up" splint is a removable device that encloses the forearm and hand, maintaining the wrist in a dorsiflexed position. The splint is fastened with Velcro straps. *Cock-up splints should not be used for fractures of the wrist or carpals* because such injuries are usually caused by forceful dorsiflexion and the splint only reproduces the position of injury, imposing considerable pain in the process. Fractures about the wrist are generally immobilized in neutral position with plaster dressings. Colles fractures may even be immobilized in slight palmar flexion after reduction.

"Cock-up" splints may be useful in some situations, such as to immobilize the wrist for tendinitis or to support it in the case of wrist drop due to radial nerve palsy. In such instances, dorsiflexion of the wrist will preserve the patient's grip strength.

SHORT-ARM ULNAR GUTTER SPLINT   This plaster splint immobilizes the wrist and ulnar half of the hand (Fig. 259-11). It extends along the ulnar surface of the hand and forearm, beginning just proximal to the tip of the fifth finger and ending high onto the forearm. The splint should be wide enough to encompass the fourth and fifth rays (fingers and metacarpals) on both the extensor and palmar aspects of the hand. The splint is wrapped in place with the fourth and fifth fingers bound together, separated by a thin layer of padding to prevent maceration of the skin. The metacarpophalangeal joints and interphalangeal joints should be positioned in gentle flexion. The dressing should be supplemented with a sling.

FIG. 259-11. Short-arm ulnar gutter splint.

The short-arm ulnar gutter is useful for fractures of the proximal phalanx of the ring or little finger, or for fractures of the fourth or fifth metacarpal (including the common "boxer's fracture"). The counterpart of this splint, the short-arm radial gutter, is designed in similar fashion but extends along the radial surface of the hand and forearm and is used for comparable injuries of the index or middle rays. It is fashioned with a hole that allows the thumb to pass through.

THUMB SPICA   This plaster dressing immobilizes the wrist and thumb (Fig. 259-12). The term *spica* applies to any dressing that encompasses a main trunk plus one or more of its branches, in this case, the forearm plus the thumb. It is used for fractures of the scaphoid or for fractures of the thumb metacarpal or proximal phalanx.

FIG. 259-12. Thumb spica splint.

A thumb spica can be fashioned from a single wide plaster splint, but a more effective and better-looking dressing can be made from two separate splints. The wrist

piece runs along the extensor aspect of the hand and forearm beginning at the metacarpal heads and ending just short of the elbow. The more narrow thumb piece, approximately 2 in wide, extends from the tip of the thumb (which has been padded separately), along the outer aspect of the thumb metacarpal, and onto the extensor aspect of the forearm, well overlapping the first splint. Along their area of contact, the two splints are molded into each other, with no padding between them, to form a sturdy dressing. The plaster is wrapped in place with gauze, and a compression wrap may be added at the physician's discretion. The dressing is supplemented with a sling.

While the plaster is setting, optimal position can be achieved by keeping the wrist in *neutral* position and having the patient oppose the tips of the thumb and index fingers in the form of an "OK" sign. This preserves thumb-index pinch function, minimizing the patient's incapacitation. It also avoids reproducing the position of injury in the case of scaphoid fractures, which are typically caused by forced dorsiflexion of the wrist.

KNEE IMMOBILIZER   This is a removable device that wraps around the upper and lower leg and maintains the knee in a fully or almost fully extended position (Fig. 259-13). The splint contains longitudinal metal struts and is fastened with Velcro straps.

FIG. 259-13. Knee immobilizer.

The knee immobilizer is useful for a variety of injuries, including fracture of the lateral or medial tibial plateau, fracture or subluxation of the patella, meniscal injuries (provided the patient's knee is not locked in partial flexion), and ligamentous strains or tears.

POSTERIOR ANKLE MOLD   This is a plaster splint that immobilizes the ankle (Fig. 259-14). It begins beneath the metatarsal heads, runs along the plantar aspect of the foot, and continues up the back of the lower leg, ending at high calf. The splint is used for severe ankle sprains or for stable ankle fractures, such as minimally displaced fractures of the distal fibula. Unstable fractures, such as those involving more than one malleolus or widening of the medial joint space (disruption of the deltoid ligament), may be supplemented by a sugar-tong component running down one side of the leg, beneath the heel, and up the other side. Where the two components overlap, they are molded together. The additional component helps minimize inversion-eversion of the ankle. Even more stability is provided by continuing the posterior splint past the back of the knee to high posterior thigh, using wider plaster for this area. With the knee slightly flexed, rotational motion at the ankle will be prevented as well.

FIG. 259-14. Posterior ankle mold.

While the plaster is setting, the ankle should be maintained in a position as close as possible to neutral, that is, at 90° to the leg. This maintains the width of the ankle joint and may allow the patient to regain range of motion more quickly after the dressing is removed. Because most patients with ankle injuries tend to keep the ankle plantar flexed, the physician will usually have to maintain passive dorsiflexion by exerting gentle pressure with a palm beneath the sole of the foot. An exception to the 90° principle is immobilization for rupture of the Achilles tendon. Patients with this injury should be immobilized in plantar flexion to reduce tension on the tendon.

ANKLE STIRRUP   Like the posterior mold, the commercially available inflatable ankle splint (Fig. 259-15A and Fig. 259-15B) is useful for ankle sprains and minor avulsion fractures. It is equipped with valves and tubes to allow the addition or removal of air, although it usually comes optimally pre-inflated. Printed instructions are typically included, describing the method of determining and creating the proper degree of inflation and also describing rehabilitation exercises for the patient.

FIG. 259-15. A and **B.** Inflatable ankle stirrup.

The ankle stirrup is essentially a "sugar-tong" splint held in place by Velcro straps. It prevents eversion and inversion but does not limit ankle plantarflexion or dorsiflexion. It is removable by the patient for purposes of bathing or when not bearing weight.

If the patient does remove the splint temporarily, a common error when re-applying it is to fail to unwrap the Velcro straps completely, specifically, to leave the straps attached posteriorly, so that the splint is "hinged" along its posterior aspect, like a "book." This may result in the foot's persistently slipping forward and out of the splint. The clinician may wish to instruct the patient that the proper way to re-apply the splint is to unwrap the straps *all the way around*, so that the sides fall apart bilaterally, with the foot pad acting as the "hinge" on the plantar aspect (Fig. 259-16). The foot can then be positioned on the lower pad, and the sides brought

together to adequately grasp the medial and lateral aspects of the ankle and lower leg. The final step is to wrap the straps about the posterior and anterior aspects of the dressing.

FIG. 259-16. Technique for applying ankle stirrup.

ADJUNCTS TO AMBULATION

Crutches

Crutches should be used by patients who can bear no weight at all on an injured lower extremity. Ideal crutch height is one hand width below the axillae. The grip bar should be adjusted to a height at which the elbows are still mildly flexed while supporting the body weight. The patient should be instructed to bear the pressure of the pads against the sides of the thorax rather than in the axillae, or brachial plexus injury might result (crutch palsy).

Any of several crutch gaits may be prescribed. With a two-point gait, the patient advances the crutches first, and then brings the well leg up to the crutches ("swing-to" gait) or just past the crutches ("swing-through" gait). With a three-point gait, the crutches and the injured extremity are all advanced together, and then the well extremity is advanced to meet them. The three-point gait results in slower forward progression than does the two-point gait, but requires less energy. Partial weight-bearing or no weight-bearing may be prescribed for the injured extremity, regardless of the gait used.

The method for negotiating stairs is similar for the two- and three-point gaits. Ascending stairs, the patient advances the well extremity up to the next step, followed by the crutches and the injured extremity. Descending stairs, the crutches are lowered first.

Walkers and Canes

Most elderly or infirm patients do not have the strength to use crutches safely. For them, a walker or cane is more suitable. Unfortunately, these devices are more appropriate for partial weight-bearing than for full non–weight-bearing conditions. Elderly patients who can bear no weight at all on an injured extremity may require initial bed rest and subsequent rehabilitation.

The technique for using a walker is essentially intuitive, with the patient simply lifting it and placing it a short distance ahead, then advancing up to it. By contrast, the technique for using a cane tends to be counterintuitive. Most patients instinctively hold a cane on the same side as the injured extremity. In fact, when the cane is held in the hand on the *well* side, much less strength is required to maintain balance, resulting in an easier and less awkward gait. The patient should be instructed to advance the cane (held on the well side) and the injured extremity simultaneously, then advance the noninjured extremity to meet them.

DISCHARGE INSTRUCTIONS

Continuous elevation of the injured part usually helps minimize swelling and pain. However, most individuals do not share the physician's knowledge that, to be effective, elevation must be above the level of the heart. Patients with an injured lower extremity often sit at home or at work with the leg resting on a chair, thinking they are complying with instructions. The patient should understand that the benefits of elevating a lower extremity can only be achieved in a recumbent or near-recumbent position, with the leg supported higher than the rest of the body.

Patients discharged in a lower-extremity plaster dressing should be cautioned not to rest the heel on the floor or any other hard surface. Plaster takes about 24 h to fully set. During this time, prolonged pressure on the heel can gradually create an indentation that may cause significant discomfort or even a pressure sore. This is not a consideration with fiberglass, which sets immediately.

If an upper-extremity sugar-tong dressing has been applied, the patient should be instructed to work the fingers (wiggle or wave) as much as possible to minimize stiffness and swelling. The sugar-tong splint should allow full flexion of the metacarpophalangeal joints.

Patients should be advised to watch the fingers or toes for excessive swelling, decreased sensation, or cyanosis, and to be alert for a significant increase in pain. Any of these signs or symptoms warrant a return to the emergency department or prompt evaluation by the follow-up physician.

When crutches, a cane, or a walker is supplied, instruction for use should be provided, and the patient's ability to navigate with such aids should be verified.

FOLLOW-UP

There is no universally prescribed follow-up interval for specific injuries. Physicians differ as to how soon patients should be seen. Generally, patients with unreduced fractures or injuries that require future surgical intervention should be seen within a few days.

Sometimes the situation may be discussed with the follow-up physician and an appointment arranged while the patient is still in the emergency department. Alternatively, the emergency physician may instruct the patient to contact the follow-up physician or clinic as soon as possible. If the name of the injury is written on the discharge instruction sheet, the patient can convey it at the time of the call. Based on this information, the follow-up physician can decide when the patient should be seen.

COMPLICATIONS

Complications associated with musculoskeletal injury may be early or delayed, and may occur minutes, days, weeks, or even months later.

Neurologic Deficit

Neurologic injury resulting from long-bone fractures or joint dislocations is usually due to traction or pressure on a peripheral nerve or a nerve plexus. Such complications usually manifest themselves early. Recovery may take hours, days, or weeks. Sometimes they are irreversible. Prompt reduction of deformity can often prevent, eliminate, or mitigate the effects of neurologic involvement, but is not a guarantee against permanent deficit.

Vascular Injury

Peripheral vessels that run close to a joint may sometimes be compressed or disrupted when that joint becomes dislocated, as, for example, with dislocation of the

ankle or knee (tibiofemoral joint). Loss of peripheral pulse, or poor-to-absent capillary refill, calls for expeditious reduction of deformity. Even after reduction, evidence of significant vascular injury may be delayed. Patients who experience tibiofemoral dislocation, for example, may undergo routine post-reduction angiography to verify the integrity and patency of the popliteal vessels, regardless of whether a circulatory deficit was noted on initial examination.

Compartment Syndrome

The limbs are divided into "compartments" by longitudinal partitions of fascia. Each compartment is a closed space, whose fascial borders are firm and relatively unyielding. With musculoskeletal injury, either a direct blow or a fracture, there may be extravasation of blood, swelling of muscle tissues, and impairment of venous flow within a given compartment. Eventually, this leads to increased pressure, which can compromise circulatory perfusion of the muscles and nerves in that compartment. If the tissues remain ischemic for a sufficient period of time, irreversible necrosis and permanent neurologic damage and muscle contracture can occur. [9]

Clinical evidence of ongoing compartment syndrome is a true emergency, requiring expeditious diagnosis and aggressive treatment, sometimes surgical fasciotomy, to try to prevent permanent disability.

Early diagnosis of compartment syndrome is typically presumptive, based on index of suspicion. Classic signs of compartment syndrome, the five "P's," have been described: pain, pallor, paralysis, pulselessness, and paresthesias. The problem is that, by the time all these signs are present, irreversible damage has almost always occurred. The emergency physician should be alert for the *earliest* sign of impending compartment syndrome, which is pain. Although some degree of pain is normally associated with fractures, it can usually be relieved by reduction, immobilization, and customary doses of oral or parenteral analgesics. Contrary to this is the pain associated with compartment syndrome, which is due to ischemia. It is perceived by the patient as deep, continuous, and poorly localized, and, unlike typical fracture pain, is extremely difficult to control, even with large and frequent doses of parenteral analgesics. In the upper extremity, the pain is typically exacerbated by passive extension of the patient's fingers. In the lower extremity, the usual exacerbating maneuver is passive flexion of the toes.

Other early signs of still-reversible compartment syndrome are tight swelling and tenseness along one aspect of an extremity, and paresthesias or hypesthesia in the area of skin served by the cutaneous nerve contained within the affected compartment. Unfortunately, none of these signs occurs consistently. However, they are sufficiently common that, when any of them is present (most commonly uncontrollable pain), the possibility of an evolving compartment syndrome should be considered and surgical consultation obtained. Patients with altered mental status, in whom pain and paresthesias cannot be relied upon as early indicators of compartment syndrome, need to be monitored for physical signs such as tenseness of the affected area, skin cyanosis (early) or pallor (late), and impaired circulatory status.

In some emergency departments, a percutaneous manometer is available to measure intracompartmental pressure. Under normal circumstances, the pressure should be close to zero. Pressures of 30–40 mm Hg usually indicate the need for fasciotomy. Once the pressure equals or exceeds the patient's diastolic blood pressure, perfusion of the tissues within the compartment is physiologically impossible, and fasciotomy may be indicated even in the presence of a palpable peripheral pulse.

Delayed and Late Complications

Patients who have sustained a fracture may be at risk for pulmonary fat embolus, usually originating from the marrow of a large bone, such as the femur. If fat embolism occurs, it usually does so within the first few days after injury, rather than in the first hours. This event may have a variable effect on pulmonary function, ranging from mild distress to severe or even fatal respiratory failure.

The most delayed complications of fractures include nonunion, malunion (healing with deformity), joint stiffness, traumatic arthritis of an involved joint, avascular necrosis of one of the bone fragments, and, in the case of open fractures, osteomyelitis.

260 INJURIES TO THE HAND AND DIGITS

Robert L. Muelleman

Hand injuries are commonly encountered in the ED. The best outcome often depends on an accurate initial evaluation and treatment. This chapter covers soft tissue injuries distal to the volar wrist crease and fractures distal to the carpal bones.

EPIDEMIOLOGY

Each year in the United States, nearly 1.4 million patients present to the ED with hand and finger symptoms. A recent series of 1000 consecutive hand problems indicated that 42 percent had lacerations, 27 percent had contusions, 17 percent had fractures, and 5 percent had infections. Two-thirds of presenters were male and one-third were under 18 years old; one-third of the injuries occurred at home. The most common mechanism was blunt trauma (50 percent) followed by sharp object (25 percent).

ANATOMY

The hand consists of 27 bones: 14 phalangeal bones, 5 metacarpal bones, and 8 carpal bones arranged in 5 rays of metacarpals and phalanxes having its base at the carpometacarpal (CMC) articulation (Fig. 260-1).

FIG. 260-1. Bones of the hand.

The carpal bones are made up of two rows of four bones. They are concave on the volar surface and bridged by flexor retinaculum. This forms the carpal tunnel through which pass the median nerve and the nine long flexor tendons of the fingers. The bases of the second and third CMC articulation are fixed. The thumb, ring, and little finger have mobility at the CMC joint and provide movement that allows for grasp and adaptive movement of the hand.

The soft tissue supporting these bones and joints are the capsular ligamentous structures that give stability, the intrinsic muscles of the hand, and the tendinous structures that generate mobility. The collateral ligaments of the MP joints are tightest in flexion (Fig. 260-2). The IP collaterals are tight throughout the entire range of motion (Fig. 260-2). The intrinsic muscles of the hand are those that have their origins and insertions within the hand. They consist of the muscle of the thenar and hypothenar eminences, adductor pollicis, the interossei, and the lumbricals.

FIG. 260-2. Ligament attachments of the metacarpophalangeal and interphalangeal joints.

The thenar muscles cover the thumb metacarpal, originate in the flexor retinaculum and carpal bones, and insert at the base of the first metacarpal and first proximal phalanx. The thenar muscles consist of abductor pollicis brevis, opponens pollicis, and flexor pollicis brevis. The median nerve innervates all three. Adductor pollicis

is innervated by the ulnar nerve and originates from the second and third metacarpals and inserts in the first proximal phalanx.

The hypothenar group includes opponens digiti minimi, the flexor digiti minimi, and the abductor digiti minimi. These muscles originate in the flexor retinaculum and carpal bones and insert at the proximal phalanx and metacarpal of the little finger. They are innervated by the ulnar nerve (Fig. 260-3).

FIG. 260-3. Anterior view of the hand showing relationship of muscles and tendon sheaths.

There are seven interossei. The three palmar and four dorsal interossei lie between the metacarpal bones and originate from them. The palmar interosseus and the palmar portion of the dorsal interosseus have an insertion into the extensor hood. The palmar interosseus adducts the index, ring, and small finger. The dorsal portion of the dorsal interosseus inserts by tendons into the base of the proximal phalanx. The dorsal interosseous muscles abduct the fingers away from the midline. The interossei are innervated by the ulnar nerve (Fig. 260-4).
FIG. 260-4. Origins, insertions, and actions of the palmar and dorsal interossei.

The lumbricals arise from the flexor digitorum profundus tendons in the palm and course radially to the metacarpophalangeal (MP) joints and reinforce the interosseous lateral band on the radial side of the digit. The lumbricals contribute little to the flexion of the MP joint; however, they contribute to the extension of the interphalangeal (IP) joints. The lumbricals play a critical role coordinating the flexor and extensor system of the digits. The median nerve innervates the radial two lumbricals, and the ulnar nerve innervates the ulnar two.

The extensor tendons course over the dorsal side of the forearm, wrist, and hand. Nine extensor tendons pass under the extensor retinaculum and separate into six compartments. In the dorsum of the hand, the extensores digitorum communis are connected by junctura. Because of this, a complete tendon laceration proximal to the junctura may still result in normal extensor function. In the finger, the extensor expansion divides into a central slip that attaches to the middle phalanx and into two lateral bands that join with the tendons of the lumbricals and interosseous muscles and that attach to the base of the distal phalanx (Fig. 260-5).
FIG. 260-5. The extensor mechanism in the finger.

The flexor tendons course over the volar side of the forearm, wrist, and hand. Flexor carpi radialis, flexor carpi ulnaris, and palmaris longus primarily flex the wrist. The remaining nine tendons pass through the carpal tunnel. One tendon goes to the base of the distal phalanx of the thumb. The other four digits have two tendons each. The flexor digitorum superficialis (FDS) inserts into the middle phalanx and flexes all the joints it crosses. The flexor digitorum profundus (FDP) runs deep to FDS until the level of the MP joint where FDS bifurcates. FDP inserts at the base of the distal phalanx and acts primarily to flex the distal interphalangeal (DIP) joint as well as all other joints flexed by FDS (Fig. 260-6). Unlike the extensor tendons, the flexor tendons are enclosed in synovial sheaths, making them prone to deep space infections.
FIG. 260-6. Anatomy of flexor digitorum superficialis (FDS) and profundus (FDP).

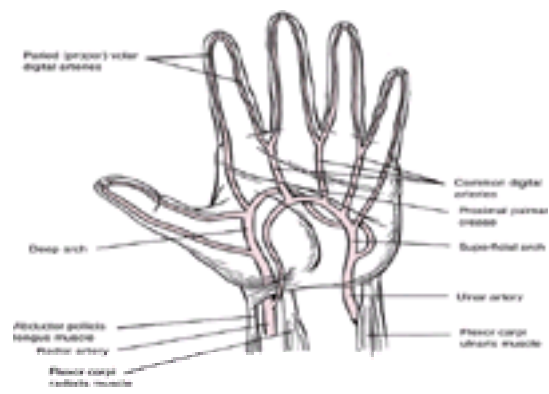
The hand and digits have dual blood supplies with contributions from the radial and ulnar arteries. The blood supply of the proximal portion of the hand is composed of a series of deep and superficial arches on the palmar and dorsal side. The blood supply of the fingers is distributed by the digital arteries that arise from the superficial palmar arch (Fig. 260-3 and Fig. 260-7).


FIG. 260-7. The dual blood supply to the hands and digits.

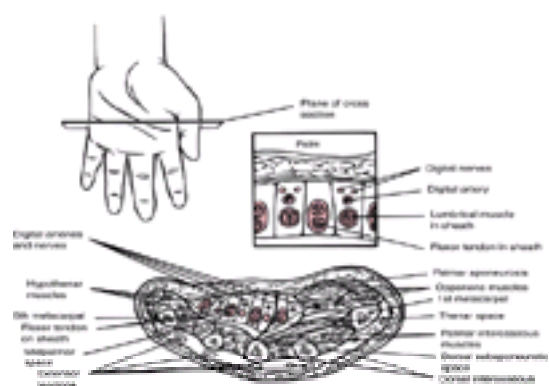
The radial, ulnar, and median nerves innervate the hand. In the hand, the median and ulnar nerves have mixed motor and sensory function. The radial nerve (C5–T1) just has sensory function to the dorsal radial aspect of the hand. The ulnar nerve (C7–T1) supplies sensory function to the ulnar one and one-half fingers and motor function to the hypothenar muscles, ulnar two lumbricals, interossei, adductor pollicis, and the deep head of the flexor pollicis longus. The median nerve (C5–T1) supplies sensory function to the thumb and radial two and one-half fingers and motor function to abductor pollicis brevis, superficial head of flexor pollicis brevis, and opponens pollicis (Fig. 260-8). As the digital nerves course through the palm, they are superficial structures and are the structures most often injured, so that digital nerve sensation and two-point discrimination should be routinely assessed when evaluating lacerations of the palm (Fig. 260-9). The palm is often called "no man's land" because penetrating injuries in this area are so difficult to evaluate and treat. Careful neurovascular testing of the hand and digits is necessary for all palmar injuries that involve more than the skin, and hand consultation is advised if the extent of injury is uncertain. In the digits, digital nerves divide into volar and dorsal branches to supply sensation to the fingers. Knowing their location is important to properly perform a digital block (see Fig. 260-3).
FIG. 260-8. The cutaneous nerve supply in the hand. M = median, R = radial, U = ulnar, PCM = palmar branch of median nerve, DCU = dorsal branch of ulnar nerve.


FIG. 260-9. Relationship of nerves, arteries, tendons, and muscles in the hand.

PRINCIPLES OF EVALUATION

It is important not to let a visually striking hand injury delay the identification and treatment of other potentially life-threatening injuries. After hemorrhage control, assessment involves a detailed history, general hand examination, testing of nerves and tendons, anesthesia, and direct wound inspection. Comparison with the uninjured hand is helpful, especially to identify partial motor or sensory deficits.

History

The history should include the time and cause of injury as well as the possibility of associated crush, burn, or chemical exposure. The position of the hand at the time of injury should be determined. Injuries with the digits in flexion may result in retraction of the cut end of the tendon when the digit is examined in neutral position. The patient's occupation, avocations, prior hand injuries, and handedness should be documented because they are important indicators of the functional impact of the injury.

General Hand Examination

The general examination should detail the extent of injury by documenting the amount of devascularization, status of the skin, posture of the fingers, and presence of deformity or active bleeding. Bilateral grip strength should be checked. Have the patient make a clenched fist to observe the orientation of the middle and distal phalanxes. They should be oriented parallel to each other with the nails positioned in the same plane when the fist is clenched. Then, starting with the fingers extended, the patient should draw the fingertips together, so that the tip of the thumb contacts the tips of the other four digits. This is a gross estimation of intact median, ulnar, and radial nerve motor function. Pincer function should also be routinely tested. Have the patient tightly grasp a piece of paper between the thumb and index finger. Weakness suggests median nerve or ulnar collateral ligament disruption, depending on the mechanism of injury being evaluated. Circulation is assessed

by regional pulses and capillary refill.

NERVE TESTING   To test the median nerve, have the patient flex the distal phalanx of the thumb against resistance. Test opposition by touching the tip of the thumb to the tip of the little finger. The patient may be able to accomplish this range of motion with loss of median nerve function due to compensation with muscle groups innervated by the ulnar nerve, but the patient will be unable to oppose against resistance if median nerve function is lost. Finally, test thumb abduction by placing the hand palm up and raising the thumb to the perpendicular while palpating the belly of the abductor pollicis muscle to insure it is contracting.

To test the ulnar nerve, spread the fingers apart against resistance and then push them together against resistance. To test the hypothenar muscles (ulnar innervation), extend the fingers and then move the fifth finger away from the others. To test thumb adduction (the ulnar nerve innervates the adductor pollicis muscles), bring the thumb tightly against the side of the index finger. Adductor strength can be further tested by interposing a piece of paper between the thumb and the side of the index finger and then trying to pull the paper away. To test the radial nerve, extend the fingers and wrist. With the thumb in the hitchhiking position, test its resistance to further extension.

Sensation is determined by two-point discrimination. Normal two-point discrimination is <6 mm at the fingertips and is often <2 mm. Both injured and noninjured fingers must be compared. Because patients are likely to guess correctly by chance, hand specialists recommend repeating two-point discrimination testing two to four times on each side of the digit. At least 80 percent accuracy is considered acceptable. Less than 80 percent or indeterminate accuracy suggests the possibility of digital nerve injury. A sensory deficit implies a potential digital artery laceration because of the close proximity of the two.

TESTING OF TENDONS   In assessing tendon function, full range of motion of each tendon against resistance should be assessed and compared with the uninjured side. It is important to test resistance because up to 90 percent of a tendon can be lacerated with preservation of range of motion without resistance. In addition, pain along the course of the tendon during resistance testing suggests a partial laceration even if strength appears adequate. Patients can distinguish deep pain of tendon laceration from the superficial pain of lacerated skin. FDP is tested by flexing the DIP against resistance while the MP and proximal interphalangeal (PIP) are held in extension. Flexing the PIP against resistance while the remaining fingers are held in full extension tests FDS. Each finger must be tested separately.

Anesthesia and Direct Wound Examination

Anesthesia and direct wound inspection is necessary because partial tendon lacerations or intraarticular injuries are not always readily apparent. Sensation and range of motion should be tested before anesthesia. In general, if a laceration needs to be extended in order to properly view the wound, hand consultation is in order. A bloodless field can be facilitated by milking the digit proximally and then applying a local tourniquet or Penrose drain around the base of the digit. The tourniquet should not be stretched to more than 150 percent of its length, and it can be held in place with a hemostat. The digit can be milked by wrapping another Penrose drain circumferentially around the entire digit, going from distal to proximal or by reconfiguring a 4 × 4 gauze dressing into a narrow band and wrapping that circumferentially around the entire digit. Only moderate compression should be used to avoid compression injury to the digit. The tourniquet should not be left in place for more than 20 min. Contaminated wounds should be copiously irrigated with normal saline and antibiotics administered. Tetanus toxoid should be administered as needed.

Radiographs, Consultation, and Disposition

Radiologic evaluation should include at a minimum a posteroanterior (PA), lateral, and oblique projection. Similar projections are used for the digits, except that the x-ray beam is centered over the digits. Actual or suspected injuries of tendons and nerves should be referred to a hand specialist. Whether consultation is provided in the emergency department or in follow-up (1 to 3 days) depends on local resources. Often the skin can be closed, the hand splinted in the position of function, and at follow-up the wound can be extended, explored, and definitive repair performed by the hand specialist. Most hand specialists prefer to do definitive repair within a 3- to 5-day window after acute injury. While most tendon injuries <20 percent may not be surgically repaired, hand specialist follow-up and rehabilitation are still necessary to accurately determine the extent of injury, minimize scarring and tendon contraction, and minimize neuroma formation.

For patients with hand or digit lacerations that are sutured in the emergency department, and where there is no suspicion of neurovascular or tendon injury, follow-up evaluation and suture removal in the emergency department should always include repeat hand examination to make sure that significant injuries have not been missed.

TENDON INJURIES

Flexor Tendons

The most common cause of flexor tendon injury is a laceration. Flexor tendon lacerations can be subtle; however, the careful examiner will identify these injuries. A classification system for flexor tendon injuries has been developed based on location, treatment considerations, and prognosis.

ZONE I   Extends from the insertion of FDS to the profundus tendon. Patients with these injuries lose flexion at the DIP. Retrieval of the proximal tendon is often difficult.

ZONE II   Involves the portion of the digital canal occupied by both FDS and FDP. The close proximity of these tendons makes it essential for exact repair with minimal operative trauma. This region is often referred to as "no man's land" because of the frequent poor outcomes prior to the 1960s when improved repair techniques were developed. Lacerations in this zone are common, and partial lacerations are more common then complete.

ZONE III   Extends from the distal edge of the carpal tunnel to the proximal edge of the flexor sheath. The lumbrical muscles originate from FDP in this region. Outcomes are generally favorable.

ZONE IV   Involves the carpal tunnel and related structures. The area must be explored carefully because so many vital structures go through the carpal tunnel. Isolated injuries are the exception.

ZONE V   Involves injuries to tendons proximal to the carpal tunnel. Injuries here tend to be severe and often involve multiple tendons as well as the median or ulnar nerve. It is essential to search for all major structures.

A hand surgeon should repair flexor tendon lacerations. Primary repair should occur within 12 h. Secondary repair can occur up to 4 weeks after the injury.

Another type of flexor tendon injury is the avulsion of FDP from its insertion in the distal phalanx. This can occur from a grasping motion against high-speed resistance. The patient will be unable to flex the distal phalanx. Prognosis depends on the size of the bony fragment, the length of time from injury to repair, and the blood supply to the tendon.

Extensor Tendon

The extensor tendons are the most common site of tendon injuries because of the superficial nature of the tendons on the dorsum of the hand. A classification system has been developed for assessing injury patterns, repair techniques, and rehabilitation.

ZONE I   Involves the area over the distal phalanx and DIP. Injury can occur from blunt or sharp trauma. Complete laceration or rupture of the tendon at this level will result in the DIP joint flexed 40°. This injury after blunt trauma is often referred to as "mallet finger," and it is the most common tendon injury in athletes. This injury has been classified as type I if there is tendon only rupture, type II if there is a small avulsion fracture, and type III if greater than 25 percent of the articular surface is involved. Types I and II can be treated with the DIP joint immobilized in slight hyperextension continuously for 6 to 10 weeks. Some hand surgeons may prefer operative treatment. Controversy exists whether treatment of type III injuries should be conservative or operative. Chronic untreated mallet finger may develop a swan-neck deformity (Fig. 260-10). This is caused when the lateral bands are displaced proximally and dorsally, resulting in increased extension forces on the PIP joint.
FIG. 260-10. Swan-neck deformity.

ZONE II   Involves the area over the middle phalanx. Injuries are usually due to laceration. Treatment is similar to zone I injuries.

ZONE III   Involves the area over the PIP. The central tendon is the most commonly injured structure. Complete disruption of the central tendon may result in the volar displacement of the lateral bands, causing them to be flexors, along with the unopposed FDP. Additionally, the extensor hood retracts, causing extension of the MP and the DIP joints resulting in the boutonnière deformity (Fig. 260-11). Closed injuries are treated with the petrosal interphalangeal (PIP) joint immobilized in extension for 5 to 6 weeks.

FIG. 260-11. Boutonnière deformity.

ZONE IV   Involves the area over the proximal phalanx. These injuries have clinical findings similar to zone III injuries. Often these injuries are less problematic because the joint is not involved and the tendon at this level is broad and flat.

ZONE V   Involves the area over the MP. Open injuries to this area should be considered human bites until proven otherwise. Wounds from human bites should have delayed repair when free from infection. Clean wounds can be repaired primarily.

ZONE VI   Involves the area over the dorsum of the hand. Because the tendons in this area are so superficial, even minor-appearing lacerations may be associated with one or more tendon injuries. If the laceration is proximal to the junctura tendineae, the patient may be able to extend the involved MP joint, because weak extensor forces are transmitted to the junctura from adjacent extensor tendons.

ZONE VII   Involves the area over the wrist. Repair here can be difficult because of the presence of the extensor retinaculum. This thick, fibrous structure on the dorsum of the wrist contains 12 extensor tendons and 6 retinacular compartments that are lined with synovium.

ZONE VIII   Involves the area of the distal forearm. Injuries to this area require a thorough exploration to identify all injured structures. The tendons frequently retract into the forearm and must be retrieved and repaired. As a general principle, lacerations of less than 25 percent don't require repair; 25 to 50 percent need simple suture repair, and greater than 50 percent need repair with a modified Kessler or similar technique. After repairs in zones V through VII, splinting should occur with the wrist in 15° extension, the MP joint in 15° flexion, and the IP in 15° flexion in the involved and adjacent digit.

LIGAMENT AND DISLOCATION INJURIES

Soft tissue injuries to the hand are extremely common. Accurate diagnosis and treatment are important to avoid complications such as joint luxatio, loss of motion, chronic pain, and deformity.

DIP

Dislocations of the DIP joint are uncommon because of the firm attachments of the skin and subcutaneous tissue to the underlying bone by osteocutaneous fibers. There is additional stability of the flexor and extensor tendons. When they do occur, they are usually dorsal. Longitudinal traction and hyperextension, followed by direct dorsal pressure to the base of the distal phalanx, accomplish reduction after digital nerve block. Irreducible cases may be due to the entrapment of an avulsion fracture, profundus tendon, or volar plate.

PIP

Dislocations of the PIP joint are one of the most common ligamentous injuries of the hand. The mechanism is usually due to axial load and hyperextension. Dorsal dislocation occurs when the volar plate ruptures. Lateral dislocations occur when one of the collateral ligaments ruptures with at least a partial avulsion of the volar plate from the middle phalanx. The digit is usually ulnarly deviated because the radial collateral ligament is six times more likely than the ulnar collateral ligament to rupture. Volar dislocations are rare. Dorsal dislocations are reduced similarly to DIP dorsal dislocations. After reduction, active motion and strength is tested. If testing is normal, the joint should be splinted at 30° flexion for 3 weeks. If the joint is irreducible or there is evidence of complete ligamentous disruption, operative repair is required.

MP

Dislocations of the MP joint are less common than at the PIP joint. The mechanism is usually due to hyperextension forces that rupture the volar plate causing dorsal dislocation. In simple dislocations (subluxation), the joint appears to be hyperextended 60 to 90° and the articular surfaces are still in contact. Reduction here does not involve hyperextension because it might convert a simple dislocation into a complex one. Reduction is performed with the wrist flexed to relax the flexor tendon and applying pressure over the dorsum of the proximal phalanx in a distal and volar direction. After reduction, the MP joint should be splinted in flexion. Complex dislocations appear less deformed. Because the volar plate is interposed in the MP joint space, closed reduction is usually not possible. Volar dislocations are rare and usually require operative reduction.

CMC

Dislocations of the carpometacarpal joint are uncommon because the joint is supported by strong dorsal, volar, and interosseous ligaments and are reinforced by the broad insertions of the wrist flexions and extensors. The cause is usually due to high-speed mechanisms such as motor vehicle crashes, falls, crushes, or clenched fist trauma. If a dislocation occurs, it is usually dorsal with associated fracture. Reduction of dorsal CMC dislocations can be attempted after regional anesthesia with traction and flexion with simultaneous longitudinal pressure on the metacarpal base. Early referral after reduction is needed to determine if further fixation is needed.

Thumb IP

Dislocations of the thumb IP are rare but, if present, usually open. The mechanism is usually hyperextension with rupture of the volar plate. Reduction is similar to the IP joints of the other digits. After reduction, the joint should be immobilized 3 weeks in mild flexion.

Thumb MP

Dislocations of the MP joint of the thumb are usually dorsal from a hyperextension force causing rupture of the volar plate. The dislocation may be simple or complex. Reduction, after radial nerve block, is accomplished with pressure directed distally on the base of the proximal phalanx with the metacarpal flexed and abducted.

Thumb MP Collateral Ligament Rupture

Rupture of the ulnar collateral ligament (gamekeeper's thumb; skier's thumb) occurs when the mechanism causes radial deviation (abduction) of the MP joint. The tear usually occurs at the insertion into the proximal phalanx. Often significant injury to the dorsal capsule and volar plate occurs. Stress testing of the ulnar collateral ligament is required and should be performed both in full extension and in 30° flexion. More than 40° of radial angulation indicates complete rupture and requires surgical consultation. Repair is best accomplished within 1 week. Radial collateral ligament rupture is not as common, and the mechanism is forced adduction.

Thumb CMC

Isolated thumb CMC dislocation is rare compared to the more common Bennett fracture dislocation. These are easy to reduce but unstable after reduction. After reduction, a thumb spica splint should be applied. These injuries should have a surgical referral for a decision on operative repair.

FRACTURES

Distal Phalanx

Fractures of the distal phalanx account for 15 to 30 percent of all hand fractures. Mechanisms are usually from crush or shearing forces. The fractures can be classified as tuft, shaft, or intraarticular. Tuft fractures can be associated with nail bed lacerations. Fractures at the base may be associated with flexor or extensor tendon involvement. Generally, these fractures are treated as soft tissue injuries with protective splinting.

Proximal and Middle Phalanx

The proximal phalanx has no tendinous attachments, therefore fractures frequently have volar angulation from the forces of the extensor and interosseous muscles. The middle phalanx has the FDS insert on the entire volar surface and the extensor tendon insert at the proximal base; therefore, fractures at the base have dorsal angulation and fractures at the neck result in volar angulation. A direct blow mechanism usually causes a transverse or comminuted fracture, while a twisting mechanism will more often result in a spiral fracture. Most often these fractures are stable and nondisplaced and can be treated with early protected motion by buddy taping. Unstable fractures amenable to closed reduction can be splinted from the elbow to the DIP with the wrist at 20° extension and the MP joint in 90° flexion. Midshaft transverse fractures, spiral fractures, and intraarticular fractures often require internal fixation.

Metacarpal (II-V) Fractures

The second and third metacarpals are relatively immobile, and fractures require anatomic reduction. The fourth and fifth metacarpals have 15 to 20° AP motion, which allows for some compensation. Metacarpal fractures are categorized as head, neck, shaft, or base fractures.

HEAD   Fractures of the metacarpal head are usually due to a direct blow, crush, or missile. These fractures are distal to the insertion of the collateral ligaments and are often comminuted. If a laceration is present, a human bite must be considered. Treatment consists of ice, elevation, and immobilization with referral to a hand surgeon.

NECK   Fractures of the metacarpal neck are usually due to a direct impaction force. A fracture of the fifth metacarpal neck is often referred to as a boxer's fracture. These fractures are usually unstable with volar angulation. Angulation of less than 20° in the fourth and 40° in the fifth metacarpal will not result in functional impairment. If greater angulation in these metacarpals occur, reduction should be attempted. In the second and third metacarpal, angulation of <15° is acceptable. These fractures should be splinted with the wrist in 20° extension and the MP flexed at 90°. Fractures of the second or third metacarpal that are significantly displaced or angulated require anatomic reduction and surgical fixation.

SHAFT   A direct blow usually injures fractures in this region. Rotational deformity and shortening are more likely in shaft fractures than in neck fractures. If manipulative reduction is necessary, operative fixation is usually indicated.

BASE   Fractures at the base of the metacarpal are usually due to a direct blow or axial force. They are often associated with carpal bone fractures. Fractures at the base of the fourth and fifth metacarpal can result in paralysis of the motor branch of the ulnar nerve.

Thumb Metacarpal

Because of the mobility of the thumb metacarpal, shaft fractures are uncommon. Fractures usually involve the base.

EXTRAARTICULAR   Extraarticular fractures are due to a direct blow or impaction mechanism. The mobility of the CMC joint can allow for 20° angular deformity. Angulation greater than this requires reduction and thumb spica splint for 4 weeks. Spiral fractures often require fixation.

INTRAARTICULAR   Intraarticular fractures are due to impaction from striking a fixed object. Two fracture types have been described.

BENNETT FRACTURE   A Bennett fracture is an intraarticular fracture with associated subluxation or dislocation at the CMC joint. The ulnar portion of the metacarpal usually remains in place. The distal portion usually subluxes radially and dorsally from the pull of abduction pollicis longus and the adductor pollicis. Treatment includes thumb spica splint and surgical referral.

ROLANDO FRACTURE   A Rolando fracture is an intraarticular comminuted fracture at the base of the metacarpal. The mechanism of injury is similar to the Bennett fracture, but less common. Treatment includes thumb spica splint and surgical consultation.

261 INJURIES TO THE ELBOW AND FOREARM

Dennis T. Uehara
Harold W. Chin

ELBOW

Elbow Dislocation

The elbow is one of the most stable joints in the body. This stability is due to the adjacent muscular attachments, collateral ligaments, and inherent stability afforded by the hingelike articulation. Because of this stability, surgical repair for acute instability is usually not required, and chronic dislocations are unusual. Despite this, however, dislocations of the elbow are commonly seen, being third in large-joint dislocations, after glenohumeral and patellofemoral dislocations.

There are five general types of elbow dislocations: (1) posterior, (2) anterior, (3) medial, (4) lateral, and (5) divergent. The vast majority of elbow dislocations are posterior, all the others being uncommon. The mechanism of injury is usually a fall on the outstretched hand.

Clinically the patient presents with the elbow in 45° of flexion. The olecranon is prominent posteriorly, and the deformity resembles a displaced supracondylar fracture. If the patient is seen immediately after the injury, the bony landmarks can be identified. Later, however, the swelling may be quite severe, with no possibility of evaluating the injury topographically. A careful assessment of the neurovascular status is performed, with specific attention to the brachial artery and the ulnar, radial, and median nerves. The examination must be performed before and after manipulation, since neurovascular complications occur in 8 to 21 percent of patients, the most frequent being injury to the ulnar nerve. Vascular complications occur in 5 to 13 percent of elbow dislocations, with brachial artery injury the most common. Endean and coworkers found absence of a radial pulse before reduction, open dislocation, and other systemic injuries (head, chest, and abdomen) to be significantly associated with an arterial injury.

Radiographically, on the lateral view, both the ulna and radius are displaced posteriorly (Fig. 261-1). In the anteroposterior view, there may be lateral or medial displacement, with the ulna and radius in their normal relationship to each other. A search for associated fractures should be performed. In the child, a fracture of the medial epicondyle is most commonly seen. In adults, fractures of the coronoid process, radial head, capitellum, or olecranon may occur. Initially, these fractures should only be noted, with primary attention focused on the dislocation.

FIG. 261-1. Posterior dislocation of the elbow.

After adequate sedation, reduction is accomplished by gentle traction on the wrist and forearm in the direction in which it lies (Fig. 261-2). An assistant applies countertraction on the arm. Any medial or lateral displacement is corrected with the other hand. Downward pressure on the proximal forearm helps to disengage the coronoid process from the olecranon fossa. Distal traction is continued, and the elbow is flexed. With reduction, a palpable "clunk" is felt as the olecranon is seated in the humeral articular surface. The elbow is then moved through its full range of motion (ROM) to assess stability. If full smooth passive ROM is not possible, the postreduction radiograph should be examined for entrapment of the medial epicondyle, especially common in children (Fig. 261-3). Instability in extension suggests associated fractures or disruption of the capsule.

FIG. 261-2. Reduction of posterior elbow dislocation. **A.** Operator applies gentle traction as assistant applies countertraction. Displacement is corrected with the other hand. Downward pressure on the proximal forearm disengages the coronoid process from the olecranon fossa. **B.** Distal traction is continued as the elbow is flexed.

FIG. 261-3. Postreduction radiograph of a posterior elbow dislocation. The medial epicondyle is fragmented in the joint space and is seen in the anteroposterior and lateral radiographs (*arrow*).

After reduction, the elbow is placed in a plaster splint from the axilla to the base of the fingers with the elbow in at least 90° of flexion. Because of the soft-tissue trauma and subsequent edema, cylinder casts should not be placed. A neurovascular follow-up examination should be obtained the following day.

Appropriate treatment of elbow dislocations requires adequate reduction and recognition of neurovascular complications, associated fractures, and postreduction instability. If there is any question of neurovascular compromise, the patient should be admitted for observation. Immediate orthopedic consultation should be sought if the dislocation is irreducible, if there is neurovascular compromise, for disruption of the joint capsule, if there are associated fractures, and for open dislocations.

Subluxation of the Radial Head (Nursemaid's Elbow)

Subluxation of the radial head is common among preschool children. The peak age is between 1 and 4 years, and it is usually not seen in children older than 7 years. The mechanism of injury is sudden traction on the hand with the elbow extended and the forearm pronated. Anatomically, during forceful traction, some fibers of the annular ligament, which encircles the radial neck, slip and become trapped between the radial head and capitellum. In the child up to age 5, the radial head is about the same size as the neck. After age 7, the size of the radial head is larger than the neck and subluxation does not occur.

Clinically the child sits comfortably with the parent, may even be playful, but does not use the injured arm. The arm is held in slight flexion and pronation. Supination is painful, and any effort to move the arm is resisted, although movement is free. The neurovascular examination is normal.

It is important to elicit the history of traction on the hand; the act may have been unrecognized by the parent or playmate or the history withheld because of a feeling of guilt or fear. Recently, an atypical history has been reported to occur in as many as 49 percent of radial head subluxations. Any child not using an arm that is flexed and pronated and without signs of trauma should be considered to have a radial head subluxation unless the history strongly suggests another diagnosis. Radiographs are unnecessary unless another diagnosis is being considered or if reduction is not accomplished.

Reduction is carried out by firmly placing the thumb over the radial head while the other hand is placed on the wrist. The forearm is fully supinated, and if a "click" is not felt, the elbow is flexed. This maneuver may be repeated if the initial attempt does not reduce the subluxation. Alternatively, the elbow may be extended. Both maneuvers are reported to be equally effective. Reduction as evidenced by a click is highly predictive and will result in relief from pain and, shortly thereafter, use of the affected arm.

After the first subluxation, no immobilization is required. For recurrent subluxations, however, orthopedic referral is needed. The patient's arm should be immobilized in a sling; some recommend a long-arm cast. Teach et al found a recurrence rate of 23.7 percent in either arm and 19.4 percent in the ipsilateral arm. Children 24 months or younger had a relative risk of 2.6 for recurrence when compared to children older than 24 months.

Intercondylar T or Y Fractures

Intercondylar fractures are much more common in adults than in children. Any distal humerus fracture in an adult should initially be assumed to be intercondylar rather than supracondylar (Fig. 261-4). A careful search should be made for a fracture line separating the condyles from each other and from the humerus. This distinguishes intercondylar T or Y fractures from other fractures of the distal humerus.
FIG. 261-4. Comminuted displaced and rotated intercondylar fracture (type IV).

The mechanism of injury is a force directed against the elbow, driving the olecranon against the humeral articular surface separating the condyles and producing the typical fracture. These fractures are associated with severe soft-tissue injuries. Treatment in the young is directed at anatomic reduction. In older patients with severe injuries, treatment is often directed at joint motion through nonoperative means. As in supracondylar fractures, patients with severe swelling or displaced fractures

should be admitted.

Supracondylar Fractures

These extraarticular fractures occur most commonly in children. Ninety-five percent are displaced posteriorly as a result of an extension force. When the mechanism of injury is due to a flexion force, the much less common anterior displacement occurs. There can also be various degrees of abduction, adduction, and rotation of the distal fragment.

EXTENSION-TYPE FRACTURES   In an extension-type fracture, the patient will have significant swelling and tenderness at the elbow. The olecranon is prominent, and there is a depression proximally over the area of the triceps muscle. This appearance may be easily mistaken for a posterior elbow dislocation.

Radiographs may reveal a fat-pad sign in undisplaced fractures (Fig. 261-5). This is due to visualization of fat from the olecranon fossa (posterior fat pad) as it is displaced by the hemarthrosis. This may also occur anteriorly (anterior fat pad), although this is a less reliable sign. In some undisplaced fractures, the fracture line may not be seen, with the fat-pad sign being the only evidence of injury. Treatment should be initiated as though a fracture were identified, with splint immobilization and orthopedic consultation. In displaced fractures, the anteroposterior radiograph usually reveals a transverse fracture line. More severely displaced fractures may show medial or lateral displacement or rotation along the axis of the humerus (Fig. 261-6). The lateral radiograph will reveal the fracture line extending obliquely from posterior proximal to anterior distal. The distal fragment will be displaced proximally and posteriorly.
FIG. 261-5. Anterior and posterior fat pad signs.

FIG. 261-6. Displaced supracondylar fracture. The distal fragment is displaced posteriorly, proximally, and medially. The proximal fragment is displaced anteriorly and distally.

Treatment of undisplaced fractures consists of plaster immobilization. Displaced fractures have the best results when reduced by closed methods followed by traction or pin fixation. Patients with displaced fractures or severe swelling should be admitted for observation of neurovascular status.

FLEXION-TYPE FRACTURES   Flexion-type fractures occur in fewer than 5 percent of supracondylar fractures. The mechanism is direct anterior force against a flexed elbow. This results in anterior displacement of the distal fragment. Since the mechanism is direct force, these fractures are often open.

Radiographs reveal an oblique fracture from anterior proximal to posterior distal. The distal fragment is anterior to the humerus.

Management consists of closed reduction and plaster immobilization or surgery if reduction cannot be maintained by closed methods.

COMPLICATIONS   There are numerous complications of supracondylar fractures, including nerve and vascular injuries and those occurring late, such as nonunion, malunion, myositis ossificans, and loss of motion.

Associated injuries to the median, ulnar, and radial nerves have been well documented and have an incidence of 7 percent. Recently, Cramer and coworkers found a high incidence of anterior interosseus nerve injuries in their patients with supracondylar fractures. This nerve arises from the median nerve and innervates the flexor pollicis longus, the radial part of the flexor digitorum profundus, and the pronator quadratus. Since there is no sensory component to the anterior interosseous nerve, identification of the injury can be made only by specific muscle testing. Testing consists of flexion at the index finger distal interphalangeal and thumb interphalangeal joints. The mechanism of injury is usually traction, contusion, or a combination. Complete transection is rare, and entrapment within the fracture occurs only occasionally. Prognosis is excellent, with complete recovery in 2 to 6 weeks.

Acute vascular injuries must always be suspected in patients with supracondylar fractures. Absence of a radial pulse is common in children. This is most frequently due to transient arterial spasm. Rarely, there is a partial or complete transection of the brachial artery, an intimal tear and thrombosis, or entrapment within the fracture fragment.

The most serious complication is Volkmann's ischemic contracture. This classically occurs after a supracondylar fracture, when edema reduces venous outflow and arterial inflow. This results in ischemia, which, if unrelieved, will lead to muscle and nerve necrosis and eventual replacement by fibrotic tissue. Refusal to open the hand in children, pain with passive extension of the fingers, and forearm tenderness are signs of impending Volkmann's ischemia. It is now well understood that the mere lack of a radial pulse does not indicate ischemia unless accompanied by these signs.

Treatment of supracondylar fractures with absent radial pulse begins with fracture reduction and pinning. Extremities still without a pulse and with signs of ischemia are taken to the operating room for fasciotomy and/or brachial artery exploration. Extremities without a pulse and no signs of ischemia may be treated in one of 3 ways: (1) close observation, (2) observation for 24 to 36 h followed by arteriography and surgery if indicated, or (3) immediate surgical exploration.

Humeral Condyle Fractures

Although rare, lateral condyle fractures occur more frequently than medial condyle fractures. The mechanism is usually a fall on the outstretched arm or direct force applied to the posterior aspect of the flexed elbow. Examination reveals swelling and tenderness laterally, crepitus, and limitation of movement. Radiographs show a fracture line extending from the supracondylar ridge through the intertrochanteric articular surface. There may be displacement of the distal fragment posteriorly and

distally from the pull of the extensor muscles.

Treatment for undisplaced and minimally displaced fractures (< 2 mm) is immobilization in a long-arm splint with the elbow flexed, the forearm supinated, and the wrist dorsiflexed to decrease the tension from the extensor muscles. The patient should be referred in 2 to 3 days to an orthopedist. Surgery is indicated for displaced fractures.

Medial condyle fractures usually occur as a result of a fall on the outstretched arm or a direct force applied to the olecranon. Pain and swelling medially are prominent findings. There is also pain with flexion of the wrist through action of the flexors. The proximity of the ulnar nerve requires a careful neurovascular examination. The fracture line is oblique from the supracondylar ridge through the trochlear groove.

Treatment of undisplaced and minimally displaced fractures is immobilization in a long-arm posterior splint with the forearm pronated and the wrist flexed to relieve tension of the flexors originating from the medial epicondyle. Referral to an orthopedist is made in 2 to 3 days and active ROM may be started in 2 to 3 weeks. Displaced fractures require open reduction and internal fixation, usually with screws.

Epicondyle Fractures

Lateral epicondyle fractures almost never occur, since the anatomic position of the condyle reduces the exposure to direct blows resulting instead in fractures of the lateral condyle. When they do occur, these fractures are usually avulsion fractures and may be treated by immobilization with the elbow flexed to 90° and the forearm in supination. The patient is referred to an orthopedist within 1 week.

Medial epicondyle fractures are more common and tend to occur in the pediatric and adolescent populations. The mechanism of injury is usually a posterior elbow dislocation with avulsion of a fragment of the medial epicondyle. In adults, the mechanism is from a direct blow to the prominent medial epicondyle. Examination reveals swelling and tenderness medially, and pain with flexion of the elbow or wrist from the forearm flexors. A careful search must be made of the radiographs to determine whether the fracture fragment is carried into the joint space after reduction of an elbow dislocation (Fig. 261-3).

Undisplaced and minimally displaced fractures are treated with a long-arm posterior splint with the forearm pronated and elbow and wrist flexed. The patient is referred to an orthopedist within 1 week, and early active ROM is begun. Fracture fragments entrapped within the joint require surgical removal if closed attempts are unsuccessful. Displaced fractures may be treated either surgically or by closed manipulation. These patients are splinted as described, and an acute referral is made to an orthopedist. Since the trochlea does not appear as an ossification center until after age 10 to 12 years, one must be mindful that a displaced medial condyle fracture may be associated with a significant trochlear fracture.

Trochlea Fractures

Owing to the anatomy and location of the trochlea, fractures are rarely seen. They are often the result of an elbow dislocation. Clinical findings include swelling, tenderness, and limitation of movement. Undisplaced fractures are treated with a posterior splint and referral in 2 to 3 days. Displaced fractures are treated by open reduction and internal fixation.

Capitellum Fractures

Like fractures of the trochlea, fractures of the capitellum are quite rare. The mechanism of injury occurs as a result of breaking a fall with the outstretched hand with the elbow in flexion or direct trauma to the elbow that is in full flexion. Three types of fractures are recognized: type I is a shearing of the capitellum from the lateral column, type II an osteochondral fracture of the anterior capitellum, and type III a comminuted or impacted fracture. Physical findings include tenderness and swelling laterally and limitation of ROM. Limitation of movement is due to mechanical obstruction from the fracture fragment in flexion or extension. Clinical as well as radiographic evaluation is also directed at determining associated injuries, especially a radial head fracture. Standard radiographs are generally sufficient to evaluate the injury. Special attention must be directed at the radiographs, since the fracture fragment consists largely of cartilage that will not be easily recognized, especially against the background of the humerus. The lateral radiograph may reveal the fragment anterior and proximal to its usual anatomic position.

Undisplaced fractures are initially treated in a long-arm splint with the elbow flexed to 90° and the forearm neutral. Although a recent paper described closed reduction for displaced fractures, most authors recommend open reduction and fixation with screws or Kirschner (K) wires.

Coronoid Fractures

Coronoid fractures are rare and often associated with elbow dislocations. Some classify these fractures according to the size of the fracture fragment and the stability of the joint. Type I fractures involve an avulsion the tip of the coronoid process, type II fractures involve 50 percent or less of the coronoid process, and type III fractures involve greater than 50 percent of the coronoid process and are unstable. Type I fractures may be treated with early immobilization. Types II and III fractures are generally unstable and are treated by open reduction and internal fixation. Emergency treatment consists of immobilization, ice, elevation, and early orthopedic consultation.

Olecranon Fractures

Fractures of the olecranon are common because of its subcutaneous location. The mechanism of injury is usually direct trauma to the tip of the elbow. Olecranon fractures may be avulsions, oblique or transverse intraarticular, or comminuted. Clinical findings include swelling and tenderness over the olecranon, limitation of movement, a palpable fracture line, and inability to fully extend the elbow. Because of its proximity, examination is especially directed at evaluation of ulnar nerve function. Ulnar nerve injuries are usually transient neuropathies. Standard anteroposterior and lateral radiographs will identify the fracture, the extent of comminution, and the articular surface involved. As many as 32 percent of olecranon fractures may be associated with other fractures, the commonest being fractures of the radial head or neck.

Undisplaced fractures (< 2 mm displacement) in both flexion and extension are treated with splint immobilization with the elbow placed in 45° of flexion. Follow-up is within 1 week. Displaced fractures (> 2 mm displacement) are treated by open reduction and excision of the proximal olecranon fragments or internal fixation with screws, plates, or tension-band wiring. Complications include loss of ROM, nonunion, ulnar nerve compression, and posttraumatic arthritis.

Radial Head Fractures

Radial head fracture is the most commonly encountered fracture about the elbow. The mechanism of injury is a fall on the outstretched hand with the force transmitted along the radius to the radial head, where it impacts on the capitellum. The result is a fracture of the weaker radial head or neck. An alternative mechanism is direct trauma to the lateral aspect of the elbow directly over the radial head. The patient complains of pain in the elbow, and examination reveals swelling and tenderness laterally. Rotation of the forearm with firm pressure over the radial head will elicit pain. Careful examination of the wrist and forearm for tenderness must be performed to determine whether there has been injury to the distal radioulnar ligaments or to the interosseus membrane. The latter injuries result in radioulnar dissociation (Essex-Lopresti) and proximal migration of the radius if the radial head is excised. Anteroposterior and lateral radiographs are generally sufficient, but occasionally radiocapitellar views are required. A fat-pad sign in a patient with an appropriate mechanism of injury is sufficient to make a presumptive diagnosis of a radial head fracture regardless of whether or not the fracture is visualized (Fig. 261-5).

Undisplaced and minimally displaced fractures are treated with sling immobilization and early ROM. Such patients have excellent results with little morbidity. All other fractures should be referred acutely to an orthopedist, since treatment varies from early motion to radial head excision and prosthetic radial head implantation.

ULNAR NEURITIS

Ulnar neuritis may be a compressive neuropathy or can be simply a result of direct repetitive stretching or friction. The two most common problem sites are at the elbow (cubital tunnel) and at the wrist (Guyon's canal). In cubital tunnel syndrome, the nerve may experience trauma or compression against the medial epicondyle,

such as from pitching or playing golf. In Guyon's canal, damage may result from direct pressure, such as in holding bicycle handlebars.

Numbness or weakness in the ring and small fingers or medial elbow pain indicate ulnar nerve pathology. Tapping along the nerve may reveal the site of involvement. Signs and symptoms of cervical spine disease or thoracic outlet syndrome should also be sought.

To test for cubital tunnel syndrome, hold the elbow in maximum flexion for 1 min. This may reproduce or exacerbate symptoms due to peripheral ulnar nerve pathology. Cubital tunnel syndrome may in addition cause numbness over the dorsoulnar hand because of inclusion of the superficial branch. Thumb adduction is also weak because of the ulnar innervation of the adductor pollicis muscle. This can be tested by having the patient tightly hold a piece of paper between the thumb and the proximal phalanx of the index finger. If the phalanx must flex more than a few degrees, then the muscle is weak (Froment's sign).

Pathology in Guyon's canal spares this deep branch so that numbness of only the ring and small fingers, not of the hand, occurs. Similarly, Froment's sign is absent because the adductor pollicis is innervated by the deep branch.

Cubital tunnel syndrome in its milder form can initially be treated with rest. Failing this, orthopedic surgery to decompress or anteriorly transpose the nerve may be needed.

Guyon's canal syndrome is first treated with the wrist splinted in mild dorsiflexion and nonsteroidal anti-inflammatory drugs (NSAIDs). While resistant cases may respond to steroid injection into the canal, the majority will require surgical decompression.

EPICONDYLITIS

Lateral Epicondylitis

In this condition, also known as tennis elbow, pain is noted at the origin of extensors of the distal arm. While it occurs from racquet sports and repetitive manual labor, it may also occur spontaneously. When it is from racquet sports, a faulty backhand stroke is usually to blame. The extensor mass, especially the deep extensor carpi radialis brevis, rubs and rolls over the lateral epicondyle and radial head. In addition, there is pulling on the extensor origin, resulting in microtears.

Pain is increased over the lateral epicondyle with pronation of the forearm and concomitant dorsiflexion of the wrist against resistance. Lifting a chair with the affected hand in pronation should also exacerbate symptoms. Picking up a full cup of liquid also reproduces the pain.

Treatment includes avoidance of the painful activity and use of NSAIDs. Utilizing supination in daily grasping activities will aid in rest of the area. In the case of racquet sports, instruction in a quality backhand should be sought after the acute injury heals. Those who use a two-handed backhand are rarely afflicted. Orthopedic referral is advised for further evaluation and treatment.

Medial Epicondylitis

Although also known as golfer's elbow, this syndrome often occurs from racquet sports and pitching. Overuse of the flexor forearm muscles stresses and inflames the tendinous insertion at the medial epicondyle.

Pain will be noted over the medial epicondyle, and grip may be suboptimal secondary to pain. Pronation or wrist flexion against resistance will increase the pain over the medial epicondyle. About two-thirds of these patients have concomitant ulnar neuritis (cubital tunnel syndrome).

Treatment is conservative, with rest and NSAIDs. Play is gradually resumed after 6 weeks.

BICEPS RUPTURE

Functional Anatomy

The biceps muscle originates on the coracoid process (short head) and the superior glenoid labrum (long head) and inserts on the bicipital tuberosity of the radius. The long tendon runs over the head of the humerus in the bicipital groove and courses to its insertion inside the shoulder joint. This makes it susceptible to repetitive microtrauma and degenerative changes from repetitive overuse.

The biceps functions to flex the elbow and supinate the forearm. Ninety-seven percent of ruptures are proximal, occurring in the long head of the biceps. Distal rupture is rare, with fewer than 200 cases reported in the literature. Tendon rupture is usually the end result of repetitive microtrauma with degenerative changes and so is seen most frequently in patients between the fourth and sixth decades of life. Chronic glucocorticoid use and/or injection are also etiologic. The injury is unusual in young athletes. Rupture is precipitated by sudden or prolonged muscle contracture against resistance, such as with heavy lifting or a checked baseball swing.

Proximal Biceps Rupture (Long Head)

CLINICAL FEATURES   Patients with acute ruptures usually relate a long history of tendinitis. Symptoms include anterior shoulder pain and an audible "pop" or "snap" during strenuous activity. Examination demonstrates tenderness, swelling, and crepitus over the bicipital groove. Flexion of the elbow elicits pain. Weakness in flexion and supination is minimal (10 to 20 percent) because of the function of the short head of the biceps. Ecchymoses and a visible gap in the muscle, caused by distal migration of the muscle mass with resulting egg-shaped swelling, are usually obvious. Slow contraction of the biceps makes this deformity more prominent. Rupture usually occurs in the proximal one-third of the tendon at the top of the bicipital groove. Occasionally this injury involves an avulsed fragment of bone. Radiographs are necessary to rule out an avulsion fracture.

DIFFERENTIAL DIAGNOSIS   The differential diagnosis includes biceps tendinitis, subluxation-dislocation, rotator cuff disease, impingement syndrome, partial rupture, and osteochondral fracture.

TREATMENT   Treatment is surgical repair of the tendon in the young athletic patient. The older patient can be treated conservatively with immobilization, followed by early and progressive mobilization and strengthening exercises as soon as pain subsides. Orthopedic consultation should be obtained in the emergency department. Admission is required only for surgical repair. Emergency department treatment consists of ice and analgesia. Outpatient treatment requires immobilization in a sling, analgesia, and intermittent application of ice for 48 to 72 h.

Distal Biceps Avulsion

CLINICAL FEATURES   Almost all cases of distal biceps rupture occur in males, and 80 percent occur in the dominant extremity. A single traumatic event causes acute rupture, resulting in symptoms of pain in the antecubital fossa accompanied by a tearing or popping sensation. Examination will demonstrate tenderness, swelling, ecchymosis, and inability to palpate the biceps tendon in the antecubital fossa. Comparison with the uninjured extremity for asymmetry will aid in making the diagnosis. Deformity in the muscle is palpable as the biceps retract proximally during contraction. The patient can still flex the elbow and supinate the forearm because of intact brachialis and supinator muscles, but strength loss will be much more prominent (40 to 50 percent) than with proximal biceps ruptures. The rupture usually occurs at the tendon-osseous insertion and leaves no distal tendon fragment at the tuberosity. Avulsion fractures are unusual but should be ruled out by radiographs.

DIFFERENTIAL DIAGNOSIS   The differential diagnosis includes biceps tendinitis, partial tear, bursitis, anterior capsulitis of the elbow, and annular ligament sprain.

TREATMENT   Treatment is surgical tendon repair, and thus orthopedic consultation to plan for timing of repair is warranted. Emergency department treatment consists of ice and analgesia. If the patient is discharged home with plans for later surgical repair, immobilization in a sling and analgesia are standard.

TRICEPS RUPTURES

Functional Anatomy

The triceps muscle acts as both an extensor of the shoulder through its attachment to the scapula and as a powerful extensor of the elbow. All three heads form a common tendon attached to the olecranon.

Clinical Features

The triceps muscle is extraordinarily injury free, but rupture of the common tendon can occur. This is the least common of all tendon ruptures. Rupture most frequently occurs in young males (mean age, 26 years) secondary to trauma. There is an equal distribution between dominant and nondominant extremities. The site of rupture is usually the tendon-osseus junction, resulting in a high percentage of avulsion fractures of the olecranon. Musculotendinous junction and muscle belly ruptures are rare. The injury usually occurs as a result of indirect trauma from a fall on the outstretched extremity. Ruptures from direct blows and spontaneous ruptures from systemic illness have been reported.

Symptoms of acute rupture include pain and soft tissue swelling at the posterior elbow. The ability to extend the elbow is lost. Examination often shows a palpable defect proximal to the olecranon, along with localized tenderness and swelling. Radiographs of the elbow must be obtained, since olecranon avulsion fractures are present in greater than 80 percent of cases.

Differential Diagnosis

Differential diagnostic possibilities include olecranon bursitis, partial rupture or strain, degenerative joint disease, and olecranon fracture. Associated fractures are common. Thus, a thorough upper-extremity examination must be carried out, and the posterior aspect of the elbow must be examined when other injuries are detected initially.

Treatment

Treatment is surgical repair of the tendon to restore extension strength. Orthopedic consultation should be obtained. Emergency department treatment consists of ice and analgesia. If the patient is discharged, a sling and analgesia, along with intermittent ice application, are usually prescribed.

FOREARM

Anatomy

The radius and ulna are joined together along their entire length by a fibrous interosseous membrane and touch only at their ends to form the complex proximal and distal radioulnar joints. The ulna is a comparatively straight bone, whereas the radius has an important outward bowing. During the motions of supination and pronation, the ulna holds a relatively fixed position, while the radius rotates around it. Because these bones have such a close relationship to one another, injury to either will have a direct impact on the other. A displaced or angulated fracture of one bone typically disrupts the other or causes a dislocation at the proximal or distal radioulnar joint, such as in the Monteggia and Galeazzi fracture-dislocations.

The radius and ulna are also under the influence of numerous muscle groups, such as those that supinate and pronate. The biceps brachii and the supinator insert on the proximal radius and are the powerful supinators of the forearm. The pronator teres inserts just distal to them and onto the midsection of the radius. As its name suggests, it is responsible for pronation. Radius fractures that are located between these muscle groups will result in marked displacement of the bone, with supination of the proximal segment and pronation of the distal portion. However, if the fracture is distal to the insertion of the pronator teres, these forces tend to neutralize one another and result in less rotational deformity.

The neuroanatomy is most easily understood by appreciating the neural control of the most basic components of wrist and finger movement (Fig. 261-7). The radial nerve travels over the lateral epicondyle and supplies the muscles involved in wrist extension before it gives off a branch, the posterior interosseous nerve. This branch travels around the proximal radius and controls the muscles that extend the fingers and thumb. The remainder of the radial nerve is purely sensory and innervates the posterior aspect of the hand from the thumb to radial half of the ring finger. Quite simply, the proximal portion of the radial nerve controls the more proximal function of wrist extension, while the distal branch (posterior interosseus nerve) controls the more distal function of finger extension and another branch that is purely sensory. So an isolated injury (e.g., to the posterior interosseous branch) would affect finger extension but spare wrist extension and sensation to the dorsum of the hand. The single best test of radial nerve function is to have the patient extend both the wrist and fingers against resistance, and check the sensation over the dorsum of the hand.
FIG. 261-7. A. The radial nerve controls wrist extension before branching into the posterior interosseous nerve. **B.** The median nerve controls wrist flexion and the flexor digitorum superficialis before branching into the anterior interosseous nerve (controls the deep finger flexors in the forearm) and a branch that innervates the thenar muscles and provides sensation to most of the palm. **C.** The ulnar nerve controls the intrinsic muscles and sensation to the ulnar side of the hand. [From Chin HW, Propp DA, Orban DJ: Forearm and wrist, in Rosen P, Barkin RM, et al (eds): *Emergency Medicine Concepts and Clinical Practice,* 3d ed, vol 1. St. Louis, Mosby Year Book, 1992.]

The median nerve controls the basic movements of wrist and finger flexion and sensation on the volar surface of the hand from the thumb to the radial half of the ring finger. The proximal portion of the median nerve innervates the muscles that control wrist flexion and the flexor digitorum superficialis before it gives off the anterior interosseous nerve. This branch controls portions of the remaining deep finger flexors: flexor digitorum profundus, flexor pollicus longus, and pronator quadratus. The remaining portion of the median nerve provides sensation to most of the volar surface of the hand plus a motor branch to the thenar muscles of the thumb (recurrent branch of the median nerve). The median nerve is evaluated by assessing each of these distal branches. A simple test of the anterior interosseous nerve is the ability to make a circle, or "OK" sign, with the thumb and index finger; if so, this nerve is likewise "OK." Abduction of the thumb (recurrent branch of the median nerve) and intact sensation on the radial side of the palm complete the evaluation of the median nerve.

The ulnar nerve provides innervation to a few forearm muscles but, more important, controls the intrinsic muscles of the hand and provides sensation to the little finger and the ulnar half of the ring finger. The ability to abduct the index finger against resistance and normal sensation on the ulnar side of the hand is an easy test of ulnar function.

Fractures of Both Radius and Ulna

A great amount of force is necessary to fracture both the radius and ulna. This injury occurs most often from vehicular trauma, falls from a height, or a direct blow to the forearm. The magnitude of the force determines the type of injury. A moderate force produces transverse or mildly oblique fractures. Comminuted and segmental fractures are produced by a high-impact force. As one might expect, these fractures are often displaced. Open fractures of the radius and ulna are second only to tibia fractures because of the subcutaneous location of the entire ulna and the distal portion of the radius.

Nondisplaced fractures of both bones are exceedingly rare because the force necessary to produce the injury is also sufficient to displace it. However, in this event, a long-arm cast is applied, and frequent reevaluation for potential displacement is necessary.

Displacement of both bones is generally the rule. Examination reveals swelling, deformity, and tenderness of the forearm. Careful assessment of the neurovascular status is imperative. Nerve injuries can be seen with severe open fractures but fortunately are uncommon with most closed injuries. Because of the excellent collateral circulation of the forearm, vascular compromise is generally not a major problem if either the radial or ulnar circulation is intact.

The fractures are clearly visible on the radiographs. Angulation and longitudinal alignment are easily evaluated, but changes in rotational alignment may be subtle. A rough estimate of rotational alignment can be made by noting the normal orientation of various bony prominences of these bones. On the anteroposterior radiograph, the radial styloid and radial (bicipital) tuberosity normally point in opposite directions, whereas the ulnar styloid and coronoid process do so on the lateral view. A change in this arrangement suggests rotation malalignment. Since these bones are also oblong rather than circular in their cross-sectional appearance, a sudden change in the bone's width at the fracture site is another clue to a rotational deformity.

Although there are some reports of adequate reduction using closed techniques, the potential for these injuries to subsequently displace, in spite of cast immobilization, makes this alternative unpredictable. An exception is the injury in a child. A child's ability to remodel bone and compensate for some malalignment makes closed reduction possible. Otherwise, these injuries invariably require open reduction and internal fixation, most commonly with compression plating and screws. The use of external fixation may be necessary in situations where infection is possible, such as severe open fractures, comminution, or bone loss. Internal fixation is delayed until the risk of infection is diminished.

Potential complications include reduced ability to supinate and pronate, osteomyelitis, nonunion, malunion, neurovascular injury, and compartment syndrome. Recognizing the development of a compartment syndrome is particularly important to prevent debilitating ischemic contractures of the forearm. The diagnostic findings are palpable induration of the area, pain with passive movement of the fingers, and pain that appears to be disproportionate to the physical findings. The presence of a palpable pulse does not exclude the diagnosis of compartment syndrome. Alterations in sensation and the pulse are late findings. Direct measurements of elevated compartment pressures confirm the diagnosis.

Ulna Fractures

Isolated fractures of the ulna most often result from direct blows to the forearm. The natural response to raise the forearm in defense of a blow from a club is why it is often referred to as a *nightstick fracture*. Undisplaced fractures are immobilized in a long-arm cast and closely followed for subsequent displacement of the fracture.

Displaced fractures are those with greater than 10° of angulation or displacement of more than 50 percent of the width of the bone at the site of the fracture. Open reduction and internal fixation with a compression plate and screws are necessary to prevent angulation, loss of length, and rotational deformity. These injuries should be closely scrutinized for any possible radius fracture or dislocation.

Fracture of the ulnar shaft with a radial head dislocation is often referred to as *Monteggia fracture-dislocation* (Fig. 261-8). It is typically a diaphyseal fracture in the proximal third of the ulna with an anterior dislocation of the radial head (60 percent of cases). Anterolateral and posterolateral dislocation of the radial head or a metaphyseal ulna fracture are other possibilities. Clinically, there are considerable pain and swelling at the elbow. The radial head may be palpable in an anterolateral or posterolateral location. The forearm may appear shortened and angulated. The ulnar fracture is clearly visible and may overshadow the less obvious radial head dislocation. As a rule, the radial head normally points to the capitellum in all radiographic views of the elbow. In a Monteggia fracture, the apex of the ulna fracture points in the direction of the radial head dislocation.
FIG. 261-8. Monteggia fracture-dislocation. The angulation of the comminuted fracture of the proximal ulna (*arrow*) points in the direction of the radial head dislocation (*arrowhead*).

Monteggia fracture-dislocations are treated with open reduction and internal fixation of the ulna and closed reduction of the radial head dislocation. Children may be treated adequately by closed reduction of both bones and long-arm cast immobilization. Complications include nonunion, redislocation, infection, and paralysis of the posterior interosseus nerve. Remember that the nerve wraps around the proximal radius.

Radius Fractures

Radius fractures can be divided into those that are proximal and those that are distal to the junction of the middle and distal thirds of the bone. Excluding radial head fractures, isolated fractures of the proximal two-thirds of the radius are not common because it is relatively well protected from direct blows by the ulna and also by the surrounding musculature of the forearm. Undisplaced fractures are rare; these are treated with cast immobilization. Fractures of the proximal two-thirds of the radius are often displaced by both the force of the injury and the action of the supinators and pronators on the radius. They require internal fixation with plating and screws to maintain the reduction and to prevent rotational deformity.

Fractures of the distal third of the radial shaft are produced by falls on the outstretched hand in forced pronation or by a direct blow. Much like the Monteggia fracture-dislocation, the distal radial shaft fracture is often associated with a distal radioulnar joint dislocation, hence the name *reverse Monteggia fracture* or, more commonly, *Galeazzi fracture*. There are localized tenderness and swelling over the distal radius and wrist. The radius fracture is usually short oblique or transverse with dorsal lateral angulation. The distal radioulnar joint injury can be subtle. Radiographs may show only a slightly increased distal radioulnar joint space on the anteroposterior view. On the lateral view, the ulna is displaced dorsally. This injury is treated by open reduction and internal fixation of the radius fracture with compression plating and screws. The distal radioulnar joint reduction is held with immobilization of the forearm in supination or with K-wire fixation for 6 weeks.

Dennis T. Uehara

The wrist comprises the area from the distal radius and ulna to the carpometacarpal joints. It is a complex unit with articulations among eight carpal bones and the distal radius and ulna. Injuries to this area are common and diagnosis is often difficult. An understanding of the functional anatomy, mechanics of injury, and clinical assessment is needed for proper diagnosis and treatment.

ANATOMY

The distal radius is the only forearm bone that articulates directly with the bones of the carpus (scaphoid and lunate). The distal radius has three articular surfaces: radiocarpal, distal radioulnar, and the triangular fibrocartilage. The radiocarpal surface of the radius is concave and tilted in two planes. The radius has an ulnar inclination or tilt of 15 to 25 degrees in the frontal plane and a volar tilt of 10 to 15 degrees in the sagittal plane. The ulna is separated from the carpal bones by a cartilage complex on its distal end, the triangular fibrocartilage complex (TFCC). This cartilage complex forms a smooth continuous ulnarly directed extension of the distal radial surface and supports the lunate and triquetrum, on the distal ulna. The triangular fibrocartilage complex is also the main stabilizer of the distal radioulnar joint. The distal radius has a concave sigmoid notch on its ulnar aspect that articulates with the curvature of the ulnar head permitting rotation of the wrist. The distal radioulnar joint is also supported by dorsal and volar radioulnar ligaments that merge with the triangular fibrocartilage complex.

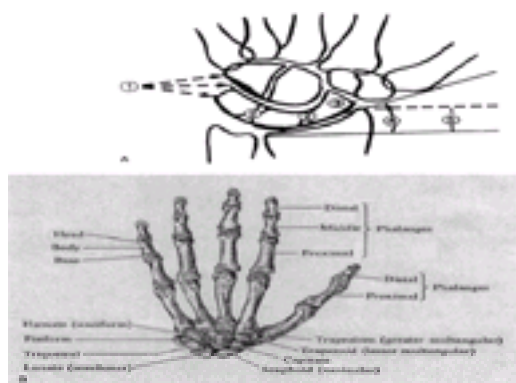
The eight carpal bones are arranged in two rows (Fig. 262-1 *A*, Fig. 262-1 *B*). The distal row (trapezium, trapezoid, capitate, and hamate) is quite stable. These carpal bones are joined tightly together and to their adjoining metacarpals. The distal carpal row and metacarpals move together as a unit forming a relatively rigid stable arch. The proximal row (scaphoid, lunate, triquetrum, and pisiform) is also arranged in an arch in the frontal plane located between the distal radius and distal carpal row. The proximal carpal row functions as a mobile middle link or "intercalated segment" in this arrangement. By virtue of its position, the proximal carpal row is potentially unstable. The scaphoid holds a unique position, acting as a stabilizing strut and linking the proximal and distal carpal rows on the radial aspect of the wrist. This explains the scaphoid's greater propensity for injury.


FIG. 262-1. **A.** Key elements on a normal PA view. (1) The carpal bones form three smooth arcs; (2) carpal bones are separated by a 1- to 2-mm space; (3) scaphoid has an elongated shape; (4) radius has an ulnar inclination of 15 to 25 degrees; (5) radial styloid projects 8 to 18 mm (average 13 mm). Half the lunate articulates with the radius, and the ulna and adjacent radial surface are equal in length (neutral ulnar variance). **B.** Bony anatomy. (With permission from Chin HW: Injuries of the wrist, in Hart RG, Rittenberry JJ, Uehara DT (eds): *Handbook of Orthopaedic Emergencies.* Philadelphia, Lippincott-Raven, 1998.)

The forearm muscles that insert onto the base of the metacarpals produce wrist motion. There are no direct tendon insertions on the carpal bones (except for the pisiform that is a sesamoid bone of the flexor carpi ulnaris). The carpal bones move passively in response to hand position. Although the radiocarpal joint is often referred to as the "wrist joint," it is important to realize that wrist motion is nearly equally divided between the radiocarpal and midcarpal joint. This is best appreciated when viewing carpal movement from the sagittal view. During flexion and extension each row moves in the same direction and with similar degrees of angulation.

The carpal bones are stabilized to one another by intrinsic ligaments and to the bones of the forearm by the extrinsic ligaments. The key extrinsic ligaments are arranged in three arcades; two are volar and one dorsal. The two volar ligaments are arranged in two inverted V-shaped arches. The apex of one arch inserts on the lunate supporting the proximal carpal row, while the other arch reaches out to the distal carpal row with its apex inserting onto the capitate. There is an inherently weak area (space of Poirier) between these two palmar arches. This area lies at the junction of the lunate and capitate and also widens with dorsiflexion of the wrist. Forceful dorsiflexion of the wrist could tear the capsule here and produce a perilunate or lunate dislocation. There is a single dorsal arcade that acts as a sling across the back of the wrist. These arcades have origins on the rim and styloid of the radius on one side, and distal ulna and triangular fibrocartilage complex on the other side; injuries to either insertion point are therefore potentially unstable.

The intrinsic ligaments are largely responsible for holding the carpal bones together as a kinematic unit in their respective carpal rows. Because the proximal carpal row is a mobile middle link in this three-link system, the intrinsic ligaments within this segment are particularly important because of their greater propensity for injury. The intrinsic ligaments of the proximal carpal row are named after the respective carpal bones they connect: the scapholunate and triquetrolunate. The proximal carpal row is also under important internal dynamic forces. The palmar flexed posture of the scaphoid produces a flexion torque on the lunate that is counterbalanced by an extension torque from the triquetrum. Unfortunately, this delicate balance is lost if either ligament is disrupted, and produces a volar or dorsal tilt of the proximal carpal row and carpal instability.

CLINICAL ASSESSMENT

An individual's age affects the maturity of the bones and influences the type of injury. Children are more likely to sustain injuries to the immature, weaker epiphyseal plate or metaphysis of the radius. Their carpus is mostly cartilage that helps cushion them from injury. Carpal injuries are rare in children. Young adults, particularly those with active lifestyles, are more likely to be injured with greater force and disrupt either the carpus or distal radial metaphysis that often involves the articular surface. In the elderly, the weak point is the brittle distal radial metaphysis.

Injuries most often occur from falls on the outstretched hand. Impact on the thenar eminence is more likely to injure the scaphoid and its supporting ligaments. An impact on the hypothenar eminence is likely to cause injury to the triquetrum and the pisiform, and to their supporting ligaments.

Pinpointing areas of tenderness and correlating it to anatomical landmarks on the wrist will help determine what structure may be injured and the best way to evaluate it with a radiograph. The most noteworthy landmark on the dorsum of the wrist is the anatomical snuffbox. The scaphoid is palpable at the base of this triangle and the radial styloid forms its proximal base. The extensor pollicis longus creates the ulnar border of the snuffbox, as it wraps around Lister's tubercle, a palpable small bony prominence on the distal radius. The scapholunate joint is located just distal to Lister's tubercle. Immediately ulnar to the scapholunate junction is a palpable indentation in the middle of the wrist that is the location of the lunate and capitate. When the wrist is flexed, the lunate is palpable as it rises out of this fossa. The ulnar styloid is the bony prominence on the ulnar aspect of the wrist. The triquetrum and triangular fibrocartilage complex are located just distal to it.

A clearly visible landmark on the volar aspect of the wrist is the wrist crease that marks the location of the proximal carpal row. The scaphotrapezium joint is palpable at the base of the thenar eminence. The pisiform is the visible bony prominence at the base the hypothenar eminence. The hook of the hamate is palpable within the soft tissue of the hypothenar eminence a centimeter away, at a 45-degree angle radial from the pisiform.

RADIOGRAPHY

The clinical examination should determine which radiographs are necessary to support the diagnosis. Standard views of the wrist include posteroanterior, lateral, and oblique views. Although these views are sufficient in the majority of cases, other projections may be necessary to profile specific carpal injuries.

The key to interpreting the radiograph is to first assure proper positioning, then identify specific features on each projection. On a properly positioned posteroanterior view, the distal radius and ulna should not overlap at their distal articulation and the axis of the third metacarpal should parallel that of the radius. Besides looking for disruption of the bony cortex, key elements on the PA view are illustrated on Fig. 262-1.

On the PA view, three smooth arcs outline the articular surfaces at the radiocarpal and midcarpal joints. Two of these arcs are formed by the proximal and distal articular surfaces of the scaphoid, lunate, and triquetrum. The third arc is formed by the proximal articular surface of the capitate and hamate in the midcarpal joint. Any distortion of these lines implies a possible fracture, dislocation, or subluxation at the site.

The carpal bones fit together like a jigsaw puzzle, the pieces are separated by a narrow 1 to 2 mm joint space. This space is increased or obliterated with ligament disruption, carpal instability patterns, or fractures/dislocations. This occurs most often around the lunate at the scapholunate and capitolunate joints. Unfortunately, incorrect positioning can produce overlap patterns that could be misinterpreted as pathological. For example, radial deviation of the wrist causes normal physiological palmar rotation of the proximal carpal row. The dorsal rim of the lunate will overlap the capitate and obliterate the capitolunate joint space. The scaphoid that should appear elongated on the PA view appears shorter as it rotates palmar and can be confused with a rotatory subluxation of the scaphoid.

The radial styloid should project 8 to 18 mm beyond the distal radioulnar joint and create an ulnar inclination to the distal radius of 15 to 25 degrees on the PA view. Distal radius fractures can alter these measurements. At the distal radioulnar joint, the ulna and adjacent portion of the radius should be of equal length, and the distal radius should articulate with at least half the lunate. The extrinsic ligaments, along with the triangular fibrocartilage complex, prevent ulnar translocation (the migration of the carpals down the ulnar tilt of the radiocarpal surface). The lunate would have less contact and support from the radius if ulnar migration were present. A shorter ulna (negative ulnar variance) also provides less support to the lunate and increases the potential shear stress to the lunate. Although negative ulnar variance is a normal variant, its presence predisposes the lunate to injury.

The lateral radiograph is important for determining carpal alignment and degree of fracture angulation. The first step, again, is assuring that the wrist is properly positioned on the radiograph. The radius and ulna should completely overlap one another, and the radial styloid should be centered over the distal radial articular surface. The key features on this view are illustrated on Fig. 262-2.
FIG. 262-2. Key elements on a normal lateral view. (1) three Cs sign; (2) capitolunate angle is <10 to 20 degrees; (3) scapholunate angle is <60 degrees; (4) radial volar tilt of 10 to 15 degrees. (With permission from Chin HW: Injuries of the wrist, in Hart RG, Rittenberry JJ, Uehara DT (eds): *Handbook of Orthopaedic Emergencies.* Philadelphia, Lippincott-Raven, 1998.)

The axis of the radius, lunate, and capitate is colinear on the lateral view. If the articular surfaces of these bones were highlighted, they would appear as three consecutive Cs in a row. This provides a simple radiographic assessment of wrist dislocation. Measurement of the capitolunate and scapholunate angles is a more precise assessment of carpal alignment. The axis of the capitate, lunate, and scaphoid runs through the center of their proximal and distal articular surfaces. The axis of the lunate and capitate should nearly overlap and form an angle that is less than 10 to 20 degrees. The scaphoid is normally palmar flexed on the lateral view; its axis should form an angle that is between 30 to 60 degrees with the lunate. Deviation from either of these angles suggests ligament disruption and carpal instability patterns Fig. 262-3.
FIG. 262-3. A. Normal wrist. Axis of the radius (R), lunate (L), and capitate (C) are colinear. The capitolunate angle (CL) is less than 20 degrees and the scapholunate

angle (SL) is between 30 and 60 degrees. **B.** Dorsal intercalated segment instability (DISI). The lunate tilts dorsal and slides palmar, increasing the capitolunate angle. The scaphoid tilts more palmar and increases the scapholunate angle. The axes of the radius, lunate, and capitate take on a zigzag pattern (dark line). **C.** Volar intercalated segment instability (VISI). The lunate tilts palmar and the capitolunate increases, but the scapholunate angle is maintained. The zigzag pattern is in the opposite direction.

Fractures of the distal radius are the most common fracture in the wrist. While a displaced fracture is the obvious deformity, the alteration of the normal volar tilt of 10 to 15 degrees of the distal articular radial surface has greater long-term consequences. The shape of the distal radius, distal ulna, and triangular fibrocartilage has a significant influence on carpal alignment and movement.

Other radiographic views profile specific areas of the wrist. Oblique views are performed in either partial pronation or supination. They project the scaphotrapezium joint or pisiform away from the overlapping adjacent carpal bones. The scaphoid view is a coned-down PA view of the scaphoid in ulnar deviation. This position extends the normal flexed posture of the scaphoid so that the bone is profiled lengthwise. This may assist in detecting subtle fractures. The carpal tunnel view is a tangential view through the carpal tunnel and is helpful in visualizing the pisiform and hook of the hamate. Motion studies are dynamic views in flexion, extension, and radial and ulnar deviation. They examine relative carpal movement to one another and stress the intercarpal ligaments for laxity characterized by widening of the intercarpal space. Likewise, the grip compression or fist view is a stress view in the PA projection of a tightly clenched fist. The capitate is pushed into the proximal carpal row and forces the carpal bones apart if the intrinsic intercarpal ligaments are torn.

LIGAMENTOUS INJURIES

The lunate is located in the middle of the wrist, so it is not surprising that the majority of ligamentous injuries are centered on the lunate. These injuries usually result from forceful dorsiflexion of the wrist, most often from a fall on the outstretched hand. The various injuries occur sequentially depending on the degree of force, and range from isolated tears to perilunate and lunate dislocations.

Scapholunate Ligament Instability

The scapholunate ligament is the intrinsic ligament that binds the scaphoid and lunate. Because the scaphoid bridges the proximal and distal carpal rows, it is not surprising that the scapholunate ligament also has a greater propensity for injury. It is the most common ligament injury of the wrist. Injury most often is from a fall on the outstretched hand with impact on the thenar eminence. These individuals will complain of pain and swelling on the radial side of the wrist and sometimes a clicking sensation with wrist movement. Examination reveals localized tenderness on the dorsum of the wrist in the area immediately distal to Lister's tubercle. Ballottement of the scaphoid may also produce pain in this area.

This injury is often referenced to the various radiographic appearances it may take. There are three different radiographic signs that may occur separately or in combination with one another. Scapholunate dissociation is a widening of the scapholunate joint space on the PA projection of more than 3 mm (Fig. 262-4). This has been called the "Terry Thomas" sign, named after a British comedian with notable dental diastema between his upper front incisors. If it is not apparent on routine views, a grip-compression stress view or motion study may be necessary to demonstrate the abnormal gap. These maneuvers are particularly helpful in identifying an incomplete tear of the ligament. Rotatory subluxation of the scaphoid is another abnormality that often accompanies scapholunate dissociation. A torn scapholunate ligament can cause the scaphoid to tilt more palmar and increase the scapholunate angle to greater than 60 degrees on the lateral view (normal angle is 30 to 60 degrees). On the PA view, the scaphoid tilts toward the observer. The scaphoid appears shorter as it is viewed more on its end and the circular cortex of the bone becomes visible like a ring (cortical ring sign; see Fig. 262-4). A third possible radiographic abnormality is a carpal instability pattern, Dorsal intercalated segment instability (DISI). The normal flexed posture of the scaphoid produces a flexion torque on the lunate that is counterbalanced by an extension torque from the triquetrum. When the scapholunate ligament is torn, this balance is disrupted. The lunate tilts dorsal from the unopposed extension torque from the triquetrum, while the scaphoid tilts more palmar (rotatory subluxation of the scaphoid) because it has lost support from the lunate. The dorsal tilt of the lunate also causes a slight flexion tilt of the capitate. In the lateral view, the normal colinear arrangement of the axes of the radius, lunate, and capitate are replaced by a characteristic zigzag pattern. Both the scapholunate and capitolunate angles are increased. The concept of the proximal carpal row being the middle-link or "intercalated segment" in this system, combined with the lunate's pathological dorsal tilt and zigzag pattern, is how this abnormality came to be named dorsal intercalated segment instability, DISI (see Fig. 262-3*B*).

FIG. 262-4. Scapholunate dissociation with accompanying rotatory subluxation of the scaphoid. The scaphoid and lunate are separated by a gap of more than 3 mm (arrowhead) and the scaphoid appears shorter from rotation with a dense ring (cortical ring sign, arrow).

These injuries are treated acutely with a radial gutter splint or posterior mold. Appropriate orthopedic referral is necessary because these injuries require either closed reduction and pinning or, more often, open reduction and surgical repair of the ligament. Early severe degenerative arthritis is a possible sequelae if left untreated.

Triquetrolunate Ligament Instability

The triquetrolunate ligament binds the triquetrum and lunate on the ulnar aspect of the wrist. Injury to this ligament is the ulnar equivalent of the scapholunate ligament injury. Triquetrolunate ligament injury, however, occurs less often and is more stable. This injury most often results from falls on the outstretched dorsiflexed hand with impact on the hypothenar eminence. There will be localized tenderness on the ulnar aspect of the wrist just distal to the ulna. Ballottement of the triquetrum may produce a painful clicking sensation.

A complete tear of this ligament removes the influence of the triquetrum to counterbalance the flexion torque from the palmar-flexed scaphoid. The lunate hence tilts palmar, and the capitate extends slightly in response. A zigzag pattern in the opposite direction of scapholunate injury is produced. The capitolunate angle is increased greater than 10 to 20 degrees; however, the scapholunate angle is unaffected because the scapholunate ligament is still intact. The lateral radiograph reveals the volar intercalated segment instability (VISI) pattern (see Fig. 262-3*C*). The PA radiograph may reveal a widening of the triquetrolunate joint space and obliteration of the capitolunate joint space because of the volar tilt of the lunate.

These injuries are treated acutely with an ulnar gutter splint or posterior mold and referred to an orthopedist. Immobilization in a cast for six to eight weeks followed by a protective splint is sufficient in most cases. Open reduction and internal fixation is generally reserved for chronic injuries. Unrecognized injuries can result in early degenerative arthritis and a chronically painful wrist.

Perilunate and Lunate Dislocations

Perilunate and lunate dislocations represent the final stages of midcarpal ligament disruption. Much like the scapholunate and triquetrolunate injuries, these injuries

are also the result of forceful dorsiflexion and impact on the outstretched hand, but usually with much greater force, such as a fall from a height or impact from a motor vehicle accident. The injury can begin on either side of the lunate, but typically starts on the radial side, tearing the scapholunate ligament. It progresses around the lunate in a semicircular fashion, tearing the volar ligament arcade at the radiocapitate ligament. Remember that the extrinsic ligaments form two strong volar arcades with an inherently weak area between them that widens with dorsiflexion of the wrist. This space of Poirier lies at the junction of the lunate and capitate. The space of Poirier is opened further as additional loading disrupts the triquetrolunate ligament. Besides ligament disruption, any number of the surrounding carpal bones can fracture along an arc around the lunate (see Fig. 262-5). If a sufficient force is applied, the ligaments and carpal bones surrounding the lunate are stripped away. The capitate is displaced posterior to the lunate, producing a perilunate dislocation. If the capitate rebounds with sufficient force, it can push the lunate off the radius and into the palm, creating a lunate dislocation. These injuries are all part of a continuous spectrum of ligamentous disruption.
FIG. 262-5. Perilunate and lunate dislocations can fracture any of the carpal bones that surround the lunate in an arc pattern.

On clinical examination, there is often generalized swelling, pain, and tenderness. However, a gross deformity, typical of many other joint dislocations, is often absent and can be misleading. Radiographic interpretation is the key to diagnosis. The perilunate dislocation is best appreciated on the lateral view. The linear arrangement of the three Cs sign is disrupted with the capitate, represented by the third C, displaced posterior to the lunate. The lunate still maintains its contact with the radius. The scapholunate and capitolunate angles are increased. On the PA view, the three smooth arcs are disrupted and the capitolunate joint space is obliterated as the bones overlap one another. The scapholunate and triquetrolunate joint space may either be increased because of torn ligaments, or obliterated by rotation of fractured carpal fragments. The scaphoid will appear shortened from rotatory subluxation or fracture. A perilunate dislocation may, unfortunately, overshadow any associated carpal bone fracture. The scaphoid and capitate are most often involved, so it is prudent to carefully inspect these bones for fractures. These fractures are designated by adding the prefix "trans" to the carpal's name; e.g., transscaphoid perilunate dislocation (see Fig. 262-6*A*, Fig. 262-6*B*).
FIG. 262-6. Transscaphoid perilunate dislocation. **A.** PA view shows subtle overlap of the lunate and capitate. A displaced scaphoid fracture is present (arrows). **B.** Lateral view shows the lunate (L) maintaining contact with the radius while the capitate (C) is positioned posterior to the lunate. (With permission from Chin HW, Visotsky J: Ligamentous wrist injuries. *Em Med Clin North Am* 11:3, 1993.)

A lunate dislocation has many similar and several distinct features when compared to a perilunate dislocation. On the lateral view, it also disrupts the three Cs sign. The lunate (represented by the middle C) is pushed off the radius and into the palm. This has been called the "spilled teacup" sign because it resembles a cup spilling in the direction of the palm. The capitate may rebound back and even rest on the radius. On the PA view, the lunate has a triangular shape ("piece-of-pie" sign) that is pathognomonic for lunate dislocation (see Fig. 262-7*A*, Fig. 262-7 *B*). The signs of ligament disruption and the associated carpal fractures described with perilunate injuries may also be present.

FIG. 262-7. Lunate dislocation. **A.** PA view reveals pathognomonic triangular shape of lunate (piece of pie sign, arrow). **B.** Lateral view shows lunate tilting into the palm (spilled teacup sign, arrow) and the capitate positioned posterior to the lunate (arrowhead). Note the associated scaphoid and triquetrum fractures. (With permission from Chin HW, Visotsky J: Ligamentous wrist injuries. *Em Med Clin North Am* 11:3, 1993.)

All patients with perilunate or lunate dislocations require emergency orthopedic consultation. Treatment is determined by the extent of injury. Closed reduction and long-arm splint immobilization is appropriate for reducible dislocations. Open, unstable, and irreducible dislocations require open reduction and internal fixation, with repair of the ligaments and fractures. Some clinicians operate on all perilunate and lunate dislocations. The complications are development of carpal instability patterns that lead to early degenerative arthritis, delayed union, malunion, nonunion, avascular necrosis, and, occasionally, median nerve compression from the volar dislocation of the lunate into the carpal tunnel.

CARPAL BONE FRACTURES

Carpal bone fractures account for 7 to 10 percent of all hand injuries. Unfortunately, they are among the most commonly missed wrist injuries. It is important that a high index of suspicion is maintained and a focused examination is used to recognize these injuries. The following carpal fractures are listed in descending order of occurrence.

Scaphoid Fracture

The scaphoid is an oblong bone that has the unique role of linking and stabilizing the two rows of carpal bones. This, unfortunately, increases its propensity to injury, making it the most common carpal fracture. The injuries usually result from a fall on an outstretched dorsiflexed hand or by an axial load directed along the thumb's metacarpal. There is pain along the radial side of the wrist and localized tenderness in the anatomical snuffbox. Examining the wrist in ulnar deviation exposes more of the scaphoid to direct palpation in the anatomical snuffbox. Eliciting pain in this area, when the patient resists supination or pronation of their hand, or pain with axial pressure directed along the thumb's metacarpal is also suggestive of injury.

Standard and scaphoid views should be carefully examined for any cortical disruption (see Fig. 262-8). The scaphoid view profiles the bone lengthwise and may assist in detecting subtle fractures. Distortion of a soft tissue fat stripe that lies adjacent to the radial side of the scaphoid is also suggestive of injury. Two-thirds of the fractures occur at the waist or middle third of the bone, 16 to 28 percent in the proximal third, and 10 percent in the distal third. A scaphoid fracture may also have an associated injury in 12 percent of cases involving either the radius, neighboring carpals, a carpal instability pattern, or dislocation.

FIG. 262-8. Scaphoid fracture in the middle third or waist (arrow).

A scaphoid fracture can develop avascular necrosis of the proximal fracture segment that can lead to disabling arthritis. There are several reasons that this occurs. The vascular supply to the scaphoid enters the distal portion of the bone through small branches off the radial artery and the palmar and superficial arteries. A fracture could therefore disrupt the blood supply to the proximal segment. In general, the more proximal, oblique, or displaced the fracture, the greater the risk of developing avascular necrosis. A scaphoid fracture is considered unstable if there is even as little as 1 mm of displacement, rotation, angulation, shortening, or if a carpal instability pattern is present. Two thirds of the scaphoid's surface is also articular. This only adds to the scaphoid's problems, because articular fractures are more difficult to heal.

Because 10 percent of initial radiographs fail to detect a fracture, it is imperative that initial treatment also be directed by clinical suspicion until follow up studies can exclude the diagnosis. Nondisplaced fractures and those that are only clinically suspected can be treated in a short-arm thumb spica splint or cast. Displaced or unstable fractures should be placed in a long-arm thumb spica splint or cast, and should be seen promptly by the orthopedic surgeon for definitive treatment. The main complications are avascular necrosis, delayed union, nonunion, malunion, and subsequent early degenerative arthritis.

Triquetrum Fractures

Triquetrum fractures are either dorsal avulsion fractures or fractures through the body. Avulsion fractures are produced when a twisting motion of the hand is suddenly resisted, or a hyperextension shear stress pushes the hamate or ulnar styloid against the triquetrum. Fractures of the body occur from direct trauma and are seen in association with perilunate and lunate dislocations (part of the arc fractures). There will be localized tenderness over the dorsum of the wrist in the area immediately distal to the ulnar styloid. The dorsal avulsion fracture is best seen on the lateral view or an oblique view in partial pronation (see Fig. 262-9). It appears as a tiny flake of bone on the dorsum of the triquetrum. Triquetral body fractures are usually nondisplaced because numerous ligaments encase the bone. These are best seen on the PA view.The dorsal avulsion fractures are treated with a wrist splint for six weeks and have an excellent prognosis for full recovery. Fractures though the body are treated with a cast for six weeks. Those associated with perilunate/lunate dislocations may require internal fixation. Nonunion is possible, but avascular necrosis has not been reported.

FIG. 262-9. Dorsal avulsion fracture of the triquetrum (arrow).

Lunate Fracture

Lunate fractures generally occur in association with other carpal injuries. It is rare to have an isolated lunate injury. Like many other carpal injuries, it usually is the result of a fall on the outstretched hand. There will be localized tenderness in the middle of the wrist. The lunate is present in the shallow indentation on the mid-dorsum of the wrist. If the wrist is flexed the lunate is easily palpable as it rises out of the floor of this indentation. Axial pressure applied along the third metacarpal ray may also elicit pain in this same area and is suggestive of injury. Like the scaphoid, the lunate's blood supply enters through the distal end. A fracture risks producing avascular necrosis to the proximal portion. Because the lunate is nestled in the middle of the wrist, overlap with other carpal bones may make it difficult to identify an injury on a plain radiograph. Clinical suspicion should dictate the acute treatment. A thumb spica splint should be applied until further evaluation by the orthopedist. MRI and CT to identify occult fractures have replaced tomography and bone scans. The major complication is avascular necrosis (Kienböck's disease) that can lead to lunate collapse, osteoarthritis, chronic pain and decreased grip strength. Repetitive trauma to the lunate can also produce microfractures of the bone and subsequent osteonecrosis (see Fig. 262-10). Individuals with ulnar negative variance are at increased risk of developing Kienböck's disease, because a shorter ulna provides less support to the lunate.

FIG. 262-10. Kienböck's disease, osteonecrosis, and collapse of the lunate. (With permission from Chin HW, Visotsky J: Wrist fractures. *Em Med Clin North Am* 11:3, 1993.)

Trapezium Fracture

The trapezium is a saddle-shaped bone that is adjacent to the thumb metacarpal. Injuries are produced by a direct blow to the thumb or from a dorsiflexion and radial deviation force. Vertical fractures are rare and are an analog of a Bennett's fracture (an intra-articular proximal thumb metacarpal fracture). Thumb movement is painful. There is tenderness at the apex of the anatomical snuffbox and at the base of the thenar eminence. This injury is best profiled on a 20-degree pronated oblique view. Nondisplaced fractures are treated in a thumb spica cast or splint for six weeks. Displaced fractures require open reduction and internal fixation. The major complication is nonunion.

Pisiform Fracture

The pisiform is a sesamoid bone within the flexor carpi ulnaris tendon. It is positioned immediately volar to the triquetrum and is the palpable bony prominence at the base of the hypothenar eminence. Injuries usually result from a fall directed on the hypothenar eminence. There will be localized tenderness on the pisiform itself. If the wrist is flexed, the pisiform can be grasped and ballotted between the examiner's fingers. This should elicit pain. Because the pisiform and hook of the hamate form the bony walls of Guyon's canal that contains the ulnar nerve and artery, it is important to exclude injury to them. Radiographs in partial supination or the carpal tunnel view are the optimal views because they remove the overlap with the triquetrum present on standard views (see Fig. 262-11). Multiple ossification centers in the pisiform may be confused with a fracture; however, these will have smoother margins and lack the perfect jigsaw puzzle fit seen with fracture fragments. Pisiform fractures are treated either in a compression dressing or a splint in 30 degrees of flexion and ulnar deviation that relaxes the tension from the flexor carpi ulnaris. These fractures have an excellent prognosis.

FIG. 262-11. Pisiform fracture PA view with a thin lucency in the center of the bone (arrow). (With permission from Chin HW, Visotsky J: Wrist fractures. *Em Med Clin North Am* 11:3, 1993.)

Hamate Fracture

Hamate fractures may involve the body of the hamate, the hook of the hamate, or any of its articular surfaces. Body fractures are rare and are generally associated with fracture/dislocations of the fourth or fifth metacarpals. Most hamate fractures involve the hamate hook, which is a small bony prominence on its volar side. The classic mechanism is an interrupted swing with golf club, bat, or racquet. The handle impacts against the hypothenar eminence and compresses the bone. The hook of the hamate is palpable in the soft tissues of the hypothenar eminence, just 1 cm distal and at a 45-degree radial angle from the pisiform. There will be localized tenderness here. Standard and carpal tunnel views are necessary to visualize the fracture. Occult fractures may be visualized by bone scan or computed tomography. These injuries are treated with compression dressing or splint. Nonunion is common and excision of the bone may be necessary. Injury to Guyon's canal and the ulnar nerve or artery are potential complications.

Capitate Fracture

The capitate is an elongated carpal bone that has a large proximal articular head that contacts the lunate; the midportion is the neck and the distal end is the body. Capitate fractures most often occur in the neck, and usually occur in conjunction with a scaphoid fracture. This association of scaphoid and capitate fractures is called the "scaphocapitate syndrome." Isolated capitate fractures are rare. These injuries result from forceful dorsiflexion of the hand with impact on the radial side. The scaphoid is fractured first, followed by the capitate through its neck. This can continue around the lunate creating other so-called arc fractures, and eventually a perilunate or lunate dislocation. Capitate fractures also share the same legacy of potential avascular necrosis of the proximal fracture segment. Like the scaphoid and lunate, the capitate's blood supply enters through the distal end.

Physical examination will reveal diffuse swelling and tenderness over the capitate. The capitate neck fractures are best seen on the lateral radiograph. The head of the capitate should be carefully noted because it can rotate as much as 180 degrees. Unfortunately, capitate fractures are most often overlooked because the accompanying scaphoid fracture or perilunate/lunate dislocation overshadows it. Most of these fractures are displaced, and require closed or open reduction with internal fixation. Avascular necrosis, delayed union, nonunion, and malunion may complicate them.

Trapezoid Fracture

This is an extremely rare fracture accounting for only 1 percent of all carpal fractures. The injury results from an axial load onto the index metacarpal. There will be tenderness on the radial side that is augmented by applying pressure along the index metacarpal ray. These injuries are difficult to see on standard radiographs, and CT or MRI may be necessary to visualize it. These fractures are treated with a thumb spica cast or splint.

DISTAL RADIUS AND ULNA FRACTURES

Fractures of the distal metaphysis of the radius and ulna are among the most common injuries affecting the wrist. Among the factors that influence the type and amount of displacement of the fracture are the point and direction of impact, the degree of force, and the patient's age. In general, the thinner cortices of the elderly make them more likely to sustain extraarticular fractures, whereas younger adults often sustain more complicated intraarticular fractures.

Colles' Fracture

Colles' fracture results most often from falls on the outstretched hand. This mechanism produces a distal radial metaphysis fracture that is dorsally angulated and displaced. Compression forces on the dorsal side often produce dorsal comminution of bone. The fracture line may also comminute and extend into the radioulnar or radiocarpal joint ("die-punch" fracture). A fracture of the ulnar styloid is often present and may be suggestive of injury to the triangular fibrocartilage complex (Fig. 262-12).
FIG. 262-12. Colles' fracture. (With permission from Chin HW, Visotsky J: Wrist fractures. *Em Med Clin North Am* 11:3, 1993.)

The wrist has the characteristic dorsiflexion, or "silver-fork," deformity. These individuals may complain of palmar paresthesias from tension or pressure on the median nerve. Anteroposterior radiographs reveal a distal metaphyseal fracture of the radius that often appears shortened from the angulation or comminution of the bone. The lateral view provides the best view of the dorsal angulation and comminution. In general, potentially unstable fractures have more than 20 degrees of angulation, intra-articular involvement, marked comminution, or more than a centimeter of shortening. These injuries are more likely to develop loss of reduction, distal radioulnar joint instability, radiocarpal instability patterns, and subsequent arthritis.

Stable fractures may be treated with a compression dressing and splint until they can be evaluated by an orthopedic surgeon. Otherwise, closed reduction is performed, with traction provided by finger traps while the fracture fragment is pushed distal and palmar while the patient's forearm is firmly held. The goal is to restore the volar tilt, radial inclination, and proper length to the radius. This is particularly important in younger patients. The volar tilt ideally should be restored to its normal position, but a minimum of neutral or zero degrees of angulation may be acceptable. Although most Colles' fractures can be treated with closed reduction and cast immobilization, those that are unstable, severely comminuted, or intra-articular may require casting with pinning, external fixation with possible bone grafting, or open reduction and internal fixation. Good to excellent results are achieved in 56 to 81 percent of patients with these more aggressive treatment alternatives. All open and neurovascularly compromised fractures require prompt evaluation by the orthopedic surgeon.

Complications include malunion, median nerve injuries, triangular fibrocartilage complex injuries, secondary radioulnar and radiocarpal instability patterns, and arthritis. These can produce a weak, stiff, and painful wrist.

Smith's Fracture

Smith's fracture, or "reverse Colles' fracture," is a volar angulated fracture of the distal radius. These injuries result from a fall or direct blow on the dorsum of the hand and wrist or from falls on the outstretched hand in supination that then shifts into a pronated position. The hand is displaced palmar in a "garden-spade deformity." The anteroposterior radiograph looks much like the Colles' fracture, with a distal metaphyseal radius fracture that may be shortened and comminuted. The lateral radiograph shows the volar angulated and displaced fracture (Fig. 262-13).

FIG. 262-13. Smith's fracture.

The treatment objectives and complications are much like those seen with Colles' fracture. In this case, however, the angulation is in the opposite direction.

Barton's Fracture

Barton's fractures are dorsal or volar rim fractures of the distal radius. The dorsal rim fractures result from a dorsiflexion and pronation force, whereas the less common volar rim fracture is produced by a fall on the outstretched hand in supination. These injuries are often fracture dislocations or subluxations, because the carpus or hand is frequently displaced in the direction of the fracture. Accompanying ligamentous injuries create radiocarpal instability. This is often not fully appreciated in the acute setting but can lead to various secondary carpal instability patterns and premature degenerative arthritis.

The anteroposterior radiograph often shows a comminuted fracture of the distal radial metaphysis. The lateral view reveals an intra-articular fracture of the volar or dorsal rim of the radius, which may be accompanied by carpal subluxation in the same direction (Fig. 262-14*A*, Fig. 262-14*B*).
FIG. 262-14. Volar Barton's fracture. **A.** AP view. **B.** Lateral view. (With permission from Chin HW, Visotsky J: Wrist fractures. *Em Med Clin North Am* 11:3, 1993.)

Minimally displaced fractures can be treated acutely with closed reduction and a splint or cast until they can be reevaluated by the orthopedist. Unstable fractures involve more than 50 percent of the radial articular surface or have accompanying carpal subluxation and require reduction and immobilization by the orthopedist. These injuries often require open reduction and fixation with pins or a buttress plate.

Radial Styloid Fracture

A force directed along the radial side of the hand can produce a transverse or oblique fracture that runs from the scaphoid fossa to the metaphysis of the radius. It is best seen on the anteroposterior radiograph as a thin, lucent line beneath the radial styloid. Because the major carpal ligaments along the radial side of the wrist insert on the radial styloid, displacement of this fracture can produce carpal instability. Displaced fractures often require open reduction and internal fixation. Displacement of as little as 3 mm is often associated with accompanying scapholunate dissociation. Failure to recognize these intercarpal ligament tears adds to the potential for subsequent posttraumatic arthritis.

Ulnar Styloid Fracture

Forced radial deviation, dorsiflexion, and rotatory stress fracture the ulnar styloid. The ulnar styloid fracture may be isolated or may accompany other injuries, such as Colles' fracture. Displaced fractures can be associated with tears of the triangular fibrocartilage complex, which is the main stabilizer of the distal radioulnar joint. These individuals complain of a painful clicking or locking sensation in the wrist.

Ulnar styloid fractures are treated acutely with a splint or cast in slight ulnar deviation and neutral positioning of the wrist. Arthrograms or MRI imaging may be necessary to delineate the full extent of these injuries.

Radioulnar Disruption

Radioulnar joint disruption is generally seen with intra-articular or distal radial shaft fractures (Galeazzi's fracture-dislocation), or with fractures of both bones of the forearm. These more apparent injuries often overshadow radioulnar joint disruption and, unfortunately, cause these injuries to be unrecognized until subsequent pain and diminished wrist movement are appreciated.

Isolated radioulnar joint dislocations are uncommon and are unrecognized acutely in as many as 50 percent of cases. Dorsal dislocation of the ulna results most often from falls on the wrist in hyperpronation. The rare volar dislocation results from forced hypersupination of the wrist. These individuals present with a painful wrist that has restricted range of motion. There may be a palpable prominence of the ulnar head, but this can be quite subtle and easily overlooked.

The anteroposterior radiograph reveals narrowing and overlap of the distal radioulnar joint. The lateral radiograph demonstrates either volar or dorsal displacement of the ulna, which is normally centered and overlapping the radius. Because slight oblique positioning of the wrist can produce a misleading appearance of ulnar displacement, it is crucial that a properly positioned lateral view be obtained. A true lateral view should have superimposition of the four-ulnar metacarpals, superimposition of the proximal pole of the scaphoid with the lunate and triquetrum, and the radial styloid centered over its distal articular surface. CT scanning may be necessary to establish the diagnosis if plain films are inconclusive. Immobilizing the wrist in supination reduces dorsal dislocations, whereas volar dislocations are placed in pronation. These injuries unfortunately have a high recurrence rate, particularly if there are delays in diagnosis, and may require reconstructive surgery.

263 INJURIES TO THE SHOULDER COMPLEX AND HUMERUS

Dennis T. Uehara
John P. Rudzinski

Function of the upper extremity is intimately dependent on the shoulder complex. Movement is effected through an intricate mechanism with integration of muscles, ligaments, osseous components, and a system of joints all working in harmony. Through its joint system, which consists of four joints, the sternoclavicular, glenohumeral, acromioclavicular, and scapulothoracic, the upper extremity is able to move through a complex and wide range of motion. The following discussion focuses on the major soft tissue and osseous components of the shoulder complex and humerus and those injuries that create loss of motion, instability, and pain.

STERNOCLAVICULAR DISLOCATIONS

The sternoclavicular joint is the most frequently moved nonaxial joint of the body because almost any movement of the upper extremity is transferred proximally to this joint. It also has the least amount of bony stability of any major joint because less than half of the medial end of the clavicle actually articulates with the upper sternum. Joint stability therefore depends on the integrity of the surrounding ligaments, which give the sternoclavicular joint surprising strength. As a result, the majority of injuries to this area are simple sprains, dislocations being uncommon.

A sprain of the sternoclavicular joint can result from the shoulder being forced forward suddenly or from a medially directed force applied to the shoulder. Pain and swelling are localized to the joint, and treatment is symptomatic with ice, sling, and analgesics. Differential diagnosis should include consideration of septic arthritis, especially in intravenous drug abusers.

Sternoclavicular dislocations are uncommon, accounting for only 3 percent of a series of 1603 shoulder girdle injuries. Dislocations usually result from motor vehicle accidents or sports injuries, but spontaneous dislocations have been reported. Posterior sternoclavicular joint dislocations are much less common than anterior dislocations. A posterior dislocation may result from a direct blow or from an indirect force to the shoulder if the shoulder is rolled forward at the time of impact. An anterior sternoclavicular joint dislocation may result from the same indirect force if the shoulder is rolled backward at the time of impact. Of note is that the medial clavicular epiphysis is the last epiphysis of the body to appear radiographically (age 18) and the last to close (age 22 to 25). As a result, physeal injuries in this age group can easily be misdiagnosed as a dislocation.

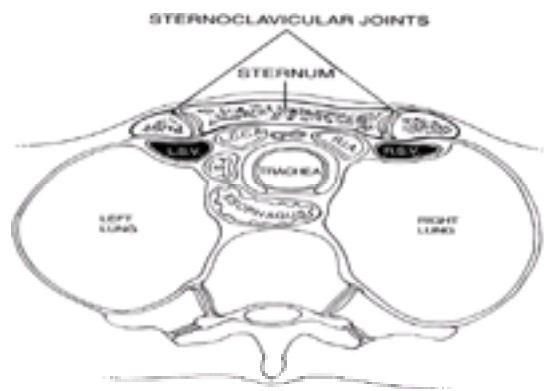
Patients with a sternoclavicular joint dislocation have severe pain that is exacerbated by arm motion and when in the supine position. The shoulder appears shortened and rolled forward. On examination, anterior dislocations have a prominent medial clavicle end that is visible and palpable anterior to the sternum. In posterior dislocations, the medial clavicle end is less visible and not palpable, and the patient may have signs and symptoms of impingement of the superior mediastinal contents (Fig. 263-1). Routine radiographs may not be diagnostic although specialized views or tomograms may be helpful. Computed tomography (CT) is the imaging procedure of choice.


FIG. 263-1. The relationship of the sternoclavicular joint to adjacent structures. RSV, right subclavian vein; RIA, right innominate artery; LCCA, left common carotid artery; LSA, left subclavian artery; LSV, left subclavian vein.

Closed reduction of anterior sternoclavicular joint dislocations is usually attempted with the patient supine and with a sandbag or pad between the shoulders. Direct pressure over the clavicle may reduce the dislocation.The patient is usually discharged in a figure-of-eight clavicle harness. Unfortunately, many anterior dislocations prove unstable and recur as soon as direct pressure is released. Patients may subsequently undergo open reduction, or the position of the deformity may be accepted and no further treatment rendered.

In posterior dislocations, life-threatening injuries to adjacent structures may result in a pneumothorax or in compression or laceration of the great vessels, trachea, or esophagus. Local swelling may obscure any deformity, and routine radiographs are often not conclusive, making diagnosis difficult. Additional injuries should be aggressively sought and addressed. Orthopedic consultation for stabilized patients may attempt closed reduction, with thoracic surgical backup. A towel clip is often used to grasp and pull the medial clavicle forward and back into place. Open reduction may be necessary.

CLAVICLE

Clavicle fractures account for 5 percent of all fractures seen in the emergency department and for 44 percent of significant injuries to the shoulder girdle. This is the most common fracture of childhood, with almost half of these injuries occurring by the age of 7. The clavicle functions as a strut, connecting the shoulder girdle to the trunk, and provides support and mobility for upper-extremity function. The clavicle also protects the adjacent lung, brachial plexus, and subclavian and brachial blood vessels.

The most common mechanism of injury is a blow to the shoulder. Transmission of the compressive force results in a buckling of the clavicle, which fractures once a critical force is achieved. Children will often have a greenstick or buckle-type fracture or a bowing deformity without a definite fracture. Open fractures, due to extreme

tenting of the overlying skin, may occasionally be seen.

Eighty percent of clavicle fractures involve the middle third, 15 percent the distal third, and 5 percent the medial third. Patients typically present with swelling, deformity, and tenderness localized to the clavicle. The arm is slumped inward and downward and is supported by the other extremity. Routine clavicle radiographs may miss fractures due to overlap of surrounding structures, particularly with fractures at either end of the bone. Diagnosis of these may require special views or specialized techniques, such as tomography or computed tomography (CT) scan.

Numerous forms of treatment have been described for this common injury. Simple immobilization with a sling is often successful, with displaced fractures often treated with a figure-of-eight brace. A shoulder spica or open reduction may be required for severely displaced fractures, poor patient compliance, or for complications. Healing may occur as rapidly as 2 weeks for infants, with most adults healing in a 4- to 6-week period.

Although the vast majority of these fractures have a benign course, serious associated injuries and complications may occasionally occur. Penetrating or blunt trauma may result in associated lung, neurovascular, or first-rib injuries. Injury to the adjacent vascular structures, usually the subclavian artery, subclavian vein, internal jugular vein, or axillary artery, may be life-threatening. Distal clavicle fractures with displacement typically are associated with rupture of the coracoclavicular ligament and may require operative intervention to avoid nonunion. Medial clavicle fractures may be associated with intrathoracic injuries or develop late complications, such as arthritis. Significant callus formation may result in subsequent compression of adjacent neurovascular structures and is cosmetically deforming.

SCAPULA

The scapula links the axial skeleton to the upper extremity and serves as a stabilizing platform for motion of the arm. Fracture of the scapula is an infrequent occurrence, accounting for less than 1 percent of all fractures. Due to the high energy typically required to fracture this protected bone, there is a greater than 80 percent association of injuries to the ipsilateral lung, thoracic cage, and shoulder girdle.

Significant scapular injury occurs most frequently in men between 25 and 40 years of age, usually as a result of motor vehicle accidents, falls, or other severe trauma. The mechanism of injury is from a direct blow, trauma to the shoulder sometimes with injury of the acromion or coracoid, or a fall on the outstretched arm. An indirect axial load transmitted via the outstretched arm may result in a scapular neck fracture, while the indirect force of a shoulder dislocation may result in fracture of the glenoid. Scapular fractures may be classified by their anatomic location: body, glenoid neck, intraarticular glenoid, spine, coracoid, and acromion (Fig. 263-2) Fractures of the body and glenoid neck are the most common.
FIG. 263-2. Sites of scapula fractures. **A.** Body. **B.** Glenoid rim. **C.** Intraarticular glenoid. **D.** Neck. **E.** Acromion. **F.** Spine. **G.** Coracoid.

A patient with an isolated scapular fracture typically will present with localized tenderness over the scapula and the ipsilateral arm held in adduction. The shoulder may have a flattened appearance. Radiographs consisting of an anteroposterior shoulder, lateral scapula, and axillary will identify most fractures. However, scapula fractures are often associated with other significant injuries, and hence diagnosis may be delayed or initially missed entirely. In Ada and Miller's series, 96 percent of scapular fractures had associated injuries, of which rib fractures were the most common, followed by pulmonary, humeral head, and shoulder girdle injuries. Other injuries may include neurovascular, abdominal, and spine trauma.

Rarely, significant trauma may result in scapulothoracic dissociation. This syndrome consists of lateral scapular displacement, clavicular disruption, and severe soft-tissue injury. This injury is sometimes associated with brachial plexus avulsion, subclavian artery disruption, or both. Its presence may be suspected by neurovascular findings or by lateral displacement of the scapula visualized on a nonrotated chest radiograph.

The vast majority of scapular fractures are treated nonsurgically, with a sling for immobilization, ice, analgesics, and early range-of-motion exercises. Surgical intervention may be necessary for significant or displaced articular fractures of the glenoid, angulated glenoid neck fractures, acromial fractures associated with a rotator cuff tear, and some coracoid fractures. Fractures of the glenoid, acromion, or coracoid are more likely to be associated with long-term disability.

Complications of scapular fractures themselves are uncommon. Although many of these fractures heal with some degree of malunion, typically this does not result in significant disability. Most long-term disability is a result of other, associated injuries.

ROTATOR CUFF INJURIES

The rotator cuff consists of the tendons of the supraspinatus, infraspinatus, subscapularis, and teres minor muscles (see also Chap. 275). These tendons coalesce with the capsule of the glenohumeral joint and attach to the greater and lesser tuberosities of the humerus. The main function of the rotator cuff is to provide dynamic stability to the glenohumeral joint. This is accomplished by contraction of muscles that compress the humeral head in the glenoid and by selective contraction resist the actions of major shoulder girdle muscles. The end result is a stable scapulohumeral articulation with the ability to perform smooth, coordinated motion. Injuries to the rotator cuff occur as a result of acute trauma, such as from a dislocation of the glenohumeral joint and as a result of chronic injuries.

Tears of the rotator cuff after glenohumeral dislocation are common but unfortunately often missed. They should be suspected in all patients over the age of 40 years, in patients with luxatio erecta, and in patients who are unable to abduct or externally rotate the arm after a glenohumeral dislocation.

Chronic injuries occur as a result of impingement and decreased vascularity, both common with advancing age. Impingement is explained by the anatomic relationship of the rotator cuff to osseus and soft-tissue structures. It is "sandwiched" among the humeral head, acromion, coracoid, and the coracoacromial ligament. Compression of the rotator cuff between the humeral head and the coracoacromial arch (acromion, coracoid, and coracoacromial ligament) leads to tendon attrition and degeneration. Disease of the rotator cuff is a continuum of injury from mild inflammation to rupture. The initial stage is characterized by inflammation and edema, resulting in mild pain with activity. There is no limitation of motion or weakness. There may be mild tenderness over the greater tuberosity. This stage of disease is most common in patients less than 25 years of age and is completely reversible.

In the second stage there is increased tendinitis, and the pain is more intense and seems to be worse at night. Tenderness is more diffuse. Overhead motion is painful, and there is some limitation of abduction and external rotation.

The third stage of disease is characterized by significant rotator cuff degeneration and tears. Most patients are over the age of 40 with a long history of symptoms. They have more pain, limitation of motion, and weakness. Patients with complete rotator cuff tears have tenderness over the greater tuberosity and acromioclavicular joint. They also have limitation of motion and weakness, especially to abduction and external rotation. Disease at this stage is considered irreversible.

Treatment in the early stages consists of rest, with sling immobilization, nonsteroidal anti-inflammatory drugs, ice, and local injections. Treatment of rotator cuff tears

is initially symptomatic, followed by consideration for surgery either arthroscopically or open. (See   Chap. 275 for more detailed discussion of shoulder pain.)

ACROMIOCLAVICULAR JOINT INJURIES

Injuries to the acromioclavicular joint are commonly seen in emergency practice. Although they may occur in any age group, the majority occur in young, active males. Emergency management consists of identifying the severity of injury, recognizing associated injuries, and managing selected patients as outpatients.

Anatomy

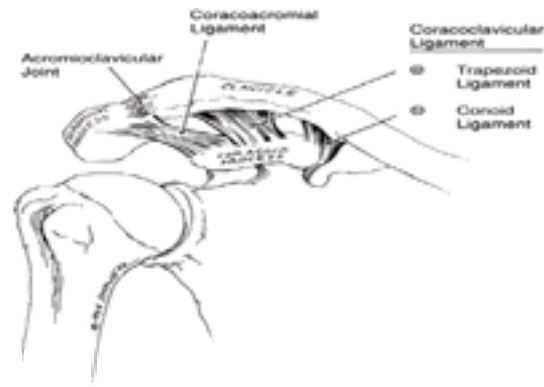
The acromioclavicular joint is a diarthrodial joint that, together with the sternoclavicular joint, connects the upper extremity to the axial skeleton. The support of the acromioclavicular joint is through the acromioclavicular and coracoclavicular ligaments and the strong attachment of the trapezius and deltoid muscles (Fig. 263-3). The acromioclavicular joint is surrounded by a thin capsule, which is reinforced by the acromioclavicular ligaments. The superior fibers of this ligament blend with the fascia of the trapezius and deltoid, which attach to the clavicle and acromion. The acromioclavicular ligaments provide horizontal stability to the joint. The tough coracoclavicular ligaments consist of two parts, the more lateral trapezoid and the medial conoid. They attach the distal inferior clavicle to the coracoid process of the scapula. The coracoclavicular ligament is the major suspensory ligament of the upper extremity and provides vertical stability to the acromioclavicular joint.


FIG. 263-3. Anatomy of the acromioclavicular joint.

Mechanism of Injury

The mechanism of injury is usually direct trauma to the acromioclavicular joint from a fall with the arm adducted, as typically may occur in a sporting activity. An indirect mechanism is a fall on the outstretched hand with transmission of force to the acromioclavicular joint. The result is that the scapula and shoulder girdle are driven inferiorly while the clavicle remains in its normal position. This is confirmed by observing the opposite clavicle, which is at the same level as the injured one.

Clinical Features

The diagnosis of acromioclavicular joint injuries is made clinically. The typical mechanism of injury, as well as tenderness and deformity at the acromioclavicular joint, is confirmatory. Radiographs are useful for identifying other fractures and determining the severity of injury. Acromioclavicular radiographs should specifically be ordered because they require only one-third to one-half the penetration of standard shoulder films. Shoulder technique will overpenetrate the acromioclavicular joint, and small fractures may be missed. Although standard acromioclavicular radiographs are generally sufficient, an axillary view is required to identify posterior clavicular dislocation (type IV, see below). Routine use of stress radiographs has been standard practice. Recently, however, Bossart and colleagues have called this practice into question. Their study suggests that stress radiographs are of low yield and that their routine use should be abandoned. Although some agree, others disagree, citing occult type III (see below) injuries that can be unmasked only with stress radiographs.

Classification of Injury

The classification of acromioclavicular joint injuries classically describes three types of injuries. Rockwood describes three others (Fig. 263-4). Types I, II, and III are common; types IV, V, and VI are rare. The anatomic injury, radiographic findings, and physical findings are summarized in   Table 263-1.
FIG. 263-4. Classification of acromioclavicular joint injuries. (From Rockwood CA, Green DP, Bucholz RW: *Rockwood & Green's Fractures in Adults,* 3d ed. Philadelphia, Lippincott, 1991, with permission.)

TABLE 263-1   Classification and Physical Findings in Acromioclavicular Joint Injuries

Treatment

Treatment of type I injuries consists of rest, ice, analgesics, and immobilization, followed by early range-of-motion exercises. Most agree that type II injuries should be similarly treated. Various straps and braces have been used to reduce the dislocation, but none has proven successful. A simple sling remains the most convenient and effective. Prognosis for type I and II injuries is excellent, with only a small percentage who develop late symptoms requiring excision of the distal clavicle. Treatment of type III injuries (Fig. 263-5) is controversial, with proponents for both conservative and operative philosophies. A recent trend among directors of orthopedic residency programs, however, reveals a shift to conservative treatment with sling immobilization. Both strategies have yielded good results in selected patients, with the specific management operator dependent. Treatment decisions are based on such factors as age, occupation, and activity level. Types IV, V, and VI are severe injuries, and most authors recommend surgical repair. Because other injuries are associated with these more severe forms of acromioclavicular joint injuries (especially type VI), a careful clinical and radiographic examination must be performed.
FIG. 263-5. Type III acromioclavicular dislocation. Note the dislocation of the acromioclavicular joint (*white arrow*) and increased coracoclavicular interspace (*black arrow*).

DISLOCATION OF THE GLENOHUMERAL JOINT

Dislocation of the glenohumeral joint is the most common major joint dislocation. Anterior dislocations are by far the most common. Posterior dislocations are described but occur in less than 2 percent of cases. Other dislocations include inferior (luxatio erecta) and superior (very rare).

Anterior Glenohumeral Dislocations

There are four types of anterior dislocations. In subcoracoid dislocation, the commonest type, the humeral head is displaced anterior to the glenoid and inferior to the coracoid. In a subglenoid dislocation, the humeral head lies inferior and anterior to the glenoid fossa. In a subclavicular dislocation, the head of the humerus is displaced medial to the coracoid below the clavicle. In the very rare intrathoracic dislocation, the head of the humerus lies between the ribs and thoracic cavity.

The mechanism of injury may be direct force, but an indirect force is commoner. The combination of abduction, extension, and external rotation with sufficient force will cause an anterior dislocation.

The patient is usually in severe pain. The arm is in slight abduction and external rotation. The shoulder is "squared off," lacking the normal rounded contour. The patient resists abduction and internal rotation. The humeral head can often be palpated anteriorly. Because neurovascular injuries occur, a careful examination must be performed. The axillary nerve is most commonly injured. This nerve may be tested by pinprick sensation over the skin of the deltoid muscle.

Anteroposterior and scapular lateral or Y radiographs should be obtained before reduction is attempted. Although the anteroposterior radiograph will reveal the dislocation, the scapular Y radiograph will indicate the direction of dislocation: anterior or posterior. Bony injuries reported in the literature include fractures of the anterior glenoid lip, greater tuberosity, coracoid, and acromion, and compression fractures of the humeral head (Hill-Sachs lesion).

Many reduction techniques have been described. The three main categories are traction, leverage, and scapular manipulation. Success rates are between 70 and 90 percent regardless of technique. The use of conscious sedation is recommended, but any reduction technique may be attempted without medication when performed slowly and atraumatically. It is important for the physician to be comfortable with two or three techniques in case of a failed first attempt. Considerations in selection of a technique include ease of performance, effectiveness, as little trauma and pain as possible, requirement for medication, number of assistants, and time for procedure.

HIPPOCRATIC (MODIFIED)   A modification of the Hippocratic method uses traction-countertraction (Fig. 263-6). The patient is supine with the arm abducted and elbow flexed at 90°. A sheet is tied and placed across the thorax of the patient and then around the waist of the assistant. Another sheet is tied and placed around the forearm of the patient at the elbow and the waist of the physician. The physician gradually applies traction as the assistant provides countertraction. Gentle internal and external rotation or outward pressure on the proximal humerus may aid reduction.

FIG. 263-6. Modified Hippocratic technique.

STIMSON   The patient is placed prone on a gurney with the dislocated extremity hanging over the side and a 10-pound weight attached to the wrist. Complete muscle relaxation is required. Twenty to 30 min is required to allow reduction to occur.

Although safe, effective, and easy to learn, the time involved and constant monitoring by a nurse are drawbacks to this technique.

MILCH   The patient is supine. The physician slowly abducts and externally rotates the arm to the overhead position (Fig. 263-7). With the elbow fully extended, traction is applied. With the other hand, pressure may be placed on the humeral head to manipulate it over the lip of the glenoid.

FIG. 263-7. Milch technique.

This technique is well tolerated by the patient, effective, and atraumatic. It is the technique of choice for many physicians

SCAPULAR MANIPULATION   The patient is positioned with weights in the same manner as the Stimson technique (Fig. 263-8). After adequate sedation, the physician pushes the tip of the scapula medially using the thumbs, while stabilizing the superior aspect with the cephalad hand.

FIG. 263-8. Scapular manipulation technique.

Several reports have recently been published. Physicians have found this technique relatively painless, fast, and in one study 90 percent successful.

EXTERNAL ROTATION   The patient is supine with the arm adducted to the patient's side. With the elbow at 90° of flexion, the arm is slowly externally rotated. No longitudinal traction is applied. It is important to perform the movement slowly to allow time for spasm and pain to resolve. Reduction is usually complete prior to reaching the coronal plane and is often not noted either by the patient or physician.

This method has been reported to be 78 percent successful, relatively atraumatic, safe, and easily learned.

COMPLICATIONS   Complications are frequently encountered in patients with anterior glenohumeral dislocations. The most common complication is recurrent dislocation, which is age dependent. Those patients less than 20 years of age have a greater than 90 percent recurrence; those older than 40 years have a 14 percent recurrence. Other complications include fractures and injuries to nerves and the rotator cuff. Vascular injuries are rare but when they occur tend to involve the axillary artery in elderly patients. Clinical findings of vascular injury include absent radial pulse, axillary hematoma, bruising of the lateral chest wall, and an axillary bruit.

Bony injuries are common and include fractures of the humeral head (Hill-Sachs lesion), anterior glenoid lip, and greater tuberosity. Neural injuries occur in 10 to 25 percent of acute dislocations. Of these injuries, which are the result of traction neuropraxia, most occur in the axillary nerve. This injury is temporary and resolves spontaneously. The common test of sensation over the skin of the deltoid muscle may not be reliable, with only an electromyogram providing an accurate evaluation. Other nerves injured are the radial, ulnar, median, musculocutaneous, and brachial plexus.

A frequent but often missed injury is a tear of the rotator cuff. This injury, which increases with age, has a greater than 80 percent occurrence in patients older than 60 years. Treatment is surgical.

Posterior Glenohumeral Dislocations

Posterior dislocation may occur with the humeral head in the subacromial (most commonly with the humeral head behind the glenoid and beneath the acromion), subglenoid, or subspinous. The latter two are rare.

The usual mechanism is an indirect force that produces forceful internal rotation and adduction. This mechanism may occur during a fall or from violent muscle contraction from a seizure or electric shock. Direct force to the anterior shoulder can also produce a posterior dislocation.

Posterior dislocations are reported to be commonly missed. Thus, a careful examination and radiographic evaluation are essential. Clinical findings include the following:

1. The arm is adducted and internally rotated.
2. The anterior shoulder is flat and the posterior aspect full.
3. The coracoid process is prominent.
4. The patient will not allow external rotation or abduction because of severe pain.

Although the anteroposterior radiograph is helpful, the scapular Y radiograph is diagnostic. In this radiograph, the humeral head is seen in a posterior position.

Since severe pain and muscle spasms are the norm, muscle relaxation and analgesia are paramount. The reduction is performed with the patient supine. Traction is applied to the adducted arm in the long axis of the humerus. An assistant gently pushes the humeral head anteriorly into the glenoid fossa.

Most complications are fractures, including fractures of the posterior glenoid rim, humeral head (reversed Hill-Sachs deformity), humeral shaft, and lesser tuberosity. Neurovascular and rotator cuff tears are less common than in anterior dislocations.

Inferior Dislocations (Luxatio Erecta)

Although inferior dislocation is a rare injury, it is one that will be seen in a busy emergency practice. It is always a severe injury and is associated with significant soft-tissue trauma or fracture. The mechanism of injury is a hyperabduction force, which levers the neck of the humerus against the acromion. As the force continues the inferior capsule tears, and the humeral head is forced out inferiorly.

The patient is in severe pain. The humerus is fully abducted, the elbow is flexed, and the patient's hand is on or behind the head. The humeral head can be palpated on the lateral chest wall. This clinical presentation is difficult to mistake for another condition.

Reduction consists of traction in an upward and outward direction in line with the humerus (Fig. 263-9). The assistant applies countertraction. Reduction is signaled by a "clunk." The arm is then brought to the patient's side and immobilized in a shoulder immobilizer.

FIG. 263-9. Reduction of luxatio erecta.

Complications include severe soft-tissue injuries and fractures of the proximal humerus. The rotator cuff, which is always detached, requires orthopedic follow-up. Neurovascular compression injuries are usually found but almost always resolve following reduction. When the humeral head is buttonholed through the inferior capsule, the dislocation is irreducible, and operative reduction is required.

HUMERUS FRACTURES

Proximal Humerus

Fractures of the proximal humerus are a relatively common problem in the emergency department, representing 5 percent of all fractures. They typically occur in elderly osteoporotic patients via an indirect mechanism, such as a fall on an outstretched hand with the elbow extended. Eighty percent of such fractures can be easily managed by the emergency physician, but the remainder have significant displacement and are a challenge to correctly diagnose and treat. Fortunately, the shoulder joint has an intrinsic reserve of range of motion, which can often provide a surprisingly functional outcome despite seemingly crippling injuries.

The proximal humerus is composed of the articular segment, the greater and lesser tuberosities, and the proximal humeral shaft. Muscles of the rotator cuff insert on the humeral tuberosities, and the biceps tendon travels between them. The humeral circumflex arteries enter in the area of the bicipital groove and the tuberosities to supply blood flow to the articular segment.

Patients with fractures typically present with pain, swelling, and tenderness about the shoulder. Crepitus and ecchymosis may be present, and the arm is generally held closely against the chest wall. A neurovascular examination should be performed, since the brachial plexus and axillary arteries are near the coracoid process and not uncommonly injured. The axillary nerve is the most commonly injured nerve, and sensation over the skin of the deltoid muscle should be tested routinely. Injury to the axillary artery is the commonest vascular injury and may be suggested by paresthesias, pallor, pulselessness, or an expanding hematoma. Vascular injuries may occur with even trivial trauma in atherosclerotic elderly patients.

Radiographs consisting of anteroposterior, lateral shoulder, and axillary views will correctly diagnose most proximal humerus fractures. Fractures of the articular surface may be suggested by a fat fluid level or by a superior joint hematoma that appears to push the humerus downward in the joint as a "pseudosubluxation." A transthoracic lateral radiograph, tomograms, CT scan, and magnetic resonance imaging scan may also be of value.

The Neer classification system uses the relationship of the proximal humerus segments (greater and lesser tuberosities, anatomic neck, and surgical neck) to guide the management of these fractures. Significant fragment displacement is defined as greater than 1-cm separation or greater than 45° of angulation between fragments. The number of fracture fragments significantly displaced determines the classification in the Neer system (Fig. 263-10).

FIG. 263-10. The Neer classification system for proximal humerus fractures.

A one-part fracture may have any number of fracture lines, but no major segment is significantly displaced. The surrounding soft tissue and periosteum hold fracture fragments together. One-part fractures comprise over 80 percent of all proximal humerus fractures. Treatment generally consists of immobilization with a sling and swathe or collar and cuff, ice, analgesics, and referral. Early exercise is important to avoid adhesive capsulitis. The overall prognosis is generally good.

Two-part fractures account for 10 percent of proximal humerus fractures, with the remaining 10 percent evenly split between three-part and four-part fractures. Such displaced fractures are more frequently associated with complications and are often difficult to manage. Treatment considerations include integrity of the blood supply, integrity of the rotator cuff, likelihood of union, associated dislocations and neurovascular injuries, and the functionality of the patient. Closed reduction, intraoperative treatment, or a combination of the two may be necessary. Emergent orthopedic consultation for multipart fractures facilitates subsequent reduction and referral.

Any fracture involving the anatomic neck or the articular surface may result in compromise of the blood supply to the articular segment. Ischemic necrosis of the articular segment may ultimately require insertion of a humeral head prosthesis for these relatively uncommon fractures. Greater tuberosity fractures accompany up to 15 percent of anterior shoulder dislocations. Significant displacement of a greater tuberosity fragment implies a concomitant rotator cuff tear, with surgical repair often necessary for the active patient. Fracture of the lesser tuberosity should alert the examiner to a potential posterior shoulder dislocation. Significantly angulated surgical neck fractures are at risk for neurovascular damage (axillary neurovascular structures and brachial plexus) and should be immediately immobilized and radiographed in the position of presentation. Children may have significant displacement or separation of the proximal humeral epiphysis and may require exact reduction if near skeletal maturity. A shoulder spica is often used after reduction.

Humeral Shaft

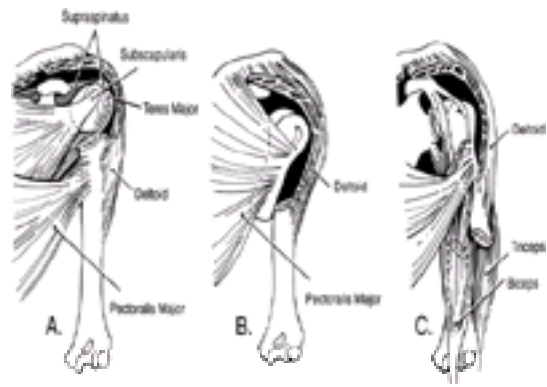
Fractures of the humeral shaft occur in a bimodal age distribution, with peaks in the third and seventh decades of life, representing active young men and osteoporotic elderly women, respectively. The most common site of fracture is the middle third. Neurovascular injuries are a common complication of these fractures and are a direct result of the anatomy of the upper extremity. Displacement of fracture fragments is common as a result of the insertions and actions of the various muscles (deltoid, biceps, triceps, supraspinatus, and pectoralis major) that act on the upper arm (Fig. 263-11).


FIG. 263-11. The actions of the muscles inserting on the humeral shaft determine fracture angulation and displacement. Humeral fractures anterior view: **A.** Angulation of fragments with fracture line distal to rotator cuff insertion. **B.** Angulation of fragments with fracture line distal to pectoralis major insertion. **C.** Angulation of fragments with fracture line distal to deltoid insertion.

Humeral shaft fractures may be caused by a direct blow that produces a bending force, which results in a transverse fracture. It may also be caused by an indirect mechanism, such as a fall on the outstretched hand that produces a torsion force, resulting in a spiral fracture. A combination of bending and torsion forces results in an oblique fracture, sometimes with comminution, producing the "butterfly" fragment. The humerus is also a common site of pathologic fractures, especially from metastatic breast cancer.

Clinical examination reveals localized tenderness, swelling, pain, and abnormal mobility or crepitus on palpation. Displaced fractures are associated with shortening of the upper extremity. Attention must be given to the initial neurovascular status, and reevaluation must be performed, especially after manipulation. Radiographs should include two views of the humerus, and consideration should be given to radiographic examination of the shoulder and elbow as well.

The vast majority of closed fractures of the shaft of the humerus are managed nonoperatively. The treatment of uncomplicated fractures includes immobilization, ice, analgesia, and referral. Closed treatment options include the coaptation splint (sugar tong), a hanging cast, functional bracing, and external fixation. A simple sling and swathe are adequate for most emergency management. Some surgeons favor internal fixation for patients with transverse fracture lines, very proximal or very distal humerus fractures, pathologic fractures, multiple trauma, and fractures associated with neurovascular injuries.

Complications include injury to the brachial artery or vein, or the radial, ulnar, or median nerves. A radial nerve injury, which is the most common, may be manifested by a wrist drop and altered sensation at the dorsal first web space. The incidence of radial nerve palsy ranges from 10 to 20 percent. Fractures of the distal third are particularly prone to entrapment of the radial nerve either as a result of the initial injury or after closed reduction. The majority of patients have eventual return of nerve function without operative intervention.

EPIDEMIOLOGY

The most important sequela of injuries to the spinal column is damage to the spinal cord. There are an estimated 10,000 new cases of spinal cord injury each year, rendering approximately 5000 people quadriplegic. [1] In addition to the personal tragedy, tremendous financial costs are involved in the care of the spinal cord-injured patient. In 1996, the costs during the first year after a spinal cord injury located from C1 through C4 averaged $417,000. Lifetime medical costs were estimated at $1,350,000 for the same patients. [1] The estimated annual cost of medical, rehabilitative, and vocational care for all spinal cord-injured patients in the United States is $2 to 4 billion. [2]

Injuries to the spinal cord are due to blunt trauma in about 90 percent of cases. The most common injury mechanism is a motor vehicle accident, followed by assaults—mostly gunshot wounds, falls, and sporting accidents. [1] The cervical spine is the most common site for injury to the spinal cord (61 percent), followed by the thoracolumbar junction (19 percent), the thoracic spine (16 percent), and the lumbosacral spine (4 percent). [3]

EVALUATION

Resuscitation

Injuries to the spine and spinal cord are frequently associated with other injuries. Initial resuscitation of the patient with multiple injuries from trauma focuses on airway, breathing, and circulation (the ABCs). The patient with a potential spine injury should undergo immobilization to prevent deterioration during resuscitation. Patients who are at risk for spine injury include those who have had automobile and motorcycle accidents, falls, and diving accidents. Any patients complaining of neck pain, weakness, parethesias, or paralysis should be considered to have a spinal cord injury. A patient with a history of trauma and an altered level of consciousness should always be treated as if a spinal cord injury were present.

Spinal immobilization is important to prevent secondary injury. The components of spinal immobilization include a long spine board, a semirigid cervical spine collar, and "sandbags" or other devices to limit head and neck motion. Cervical spine collars alone are ineffective at limiting spine motion. [4] The process for moving a patient onto a spine board or for examination of the back involves a "log-roll." One person is required to maintain the head and neck in neutral position while a minimum of two other people gently roll the patient. The person holding the head directs the team to avoid nonsynchronous motion.

The patient with a spinal cord injury may also present with hypotension due to a loss of sympathetic function and vasodilation below the level of the injury. In a multiply injured patient, other causes of hypotension should be vigorously pursued. Hypotension due purely to a spinal cord injury will be associated with a bradycardia. Hypotension from acute hemorrhage and hypovolemia will be associated with a tachycardia. The initial treatment of hypotension is intravenous fluid. Atropine may be used for significant bradycardia, and vasopressors such as dopamine can be employed if the patient does not respond to fluid boluses.

Airway Management

Patients with multiple trauma are frequently intubated without knowledge of the condition of the cervical spine. Regardless of the airway management technique selected, movement of the spine should be minimized. Intubation techniques for patients with possible spinal injury include nasotracheal intubation with and without bronchoscopic guidance, orotracheal intubation, transtracheal intubation, and cricothyrotomy. [5] Methods for protecting the spinal cord during orotracheal intubation to prevent further injury have been studied in cadavers. These studies have shown that manual in-line stabilization using a dedicated person to hold the head and neck in a neutral position is superior to the use of a Philadelphia collar alone. [6,7 and 8] During proper in-line stabilization, no traction is applied to the head and spine. Axial traction is discouraged because it can cause distraction of cervical spine fractures. [9]

Physical Examination

After the primary survey has been performed and any immediately life-threatening conditions have been addressed, a complete neurologic examination should be performed. The motor exam should assess the strength of all extremities. Any deficits should be localized to a nerve root level (Table 264-1). The sensory exam should ensure that sensation is present in all extremities. Sensory innervation follows the dermatome pattern. The loss of sensation at and below a given dermatome can localize the level of the injury (Fig. 264-1). Priapism should be considered as evidence of a spinal cord injury. Rectal examination may reveal decreased tone due to spinal cord injury. Prognosis can be difficult to determine in the early stages of a spinal cord injury owing to the temporary condition of spinal shock. Spinal shock as defined here is different than the spinal neurogenic shock discussed in Chap. 31. Spinal shock, a condition seen frequently in the first 24 h after injury, is defined by a complete loss of segmental cord reflexes in addition to paralysis. Only after the spinal shock has remitted can any definitive prognosis be given. Resolution of spinal shock is heralded by return of segmental reflexes (bulbocarvernosus in males).

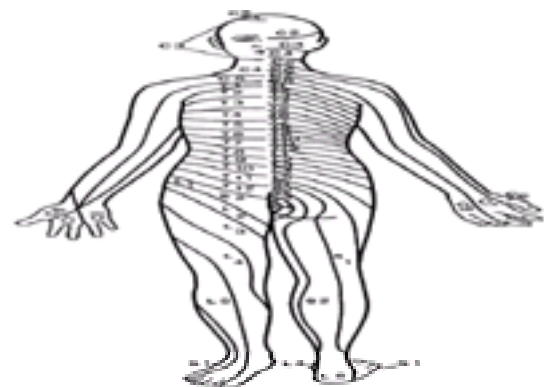

FIG. 264-1. Dermatomes.

RADIOGRAPHIC EVALUATION

The Asymptomatic Patient

The use of clinical criteria to "clear" the cervical spine and avoid unnecessary radiographs in selected trauma patients has been suggested by authors of several studies.[10,11 and 12] The criteria examined were a combination of relevant historical and physical examination features. Patients meeting the criteria did not have significant cervical spine injury requiring radiographs.[13] The criteria that excluded cervical spine injury in these blunt trauma patients were:

1. Alertness, absence of intoxication
2. Absence of neck pain
3. Absence of neck tenderness
4. Absence of painful distracting injuries
5. Absence of sensory or motor deficit

Trauma patients who do not meet all of these criteria should have plain radiographs to evaluate the cervical spine. These should include lateral, anteroposterior, and odontoid views. If these views are normal and the patient is cooperative and has no neurologic signs or symptoms, active range of motion and/or flexion-extension views can be used to further evaluate the cervical spine.

Cervical Spine Radiographs

LATERAL VIEW   The lateral view radiograph detects 70 to 80 percent of traumatic cervical spine injuries.[14] The lateral view should include the cervothoracic junction, as 10 percent of cervical spine fractures will occur at this level.[15] Gentle traction on the upper extremities may move the shoulders out of the way and increase the yield of the interval view. Another radiographic technique for defining the bony anatomy of the cervicothoracic junction is the "swimmer's" view. This can be difficult to perform because of the positioning of the patient and film and difficult to interpret owing to overlying bone shadows and obliteration of the posterior spine. If plain radiographs do not define the cervicothoracic junction in a patient with suspected cervical spine injury, the patient should remain in cervical immobilization and alternate methods such as computed tomography (CT) should be employed.[16]

The lateral view should be inspected methodically to detect abnormalities (Table 264-2). Alignment should be evaluated by following anatomic lines (Fig. 264-2). There should be no stepoffs or breaks in the lines. The anterior longitudinal ligament line follows along the anterior surface of the vertebral bodies. This line should follow the normal lordotic curve of the spine. The line of the posterior longitudinal ligament runs along the posterior bodies of the vertebrae and is immediately anterior to the spinal cord. A change of 11° or more in the angle of this line at an interspace should be considered evidence of ligamentous injury (Fig. 264-3). The spinolaminal line is formed by the junction of the lamina with the spinous process at each vertebra. Fractures of the odontoid or C2 pedicles can be detected by examining the spinolaminal line. The spinolaminal line connecting C1 with C3 should pass within 1 mm of the spinolaminal junction of C2. Displacement of more than 1 mm suggests anterior or posterior displacement of the odontoid or a hangman's fracture [5] (Fig. 264-4). The last line is the line connecting the tips of the spinous processes.

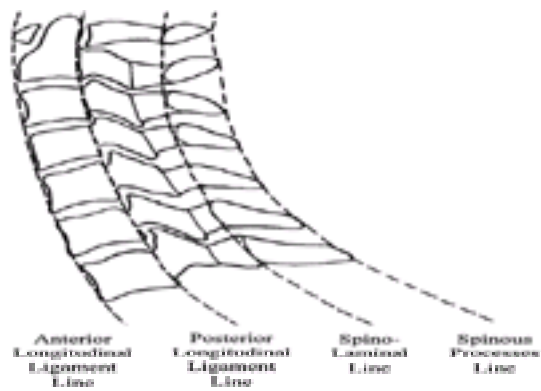
TABLE 264-2   Criteria for Clearing the Cervical Spine Cross-Table Lateral View


FIG. 264-2. Alignment of the lateral cervical spine. (From ..., with permission.)
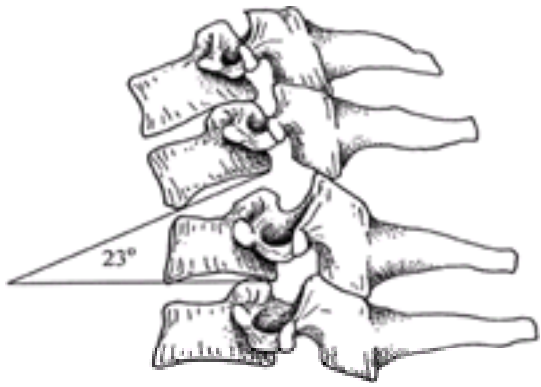

FIG. 264-3. Angulation. (From Galli et al,[29] with permission.)
FIG. 264-4. Spinolaminal alignment. (From Galli et al,[29] with permission.)

Examination of the soft tissues of the neck may be helpful in defining injury. The upper limits of normal dimensions of the prevertebral tissue are 6 mm at C2 and 22 mm at C6.[17] Injury to the cervical spine can cause hematomas and edema that increase the size of the prevertebral space as seen on the lateral view radiograph. Abnormal width of the prevertebral tissues occurs in 33 to 60 percent of cervical spine injuries.[17]

ANTEROPOSTERIOR (AP) VIEW   The AP view is ineffective in evaluating the upper cervical spine because the structures of the face and mandible obscure the bony anatomy. The lateral cortex of the articular masses can show evidence of fracture or dislocation if they are angled as compared with superior or inferior neighbors. The spinous processes can be seen on end, and abnormal widening may indicate a hyperflexion sprain or interfacetal dislocation.

ODONTOID VIEW   The odontoid or open-mouth view shows the odontoid and its relationship to the lateral masses of C1. The dens should be centered between the lateral masses, and the lateral masses of C1 should be directly over the lateral portions of C2. Rotation of the head may cause some displacement of the lateral masses and asymmetry of the relationship of the dens and C1. Rotation can be detected by using the space between the central incisors, which should be in the midline in an unrotated view. Displacement of the lateral masses due to rotation will cause one side to be displaced medially and the opposite side displaced laterally.[5]

FLEXION-EXTENSION VIEWS   An injury to the ligamentous structures of the spine may occur without a bone fracture. If the initial radiographs show no evidence of fracture but are suggestive of subluxation or if suspicion of a ligamentous injury exists, flexion and extension views may be performed. Anterior subluxation injuries are exacerbated in flexion and reduced in extension. This should only be performed in awake, cooperative patients. The flexion and extension should be halted at the point where they cause the patient pain.[16]

Computed Tomography Scanning

CT scanning is indicated in any major fracture or fracture/dislocation of the spine. CT scanning can improve the detection of fractures in areas poorly visualized by plain radiography; these areas comprise the C1, C2, C6 and C7 vertebrae. CT scanning is less useful for purely soft tissue injuries seen with ligamentous disruption.

CT scanning can miss fractures oriented in the axial plane.[18] Subluxations and dislocations are also sometimes missed with CT scanning.[19] When plain radiography is combined with CT for difficult-to-visualize vertebrae, almost all abnormalities will be identified.[19]

Magnetic Resonance Imaging (MRI)

MRI is better than CT for defining the soft tissue injury seen with spine fractures and is indicated in all patients who have neurologic deficits from a spinal cord injury. MRI can evaluate the epidural space for herniated intervertebral disks, hematoma, and bone fragments and can image the spinal cord for edema, hemorrhage, or laceration.[20] MRI is more time-consuming than CT scanning and should be used only for patients who are hemodynamically stable.

CERVICAL SPINE INJURIES

Anatomy

The forces that lead to cervical spine injury have been studied in laboratory settings. These experiments have revealed that specific patterns of injury are associated with the initial dominant force present at the time of injury. A classification system for describing cervical spine injuries based on the biomechanical force responsible for the injury has been proposed by Harris Table 264-3. A description of selected cervical spine fractures based on this classification follows.

Flexion
    Anterior subluxation (hyperflexion sprain)
    Bilateral interfacetal dislocation
    Simple wedge (compression) fracture
    Clay-shoveler's (coal-shoveler's) fracture
    Flexion teardrop fracture
Flexion-rotation
    Unilateral interfacetal dislocation
Pillar fracture
    Fracture/separation (pedicolaminar fracture)
Vertical compression
    Jefferson burst fracture of atlas
    Burst (bursting, dispersion, axial-loading) fracture
Hyperextension
    Hyperextension dislocation
    Avulsion fracture of anterior arch of atlas
    Extension teardrop fracture
    Fracture of posterior arch of atlas
    Laminar fracture
    Traumatic spondylolisthesis ("hangman's" fracture)
Lateral flexion
    Uncinate process fracture
Injuries caused by diverse or poorly understood mechanisms
    Occipitoatlantal dissociation
    Occipital condylar fractures
    Dens fractures

TABLE 264-3   Cervical Spine Injuries: Mechanism of Injury

An understanding of the anatomy of the cervical spine is essential to the classification of injuries. For the purpose of understanding how mechanisms of injury affect the spine, consider the spine as consisting of two columns. The anterior column is composed of those structures anterior to the posterior longitudinal ligament. The ligamentous structures in the anterior column are the intervetebral disk, the annulus, and the anterior and posterior longitudinal ligaments. The posterior column is made up of the vertebral arch, the ligamentum flavum, the capsular ligaments and the interspinous and supraspinous ligaments. The posterior ligamentous elements resist flexion forces and the anterior ligamentous elements resist extension forces.

Mechanism: Hyperflexion

ANTERIOR SUBLUXATION   Anterior subluxation is also known as *hyperflexion sprain*. The posterior ligamentous structures fail because of the hyperflexion of the cervical spine. A pure subluxation injury has no associated fractures. Radiographic findings can include a "fanning" or widening of the spinous processes at the level of injury. The disc space may be widened posteriorly and narrowed anteriorly. Abrupt angulation change of more than 11 degrees at a single interspace may also signal an injury[21] (Fig. 264-3).

Cervical spine radiographs may be normal if the hyperflexion sprain has not caused a fracture and the subluxation has been reduced. Flexion and extension views should be obtained in awake and cooperative patients to further evaluate for injury. Flexion views will exaggerate the radiographic abnormalities and extension views will reduce them. Anterior subluxation is a stable injury but mandates consultation to institute proper treatment, ensure absence of any associated spinal injuries, and prevent the development of delayed instability and pain syndromes.

BILATERAL INTERFACETAL DISLOCATION (BID)   BID occurs when disruption to all ligamentous structures due to hyperflexion allows the articular masses of the involved vertebra to dislocate superiorly and anteriorly over into the intervertebral foramen inferior to the involved vertebra (Fig. 264-5). Radiographically, the vertebra can be seen dislocated anteriorly to at least 50 percent its width. The injury is mechanically unstable and usually presents with neurologic findings. [16] A "perched" vertebra is seen in partial BID, when the articular masses of the involved vertebra are perched on the superior articular processes of the subjacent vertebra. This configuration is also mechanically unstable but may not present with neurologic compromise. [16] Using the term *locked facets* to describe a BID is misleading because the injury is unstable. Immediate specialist referral is necessary to reduce the dislocation.
FIG. 264-5. Bilateral intrafacetal dislocation.

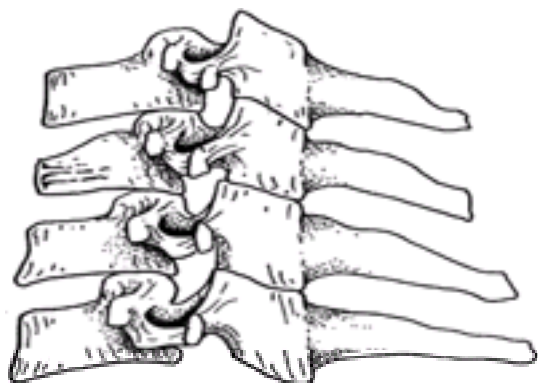
SIMPLE WEDGE FRACTURE   A wedge fracture of a vertebra is caused by compression between two other vertebrae. The superior end plate fractures while the inferior surface of the vertebra remains intact (Fig. 264-6). The posterior ligaments may be disrupted, leading to an increase in the distance between spinous processes. Posterior element disruption makes the injury unstable. The simple wedge fracture is differentiated from a burst fracture by the absence of a vertical fracture of the vertebral body. Immediate specialist consultation is necessary if stability of the posterior ligament is not assured. [16]


FIG. 264-6. Wedge fracture.

CLAY-SHOVELER'S FRACTURE   An avulsion of the spinous process of the lower cervical vertebrae, classically C7, is known as a clay-shoveler's fracture (Fig. 264-7). Intense flexion against contracted posterior erector spinal muscles causes avulsion of the spinous process. An isolated clay shoveler's fracture is mechanically stable. Conservative treatment with ice, analgesia, rest, and early referral is indicated. [16]
FIG. 264-7. Clay-shoveler's fracture.

FLEXION TEARDROP FRACTURE Extreme flexion can cause the flexion teardrop fracture (Fig. 264-8). The associated anterior cord syndrome is due to impingement of the spinal cord by the fracture hyperkyphosis. There is complete disruption of all ligamentous structures at the level of the injury. The "teardrop" is the anteroinferior portion of the vertebral body, which is separated and displaced from the remaining portion of the vertebra. This injury is mechanically unstable and requires immediate attention from a spine specialist. [16]
FIG. 264-8. Flexion teardrop fracture.

Mechanism: Flexion and Rotation

UNILATERAL INTERFACETAL DISLOCATION Simultaneous forces of flexion and rotation can produce a unilateral facet dislocation. The articular mass and inferior facet on one side of the vertebra are anteriorly dislocated (Fig. 264-9). Radiographically, the AP view will reveal the rotation, because the spinous processes will not be projected directly over one another. The affected spinous process will point toward the side of the vertebra that is dislocated. The involved vertebra will be displaced anteriorly less than 50 percent of the width of a vertebra on the lateral view. The dislocation is mechanically stable unless there is a fracture at the base of the inferior articular mass of the dislocated vertebra or a fracture of the superior articular mass of the inferior vertebra. Immediate consultation of a specialist is recommended because of the long-term complications of an unreduced injury. [16]
FIG. 264-9. Unilateral facet dislocation.

Mechanism: Extension and Rotation

PILLAR FRACTURE Extension and rotation can cause impaction of a superior vertebra on the articular mass of its inferior neighbor. The resultant vertical or oblique fracture of the articular mass is called a *pillar fracture* (Fig. 264-10). The adjacent lamina and pedicle remain intact. The lateral view may show a "double-outline" sign at the level of the injury. This can be differentiated from the normal lateral radiograph, in which the articular masses are imposed on one another and only a single radiographic density is seen. The double outline occurs when the fractured articular mass is displaced posteriorly and causes two radiographic shadows. The AP projection will show an abnormality of the lateral column and a fracture at the level of the injury. The fracture is considered stable. Immediate specialist consultation is indicated. [16]
FIG. 264-10. Pillar fracture.

FRACTURE SEPARATION Harris has described the fracture/separation as a pedicolaminar fracture because it involves fractures of the pedicle and lamina. There

are varying degrees of fracture, ranging from fractures without displacement to disruption of the anterior longitudinal ligament and disk rupture. The lateral radiograph may show rotation of the involved articular mass as compared with the uninvolved lateral mass at the level of the injury. Anterior listhesis may be seen in more severe mechanisms. The AP view may show disruption of the lateral column. Immediate consultation is recommended.

Mechanism: Vertical Compression Injuries

BURST FRACTURE OF THE LOWER CERVICAL SPINE   A direct axial load causes a burst fracture of the lower cervical spine. The axial force causes the vertebra to burst with fragments displacing in all directions (Fig. 264-11). The spinal cord may be injured if a fragment enters the spinal canal. The lateral radiograph may show a fracture of the superior and inferior vertebral end plate and retropulsion of the posterior segment of the vertebra into the spinal canal. The AP view will show a vertical fracture and widening of the interpedicular distance. This injury is unstable. Immediate consultation is recommended. [16]
FIG. 264-11. Burst fracture.

JEFFERSON FRACTURE   The Jefferson fracture is usually produced when the cervical spine is subjected to an axial load due to a direct blow to the top of the head. The occipital condyles are displaced downward and produce a burst fracture by driving the lateral masses of C1 apart (Fig. 264-12). The lateral masses will be displaced laterally on the open-mouth odontoid radiograph. A fracture through only one lateral mass will cause unilateral displacement on the open-mouth view. Instability is likely if the lateral masses are displaced significantly. If the displacement of the lateral masses on each side added together is greater than 7 mm, rupture of the transverse ligament is likely. Immediate specialist consultation is necessary for all Jefferson fractures.
FIG. 264-12. Jefferson fracture.

Mechanism: Hyperextension Injuries

HYPEREXTENSION DISLOCATION   A hyperextension injury involves a complete tear of the anterior longitudinal ligament and intervertebral disk with disruption of the posterior ligamentous complex. Facial trauma with a central cord syndrome is the most common clinical presentation. Radiographically the vertebrae are normally aligned because the dislocation will be reduced. Diffuse prevertebral soft tissue swelling is usually present. Other signs include a disk-space widening anteriorly or a fracture of the anteroinferior end plate of the vertebrae. [16] If the patient has no neurologic deficit and no evidence of fracture, flexion-extension films may be used to help define ligamentous instability. Any evidence of instability requires immediate specialist consultation.

AVULSION FRACTURE OF THE ANTERIOR ARCH OF ATLAS   A hyperextension may avulse the inferior pole of the anterior tubercle of C1. This is most readily detected on the lateral view (Fig. 264-13). The presence of perivertebral soft tissue swelling and absence of cortication distinguish it from the ununited secondary ossification center of the inferior pole of the tubercle. A fracture involving the entire anterior arch is unstable. Immediate specialist consultation is recommended. [16]

FIG. 264-13. Avulsion fracture of the anterior arch of the atlas.

EXTENSION TEARDROP FRACTURE   A hyperextension mechanism may cause the anterior longitudinal ligament to avulse the inferior portion of the anterior vertebral body at its insertion (Fig. 264-14). The most common location is at C2. The height of the fragment usually exceeds its width. This fracture is more common in older patients with osteoporosis. The extension teardrop fracture is unstable in extension and immediate specialist consultation is necessary. [16]
FIG. 264-14. Extension teardrop fracture.

FRACTURE OF POSTERIOR ARCH OF THE ATLAS Hyperflexion of the cervical spine may compress the posterior arch of the atlas between the occipital bone and the spinous process of the axis. This is to be differentiated from the Jefferson fracture of C2. Prevertebral soft tissue swelling is much more prevalent with the more extensive Jefferson fractures. CT scanning will ultimately define which fracture is present. This fracture is frequently associated with other cervical spine fractures, and specialist consultation is recommended.

LAMINAR FRACTURE Isolated laminar fractures are caused by hyperextension and may be subtle on plain radiographs. Associated spinous process fractures may be present. CT scanning is required to define the extent of spinal cord involvement. This injury is considered stable; immediate specialist consultation is recommended.

HANGMAN'S FRACTURE The hangman's fracture is located in the pedicles of C2, with C2 displacing anteriorly on C3 (Fig. 264-15). The fracture is caused by an extension mechanism and is seen in judicial hangings. Suicidal hangings do not usually cause the extreme hyperextension seen in judicial hangings and do not cause a hangman's fracture. The same fracture is seen in motor vehicle and diving accidents where sudden hyperextension forces are applied in deceleration. Owing to the large diameter of the spinal canal at the level of C2, even displacement of C2 on C3 may not cause neurologic injury, and these patients may be neurologically intact. This injury is unstable and mandates immediate consultation.
FIG. 264-15. "Hangman's" fracture.

Mechanism: Lateral Flexion

UNCINATE PROCESS FRACTURE Pure lateral flexion is rare in most mechanisms of injury. Lateral flexion can cause a transverse fracture at the base of the uncinate process as the lateral aspect of the superior vertebral body fractures the inferior uncinate process. During the initial injury, the degree of lateral neck flexion is limited because the head strikes the shoulder. This fracture may be seen in the AP or lateral view. Immediate consultation is recommended.

Poorly Understood Mechanisms

OCCIPITOATLANTAL DISSOCIATION (OAD) In occipitoatlantal dissociation, the skull may be displaced anteriorly or posteriorly or distracted from the cervical spine. OAD frequently results in death. Severe OAD is easily detected on the lateral radiograph. Occipitoatlantal subluxation is more difficult to detect on radiographs. Harris has described a method for detecting occipitoatlantal injury. The basion-axial interval (BAI) can be measured in most lateral radiographs. This is the distance between the basion and a line extending from the posterior cortex of C2. The BAI should not exceed 12 mm (Fig. 264-16). The basion-dental interval (BDI) is the distance between the basion and the superior cortex of the dens. This distance should also be less than 12 mm (Fig. 264-17). Atlantooccipital injuries are extremely unstable and mandate immediate specialist consultation.
FIG. 264-16. Basion-axial interval (BAI).

FIG. 264-17. Basion-dental interval (BDI).

TRANSVERSE LIGAMENT DISRUPTION   The transverse ligament is located anterior on the inside of the ring of C1 and runs along the posterior surface of the dens. The transverse ligament is crucial to maintaining the stability of the first and second vertebrae. Pure ligamentous rupture without an associated fracture can occur in older patients with a direct blow to the occiput, as would occur in a fall. Without a fracture present, radiographic diagnosis relies on identifying the atlanto-dens interval, also known as the *predental space*, which is viewed on the lateral x-ray. The space is between the posterior aspect of the anterior arch of C1 and the anterior border of the odontoid. The space should be 3 mm or less in adults. More than 3 mm of space implies damage to the transverse ligament; more than 5 mm implies rupture of the transverse ligament. Immediate specialist consultation is necessary for these injuries.

ODONTOID FRACTURES   One-third of all fractures of the ring of C1 occur in combination with fractures of the odontoid. [22] Odontoid fractures make up 7 to 14 percent of cervical spine fractures. [23] Fractures of the odontoid are usually due to major forces and frequently involve other injuries to the cervical spine as well as multisystem trauma. [24] Awake patients will usually complain of immediate and severe high cervical pain with muscle spasm aggravated by movement. The pain may not be severe and can radiate to the occiput of the head. Neurologic injury presents in 18 to 25 percent of cases. This can range from minimal sensory or motor loss to quadriplegia. [25] Classification of odontoid fractures relies on identifying the level of injury. Type I fractures are avulsions of the tip. The transverse ligament remains attached to the dens, the fracture is stable, and the injury carries a good prognosis. Type II fractures occur at the junction of the odontoid and the body of C2. This is the most common odontoid fracture. Type III odontoid fractures occur through the superior portion of C2 at the base of the dens (Fig. 264-18). Immediate specialist consultation is recommended.
FIG. 264-18. Odontoid fractures.

THORACOLUMBAR SPINE INJURIES

Anatomy

The thoracolumbar spine (TLS) is relatively more protected and stable than the cervical spine. Vertebrae T1 through T10 are fixed, owing to their articulation with the thoracic cage. Large forces are required to fracture thoracic vertebrae and neurologic abnormalities are common. The mobility of the thoracolumbar junction predisposes it to injury. The thoracolumbar junction is second only to the cervical spine in frequency of injury. The spinal cord ends at approximately L1 at the conus medullaris. The individual nerve roots extending from the conus medullaris constitute the cauda equina. These nerve roots are less susceptible to damage and neurologic injury, as trauma to the lower lumbar and sacral segments occurs less often and is less severe.

Mechanism of Injury and Classification

McAfee et al.[26] have classified TLS injuries into major and minor fractures (Table 264-4). A discussion of the classification follows. Wedge compression fractures are the result of flexion causing compression of the anterior body of the vertebra. Plain radiographs demonstrate loss of anterior height in the traumatized vertebra. The posterior height and cortex are intact. CT scanning should be performed to define the stability of the posterior elements and sparing of the neural canal. These fractures are not usually associated with neurologic compromise but should be treated as unstable until evaluation is complete. A flexion mechanism causing anterior vertebral compression with involvement of the posterior cortex defines the burst fracture. Lateral plain radiography will show the loss of anterior and posterior height; AP views will show and increase in the interpedicular distance; and a CT scan will define the extent of the injury. The burst fracture should be considered unstable. A Chance fracture is caused by a flexion around an axis anterior to the anterior spinal longitudinal ligament. A high-speed motor vehicle accident with the occupant in a lap belt will produce this mechanism. The Chance fracture involves the spinous process, lamina, transverse processes, pedicles, and vertebral body. [27] The lateral radiograph will show the fracture through the posterior elements and vertebral body. A CT scan may help to define the injury but can miss it if the fracture is in the same plane as the scan. The Chance fracture should be considered unstable.

Major Injuries*	Minor Injuries†
Wedge compression fractures	Transverse process fracture
Chance fractures	Spinous process fracture
Burst fractures	Pars interarticularis fracture
Flexion distraction injuries	
Translational injuries	

*Assume to be unstable; should be cared for at a center with either orthopedic or neurosurgical spine specialists.
†Implies isolated fracture with no neurologic deficits, generally are stable.
Source: From Savitsky and Votey,[B] with permission.

TABLE 264-4 Classification of Thoracolumbar Spine Injury

A flexion-distraction mechanism places the anterior portions of the spine under compression while distracting the posterior elements. The lateral radiograph shows loss of height in the anterior portion of the vertebra with increased interspinous spaces posteriorly ("fanning"). This injury is unstable.

Translational injuries are the result of large shear forces that cause complete disruption of spine stability. The lateral radiograph will show translation of one or more vertebral segments on subsequent segments. Associated neurologic injury is common. Specific injuries include slice fractures, rotational fracture/dislocations, and pure dislocations. [28] Minor fractures include spinous process fractures, transverse process fractures, and pars interarticularis fractures. Minor fractures have no associated neurologic compromise and are considered stable.

265 TRAUMA TO THE PELVIS, HIP, AND FEMUR

Mark T. Steele

TRAUMA TO THE PELVIS

Pelvic fractures constitute 3 percent of all skeletal fractures and about 5 percent of patients admitted to hospitals because of trauma have pelvic fractures. [1] These fractures and concomitant injuries are a frequent cause of death from blunt trauma sustained in automobile accidents. Fortunately, the mortality has decreased. Most pelvic fractures are secondary to automobile passenger or pedestrian accidents, but about one-third are the result of minor falls in older persons and from major falls or industrial accidents. [2] This chapter discusses the most common fractures of the pelvis, femur, and hip, the mechanisms of injury, radiologic evaluation, and treatment.

Anatomy and Biomechanics

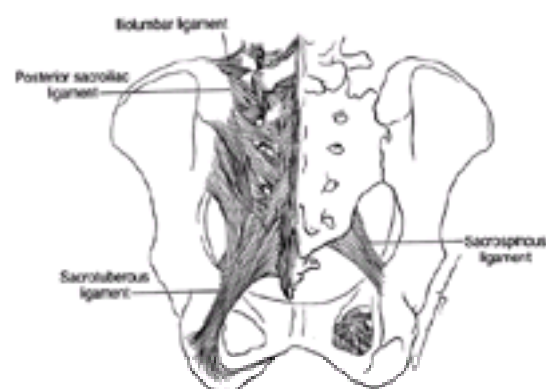
The major functions of the pelvis are protection, support, and hematopoiesis. The pelvis consists of the two innominate bones, which are made up of the ilium, ischium, and pubis; the sacrum; and the coccyx. The two innominate bones and sacrum form a ring structure, which is the basis of pelvic stability. This stability is dependent on the strong posterior sacroiliac, sacrotuberous, and sacrospinous ligaments (Fig. 265-1).[3] Any single break in the ring will yield a stable injury without significant risk of displacement. An injury with two breaks in the ring is unstable with the risk of displacement. The iliopectineal, or arcuate, line divides the pelvis into the upper, or false, pelvis, which is part of the abdomen, and the lower, true pelvis. In addition, this line constitutes the major portion of the femorosacral arch, which, along with the subsidiary tie arch (bodies of pubic bones and superior rami), supports the body in the erect position. In the sitting position, the weight-bearing forces are transmitted by the ischiosacral arch augmented by its tie arch, the pubic bones, inferior pubic rami, and ischial rami. When traumatized, the tie arches fracture first, especially at the symphysis pubis, pubic rami, and just lateral to the sacroiliac (SI) joints. Incorporated in the pelvic structure are five joints that allow some movement in the bony ring. The lumbosacral, SI, and sacrococcygeal joints, and the symphysis pubis allow little movement. The acetabulum is a ball-and-socket joint that is divided into three portions: the iliac portion, or superior dome, is the chief weight-bearing surface; the inner wall consists of the pubis, and is thin and easily fractured; and the posterior acetabulum is derived from the thick ischium.


FIG. 265-1. The major posterior stabilizing structures of the pelvic ring, that is, the posterior tension band of the pelvis, include the iliolumbar ligament, the posterior sacroiliac ligaments, the sacrospinous ligaments, and the sacrotuberous ligaments. (From Tile M. Anatomy. In: *Fractures of the Pelvis and Acetabulum.* Baltimore: Williams & Wilkins, 1984, p 11. Used with permission.)

The pelvis is extremely vascular, a fact that is significant in pelvic fractures. The nerve supply through the pelvis is derived from the lumbar and sacral plexuses. Injury to the pelvis may produce deficits at any level from the nerve root to small peripheral branches.

The lower urinary tract is contained in the pelvis (Fig. 265-2). In the adult, the bladder lies behind the symphysis and pubic bones, and the peritoneum covers the dome and base posteriorly. The location of the bladder and the degree of peritoneal reflection are determined by urine content. The lower gastrointestinal tract housed in the pelvis includes a small portion of the descending colon, the pelvic, or sigmoid, colon, the rectum, and the anus. In women, the uterus and vagina are also housed in the bony pelvis.
FIG. 265-2. Sagittal section of the male pelvis showing the relation of the full bladder. [From Kane WJ: Fractures of the pelvis, in Rockwood CA Jr, Green DP (eds): *Fractures,* Vol. 2. Philadelphia, Lippincott, 1975, pp 916, 917. Used with permission.]

Clinical Evaluation

HISTORY   Assume that all victims of serious or multiple trauma have fractures of the pelvis. A patient with a suspected pelvic fracture should be questioned about details of the accident to determine the mechanism of injury and about prehospital evaluation and treatment. The patient should be specifically questioned to determine areas of pain, last urination or defecation, present bladder sensation, and the last solid and fluid intake. In addition, the time of the last menses or the presence of pregnancy, current medications, and allergies should be ascertained.

PHYSICAL EXAMINATION   Symptoms and signs of pelvic injuries vary from local pain and tenderness, especially with walking, to pelvic instability and severe shock. The physician must maintain alertness, perception, and concern in evaluating these patients. On inspection look for perineal and pelvic edema, ecchymoses, lacerations, and deformities. Look for hematomas above the inguinal ligament or over the scrotum (Destot's sign). Roll the patient over if appropriate and examine the areas over-lying the sacrum and coccyx. On palpation feel for irregularities, crepitance, or movement at the iliac crests, pubic rami, and ischial rami. Palpation of a bony prominence or large hematoma or tenderness along the fracture line is possible by rectal examination (Earle's sign). Compress the pelvis lateral to medial through the iliac crests, anterior to posterior through the symphysis pubis, and anterior to posterior through the iliac crests. Compress the greater trochanters and determine the range of motion of the hips. On rectal examination, superior or posterior displacement of the prostate, or rectal injuries are indicative of intraperitoneal and urologic injury. Proctoscopic examination may be required to fully assess for the presence of rectal tears. [4] Decrease in anal sphincter tone may suggest neurologic injury and blood at the urethral meatus, urologic injury. Pelvic examination should be carefully performed in women to detect the presence of blood or lacerations suggesting the possibility of open fracture. Carefully evaluate neurovascular function. If a pelvic fracture is found, assume intra-abdominal, retroperitoneal, gynecologic, and urologic injuries until proved otherwise.

RADIOLOGIC EVALUATION   Stabilization of the patient takes priority over obtaining x-ray films. Unnecessary movement may produce further injury or cause more blood loss. After stabilization, roentgenographic evaluation of the pelvis is a must in all unconscious patients who have sustained multiple injuries. Lower extremity long bone fractures as well as pelvic symptoms or signs are also indications for roentgenograms. A standard anteroposterior (AP) view of the pelvis is indicated in the presence of multisystem blunt trauma or if pelvic fracture is suspected. If additional studies are needed, lateral views, AP views of either hemipelvis, internal and external oblique views of the hemipelvis, or inlet and outlet views of the pelvis may be done. An inlet view shows anterior-posterior displacement of ring fractures (Fig. 265-3 and Fig. 265-4). An outlet view shows superior-inferior displacement. Oblique views of the hemipelvis are true AP and lateral views of the acetabulum. Tomography, computed tomography (CT) scans, and special studies may be needed to fully evaluate and manage patients, particularly for acetabular and sacral fractures. CT is superior to plain radiography in assessing the posterior pelvic arch and acetabulum [5] and has the added advantage of being able to identify the presence or absence of ongoing pelvic hemorrhage. [6] Angiography or venography may be necessary to determine a source of bleeding. The patient's condition must dictate what is done and when.

FIG. 265-3. A. Anatomic appearance in the inlet projection. **B.** Radiologic appearance in the inlet projection. (From Tile M. Assessment. In: *Fractures of the Pelvis and Acetabulum.* Baltimore: Williams & Wilkins, 1984, p 63. Used with permission.)

Classification and Treatment of Pelvic Fractures

BREAK IN THE PELVIC RING   Pelvic fractures include those that involve a break in the pelvic ring, fractures of a single bone without a break in the pelvic ring, and acetabulor fractures. Pelvic fractures involving a break in the pelvic ring can be complex and therefore difficult to classify. These injuries range from low-energy stable fractures to high-energy unstable patterns. The most clinically useful classification by Young (Table 265-1), is presented. [7] It differentiates fracture patterns based on mechanism of injury and direction of causative force. Incidence of complications (i.e., urogenital and vascular) is correlated with the fracture pattern, making identification of the type more clinically significant and useful.

TABLE 265-1   Injury Classification Keys According to the Young System

Three main types of patterns have been identified. The first and most common mechanism, lateral compression (LC) (Fig. 265-5, Fig. 265-6, Fig. 265-7 , Fig. 265-8 and Fig. 265-9), accounts for close to half the injuries. Motor vehicle accidents in which a car is broadsided or a pedestrian struck from the side are examples. Anteroposterior compression (APC) (Fig. 265-10, Fig. 265-11, and Fig. 265-12) is the second type, accounting for about 25 percent of injuries. Head-on motor vehicle accidents are the classic example. The least common mechanism is vertical shear (VS) (Fig. 265-13) typified by a fall or jump from a height, accounting for about 5 percent of fractures. A combination (CM) of other injury patterns make up the other 20 to 25 percent of injuries.
FIG. 265-5. Type I—lateral compression fracture: The lateral force is applied posteriorly (*arrow*). This causes a crush effect on the SIJ: this may be visible radiographically as a sacral fracture (**A**). The characteristic fracture pattern of the pubic rami will be seen (**B**). No ligamentous injury is seen.
FIG. 265-6. Type II—lateral compression fracture: The force is applied anteriorly (*arrow*), causing the typical anterior public rami fractures (**B**). In this case, however, rotation of the pelvis around the anterior sacral margin may occur, causing rupture of the posterior sacroiliac ligaments (*R*). A crush fracture of the sacrum may also be seen (**A**).

FIG. 265-7. Alternatively (compared to Fig. 265-6), a fracture of the iliac wing may occur which dissipates the rotational forces and thus leaves the posterior ligaments intact.
FIG. 265-8. Type III—lateral compression fracture: The force is applied anteriorly (*arrow*), causing internal rotation of the anterior hemipelvis. Continuing through to the contralateral hemipelvis (*arrow*), the force causes it to rotate externally. The result is a pattern of lateral compression on the ipsilateral side, with apparent AP compression on the contralateral side. This results in rupture of the posterior sacroiliac ligaments on the ipsilateral side (*R*) and sacrospinous/sacrotuberous complex (*T*) and anterior ligaments (**A**) on the contralateral side. Typical public rami fractures (**B**) are to be expected.

FIG. 265-9. Alternatively (compared to Fig. 265-8), as in type II B fractures (Fig. 265-7) there may be an iliac wing fracture sparing the posterior SIJ on the ipsilateral

side.

FIG. 265-10. Type I—AP compression fracture: The force is delivered in an AP direction (*large arrow*), tending to "open" the pelvis. This gives rise to mild splaying of the symphysis, due to rupture of the anterior sacroiliac ligaments.

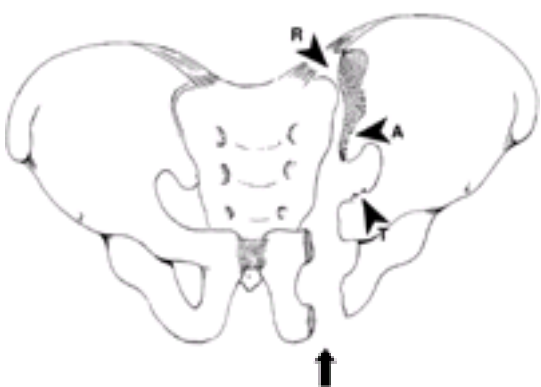
FIG. 265-11. Type II—AP compression fracture: The AP force vector (*large arrow*) has caused further "opening" of the anterior pelvis, with additional rupture of the anterior sacroiliac, sacrotuberous, and sacrospinous ligaments.
FIG. 265-12. Type III—AP compression fracture: There is total disruption of the SIJ due to wide "opening" of the pelvis. All supporting ligament groups, including the posterior sacroiliac ligaments, may be disrupted.


FIG. 265-13. Vertical shear vector: The injury force vector is delivered in a vertical plane (*large arrow*), causing disruption along this line. Fractures of the pubic rami are usually seen anteriorly, while fractures of the sacrum, SIJ, or iliac wing are usually seen posteriorly. The fractures are vertical and are associated with vertical displacement of fragments. Ligamentous injury to the posterior (*R*) and anterior (*A*) sacroiliac ligaments may be seen, as well to sacrospinous/sacrotuberous (*T*), and (possibly) symphysis ligaments.

The different injury types may be suggested by history, but can also be differentiated radiographically. The alignment of pubic rami fractures is one such clue to the mechanism and direction of force. Horizontal fractures suggest lateral compression injury, whereas vertical ones point to an anteroposterior direction of force. If there is sacroiliac joint diastasis and an associated crush fracture of the sacrum, then the injury is due to lateral compression. Central hip dislocations suggest a lateral compression mechanism whereas posterior dislocation suggests an anteroposterior force. With vertical shear patterns, fractures are vertical in alignment with vertical displacement of fragments. Based on the recognition of the fracture pattern, one can then predict the likelihood of severe hemorrhage or urogenital injury (Table 265-2).

TABLE 265-2 Local Associated Injuries

Mortality usually is due to associated injuries, although pelvic hemorrhage is also a contributor. Mortality rates approach 25 percent for severe APC and VS injuries, whereas it is about 13 percent with LC injuries.[8] Mortality has been shown to be reduced with early fracture fixation and patient mobilization.[9] In addition to mortality, the fracture type and severity can also predict the organ injury pattern and resuscitation needs. The treatment of LC-I and APC-I injuries consists of a few days of bedrest followed by protected weight-bearing. The treatment of LC-II injuries generally requires three to six weeks of bedrest followed by progressive weight-bearing or open reduction and internal fixation. LC-III, APC II and III, and VS injuries typically require open reduction and internal fixation within 5 to 14 days of injury.[10] The long-term outcome/disability following open reduction and internal fixation of unstable pelvic fractures is generally fair with three-quarters having some mild disability and about 75 percent of those employed preinjury returning to their preinjury occupations.[11]

True open-book type fractures with an intact posterior ring have the greatest potential benefit from anterior external fixator placement. Stabilization decreases the volume of the pelvis with resultant tamponade of hemorrhage.[5] The tamponade effect is less if the posterior arch of the pelvis has been disrupted. Anterior stabilization should be considered in hemodynamically unstable patients with unstable pelvic fractures.[12] Fracture patterns potentially amenable to external fixator placement include LC-III, APC II or III, and VS fractures. There is evidence that external fixation improves clinical outcome, but there is no prospective randomized trial to prove that acute external fixation decreases morbidity and mortality in those patients.[13] The risk of fixator placement is higher in obese patients due to the development of skin breakdown and infection.

AVULSION AND SINGLE BONE FRACTURES   **Anterior Superior Iliac Spine (Fig. 265-14)** This fracture typically occurs in adolescents because of forceful contraction of the sartorius muscle. Symptoms and signs are local pain, tenderness, and swelling and pain with flexion or abduction of the thigh. There is minimal displacement of the anterior superior iliac spine visible on the AP film of the pelvis.
FIG. 265-14. Pelvic fractures (type I, II, and III) according to classification by Key JA, Conwell HE: *The Management of Fractures, Dislocations, and Sprains,* 4th ed. St. Louis, Mosby, 1946, p 857, as adapted by Kane WJ: Fractures of the pelvis, in Rockwood CA Jr, Green DP (eds): *Fractures,* 4th ed. Philadelphia, JB Lippincott, 1996. vol. 2, pp 1119–1142.

Anterior Inferior Iliac Spine   This fracture occurs because of forceful contraction of the rectus femoris muscle. Symptoms and signs are sharp pain in the groin, difficulty with ambulation, and inability to flex the hip. The AP film shows downward displacement of the fragment, but this must be differentiated from the epiphyseal line of the os acetabuli.

Ischial Tuberosity   This fracture results from forceful contraction of the hamstrings (such as with kicking), and the fracture is seen in youths whose apophyses are not united. Symptoms and signs include acute or chronic pain with sitting or on flexing the thigh with the knee extended. Rectal examination reveals tuberosity tenderness. The roentgenogram shows detachment of the apophysis from the ischium with minimal displacement. The apophysis closes between ages 20 and 25 years.

Treatment of avulsion fractures is conservative including the use of nonsteroidal antiinflammatory drugs (NSAIDs), rest in a position of comfort, and the use of crutches with partial weight bearing initially followed by full weight bearing.[11] Follow-up with the patient's primary care physician or orthopedist within 1 to 2 weeks is recommended. Patients generally resume normal activities within 3 to 4 weeks of those injuries.

Single Ramus of Pubis or Ischium (Fig. 265-14)   These injuries are commonly seen in the elderly, and the mechanism of injury is usually a fall with direct trauma.[10] Symptoms and signs include local pain and tenderness and inability to ambulate. Examination of the pubic bones will usually distinguish a fracture of the pubis from a femoral neck fracture. The AP roentgenogram of the pelvis typically shows a nondisplaced fracture of the ramus. Treatment is symptomatic including the use of NSAIDs or opioid analgesics and crutches as needed. Orthopedic or primary care follow-up within one to two weeks is recommended.

Ischium Body Fractures   The incidence of ischial body injury is very low. The mechanism of injury is violent, external trauma, such as a fall in a sitting position. Symptoms and signs include local pain and tenderness, and pain with hamstring movement. The x-ray film shows fracture of the body or tuberosity of the ischium. A large fragment with comminution or a butterfly pattern may be seen on the AP film of the pelvis. Treatment consists of rest, analgesics, the use of a donut-ring cushion for sitting and crutches as needed. Outpatient primary care or orthopedic follow-up within one to two weeks is recommended.

Iliac Wing (Duverney) Fractures (Fig. 265-14)   The mechanism of injury in an iliac wing fracture is direct trauma, usually lateral to medial.[10] Symptoms and signs include pain, swelling, and tenderness over the iliac wing. There is severe pain on ambulation, and Trendelenburg's sign (waddling gait) is present. Although accompanying abdominal injuries are infrequent, abdominal rigidity, lower quadrant tenderness, and ileus are common findings. The AP film of the pelvis typically shows minimal displacement of fragments. Treatment is conservative[5] including analgesics and outpatient primary care or orthopedic follow-up. Hospital admission is not necessary unless the fracture is open or there is significant abdominal muscle spasm associated with the fracture making abdominal exam difficult.

Sacral Fractures   These fractures account for approximately 4 to 5 percent of all pelvic fractures. Transverse fractures of the sacrum (Fig. 265-14) are more common with massive pelvic injuries. The mechanism of injury of lower transverse sacral fractures is direct trauma by a posterior-to-anterior force. Upper transverse fractures are typically the result of a flexion injury such as associated with a fall from a height or being struck in the lower back with a heavy load. A rectal examination with the other hand on the sacrum causes pain and movement at the fracture site. Roentgenogram interpretation may be difficult, and exactly aligned AP views are necessary to show the fracture. Look for a transverse fracture line at the level of the lower SI joint, and irregularity, buckling, or sharp angulation of the foramina. Examine the body and wings closely. A lateral view may show displacement anteriorly. Neurologic injury does not occur with fractures below the S4 level. Sacral root injury may be present in up to one-third of patients with upper transverse fractures.[15,16] Treatment of simple transverse fractures without neurologic deficit consist of bedrest,

analgesics, and orthopedic follow-up. Early orthopedic consultation and surgery is generally indicated for fractures associated with neurologic disability. Lengthy disability may occur with these latter injuries.

Coccyx Fractures   Coccygeal fractures are more frequent in women and are generally caused by direct violence or a fall in the sitting position. Symptoms and signs include pain, tenderness, and swelling and ecchymoses over the lower sacral region. There may be pain on getting up from a sitting position or straining at stool. The rectal examination reveals pain with movement of the coccyx. A roentgenogram is not needed if physical examination verifies that this is the only fracture, but AP and lateral views with sharp flexion of the thighs may demonstrate the fracture. Treatment consists of bedrest, sitz baths, stool softeners, and sitting on a donut-ring cushion. Primary care or orthopedic follow-up within 2–3 weeks is recommended. Surgical excision of the distal fracture fragment is rarely indicated if symptoms become chronic.

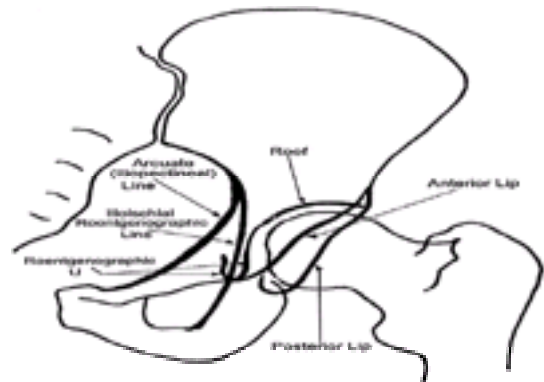
ACETABULAR FRACTURES   Acetabular fractures account for 20 percent of pelvic fractures and are usually secondary to automobile accidents. [17] The fracture force is either transmitted laterally through the hip or through the femur as with a knee-versus-dashboard mechanism. Acetabular fractures are seen commonly with other injuries including femur, hip fractures and dislocations, and knee injuries. The roentgenographic anatomy of acetabular fractures is shown in   Fig. 265-15. There are four anatomic types of fractures, and all are associated with hip dislocations: posterior, ilioischial column, transverse, and iliopubic column. In addition, combinations of any of these fractures can occur.


FIG. 265-15. Roentgenographic anatomy of type IV acetabular fractures. (*From* Judet R, Judet J, Letournel E: Fractures of the acetabulum: Classification and surgical approaches for open reduction. *J Bone Joint Surg* 46A:1616, 1964. Used with permission.)

Posterior Fracture   The mechanism of injury in a posterior fracture is direct trauma to a flexed knee and hip. Anteroposterior and lateral radiologic views easily demonstrate the posterior acetabular fracture with the posterior hip dislocation. Complications are sciatic nerve injury, which may occur in up to 40 percent of this fracture type, and femoral fractures.

Ilioischial Column Fracture   The mechanism of injury is posteriorly directed force to a knee with the thigh abducted and flexed. The AP x-ray film demonstrates a large, medially displaced fragment with central dislocation of the femoral head. The most common complication is sciatic nerve injury.

Transverse Fracture of Acetabulum   The mechanism is force lateral to medial over the greater trochanter, or force posterior to anterior on the posterior pelvis with the hip flexed. An AP x-ray film clearly demonstrates the fracture with a central hip dislocation.

Iliopubic Column Fracture   The mechanism of injury is a lateral force to the greater trochanter with the hip externally rotated. On roentgenography, there is marked external rotation of the hip. The ilioischial line is disrupted, and the anterior lip is fractured. Further discussion on acetabular fractures appears below under "Trauma to the Hip and Femur."

Early orthopedic consultation and hospital admission is indicated for patients with acetabular fractures. Nondisplaced fractures may be treated with bedrest and analgesics. Early reduction and internal fixation is indicated for displaced fractures. Significant long-term disability is associated with acetabular fractures.

Complications of Pelvic Fractures

It is imperative to recognize associated injuries. Acute complications include hemorrhage, urogynecologic injury, rectal injury, ruptured diaphragm, and nerve root injury.

HEMORRHAGE   Hemorrhage is estimated to be the cause of death in about 50 percent of total pelvic injuries. [18] Retroperitoneal bleeding is an inevitable complication, and up to 4 L of blood can be accommodated in this space until vascular pressure is overcome and tamponade occurs. It is thought that approximately 90 percent of pelvic bleeding is from the fractures and low pressure venous plexus. Both small and large vessels, especially the superior gluteal and internal pudendal branches of the internal iliac artery, can also be disrupted, with hemorrhage dissecting from the back to the buttocks.

General resuscitative measures include massive crystalloid, colloid, and blood replacement. In one series of high-energy pelvic fractures, patients on average required about six units of blood transfused. [19] The average transfusion requirement for APC injuries was about 15 units, VS injuries 9 units, and LC injuries about 3.5 units. Aggressive resuscitation of these patients along with treatment of extrapelvic injuries and early or delayed open reduction and internal fixation of the fractures may reduce mortality. [20]

The use of the antishock garment is controversial. It may be helpful in controlling bleeding sites by immobilizing fractures and compressing the pelvis. Disadvantages include decreased visibility and access to the abdomen and lower extremities and the risk of compartment syndrome with prolonged application. This garment is generally only recommended for pelvic stabilization in the pre-hospital and ED setting. Early orthopedic consultation should be considered for placement of external fixator device to help control hemorrhage in patients with persistent hemodynamic instability.

If the patient is exsanguinating, angiography can be done and small arterial bleeding sites controlled by transarterial embolization. Most authorities agree that aggressive fluid and blood replacement is the best initial therapy along with correction of hypothermia and coagulopathy. Placement of an external fixator and laparotomy should also be considered prior to angiography. [21] Overall, only about two percent of patients with pelvic fracture require embolization and efficacy approaches 100 percent when utilized. [22] Younger age, shorter time from injury to embolization, and hemodynamic stability are associated with improved survival.

UROGYNECOLOGIC INJURY   Urinary tract injuries are discussed in Chap. 254. Gynecologic injuries are uncommonly associated with pelvic trauma. Vaginal laceration is the most common injury seen with anterior pelvic fractures. A bimanual pelvic examination should be performed on all women with pelvic fractures. If blood is found in a woman of childbearing age, a speculum examination must be carried out to distinguish menses from laceration. Treatment is irrigation and debridement in the operating room with repair of wounds and antibiotic therapy.

A high fetal death rate is associated with pelvic trauma in pregnancy if the mother is in shock; if there is placental, uterine, or direct fetal injury; or if the mother dies. Immediate caesarean section must be considered (see Chap. 246, "Trauma in Pregnancy").

RECTAL INJURIES   Rectal injuries are uncommon and are usually associated with urinary injuries and ischial fractures. Diagnosis is by rectal examination or by protoscopy, whereupon blood is found in the rectum. Treatment includes a diverting colostomy with washout of the distal colon, and presacral space drainage. Antibiotics should be given as soon as the injury is discovered.

RUPTURED DIAPHRAGM   Ruptured diaphragm associated with fracture of the pelvis may be more common than previously thought. It may be associated with rib injuries. Suspect the diagnosis with physical findings such as displacement of the heart toward the right, absent breath sounds, or presence of bowel sounds in the

chest. Confirmation is by x-ray and CT scan. Diagnosis is difficult if the defect is small.

NERVE ROOT INJURY   Nerve root or peripheral nerve injuries can occur because of traction, pressure from hemorrhage, callus or fibrous tissue, and impingement-laceration by bone fragments. The onset of symptoms and signs may be delayed, but deficits usually follow a nerve root pattern. Lumbar nerve root injuries are associated with SI joint dislocation or fracture. Sacral root injuries are associated with sacral fractures, especially fractures of S1 and S2.

Pelvic Fractures in Children

Commonly caused by automobile-pedestrian accidents, pelvic fractures in children have a high incidence of concomitant injuries because of the smaller protection afforded by the developing pelvis and the significant trauma incurred. [14] Hemorrhage determines mortality. Children in shock who respond poorly to fluid replacement have the highest mortality. Frequent concomitant injuries include head and neck injuries, intra-abdominal injuries, and long bone fractures. The incidence of genitourinary injuries is similar to that of adults. Major thoracic injuries are rare but particularly dangerous because they are often overlooked.

Postponement of surgery until stabilization of circulation is recommended unless the patient is exsanguinating despite treatment. If the child does not respond to transfusions equal to the estimated total blood volume (TBV) (88 mL/kg × wt [kg] = TBV) within 1 h, suspect major vascular injury and operate. Both arterial and venous injuries are associated with significant SI joint injury.

Except for pelvic avulsion fractures, early orthopedic consultation and hospitalization is indicated. Surgical treatment for pelvic fractures is indicated less frequently in children than in adolescents or adults because of children's ability to remodel pelvic fractures and because early ambulation is not critical. [14] Nondisplaced fractures can generally be treated with bedrest alone. Displaced fractures can be treated with distal femoral skeletal traction on the displaced side of the hemipelvis. Severely malaligned Malgaigne fractures may occasionally require open reduction and internal fixation.

TRAUMA TO THE HIP AND FEMUR

Anatomy

The hip is a ball-and-socket joint made up of the acetabulum and the femur. The hip includes the acetabulum and the proximal femur two to three inches below the lesser trochanter. The functions of the hip are weight-bearing and movement. The fibrous capsule that surrounds the joint on all sides is exceedingly strong. It attaches around the acetabulum proximally and runs to the intertrochanteric line distally on the anterior surface. Posteriorly, it falls short of the intertrochanteric crest and inserts on the neck of the femur. It is weakest posteriorly.

The blood supply of the femoral head is derived from nutrient branches of the obturator, medial femoral circumflex, lateral femoral circumflex, and superior and inferior gluteal arteries. These course beneath the reflection of the capsule on the neck of the femur and also along the ligamentum teres. The capsular vessels are much more important than those of the ligamentum teres.

Clinical Evaluation

PHYSICAL EXAMINATION   The examination of the hip begins with a detailed history and complete examination of the patient. The pelvis and hip are then carefully evaluated. The unclothed, erect patient is inspected for a list, injuries, scars, or asymmetry of the muscles. Gait should be tested, if possible.

If the patient is a trauma victim, after primary survey and initial stabilization observe the position of the extremities, looking for deformities, shortening, rotation, lacerations, or bruises, and test for stability and range of motion. On palpation, feel for irregularities in movement at the iliac crest, pubic rami, and ischial rami. Compress the pelvis lateral to medial through the iliac crest; anterior to posterior through the symphysis pubis; and anterior to posterior through the iliac crest, seeking pain and tenderness. Also, compress the greater trochanters of the hips.

If no significant abnormalities are found, range of motion of the hips should then be studied. If rotation of the hip with the leg in extension is painful all other maneuvers should be done cautiously. If a hip or pelvic fracture or dislocation is identified in a trauma victim, *assume* that intra-abdominal, retroperitoneal, and urologic injuries have occurred as well, until it has been proved otherwise. Always perform a detailed neurovascular examination and a rectal examination, looking for displacement of the prostate in male patients. Associated femoral shaft fractures should be ruled out.

RADIOLOGIC EVALUATION   Roentgenographic evaluation of the pelvis and hips is a must in all unconscious patients who have sustained multiple injuries. The threshold for obtaining radiographs in demented elderly patients who have sustained minor falls should also be relatively low because those patients may be particularly difficult to evaluate. [23] Lower extremity long bone fractures, as well as pelvic symptoms or signs, are also indications for these x-ray examinations. The x-ray evaluation should include a standard AP and a lateral view of the pelvis. If further studies are needed, AP views of either hemipelvis, internal and external oblique views of the hemipelvis as described by Judet and colleagues, or "inlet" and "tilt" views may be done. In certain instances, such views allow better identification and detail of the acetabulum and femoral head and neck. Always inspect not only the hip joint but also the femur and knee when evaluating hip disorders on x-ray films. Disorders to the knee and the femoral shaft often occur with hip injuries. Significant hip pain with weight-bearing following trauma and normal radiographs suggest the possibility of occult fracture, especially at the femoral neck or acetabulum. [24] The patient should be prescribed protected weight-bearing and the emergency physician should communicate with the patient's primary care provider or orthopedist regarding close follow-up for possible CT or MR hip imaging to rule out occult fracture. [25,26] MR is reliable in detecting occult fractures within 24 h of injury.

Classification/Epidemiology of Hip Fractures

The estimated incidence of hip fractures in the United States is about 80 per 100,000 population. [27] The incidence increases with age and doubles for each decade past the age of 50. The incidence is about two to three times higher in women than men and fractures are more common in white than nonwhite women.

The possibility of elder abuse should be considered in all elderly patients with falls and fractures. Evidence of physical abuse such as bruises and burns, especially if they are unexplained, and of various ages and certain patterns should raise the physician's clinical suspicion of abuse. Patterns or well-defined shapes, such as an emersion pattern or rope or restraint marks on the wrists or ankles, should also raise suspicion. Signs of neglect, such as dehydration, malnutrition, poor hygiene, extensive bed sores, urine burns or excoriations, and fecal impactions, should also increase suspicion for elder neglect. Interactions between family or caregivers and the patient should be observed and Social Services should be consulted and abuse reported as required by law when appropriate. [28]

Hip fractures are classified as femoral head and neck (intracapsular) and trochanteric, intertrochanteric, and subtrochanteric (extracapsular) (Fig. 265-16). The prognosis for successful union and restoration of normal function varies considerably with the fracture.

FIG. 265-16. Fractures of the proximal femur are traditionally classified as intracapsular and extracapsular. (From Greenspan A. *Orthopedic Radiology.* Philadelphia: JB Lippincott, 1988, p 5.17. Used with permission.)

In intracapsular fractures with displacement, the femoral neck vessels are compromised due to a tear or compression secondary to an intracapsular hemarthrosis. The blood supply through the ligamentum teres may not be sufficient to nourish the entire femoral head. Therefore, avascular necrosis inevitably results (15 to 35 percent overall) unless some of the capsular vessels remain intact. Basilar neck and intertrochanteric fractures below the capsule rarely sever important arteries. Morbidity and mortality associated with hip fractures is primarily due to patient immobilization and the development of deep venous thrombosis and pulmonary embolus. Even with modern treatment modalities, mortality following hip fracture ranges from 15 to 35 percent within one year of surgery and 25 to 50 percent of the survivors will not regain their ability to ambulate.[29] Factors predictive of increased mortality include male sex, increased age, dementia, institutionalization, poorly controlled systemic disease, and the development of postoperative complications. There is some evidence that early (<72 h) hip fracture fixation of low impact hip fractures in the elderly reduces morbidity and mortality.[30],[31] and [32]

FEMORAL HEAD FRACTURES   Isolated femoral head fractures occur infrequently. They are usually associated with dislocations of the hip. Shear fractures of the superior aspect of the femoral head are associated with anterior dislocations, and shear fractures of the inferior femoral head are associated with posterior dislocations.

In most instances, the symptoms and signs are those of the associated dislocation rather than of the fracture itself. The standard AP and lateral x-ray views usually demonstrate the fragment adequately. When there is an associated dislocation, the postreduction films offer a better view of the fracture fragment.

Orthopedic consultation should be obtained in the ED for these fractures. Treatment is to reduce the associated dislocation and then attain anatomic reduction of the fracture fragment. Complications are associated with the high-energy trauma that produces the fracture-dislocation, that is, the more comminuted the fracture, the more severe the dislocation and the greater the severity of trauma to the patient. Life-threatening injuries must then be ruled out.

The prognosis is related to the severity of the initial trauma resulting in the dislocation. Poor prognostic indicators include delay between hip dislocation and reduction, repetitive unsuccessful relocation attempts and associated injuries. Posttraumatic arthritis occurs in one-third to two-thirds of patients, avascular necrosis in 10 to 20 percent and myositis ossificans in approximately 1 to 2 percent.[33]

FEMORAL NECK FRACTURES   Femoral neck fractures are commonly seen among older adults, due to osteoporosis, and occur more frequently in women than in men. These fractures are rare among the younger population. The cause of such fractures is usually minor trauma secondary to falls (90 percent) or torsion in the patient with osteoporosis or osteomalacia. In younger patients, the high kinetic energy sustained in the major trauma causes a fracture through normal bone with marked soft tissue disruption and comminution.

The classification of femoral neck fractures is by fragment displacement. The symptoms seen with femoral neck fractures range from complaints of mild pain in the groin or inner thigh in patients with an incomplete fracture to moderate to severe pain in patients with displaced fractures.

Patients who have sustained a fracture without displacement may walk with some limping rather than being completely unable to bear weight. Their only physical findings are minor pain with movement and minimal muscle spasm limiting range of motion. In contrast, displaced fractures cause severe pain, inability to ambulate, limited range of motion, and no palpable movement of the extracapsular head. The patient lies with the extremity in *slight* external rotation, abduction, and shortening.

Radiographic evaluation is essential in any patient suspected of having a femoral neck fracture. Stress fractures, however, may not show up on x-ray for days or weeks, so repeat films or bone scans in symptomatic patients are necessary. The standard AP view should have the patient maximally internally rotated to best demonstrate the femoral neck. The AP view should be inspected for a fracture line starting on the superior surface of the neck. These fracture lines routinely become complete within 10 to 14 days. Also, disruption of Shenton's line may be appreciated on the AP view in some instances. If there is any concern that the patient has sustained a fracture that is not visible on the initial x-ray examination, the patient should be conservatively treated and x-ray films should be made again in 10 to 14 days; or the physician may order a CT or MRI, which demonstrates the fracture in most instances. In contrast, displaced fractures are obvious on the AP film, but a lateral view should also be done to ascertain the exact position.

Orthopedic consultation should be obtained in the emergency department for these fractures. The orthopedic surgeon's goal of treatment for femoral neck fractures is anatomic reduction and stability. Treatment for nondisplaced or impacted fractures is somewhat controversial but usually involves a form of internal fixation. This is due in part because up to 15 percent of impacted fractures can develop secondary displacement without surgery. Conservative treatment is generally only considered if the patient is medically unfit for surgery or the fracture is several weeks old and the patient is walking without pain. [22] Displaced fractures definitely require emergency surgery for fixation. Prosthetic hip replacements may be required in certain instances, particularly in those patients over age 70. [27] The timing of surgery remains controversial. Early surgery (<72 h) is indicated in fit patients, whereas surgery should be delayed if correctable comorbidities are present. Special note should be made of stress fractures because some are treated in a conservative manner and others are treated with internal fixation, depending on the type of fracture and the patient's cooperation. Skeletal traction is contraindicated with femoral neck fractures because it may further compromise femoral head blood flow.

The complications of femoral neck fractures are significant. They include infections, emboli, and avascular necrosis, which is the most feared early complication. Avascular necrosis has an incidence of 15 percent in nondisplaced fractures and rises to near 90 percent with untreated, completely displaced fractures. A higher incidence is also associated with more severe fractures or fractures that are not surgically reduced to anatomic position within 48 h. Nonunion in nondisplaced fractures is rare but occurs in approximately 20 to 30 percent of patients with displaced fractures. [22]

TROCHANTERIC FRACTURES   Greater trochanteric fractures are usually due to avulsions at the insertion of the gluteus medius. In the younger population (7 to 17 years of age), this is a true epiphyseal separation, in contrast to the adult population, in which this is due to direct trauma. [22] The patient presents with pain, especially with abduction and extension, and a limp. Also, there is tenderness to palpation over the greater trochanter.

Standard AP and lateral x-ray views reveal displacement in the superior-posterior area, or comminution. The treatment is generally conservative with protected weight-bearing recommended until the patient is asymptomatic. Outpatient orthopedic referral is indicated. Orthopedic consultation for possible surgical fixation may be indicated for fracture displacement of greater than 1 cm.[22]

Lesser trochanteric fractures due to an avulsion secondary to a forceful contraction of the iliopsoas are commonly seen in children and young athletic adults, particularly gymnasts and dancers. These patients present with pain during flexion and internal rotation maneuvers. In most instances, the treatment is bedrest and then gradual weight-bearing to regain full activity. Outpatient followup by primary care or orthopedics is advised. Full recovery generally occurs within three weeks.

If greater than 2-cm displacement is seen on the standard AP and lateral views, then screw fixation by the consulting orthopedic surgeon may be indicated.

INTERTROCHANTERIC FRACTURES   These fractures are defined as extracapsular fractures occurring in a line between the greater and lesser trochanters. Intertrochanteric fractures generally occur in the elderly and are more common in women, again due to the high incidence of osteoporosis. The mechanism of injury is usually a fall or occasionally an automobile accident. It is postulated that a rotational component along with the direct trauma is involved in some instances as well.

Symptoms and signs include pain, swelling of the hip, local ecchymosis, and pain with any hip movement or weight-bearing. Moreover, the extremity is markedly externally rotated and shortened, in contrast to the minimal deformities associated with femoral neck fractures. These fractures are classified as stable or unstable. Stable fractures are defined as ones in which the medial cortices of the neck and femoral fragments abut. X-ray evaluation should include AP and lateral views, with the AP view having as much internal rotation as possible to adequately visualize the neck.

Severe life-threatening injuries must be excluded. The consulting orthopedic physician can then admit the patient to the hospital and perform surgical fixation to attain a stable reduction as soon as possible, although this is not an emergency. Buck's traction (Fig. 265-17) may temporarily help reduce pain.
FIG. 265-17. Buck's traction.

The complications and prognosis are related to other associated injuries and prior disease. The overall mortality is approximately 10 to 30 percent. Infection can be a major problem, with an incidence of up to 17 percent.[34] Thromboembolic disease is especially a problem if postoperative mobilization does not occur quickly. Avascular necrosis is rare in these patients, and nonunion is also uncommon. Morbidity is due to the patient's inability to return to prefracture activity.

SUBTROCHANTERIC FRACTURES   Subtrochanteric fractures may be seen in two different populations. They usually occur secondary to falling in the 40- to 60-year-old patient with osteoporotic or weakened bone. The second population is young persons who have suffered major trauma with significant kinetic energies directed into the femur. These fractures may be an extension of an intertrochanteric or other isolated fracture and are usually classified as stable or unstable, with stable defined as bony contact of the medial and posterior femoral cortices.

The symptoms and signs are similar to those of trochanteric or femoral fractures, with local pain, deformity, swelling, crepitance, etc. These patients can lose a large amount of blood into the thigh area and may present in hypovolemic shock. Because this injury is due to significant trauma, other, more life-threatening injuries must be excluded prior to treatment of this specific fracture.

Standard AP and lateral x-ray views of the hip are necessary to properly assess the fracture. Moreover, x-ray studies of the pelvis, femur, and knee are indicated to rule out associated fractures.

Treatment consists of immobilization with a traction apparatus. Hare (Dyna-Med, Carlsbad, CA) or Sager (Minto Research & Development, Redding, CA) splints (Fig. 265-18 and Fig. 265-19) may be employed in the prehospital setting. Proper evaluation of the entire patient to rule out associated severe injuries should be conducted. After the patient has stabilized and secondary evaluation has occurred, orthopedics should be consulted. Open reduction and internal fixation is generally indicated for fracture management.[34]

FIG. 265-18. Hare traction splint.
FIG. 265-19. Sager traction splint.

The complications are similar to those of intertrochanteric fractures, except that there is a higher incidence of nonunion. Malunion and delayed union occur as well in this population. Prognosis is better for proximal fractures that are not comminuted.

Hip Dislocations

Hip dislocations can be classified as anterior, posterior, and central. Acetabular fracture with central hip dislocation has been discussed under acetabular fractures.

ANTERIOR DISLOCATIONS   About 10 percent of hip dislocations are anterior (Fig. 265-20*A* and Fig. 265-20*B*), and the majority are secondary to automobile accidents, but they may also result from a fall, or a blow to the back while squatting. In anterior dislocations, the femoral head rests anterior to the coronal plane of the acetabulum. Anterior dislocations can be superior or inferior (obturator, thyroid, perineal) depending on the degree of hip flexion present at the time of injury. If the hip is abducted, externally rotated, and flexed at the time of injury, inferior dislocation occurs. If the hip is abducted, externally rotated, and extended, superior dislocation occurs. The mechanism of injury is forced abduction that causes the femoral head to be levered out through an anterior capsular tear. The affected extremity is in abduction and external rotation. However, the clinical appearance of superior versus inferior dislocations is dramatically different (Fig. 265-20*C* and Fig. 265-20*D*). Neurovascular compromise is an unusual, but possible complication.

FIG. 265-20. A. Anterior superior dislocation of the hip. **B.** Inferior dislocations (obturator, thyroid, or perineal). **C.** Clinical appearance of a superior-type anterior dislocation of the hip. **D.** Clinical appearance of an inferior-type dislocation of the hip. (From Rockwood CA Jr, Green DP, Bucholz RW (eds). *Fractures in Adults,* 3rd ed, vol. 2. Philadelphia: JB Lippincott, 1991, pp 1576, 1578, 1587, 1588. Used with permission).

An AP film of the pelvis easily demonstrates the femoral head to be anterior to the acetabulum. A lateral view illustrates the anterior dislocation more clearly, although it may be difficult to obtain because of the patient's pain.

Treatment for the dislocation is early closed reduction, usually under conscious sedation. Strong, in-line traction is done with simultaneous flexion and internal rotation. Finally, the hip is abducted once the head clears the rim of the acetabulum. The dislocation should be reduced quickly, within a few hours, because the longer the delay in reduction, the higher the incidence of avascular necrosis. Postreduction radiographs should be specifically examined for acetabular or femoral head fractures and the possibility of small fragments in the joint not appreciated on the initial films.

POSTERIOR DISLOCATIONS   Posterior dislocations (Fig. 265-21 *A*) constitute 80 to 90 percent of hip dislocations. They are caused by force applied to a flexed knee, directed posteriorly. Acetabular fractures may result as well. On examination, the extremity is found to be shortened, internally rotated, and adducted (Fig. 265-21 *B*). Concomitant life-threatening injuries must be ruled out.

FIG. 265-21. A. Posterior dislocation of the hip. **B.** The clinical appearance of a posterior dislocation of the right hip. (From Rockwood CA Jr, Green DP, Bucholz RW (eds). *Fractures in Adults,* 3rd ed, vol. 2. Philadelphia: JB Lippincott, 1991, pp 1580, 1591. Used with permission.)

Anteroposterior and lateral x-ray films of the pelvis and hip will reveal the dislocation, but further assessment of the acetabulum and femur must be done to rule out fractures. The oblique views of Judet and colleagues will reveal an acetabular fracture. Also, inferior femoral head fracture will be seen on the AP or oblique view. Hip dislocations are difficult to recognize if there is an associated femoral shaft fracture, so roentgenograms of the pelvis and hips should be routinely obtained in such cases.

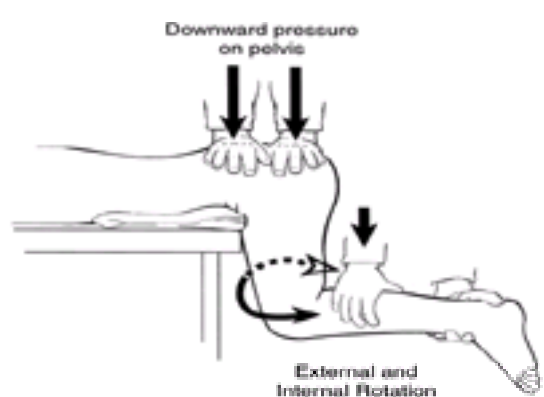
The treatment of posterior dislocation without fracture is closed reduction under conscious sedation or general anesthesia, as quickly as possible and always within six hours. In-line traction, gentle flexion to 90°, and then gentle internal-to-external rotation is done (Allis maneuver, Fig. 265-22). The Stimson maneuver (Fig. 265-23) may prove useful in certain situations.
FIG. 265-22. A and **B.** Allis maneuver.


FIG. 265-23. Stimson maneuver.

Complications include sciatic nerve injury in about 10 percent of the patients and avascular necrosis that increases in direct proportion to the delay in adequate

reduction.

Hip Injuries in Children

FRACTURES AND DISLOCATIONS   Fractures of the proximal end of the femur are extremely rare in children and are usually due to severe trauma. Trauma may produce a displaced epiphysis or a fracture of the neck, trochanteric, or subtrochanteric region. Traumatic epiphyseal separation is probably less common than the previously mentioned fractures, but is more common than dislocation. The treatment of displaced fractures is anatomic reduction, followed by internal fixation surgically. Nondisplaced fractures of the intertrochanteric and subtrochanteric regions may be treated with skin or skeletal traction followed by abduction spica casting.[35] There is a significant complication rate, especially avascular necrosis with transepiphyseal and transcervical (femoral neck) fractures.

Traumatic dislocations in children are rare, but are more common than hip fractures. They are more common in boys and more common between ages 2 and 5, and 11 and 15. The frequency of left versus right is equal, and bilateral dislocations are reportable. Posterior dislocations occur with an 80 to 85 percent frequency. The mechanism of injury and the clinical picture are similar to those seen in traumatic dislocation in the adult. The presence of an associated fracture is rare.

The treatment is closed reduction. Dislocation is an orthopedic emergency, and reductions should be done within six hours. Delay in reduction past 24 h is associated with a much higher incidence of complications.

Bursitis

Approximately 18 bursae surround the hip joint. These are derived developmentally from and are physiologically similar to synovium and tendon sheaths. As a result, they suffer from the same inflammatory afflictions which cause problems to the joint itself. Conditions that affect the bursae include traumatic inflammation, which is usually secondary to overuse or excessive pressure; infections; metabolic disorders such as gout; and benign and malignant growths.

Treatment consists of rest, ice, anti-inflammatory medications orally and, occasionally, intrabursal injections. Ultrasound physical therapy may help as well. The prognosis is good as long as associated problems such as infection and low-back disk disease are ruled out. Mechanical problems, especially leg length discrepancies, must be sought and, if found, properly treated so that further trochanteric bursitis does not occur.

Femoral Shaft Fractures

Fractures of the shaft of the femur most often occur in men during their most active period in life. Falls, industrial and automobile accidents, and gunshot wounds account for the majority of these fractures.[36] Severe, direct trauma may result in transverse fractures (most common) with displacement, oblique or spiral oblique fractures, or badly comminuted segments. Pathologic fractures are uncommon but can occur secondary to metastases (breast, lung, or prostate most common) or rarely secondary to primary bone tumors such as osteogenic sarcoma.

Spiral midshaft femur fractures can occur in toddlers who are running and trip with a twisting motion.[37] Midshaft femur fractures in children are often the result of neglect or abuse; however, up to 80 percent of fractures during the first year of life are possibly due to abuse.[38] The suspicion of abuse should be greater if the fracture occurs in an infant, child with preexisting brain damage, child with bilateral femur fractures, subtrochanteric femur fractures, or fractures occurring in children with other concomitant trauma. Distal metaphyseal chip fractures and delays in the family seeking medical care for the child should also raise the clinical suspicion for abuse. A femoral fracture in a young child with no history suggestive of abuse or significant trauma should suggest the possibility of osteogenesis imperfecta.

The femur is surrounded by large muscle groups with a rich vascular supply. Therefore, femoral fractures may result in a loss of 1 L or more of blood into the soft tissue of the thigh, producing clinical shock. The initial evaluation should always include careful neurovascular examination of the extremity. Vascular occlusion or disruption can occur, but nerve damage is rare.

Femoral shaft fractures are generally evident in the field to prehospital personnel because of the shortening, deformity and associated swelling. Initially, basic stabilization of the patient should take place in the field, along with spinal assessment and immobilization. External hemorrhage should be controlled by direct pressure, open wounds covered with a sterile dressing and then neurovascular examination of the extremities performed. It is best to splint the affected extremity with a traction splint at the time of injury. Hare (Dyna-Med, Carlsbad, CA) or Sager (Minto Research & Development, Redding, CA) traction splints can be placed over the trousers, applying traction to a sling around the ankle and forefoot. Traction splints are relatively contraindicated in cases of open fracture with grossly contaminated exposed bone ends or when sciatic nerve injury is probable because traction can exacerbate nerve injury. For the latter, splint placement without application of traction is indicated.

Emergency Department management includes basic stabilization of the patient followed by careful neurovascular examination of the affected extremity. Open fractures require broad spectrum antibiotics, debridement, and copious irrigation, generally in the operating room. Radiographs of the femur are generally lower priority in the acute resuscitation phase and parenteral analgesics are generally required if there is no contraindication to their use. Orthopedic consultation should be obtained early and most patients require hospitalization and surgical intervention.

Definitive management options include traction, external fixation, pins and plaster, and internal fixation. In infants and in children up to 2 years of age or 30 pounds, fractures of the shaft of the femur are treated by direct overhead traction applied to both legs (Bryant's traction) followed by spica casting. Spica casting is also used for children up to age six. In an older child or young adult, the Fisk-type of traction by means of a half-Thomas ring and Pearson attachment, to allow flexion of the knee, is satisfactory for unstable fractures followed by spica casting or cast bracing. External fixation and flexible intramedullary rod fixation are being employed more frequently in this age group.[35] The intermedullary interlocking nailing is the method of choice for the treatment of uncomplicated fractures of the mid shaft and junction of the upper and middle third of the femur in adults, except where comminution is so extensive that stability with the rod cannot be maintained. In cases where comminution is severe, either dual-plating or the use of a compression plate device can result in excellent fixation. Open femur fractures require early orthopedic consultation for copious irrigation and debridement in the operating room. These injuries can generally be nailed immediately.[40] In severely contaminated open fractures, external fixation may be the preferred method of treatment.

The overall prognosis of midshaft femur fractures is very good, with most patients being able to return to work within six months. Union rates approach 100 percent, with non-union being very uncommon. Mild degrees of limb shortening or malalignment can result in limp and posttraumatic arthritis.

Patients with preexisting internal hardware may suffer recurrent fractures with trauma. These fractures tend to be very severe and comminuted because the bone is weaker than the hardware. Evaluation and treatment principles are the same as without hardware. Hardware migration, loosening and rarely breakage can occur. Pain at the site and radiographic changes compared to old films are present. Infection, suggested by pain at the fracture site and fever, may also occur, but is uncommon with closed procedures.

266 KNEE INJURIES

Mark T. Steele

Injuries to the knee are common in our exercise and sports-oriented society. Because the knee is essential for ambulation, one must be familiar with the examination of the normal and abnormal knee to be able to recognize, treat, and appropriately refer specific injuries. This chapter deals with examination of the knee and with recognition of fractures and dislocations of the patella; fractures of femoral condyles; fractures of the tibial spines, tuberosity, and plateaus; ligamentous and meniscal injuries of the knee joint; knee dislocation; quadriceps and patellar tendon ruptures; patellar tendinitis and chondromalacia patellae; penetrating injuries and foreign bodies; total knee replacement and postarthroscopy problems; and osteochondritis dissecans.

An accurate diagnosis of the injured knee is required before proper treatment can be instituted. The first examination is usually the easiest to perform and may be the most valid because the patient does not anticipate pain and therefore does not guard, and involuntary muscular spasm, inflammation and effusion causing further limitation of the examination may not yet have occurred.

EXAMINATION

The examination of the knee is divided into five phases: history, observation, inspection, palpation, and stress testing.

The current mechanism of injury as well as any prior serious injuries or surgical procedures frequently clarifies subtleties in the examination, allowing a more accurate diagnosis and appropriate treatment.

The patient should be examined while walking, if possible, and in both the sitting and lying positions. Take note of the gait, muscular development, functional range of motion, and the ability of the patient to extend the flexed knee against minimal resistance.

The knee should be inspected for swelling, ecchymoses, effusion, masses, patella location and size, muscle mass, erythema, and evidence of local trauma. With the patient supine, note whether leg lengths are equal or unequal. Lastly, ask the patient to perform the best possible active range of motion.

Initially the neurovascular status of the leg should be noted. As with all orthopedic examinations, the noninjured or normal knee should be compared with the injured knee during all aspects of the examination but especially during palpation and stress testing. When palpating the knee, begin in the nontender areas and work lastly toward the tender area so that the patient does not guard or become apprehensive. The patella and patellar facets, as well as the femoral and tibial condyles, should be palpated for pain and crepitance. Effusion, tenderness, increased temperature, strength, sensation, and location of pulses should be noted.

Examine the patella for size, shape, and location with the knee in flexion; check mobility with the knee in extension. The patella should be compressed to check for pain as well as moved laterally and medially to ascertain possible subluxation. The popliteal space should be palpated for masses, swelling, and pulses. Both the medial and lateral joint lines should be palpated because tenderness at those locations suggests the possibility of meniscal injury. Palpation of the medial and lateral collateral ligaments should also be performed with tenderness once again suggesting the possibility of injury.

The final phase of the examination of the knee is stress testing (also see section on Ligamentous and Meniscal Injuries). This is the most difficult aspect of the examination although potentially the most informative. The patient must be reassured and relaxed and made as comfortable as possible. This may require allowing the leg to hang over the side of the bed with the bed supporting the posterior thigh rather than the physician holding the leg, as is usually done during stress testing. The uninjured, hopefully normal, opposite knee should be examined first to determine the patient's normal laxity. A brief summary of the instabilities and tests to demonstrate them are presented in the section on ligamentous and meniscal injuries.

RADIOGRAPHIC EVALUATION

The Ottawa Knee Rules (Table 266-1) for determining the need for x-rays have proven sensitive for fracture [1] and have resulted in reduced emergency department waiting times and costs. The Pittsburgh Knee Rules (Table 266-2) are similar and recently were prospectively shown to be as sensitive, but more specific than the Ottawa Rules.[2] They also have the added advantage of being applicable to both children and adults. A recent evaluation [3] suggested that point tenderness is not a good predictor of knee fracture in children. This study suggested that applying a rule of an inability to bear weight and inability to flex the knee to 90° would decrease x-rays ordered by 75 percent without any missed fractures.

---

1. Patient older than 55 years

2. Tenderness at the head of the fibula

3. Isolated tenderness of the patella

4. Inability to flex knee to 90 degrees

5. Inability to transfer weight for four steps both immediately after the injury and in the ED

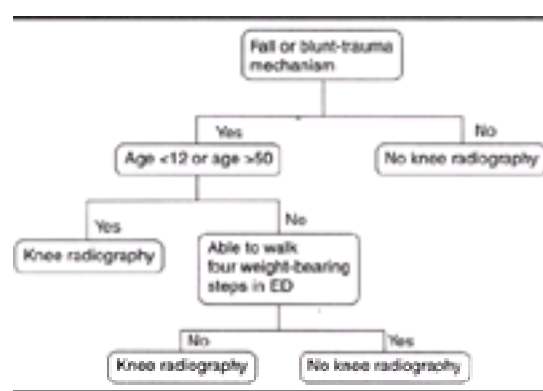
TABLE 266-1   Ottawa Knee Rules: Guidelines for X-Ray


TABLE 266-2   Pittsburgh Knee Rules

Anteroposterior, lateral, and oblique radiographs are typically obtained if x-rays are determined to be necessary. [4] Fat fluid levels (lipohemarthrosis) may be identified on a lateral view of the knee which is suggestive of intra-articular fracture. [5] Oblique views are particularly helpful at detecting subtle tibial plateau fractures (internal oblique view is best to visualize lateral plateau, external oblique film best to visualize medial plateau). A tunnel or intercondylar view provides a clear view of the intercondylar region and is particularly useful in identifying tibial spine fractures. The sunrise (skyline, axial, or tangential) view is most useful in detecting nondisplaced vertical or marginal fractures of the patella which may be missed with the conventional three views. The sunrise view is indicated if patellar subluxation or fracture is suspected. CT scanning may be necessary to fully delineate the extent of tibial plateau fractures. [6] MRI is also helpful in this regard, having the added benefit of being able to assess soft tissue injury (i.e., ligamentous and meniscal).

FRACTURES

Fractures of the Patella

Fractures of the patella occur from a direct blow such as with the knee striking a car dashboard in an MVA, a fall on the flexed knee, or forceful contraction of the quadriceps muscles, which can occur with falling or stumbling. Fractures may be transverse, comminuted, or of the avulsion type, when the quadriceps or patellar tendon pulls off a small portion of the patella (Fig. 266-1).
FIG. 266-1. Classification of patellar fractures. (From Hohl M, Johnson EE, Wiss DA. Fractures of the knee, in Rockwood CA Jr, Green DP, Bucholz RW (eds): *Fractures in Adults,* 3d ed, vol. 2. Philadelphia, Lippincott, 1991, p. 1765. Used with permission.)

Transverse fractures of the patella are most common, followed by stellate and comminuted fractures. [7] Patients with nondisplaced fractures may be ambulatory. Physical examination reveals focal patellar tenderness, swelling, and effusion. It is imperative that the integrity of the extensor mechanism of the knee be checked by having the patient perform a straight-leg raise against gravity. Transverse fractures are more likely to be displaced and have a disrupted extensor mechanism. Differential diagnosis of patellar fractures radiographically includes bipartite patella. This condition involves the superior lateral corner of the patella, is typically bilateral, and is differentiated from fracture by its smooth cortical margins.

A nondisplaced fracture of the patella with an intact extensor mechanism is initially treated in the emergency department with a knee immobilizer, ice, elevation, and nonsteroidal anti-inflammatory drugs and/or opioid analgesics. Such fractures are generally treated in a long leg cast for a total of six weeks of immobilization. [7] During this period the patient should be encouraged to walk on crutches initially, with partial weight-bearing progressing to full weight-bearing as tolerated. Fractures that are displaced greater than 3 mm, or that are associated with the disruption of the extensor mechanism, require early referral to orthopedics for open reduction and internal fixation. [7] This generally consists of tension-band wiring of the patella and suturing of the retinaculum. Severely comminuted fractures may be treated surgically by removal of smaller fragments (or all fragments if they are small) and suturing of the quadriceps and patellar tendons. All open fractures must be debrided and irrigated by orthopedics in the operating room and antistaphylococcal antibiotics should be administered. The overall prognosis for patellar fractures is good. [7]

Fractures of Femoral Condyles

Fractures of the femoral condyles account for 4 percent of femur fractures and include supracondylar, intercondylar, condylar, and distal femoral epiphyseal fractures (Fig. 266-2). Most often, these injuries are secondary to direct trauma from a fall with axial loading or a blow to the distal femur. Examination reveals pain, swelling, deformity, rotation, shortening, and an inability to ambulate. Although neurovascular injuries are uncommon, the potential for popliteal artery injury exists so the status of distal sensation and pulses must be checked. The space between the first and second toe, innervated by the deep peroneal nerve, should be tested for sensation. In addition, a search for ipsilateral hip dislocation or fractures, and damage to the quadriceps apparatus must be made. Incomplete or nondisplaced fractures in any age group and stable impacted fractures in the elderly can be treated with cast immobilization. [7] Open reduction and internal fixation is generally required for displaced fractures or if there is any degree of joint incongruity present. [8] Therefore, leg splinting and orthopedic consultation is essential. The overall progress of these injuries is fair. Complications include deep venous thrombosis, fat embolus syndrome, delayed or malunion, and the subsequent development of osteoarthritis.
FIG. 266-2. The supracondylar and condylar areas of the femur, and the medial and subcondylar areas of the tibia. [Modified from Hohl M, Larson RL: Fractures and dislocations of the knee, in Rockwood CA Jr, Green DP (eds): *Fractures,* vol 2. Philadelphia, Lippincott, 1975, pp 1132, 1147. Used by permission.]

Fractures of the Tibial Spines and Tuberosity

Although isolated injuries of the tibial spine are uncommon, they usually result in cruciate ligament insufficiency. The injury is most often caused by a force directed against the flexed proximal tibia in an anterior or posterior direction, resulting in incomplete avulsion of the tibial spine, with or without displacement, or complete fracture of the spine. Vehicular and sporting accidents are the most common causes of these injuries. [7] Fracture of the anterior tibial spine is about tenfold more common than fracture of the posterior spine. Examination shows a painful, swollen knee, secondary to hemarthrosis, inability to extend fully, and a positive Lachman's sign (see section on Ligamentous and Meniscal Injuries). If the fracture is incomplete or nondisplaced, it should be immobilized in full extension in a knee immobilizer. Protected weight bearing and outpatient orthopedic follow-up within a few days to a week is advised. Complete, displaced fractures require early orthopedic consultation and often need open reduction, and internal fixation.

The quadriceps mechanism inserts on the tibial tubercle. A sudden force to the flexed knee with the quadriceps muscle contracted may result in a complete or incomplete avulsion of the tibial tubercle. The fracture line may extend into the joint. Examination reveals pain and tenderness over the proximal anterior tibia with pain on passive or active extension. If the avulsion is small or nondisplaced, the fragment may be maintained in position by immobilization; otherwise, open reduction and internal fixation are necessary. [7] (See also section on Injuries to Tibial Tubercle.)

Fractures of the Tibial Plateaus

Fractures of the tibial plateaus are seen more commonly in the older population and can be very difficult to detect. They are produced by valgus or varus forces combined with axial loading, which drives the femoral condyles into the articulating surface of the tibia. A fall from a height or the leg being struck by the bumper of a car are common causes of these fractures. [9] Both medial and lateral plateaus may be fractured simultaneously although the lateral plateau is more often fractured. [7] Direct trauma to the lateral aspect of the knee may account for the preponderance of lateral tibial plateau fractures. The patient presents with painful swelling of the knee and limitation of motion. Radiographs may demonstrate a fracture but often only show a lipohemarthrosis on the lateral view. Careful review of the x-rays is essential. Ligamentous instability may be present in up to one-third of those injuries. Anterior cruciate and medial collateral ligament injuries are associated with lateral plateau fractures whereas posterior cruciate and lateral collateral ligament injuries occur with medial plateau fractures. [7] If one plateau is fractured but not displaced, treatment in a knee immobilizer, without weight-bearing, is indicated with outpatient orthopedic follow-up scheduled within a few days to a week. Long-term treatment of these nondisplaced fractures consists of a long leg cast and prolonged non weight-bearing. Depression of the articular surface necessitates early orthopedic consultation and open reduction and elevation of the bony fragment. The treatment goal is precise reconstruction of the articular surfaces to allow for early range of motion so as to minimize the development of osteoarthritis. [7] Potential complications of those fractures include popliteal artery injury with high energy displaced fractures, the development of deep venous thrombosis and osteoarthritis. The prognosis for these injuries is fair.

LIGAMENTOUS AND MENISCAL INJURIES

The knee joint depends on ligaments and muscles for support (Fig. 266-3). It is frequently subjected to injuries from traumatic forces while extended or in various stages of flexion. These traumatic forces include abduction, flexion, and internal rotation of the femur on the tibia; adduction, flexion, and external rotation of the femur on the tibia; hyperextension; and anteroposterior displacement. By far the most common are abduction, flexion, and internal rotation of the femur on the tibia, which produce injuries to the medial side of the knee. Injuries to the lateral side of the knee are produced by adduction, flexion, and external rotation. Such forces may result in a strain or rupture of the medial or lateral collateral ligaments, the anterior or posterior cruciate ligaments, the capsular structures, or a tear in the medial or lateral meniscus, singularly or in combination. Functional instability of the knee is determined by stress testing, which will demonstrate abnormal laxity when properly done.
FIG. 266-3. Ligaments of the right knee joint. The articular capsule and the patella have been removed. (From Spencer AP, Mason EB: *Human Anatomy and Physiology.* Menlo Park, Benjamin/Cummings, 1979, p 174. Used by permission.)

Initial stress testing is an abduction or valgus deformity (Fig. 266-4) applied to the knee, which is in approximately 30° of flexion, to determine the integrity of the medial capsular and ligamentous structures. The medial collateral ligament supplies the majority of restraint to valgus deformities of the knee in all stages of flexion. A varus or adduction force is then applied to the lateral aspect of the knee, again with approximately 30° of flexion, to ascertain the integrity of the lateral structures. The lateral collateral ligament, similar to the medial collateral ligament, is the major restraint to varus laxity on the knee at all positions of flexion. If there is a demonstrated laxity of greater than 1 cm without a firm end-point as compared to the other knee, there is a complete rupture of the medial or lateral collateral ligament. [10] If there is laxity with a firm end-point or a laxity of less than 1 cm, an incomplete or partial tear is present. If there is no demonstrated instability but there is pain, the patient has suffered a strain in the ligamentous structures tested. The patient who is unstable with the varus or valgus test performed with 30° of flexion should be brought into full extension, if possible, and similar maneuvers carried out. Medial instability in full extension indicates a severe lesion involving the cruciate ligaments and posterior capsule along with the medial ligaments. Lateral instability in extension likewise indicates a severe injury that may involve the posterolateral corner of the knee as well as the cruciate ligaments. Peroneal nerve injuries may also occur in lateral injuries.
FIG. 266-4. Valgus stress in full extension **(A)** and in 30° of flexion **(B).** (From Scott WN. *Ligament and Extensor Mechanism Injuries of the Knee: Diagnosis and Treatment.* St. Louis, Mosby-Year Book, 1991, p 91. Used with permission.)

Injury to the anterior cruciate ligament may be the most common ligamentous injury today.[10] The mechanism of injury is usually noncontact; a deceleration, hyperextension, or marked internal rotation of the tibia on the femur results in an injury to the cruciate. This injury is often associated with a "pop" and swelling that develops within hours. This pop is considered pathognomonic for anterior cruciate injury. [11] There may be an associated medial meniscal tear as well. Such a mechanism of injury combined with the presence of a traumatic effusion is very suggestive of a disruption of the anterior cruciate ligament.

The diagnosis of the anterior cruciate ligament injury is ascertained by using the Lachman test (Fig. 266-5), the anterior drawer sign, (Fig. 266-6) and the pivot shift (Fig. 266-7).[12] Although the anterior drawer sign has been used for a long time, it is not very sensitive. The maneuver is done with 45° flexion at the hip and 90° flexion at the knee. The physician then attempts to forwardly displace the tibia from the femur. A displacement of greater than 6 mm as compared to the normal, opposite knee indicates that there has been an injury to the anterior cruciate ligament. There are false-negatives associated with this maneuver. The Lachman test is a much more sensitive test.[10] The examiner places the knee in 20° of flexion by resting it on a pillow and stabilizes the femur above the knee with his or her nondominant hand. The dominant hand is placed behind the leg at the level of the tibial tubercle, and the examiner introduces an anterior force, attempting to displace the tibia forward. If a displacement of greater than 5 mm as compared to the opposite knee occurs, or if there is a soft, mushy end-point, then a tear in the anterior cruciate ligament has occurred. Although this examination is more sensitive than the anterior drawer and able to identify partial tears in the anterior cruciate ligament when the examiner is skilled, it is difficult on patients who have large legs. The pivot shift is the third maneuver by which the examiner can determine the integrity of the anterior cruciate ligament. The pivot shift is easily performed once the examiner is familiar with it, but it may be somewhat painful to the patient. While the patient is supine and relaxed, the examiner lifts the heel of the foot to approximately 45° of hip flexion with the knee fully extended. The opposite hand grasps the knee with the thumb behind the fibular head. The examiner then internally rotates the ankle and knee, applies a valgus force to the knee, and flexes the knee. If an anterior subluxation of the tibia is present, a sudden visible, audible, and palpable reduction of the subluxation occurs at about 20 to 40° of flexion. This indicates a deficit in the anterior cruciate ligament, which is required to stabilize the knee in this position. There are other tests described in the literature to determine the integrity of the anterior cruciate ligament, including the jerk test and dynamic extension testing.

FIG. 266-5. The Lachman test is performed with the knee flexed between 15° and 30°. (From Scott WN. *Ligament and Extensor Mechanism Injuries of the Knee: Diagnosis and Treatment.* St. Louis, Mosby-Year Book, 1991, p 94. Used with permission.)

FIG. 266-6. Anterior drawer test. (From Scott WN. *Ligament and Extensor Mechanism Injuries of the Knee: Diagnosis and Treatment.* St. Louis, Mosby-Year Book, 1991, p 95. Used with permission.)

FIG. 266-7. In the pivot shift of Galway and MacIntosh, the test is done with the knee in full extension with application of a valgus and internal rotation stress. The "clunk" of reduction is felt in the first 20° to 30° of flexion. (From Scott WN. *Ligament and Extensor Mechanism Injuries of the Knee: Diagnosis and Treatment.* St. Louis, Mosby-Year Book, 1991, p 95. Used with permission.)

The posterior cruciate ligament can also suffer an isolated injury or be injured in combination with other ligamentous structures of the knee. In contrast to anterior cruciate injuries, isolated posterior cruciate injuries are seen much less frequently. The posterior cruciate ligament provides initial resistance to posterior translation at all angles of flexion of the knee. The mechanism of injury then is usually an anterior to posterior force applied to the tibia or lower leg. Posterior cruciate injuries are seen in association with other ligamentous injuries when a serious injury has occurred to the knee. A deficit in this ligament is determined by the posterior drawer test (Fig. 266-8). The knee is examined with flexion at the hip and at the knee as described for the anterior drawer sign. The physician applies a posterior force to the tibial tubercle. If there is displacement posteriorly, then the examiner can diagnose an injury to this ligament. The physician might also notice a posterior sag or drop back of the tibial tubercle due to loss of integrity of the posterior cruciate when observing the knee with 45° flexion at the hip and 90° flexion at the knee. This test can be misleading, however, if there is a straight anterior instability resulting in a subluxation of the knee forward. This abnormal position would give the physician the false impression of too much posterior play when performing the posterior drawer test because the knee would be reduced to its normal anatomic alignment from the forwardly subluxed position.

FIG. 266-8. Posterior drawer test. (From Scott WN. *Ligament and Extensor Mechanism Injuries of the Knee: Diagnosis and Treatment.* St. Louis, Mosby-Year Book, 1991, p 97. Used with permission.)

Combined instabilities of the knee are often seen, especially in athletes. Anteromedial and anterolateral instability are the two that occur most frequently. They result from external rotation and abduction or adduction forces placed on the knee. Virtually any combination of medial and lateral instabilities of the knee can occur, however.

One knee injury that is especially difficult to detect is injury to the posterolateral structures. Posterolateral instability usually involves a tear of the popliteus-arcuate complex, which may occur in combination with lateral ligament injury and possible anterior or posterior cruciate ligament injury. Isolated injuries to the popliteus-arcuate complex can occur themselves but are rare. Isolated posterolateral instability is demonstrated by testing at 0 to 30° of flexion for maximal posterior translation, and at 90° of flexion for maximal external rotation as compared to the normal opposite knee. Further testing to determine the integrity of the lateral collateral ligament and anterior or posterior cruciates must be done as well.

Most ligamentous injuries of the knee present with hemarthroses. In fact, approximately 75 percent of all hemarthroses are due to disruption of the anterior cruciate ligament.[10] Serious ligament injuries, however, may present with minimal pain and no hemarthrosis due to complete disruption of the ligamentous and capsular fibers, allowing leakage of the blood into the soft tissue spaces. Hemarthrosis can also be due to osteochondral fractures or fractures that extend into the joint line or peripheral meniscal tears. Traumatic hemarthroses usually occur within minutes to hours of injury, in contrast to chronic effusions of the knee due to synovial inflammation, which occur one to two days after strenuous use of the joint.

Plain radiographs in ligamentous injuries are typically normal or only reveal an effusion. An avulsion fracture at the site of attachment of the lateral capsular ligament on the lateral tibial condyle (Segond fracture) is a marker for anterior cruciate ligament rupture. [13] Cortical avulsion of the medial tibial plateau (very uncommon) is associated with tears of the posterior cruciate ligament and medial meniscus. [14] Continued refinements in MRI have resulted in high-quality images of the ligamentous and meniscal structures of the knee resulting in an accuracy rate of close to 90 percent for meniscal and cruciate ligament disruption. [7] The ordering of this examination, however, is typically done by the patient's primary care provider or orthopedist in follow-up.

Stable injuries involving a single ligament with minor strain can be managed with a knee immobilizer, ice packs, elevation, nonsteroidal anti-inflammatory agents, and ambulation as soon as is comfortable for the patient. [15] When knee immobilizers are placed, the patient must be instructed to perform daily range of motion exercises to avoid contracture and maintain mobility. These complications are more common in the elderly and can occur after only a few days of immobilization. While there is no universally accepted regimen for range of motion exercise, one regimen is to apply ice first to relieve pain, and then perform 10–20 knee flexion-extensions (no weights should be added) three or four times a day. These injuries should be referred to an orthopedic surgeon or the patient's primary care provider within the next few days to a week for follow-up examination. Complete rupture of an isolated ligament can generally be treated conservatively in the same fashion with quadriceps strengthening, range of motion exercises, and functional bracing being part of the follow-up care. [11] Professional athletes with single ligament ruptures or patients with more than one ligament torn and an unstable knee necessitate immediate orthopedic consultation so that definitive surgical management can be planned.

Arthrocentesis may be of therapeutic benefit in patients with large, tense effusions of the knee. Recurrence of the effusion following aspiration, however, is common. Arthrocentesis may also be of assistance diagnostically if the etiology of the effusion is not clearly due to trauma. The presence of blood and glistening fat globules is pathognomonic of lipohemarthrosis, which indicates intra-articular knee fracture. The major complication of arthrocentesis is septic arthritis.

Meniscal Injuries

Meniscal injuries of the knee occur by themselves or in combination with ligamentous injuries. For example, anterior cruciate injuries are commonly associated with meniscal injuries. Cutting, squatting, or twisting maneuvers may cause injury to the meniscus. The medial meniscus is approximately twice as likely as the lateral meniscus to be injured. Four-fifths of the tears involve the peripheral posterior aspect of the meniscus. [16] Many maneuvers have been described in the literature to determine whether a meniscus has been injured. Most of these tests, however, have an unacceptable specificity and sensitivity. Although the diagnosis of a meniscal tear is difficult to make in certain patients, a combination of a suggestive history and physical findings on examination should lead the emergency physician to consider the diagnosis. On questioning the patient, the physician should ask if the patient experiences locking of the knee joint on either flexion or extension that is painful and limits further activity. This sign clearly points to the diagnosis of a torn meniscus. Effusions that occur after activity; a sensation of popping, clicking, or snapping; a feeling of an unstable joint, especially with activity; or tenderness in the anterior joint space after excessive activity suggests the diagnosis of a meniscal tear. When performing a physical examination, a physician should attempt to identify atrophy of the quadriceps muscle due to disuse, and joint line tenderness, which is very suggestive. Various maneuvers, such as McMurray's test or the grind test, are useful but, as mentioned earlier, are positive only about 50 percent of the time. [17] If a tentative diagnosis of a meniscal tear is considered, referral to an orthopedic surgeon or the patient's primary care provider is warranted. Nonsteroidal anti-inflammatory agents and partial weight-bearing are advised pending follow-up. Definitive diagnosis can be made by MRI or arthroscopy with the latter having the advantage of allowing for definitive surgical treatment (usually partial meniscectomy or meniscal repair).

The patient who presents to the emergency department with a locked knee can experience a great deal of pain along with loss of mobility. Following conscious sedation, one can attempt to unlock the knee by positioning the patient with the leg hanging over the edge of the table with the knee in 90° or greater of flexion. After a period of relaxation, the physician can apply longitudinal traction to the knee with internal and external rotation in an attempt to unlock the joint. If this maneuver is unsuccessful, consultation with the orthopedic surgeon is recommended.

Knee Dislocation

Knee dislocation (Fig. 266-9) is a result of tremendous ligamentous disruption due to hyperextension, direct posterior force applied to the anterior tibia, force to the fibula or medial femur, force to the tibia or lateral femur, or rotatory force resulting in anterior, posterior lateral, medial, or rotatory dislocation. This injury typically occurs following sporting accidents and falls and posterior dislocation is most common. With posterior dislocation, there is complete disruption of the anterior and

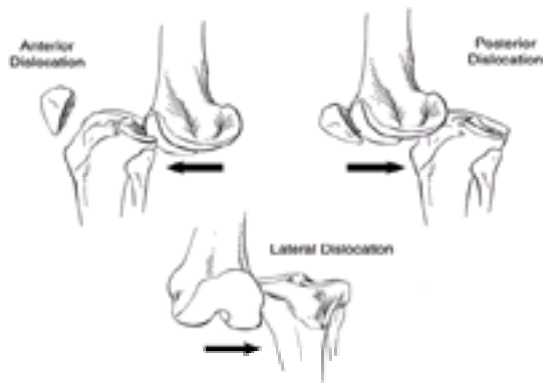
posterior cruciate ligaments and the posterior joint capsule. The extensor mechanism of the knee may also be disrupted and should be checked postreduction. Because of knee instability reduction very often occurs spontaneously. A severely unstable knee in multiple directions is suspicious for a spontaneously reduced knee dislocation. Suspicion of the injury is important because of the high incidence of associated complications, including popliteal artery injury (50 percent incidence) and peroneal nerve injury (mostly with posterolateral dislocations), in addition to ligamentous and meniscal injury.


FIG. 266-9. Types of dislocations. 1. Anterior; 2. posterior; and 3. lateral. (From DePalma AF. *Management of Fractures and Dislocations: An Atlas.* Philadelphia, WB Saunders, 1970, p 1621. Used by permission.)

Early reduction of the dislocation employing longitudinal traction is essential. Neurovascular status of the extremity should be documented pre- and postreduction. Hospitalization is required and orthopedic consultation should be obtained immediately.

Controversy exists regarding when to obtain arteriography in patients with knee dislocation. Because of the high incidence of popliteal artery injury (up to one-third of patients) and poor outcomes related to delays in vascular reconstruction, some authors recommend arteriography for all confirmed knee dislocations. [18] Others have suggested clinical examination alone is reliable in identifying patients requiring arteriography and/or surgical intervention. [19] Patients with an absent pulse or other signs of vascular injury (i.e., bruit, distal ischemia) require immediate vascular surgical consultation for surgical exploration. Patients with an absent pulse prereduction with return of a pulse postreduction probably necessitate arteriography. [20] Patients with normal pulses pre- and postreduction along with normal Doppler pressure indices (Ankle-Brachial Index) (see Chap. 55) can probably be safely observed in the hospital with serial vascular examinations. Presence of normal distal pulses, however, does not preclude occult popliteal artery injury. [21] As a result, if any doubt exists, arteriography should be performed.

Patella Dislocation

Dislocation of the patella usually occurs from a twisting injury on the extended knee and is more common in women. The patella is displaced laterally over the lateral condyle, resulting in pain and deformity of the knee (Fig. 266-10). Tearing of the medial knee joint capsule often occurs. Reduction is accomplished following conscious sedation by flexing the hip, hyperextending the knee, and sliding the patella back into place. This results in immediate relief of pain, but further soreness from capsular injury persists for a period of time. The patella and knee should be x-rayed to rule out a fracture, and the knee should be immobilized after reduction. Follow-up with a primary care provider or orthopedist within one to two weeks is suggested. Partial weight-bearing progressing to full weight-bearing, nonsteroidal anti-inflammatory agents, and isometric quadriceps strengthening exercises are also indicated. Recurrent lateral dislocation of the patella occurs in about 15 percent of patients, and superior, horizontal, and intercondylar dislocations require referral to an orthopedic surgeon for possible surgical intervention.

FIG. 266-10. Lateral dislocation of the patella. (From Lyman JI, Ervin ME. Management of common dislocations, in Roberts JR, Hedges JR (eds). *Clinical Procedures in Emergency Medicine.* Philadelphia, WB Saunders, 1985, p 634. Used with permission.)

Quadriceps/Patellar Tendon Rupture

Rupture of the quadriceps or patellar tendons can occur from forceful contraction of the quadriceps muscle or falling on a flexed knee. Patellar tendon rupture occurs most commonly in individuals under age 40 with a history of tendinitis or past steroid injections. Quadriceps tendon rupture is most frequent in the over 40 age group. [7] There is significant pain, diffuse swelling, and the patient is unable to extend a flexed knee against mild resistance in both instances. Depending on the tendon ruptured, a defect may be palpable above or below the patella. A "high-riding patella" may be seen on the lateral x-ray of the knee with patellar tendon rupture (Fig. 266-11). The treatment is surgical repair of the involved tendon[22] within the first 7 to 10 days following rupture to achieve the best results. Orthopedic consultation in the emergency department is indicated.

FIG. 266-11. Patella alta.

Osteochondritis Dissecans

Osteochondritis dissecans is a disorder in which a segment of articular cartilage and subchondral bone become partially or totally separated from the underlying bone. It is a rare condition of unknown etiology that has been thought to result from acute or chronic trauma. It typically is found in adolescents, is generally unilateral, and most often involves the nonweight-bearing lateral aspect of the medial femoral condyle. Patients generally complain of pain and swelling but typically do not recall any specific incident of trauma. The condition can be diagnosed on routine radiographs with tunnel views being particularly helpful. Treatment is conservative with protective weight-bearing if the epiphyses are still open. If the epiphyses are closed and the fragments are detached, the prognosis for healing is poor. Arthroscopy for the retrieval of loose bodies or arthrotomy for pinning or bone grafting of the detached lesions is suggested in this instance. [23]

Osteonecrosis

Osteonecrosis is a bony infarction caused by disruption of blood supply to the bone. Osteonecrosis is divided into two main categories, primary (spontaneous, idiopathic) and secondary. The etiology of primary osteonecrosis remains unknown. Secondary causes include steroid therapy, systemic lupus erythematosus, alcoholism, sickle cell disease, and renal transplantation. Patients with osteonecrosis are typically elderly women who present with acute knee pain. The weight-bearing surface of the medial femoral condyle of the knee is the most common site of involvement. Physical exam generally reveals tenderness over the involved femoral condyle or tibial compartment. Secondary osteonecrosis occurs in a younger age group. Plain radiographs are typically normal early in the course of the disease but MR scanning is diagnostic. Initial treatment is nonoperative and consists of protected weight-bearing and the use of nonsteroidal anti-inflammatory drugs. The outcome of the disease depends on the percentage of the weight-bearing surface of the joint involved. Treatment options for advanced stages of the disease include arthroscopic debridement, curettage or drilling of the lesion, bone grafting, high tibial osteotomy, use of osteochondral allografts, and total knee arthroplasty. [24]

Patellar Tendinitis

Also known as "jumpers knee," patellar tendinitis is primarily seen in runners, basketball and volleyball players, and high jumpers. Pain is referred to the area of the patellar tendon and is worsened when going from sitting to standing or when running up hills. Point tenderness can be found at the distal aspect of the patella or proximal part of the patellar tendon. Treatment consists of heat, nonsteroidal anti-inflammatory agents, and quadriceps strengthening exercises. Steroid injections predispose to tendon rupture so should be avoided.

Chondromalacia Patellae

Chondromalacia patellae is an overuse syndrome of the articular cartilage of the patella. The condition is caused by patellofemoral malalignment, which leads to a tracking abnormality of the patella, placing excessive lateral pressure on the articular cartilage. It is most common in young, active women and the pain is generally localized to the region of the anterior knee. Stair climbing and rising from a chair exacerbate the pain.

Two tests may aid in the diagnosis. The patellar compression test is performed by pushing the patella distal in the trochlear groove with the knee extended and quadriceps muscles tightened. This maneuver illicits pain. The apprehension test is performed on a relaxed leg. When the patella is pushed laterally, the quadriceps muscles contract in anticipation of pain. Treatment of this condition consists of rest, nonsteroidal anti-inflammatory medication, and quadriceps strengthening exercises. [25]

Post Arthroscopy Presentations

Patients may rarely present to the emergency department following arthroscopy secondary to pain and swelling. Effusions are common following arthroscopy, but joint infection is very uncommon. Diagnostic arthrocentesis should be performed if joint infection is suspected. Arthrocentesis may be helpful therapeutically for large tense effusions. Intra-articular injection of bupivacaine and morphine after traumatic knee injuries and arthroscopy reduces the need for systemic analgesia, but morphine is more effective and can provide relief longer. [26]

Penetrating Knee Injury/Joint Foreign Bodies

If the knee joint has clearly been violated due to penetrating injury, orthopedic consultation should be obtained for joint irrigation in the operating room. If penetration is suspected, but is in doubt, injection of the joint with sterile methylene blue can help to confirm the diagnosis. Extravasation of dye indicates penetration and the need for irrigation. Remember that the history obtained must recreate the position of the knee when the penetrating injury occurred. Many occupational injuries occur with the knee flexed, but the joint is examined with the knee resting in extension. Failure to anticipate the trajectory of injury with the knee flexed could lead to misdiagnosis and failure to anticipate joint penetration.

Radiopaque foreign bodies (i.e., metal, glass) will visualize on conventional radiographs. In general, foreign bodies in the knee joint need to be removed. A bullet in the joint can destroy the cartilage and lead poisoning can occur. [27] A bullet lodged in the bone only, however, does not necessitate removal. Antibiotics to cover streptococci and staphylococci are generally indicated for both penetrating knee wounds and foreign bodies. Tetanus prophylaxis should be administered if indicated.

KNEE INJURIES IN CHILDREN

Although knee injuries do occur in children, they are usually the result of fractures of the bone rather than significant ligamentous injuries. Ligamentous injuries can occur in children but are not common. Careful examination and radiographic evaluation usually reveal that the ligaments are intact and there has been an epiphyseal injury. Meniscal tears also occur in children with a much lower incidence than in adults. The characteristic finding of meniscal tears in children is that they have a more insidious history than in the adult. Patellar fractures are also infrequent in children. They can be difficult to diagnose because of the difficulty in evaluating the radiographs. The opposite knee should be x-rayed for comparison views to help the physician in the diagnosis of a fracture. Lastly, dislocations are, fortunately, an extremely rare condition in children. If they occur, however, they have the same ominous complications as in the adult.

Separation of Distal Femoral Epiphysis

This is a common epiphyseal injury in adolescents that can occur in the anterior plane or coronal plane. The anterior separation is usually the result of a hyperextension injury. The more common coronal separation is a result of abduction and adduction forces, most often occurring during sports activities or play. The patient complains of acute injury with inability to bear weight with displaced fractures and presents with a flexion deformity. As with most epiphyseal injuries, the examiner finds circumferential tenderness around the entire epiphyseal plate, and effusion and swelling are typically present. The standard radiographic views for evaluating the knee are required. The Salter-Harris classification is used to classify these fractures, with type II being the most common. Stress films may be necessary to diagnose Salter-Harris I injuries. The treatment of nondisplaced fractures is above the knee cast immobilization with the knee in 20° of flexion for four to six weeks. Displaced Salter-Harris I or II fractures require reduction with gentle traction followed by cast immobilization. Displaced Salter-Harris III and IV fractures typically require open reduction and internal fixation. The prognosis of these fractures is generally good, with return to normal activities expected within four to six months. Complications include popliteal artery injury with markedly displaced fractures and peroneal nerve injury. [28]

Separation of Proximal Tibial Epiphysis

The separation of the proximal tibial epiphysis is a rare phenomenon because the tibia is well protected. The mechanism of injury is usually indirect forces of abduction or hyperextension against a fixed knee. Occasionally this injury is due to a direct force such as encountered in an automobile-pedestrian accident. Again, the classification is the Salter-Harris method. The symptoms and signs are similar to those of all other knee injuries, with pain, swelling, effusion, and a limited range of motion, especially extension-flexion. As with all epiphyseal injuries, there is circumferential tenderness over the injured growth plate. Stress examination reveals instability to the various maneuvers. Standard radiographs to evaluate the knee are recommended, with stress films required if no injury is seen, but one is suspected. Careful evaluation looking for an occult fracture line is important. The treatment for nondisplaced fractures is a long-leg cast with the knee flexed approximately 30° for six to eight weeks. Displaced injuries require closed reduction followed by casting. If reduction is not anatomic, which is commonly the case with types III and IV, closed or open reduction followed by external or internal fixation is indicated. Vascular compromise is the primary complication occurring in up to 10 percent of cases. Knee instability, joint disease, and growth disturbances can occur in up to 10 to 20 percent of these injuries. The overall prognosis is fairly good for these injuries. [28]

Injuries to the Tibial Tubercle

Two problems can occur at the tibial tubercle. The first is the acute avulsion of the tibial tubercle; the second is the classic Osgood-Schlatter lesion. Avulsion injuries are usually incurred as an acute event during sports and play. The patient presents with the inability to walk, because of the injury, as well as with localized tenderness and swelling. The lateral radiographic view is most important because it demonstrates both the size of the fracture fragment and the degree of displacement. A minimally displaced, small avulsion fragment can be treated in a long-leg cast. Larger fragments are treated by open reduction and internal fixation. The overall prognosis is good. In contrast, Osgood-Schlatter lesions present with a vague history in adolescent boys. The pain is mild and intermittent, allowing the child to continue to participate in sports and play but not at a full level of involvement. Pain is aggravated by running, jumping, kneeling, squatting, and climbing or ascending stairs. Osgood-Schlatter disease is seen bilaterally in approximately 25 percent of the cases. In contrast to patients with avulsion injuries, patients with Osgood-Schlatter lesions experience pain with range of motion, especially range of motion against resistance, and not at rest. The treatment is symptomatic and supportive. There are minimal complications, and the prognosis is excellent. [28]

Fracture of the Intercondylar Eminence of the Tibia

This fracture is usually encountered in 8- to 15-year-old youths, who most often relate a history of a fall from a bicycle. This causes the intercondylar eminence to be avulsed from the tibia, resulting in a painful and acutely swollen knee. The patient has a positive Lachman's test and a drawer sign, and may have concomitant medial collateral ligamentous instability to valgus stress testing. Radiographs usually reveal evidence of a fracture on the lateral view with the knee slightly flexed. The treatment is immobilization in full extension in most instances, as this can reduce the fracture fragment to its anatomic state. Persistent displacement of the fracture should be treated surgically. The concomitant injuries to the medial collateral ligaments do not often require surgical intervention and can be treated while the patient is recovering from the fracture. The prognosis with proper treatment is good. [28]

Osteochondral Fractures

Osteochondral fractures occur infrequently in children and adolescents. If they do occur, they occur most often in adolescent boys and are usually fracture fragments from the femoral condyles or the patella. The mechanism of injury is a direct blow to the knee, flexion-rotation of the knee, or patellar dislocation. The history is typically one of an acute injury with a pop or snap, causing severe pain and an acute effusion. The fracture is difficult to see on radiographs, so careful attention should be paid to the femoral condyles as well as to the patella. Treatment is surgical removal of the fracture fragment or surgical fixation of the fragment. Prognosis is good for small fragments not involving the weight-bearing surface of the joint. Prognosis is less favorable for larger fragments involving the weight-bearing surface. [28]

Paul R. Haller
Ernest Ruiz

Lower leg injuries are common. The tibia is the most common long bone fractured. Significant soft tissue injuries to the leg can also occur. Documentation of the history and the physical examination are crucial to the proper evaluation of lower leg injuries. A knowledge of the anatomy aids in the interpretation of findings.

ANATOMY

Bone

Support for weight bearing is provided primarily by the tibia, a bone triangular in cross section that lies subcutaneously in the anterior aspect of the leg. Although it is in harm's way, it has a thick cortex and significant force is required to fracture it. Proximally, the tibia is splayed out to form the medial and lateral plateaus that articulate with the femoral condyles. The lateral plateau is higher and smaller than the medial and is more susceptible to fracture. The distal tibia articulates with the fibula laterally and the talus inferiorly. This articulation is supported by the ankle syndesmosis, a series of ligaments that lie inferior to the interosseous membrane. The fibula lies lateral and posterior to the tibia. Its smaller diameter allows it to be broken with less force than the tibia. Patients can remain ambulatory after a fibula fracture, because it bears little weight. The tibia and fibula are connected by a dense interosseous membrane.

Compartments

The cylinder of the lower leg is divided into four chambers or compartments by bone and dense layers of fascia. It is useful to describe the neurovascular and muscular anatomy in terms of the position of the nerves and muscles in these four compartments: (1) The anterior compartment is bordered by the tibia medially, the interosseous ligament posteriorly, and the anterior crural septum on its lateral aspect. It contains the muscles that dorsiflex the ankles and toes. The anterior tibial artery runs through this compartment before becoming the dorsal pedal artery of the foot. The deep peroneal nerve that also traverses this compartment supplies motor function to the dorsal flexors of the foot and toes. It provides sensory innervation to the web space of the first and second toes. (2) The lateral compartment is circumscribed by the anterior peroneal septum, the fibula, and the posterior peroneal septum. It houses the superficial peroneal nerve, which is sensory to the lateral dorsum of the foot, and motor control for the muscles within the compartment that evert the foot. The peroneal nerve runs just lateral to the fibular head, where it is exposed to direct trauma. (3) The superficial posterior compartment contains muscles that plantar flex the ankle (gastrocnemius, soleus, and plantaris). The sural nerve runs through it before providing sensory innervation to the lateral heel. No major arteries traverse this compartment. (4) The deep posterior compartment contains muscle groups that plantar flex the toes. The tibial nerve provides motor control to these muscles and sensation for the sole of the foot. This compartment also contains the posterior tibial artery, whose pulse can be felt posterior to the medial malleolus of the ankle. The physical findings produced by increased pressure within each compartment are tabulated in Chap. 270.

EVALUATION

Leg injuries are initially evaluated with a directed history, including the amount and type of violence that occurred. The history may also give clues about nontraumatic soft tissue injuries. On examination, nerves should be evaluated by checking sensation in the web space, lateral heel, and sole of the foot. Motor tests should include the ability to plantar and dorsal flex the foot, as well as to evert the foot. The extent of soft tissue injury is evaluated visually and by palpating the muscle groups. The tibia and fibula should be palpated along their entire lengths. The popliteal, dorsal pedal, and posterior tibial pulses should be palpated. An absent or decreased pulse may indicate the need for urgent fracture reduction and vascular evaluation. Patients with tibial shaft fractures are unable to bear weight or lift their foot off of the cart. Patients with fibular fractures alone are often able to bear weight.

Simple anteroposterior and lateral x-rays of the leg that include the knee and ankle are sufficient to evaluate leg injuries. If ankle or knee injuries are suspected, then further x-ray evaluation is needed. If a tibial shaft fracture is suspected, the leg should be splinted with a radiolucent device to control pain and prevent further soft tissue damage prior to obtaining films. Check pulses, movement, and sensation before and after moving the leg.

TREATMENT

Detailed attention to soft tissue injuries is critical to treating lower leg injuries properly. Often it is the extent of such injury, rather than the fracture itself, that determines the outcome. Wounds should be cleansed and debrided of loose tissue and foreign material. Tetanus immunization should be given, if indicated. Splinting of fractures will prevent further damage to soft tissue caused by movement of the sharp bone fragments. Carefully palpate the compartments to detect any possible compartment syndrome. If such is suspected, inform the consulting surgeon so that appropriate priorities can be set in the management of the injury. Parenteral antibiotics should be administered in open-fracture cases.

COMPLICATIONS

Wounds that are not adequately cleansed and debrided are very prone to infection, an event not preventable by the use of antibiotics alone. Patients with compartment syndromes may develop permanent disability if the syndromes are not suspected or diagnosed. Fractures that are not adequately aligned or immobilized heal poorly or not at all. If a vascular injury is not urgently repaired, amputation can result.

SPECIFIC INJURIES

Fibula Fractures

Isolated fibula fractures usually result from a direct blow. They are relatively uncommon. Since this bone only bears 15 percent of the body weight, patients are often able to walk despite the fracture. Proximal fibular fractures are often the result of external rotation, whereas distal fractures usually result from internal rotation. Repetitive trauma, particularly in runners beginning their training, may result in stress fracture of the distal fibula. A mild soreness caused by a low-velocity injury and a fibula fracture can be treated with immobilization using an elastic wrap (distal fibula) or a knee immobilizer (proximal fibula). More impressive pain and disability can be treated with crutches and casting or Robert Jones splinting. Nonunion is uncommon. Pain medication, cessation of the activity that caused the activity, and the use of ice and elevation are also recommended.

Tibia Fractures

A low-energy event such as a skier falling down and suffering a boot-top "tib/fib" fracture will have a more benign course than a motorcyclist who shatters a tibial shaft. In the setting of a tibial fracture, an intact fibula is a welcome finding in that this suggests that less energy was involved. The fibula may also help support or splint the fractured tibia. The extent and type of soft tissue damage incurred may determine the method used to immobilize the tibia. The majority of fractures of the tibia will require a prompt evaluation by an orthopedist while the patient is in the emergency department. Information that will assist the orthopedist includes (1) the general health of the patient and the presence of other injuries, (2) location of the fracture, (3) the pattern of the fracture lines, (4) the number of fracture fragments, (5) whether the fibular shaft is also fractured, and (6) the extent of soft tissue damage, including vascular compromise, soilage, and the possible presence of compartment syndromes.

Achilles Tendon Rupture

When the soleus and gastrocnemius muscles contract, the Achilles tendon pulls up the calcaneous, plantar flexing the foot. Rupture often occurs in sports settings, especially in poorly conditioned players. Forceful plantar flexion results in rupture of the tendon. A popping sound is heard by the patient, who then has difficulty ambulating. This injury is also likely to occur in individuals who have rheumatoid arthritis, lupus erythematosus, or prior steroid injection of the tendon. It frequently ruptures 2 to 6 cm above its attachment to the calcaneous, where it has its poorest vascular supply. A gap may be palpated at this point, and a dent may be visible. The Thompson-Doherty test is performed by squeezing the midportion of the calf of the patient lying in the prone position. An intact Achilles tendon is demonstrated by a plantar flexion of the foot. Another test is to have the patient walk on his or her toes. The diagnosis does not usually require imaging, but computed tomography or magnetic resonance imaging can be helpful in ambiguous cases. In the emergency department, the patient should be splinted in neutral position with a Robert Jones splint, with prompt referral to an orthopedist. Crutches will be needed for ambulation.

Gastrocnemius Rupture

The medial head of the gastrocnemius is frequently injured during athletic events. A forceful plantar flexion of the foot, often with an extended knee, results in partial tear or rupture of the medial head of the gastrocnemius near its origin on the distal femur. This may be the result of a fall on a plantar-flexed foot or the sudden plantar flexion that occurs in the back leg of an athlete serving a tennis ball. Predisposing factors include inadequate stretching, prior muscle injury, and advanced age.

The athlete feels a sudden sharp pain on the medial aspect of the proximal gastrocnemius. It is painful to ambulate and plantar flexion is uncomfortable. On exam, the proximal medial calf is tender, and may be swollen and bruised. Walking on tiptoes is possible, but uncomfortable. The history is similar to that of Achilles tendon rupture, but the pain and tenderness are more proximal, and the Thompson test is negative in patients with gastrocnemius muscle rupture. Rupture of a Baker cyst should also be considered in the diagnosis, along with deep vein thrombosis.

Treatment typically consists of immobilization with a posterior splint, crutches for ambulation, ice, and pain medications. A mild rupture may be treated simply with rest and non-weight bearing.

Shin Splints

The term *shin splints* describes pain over the lateral and anterior tibia that occurs with exertion and is relieved by rest. Athletes may suffer this early in their training, particularly when running on a hard surface. The only physical finding may be tenderness to the anterior or lateral tibia. Radiographs may be useful to detect a stress fracture of the tibia, but a bone scan is more sensitive. Treatment consists of cessation of the offending activity, usually for several weeks.

Osgood-Schlatter Disease

This lesion is typically seen in athletic teenagers. Girl and boy athletes are both affected. Football, soccer, basketball, gymnastics, and ballet can cause this injury. The anatomic lesion is the partial separation of the tibial tuberosity at the insertion of the patellar tendon. In about one-fourth of cases, it is a bilateral process. Palpation of the tibial tuberosity reveals tenderness and induration. A lateral x-ray of the proximal tibia with the knee flexed 30 degrees reveals an elevation of the distal portion of the tubercle off of the tibia. Alternatively, ultrasound can be used. Cold compresses, anti-inflammatory drugs, and stopping the offending activity is standard treatment. Follow-up with an orthopedist is advisable for this sometimes chronic condition.

Tibial Tuberosity Fractures in Children

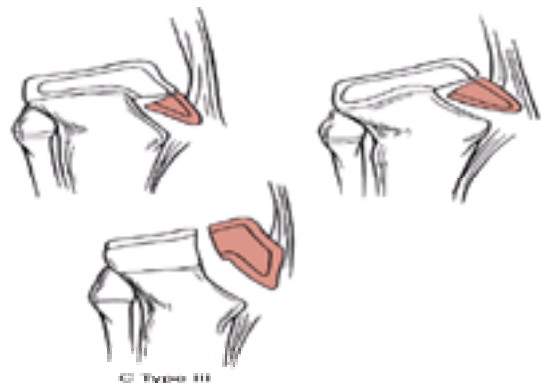
Acute fracture of the tibial tuberosity is the result of contraction of the quadriceps, resulting in a strong pull on the infrapatellar ligament in a young athlete. Usually a leaping motion is involved. On examination, there is pain and tenderness at the tibial tuberosity. There may be a knee joint effusion if the fracture extends into the knee (Salter III). Anteroposterior and lateral x-rays are used to define the fracture. The fracture may be in the plane of the growth plate (Ogden type II) or the fracture plane may be distal to the growth plate (Ogden type I) (Fig. 267-1). A type III Ogden fracture extends into the knee joint. Orthopedic consultation should be obtained for these fractures, because operative reduction and fixation are often needed. Some Ogden type I injuries can be managed with a knee immobilizer and crutches. However, orthopedic follow-up is needed within 1 to 2 days.


FIG. 267-1. Ogden's classification of tibial tuberosity fractures: **A.** type I (fracture between secondary ossification centers), **B.** type II (fracture splitting secondary ossification centers from primary ossification center), and **C.** type III (fracture into the articular surface of the knee). From Ruiz and Cicero (1995), with permission.

Toddler Fractures

A twisting of the lower leg caused by a fall can result in this spiral fracture of the distal third of the tibia. Although it is most often seen in children just learning to walk, it may occur up to age 6. Examination of a frightened child may be difficult. Tenderness and swelling may be palpated at the fracture site. More often, the presentation is one of a limping child with no clear history of injury. In this setting, an x-ray of both the tibia and the femur should be obtained. The fracture may be subtle and visible on only one view. Sometimes the fracture is only seen during resorption and callus formation. Treatment involves a long leg cast for 2 to 4 weeks, with weight bearing as tolerated. Orthopedic consultation should be obtained.

268 ANKLE INJURIES

John A. Michael
Ian G. Stiell

EPIDEMIOLOGY

Injuries to the ankle are a common presenting complaint in emergency departments (EDs). The majority of patients are younger than age 40 and are equally distributed between males and females. Fractures, most commonly of the lateral malleolus, are seen in 15 percent of these patients. [1,2] Below the age of 50, fractures are more common in men and, above this age, fractures are more common in women. Fracture-dislocations are more common in women.

ANATOMY

The ankle joint bears the weight of the body. An understanding of ankle injuries depends on not only a thorough knowledge of the anatomy of the joint but also on the mechanism of force that caused the injury.

The proximal part of the joint, or mortise, is comprised of distal fibula and tibia. This fits on top of the talus, or plafond, the distal part of the joint. These three bones are bound together by three groups of ligaments. Bony stability is provided by the medial and lateral malleoli extending over the plafond. Ligamentous stability is provided by the lateral ligament complex, the medial deltoid ligament, and the syndesmosis. The lateral malleolus is attached to the anterior and posterior aspects of the talus and to the calcaneus, respectively, by the anterior talofibular, posterior talofibular, and the calcaneofibular ligaments. The medial collateral or deltoid ligament is a thick triangular band of tissue that originates on the medial malleolus. The superficial fibers insert on the navicular, the sustentaculum of the calcaneus, and the talus, while a deep set of fibers insert on the medial aspect of the talus. The syndesmosis is a group of four distinct ligaments that attach the distal fibula to the tibia just above the plafond (Fig. 268-1).
FIG. 268-1. Anatomy of the ankle joint.

The ankle joint is sometimes described as having a range of motion in only the plantar-dorsiflexion plane, however, a small degree of medial-lateral movement does occur. The four groups of muscles that serve the ankle joint are supplied by branches of the sciatic nerve. Dorsiflexion is accomplished by tibialis anterior, extensor digitorum longus, and extensor hallucis longus muscles that run over the anterior aspect of the joint. On the medial side of the joint, the tibialas posterior, flexor digitorum longus, and flexor hallucis longus run behind the medial malleolus and contribute to inversion of the joint. Laterally, running behind the distal fibula, the peroneous and brevis muscles contribute to eversion and plantar flexion. These two peroneal tendons share a common synovial sheath that is held in place by a groove on the posterior aspect of the lateral malleolus and the superior retinaculum. Plantar flexion is provided by the soleus and gastrocnemius muscles. The blood supply of the foot is served by branches of the popliteal artery.

Almost all injuries of the ankle joint are due to an abnormal motion of the talus within the mortise. Motion of the talus causes a stress on the malleoli and the ligaments, causing injury. If the injury allows shifting of the position of the talar dome within the mortise, then the injury has the potential to be unstable. Fractures above the plafond may be unstable, and injuries that cause disruption on both sides of the joint are unstable. Instability can result from a fracture of a malleolus and rupture of a ligament, fracture of both malleoli, or rupture of both ligaments.

EVALUATION

History

Although knowledge of the mechanism of the injury is important, many patients can not recollect the exact movement that caused the injury. The classification systems used to describe ankle injuries utilize the direction of the deforming force to describe the potential injury. This information is useful, but, to emergency physicians, the circumstances surrounding the injury are of greater importance in consideration of other injuries. The potential for associated injuries is greater in an individual who has jumped from a 12-foot fence than in a basketball player who came down on one foot from a hoop jump. Likewise, an elderly woman is more likely to have a second injury when she trips on a curbstone and falls to the pavement on an outstretched hand. The treatment of patients who have chronic medical conditions like diabetes or peripheral vascular disease, which can cause sensory deficits, or who are on chronic immunosuppressive therapy has to be approached with caution. A normal-appearing ankle or minimal tenderness on examination does not exclude the necessity of further evaluation. The ability to bear weight immediately after an injury, with subsequent increase in pain and swelling as the patient continues to ambulate, suggests a sprain rather than a fracture. Finally, the time of the injury, as well as previous bony or soft tissue injuries to the ankle, need to be documented.

Physical Examination

Once significant swelling has taken place, the examination of the ankle becomes more difficult. This may be temporized in the busy ED by the application of ice at triage and getting the patient to elevate the foot. Although tempting, the patient should not be examined in a wheelchair, but on a stretcher. It is critical to examine the

joint above and below the injury. Note the position, swelling, and skin integrity of the injured ankle. Ask the patient to plantar and dorsiflex the ankle actively, then put the ankle through a passive range of motion. Soft tissue injuries are more likely when there is a significant difference between the passive and active range of motion. Increased pain with dorsiflexion is suggestive of a syndesmosis injury. Palpate the area of obvious injury last: Hurt the patient initially and their cooperation will rapidly diminish. Compare the injured ankle to the normal ankle. Tenderness of the knee, the fibular head, or the proximal fibular shaft suggests a fibulotibial ligament tear or a Maisonneuve fracture. Compress the fibula toward the tibia just above the midpoint of the calf in order to exclude clinically an isolated syndesmotic sprain. Starting at least 6 cm proximal, palpate the posterior aspects of lateral and medial malleoli to the distal tips of the shaft. Examine the Achilles tendon. If there is tenderness or a defect, perform the Thompson test. With the patient prone on a stretcher, squeeze the calf: loss of plantar flexion indicates a complete rupture of the tendon. Palpate the midfoot and hindfoot over the calcaneus, the tarsals, and the base of the fifth metacarpal. Patients can complain of an ankle injury when they have actually injured the foot or the Achilles tendon. Injuries to these structures are not excluded with the three-view ankle series.

Many acutely injured ankles are too painful or swollen for tests of ligamentous stability to be performed accurately. In these circumstances, the tests can be deferred to the physician who is going to follow the case. If the circumstances allow an examination, perform the following: With the foot hanging freely, grasp the posterior calcaneus with one hand and stabilize the distal leg with the other hand. With the foot in a few degrees of plantar flexion, test the anteroposterior stability of the joint by moving the foot while holding the tibia in a stable position. A positive anterior drawer test is greater than 5 mm of movement in comparison to the normal ankle. Evert and invert the foot. More than a 10° movement in comparison to the other foot is a positive talar tilt test. Inversion instability or anterioposterior laxity suggests the disruption of two or more of the lateral collateral ligaments. Eversion instability suggests a disruption of the deltoid complex. Some orthopedists feel that the anterior drawer test and the talar tilt test should be performed as stress radiographs, with comparison films of the other ankle before any conclusions are made. This is not practical in the ED, and these tests can be done in follow-up or consultation.

Perform a neurovascular examination. This includes palpation of the dorsalis pedis and posterior tibial pulse and capillary refill. Check the foot for motor and sensory impairment. Ask the patient to walk four steps: if the patient can transfer weight from one foot to another and the findings on physical examination as outlined above are normal, the likelihood of a significant fracture is nil.

IMAGING

The Ottawa Ankle Rules have provided a significant advance in the evaluation of ankle injuries in the ED. Previous studies suggested that not all patients who presented to the ED needed radiographs.[3] The Ottawa Ankle Rules were derived from an initial series of studies[4,5 and 6] and then were prospectively validated.[1,7,8] These studies involved over 9000 patient encounters and 200 emergency physicians. Two further studies by the same group found the implementation of the rules to be cost effective and that, once taught, emergency physicians continued to use them.[9,10] Although these studies were carried out in eight academic and community emergency departments in Canada, other studies at independent sites in the United States,[11,12] the United Kingdom,[13] and France[2] have further validated their use. Additionally, it has been demonstrated that nurses at triage can apply the rules successfully.[11,13] Only two studies have failed to replicate these results,[14,15] but these studies were found to have either a flawed methodology or did not accurately assess the rules as developed.

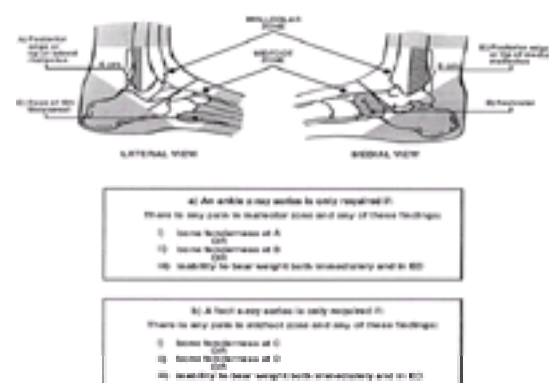
The rules are simple to apply and are illustrated in Fig. 268-2. The rules can be used on patients with an injury to the ankle, which is clinically broadly defined as the area of the distal leg and the midfoot subject to twisting injuries. Mechanisms of injury include twisting, direct blunt trauma, and falls. The rules were not developed for patients under the age of 18. Clinical judgment should prevail if the examination is unreliable due to lack of cooperation, intoxication, distracting injuries, or a diminished sensation in the leg. To assess the ability to bear weight, ask the patient to take four steps. If the patient can complete two transfers to the injured ankle, the patient passes the test.


FIG. 268-2. The Ottawa Ankle Rules for ankle and midfoot injuries.

Various objections that have been raised in the United States to applying these rules include, but are not limited to, the malpractice potential of missing any fracture, however insignificant; the patient's expectation of a radiograph and perception of a full assessment; and the physician's perception that the proportion of patients with fractures who present with ankle injuries is higher in the United States. Communication with the patient, such as an explanation of the thoroughness of the clinical examination, and the fact that a chip fracture, if missed, is treated like a sprain, is often effective. The saving of time and money for the patients should help them to accept the completeness of the evaluation. Additionally, studies done in the United States show a similar 15 percent fracture rate as demonstrated in Canada, the United Kingdom, France, and Scandinavia.

An excellent review of radiologic subtleties in the diagnosis of extremity injuries is found in Weissman.[16] Utilization of computed tomography and magnetic resonance imaging in the assessment of ankle injuries, although useful, is not appropriate for the ED.

INJURIES, TREATMENT, AND PROGNOSIS

Soft Tissue

LIGAMENTOUS SPRAINS **Lateral Ligament Complex** Sprains of the lateral ankle are the most common ankle injury, and the great majority are minor. The classification systems for ligamentous injuries to the lateral ankle are quite confusing. Older texts describe a purely anatomic classification scheme: A grade 1 injury is described as a complete rupture of one ligament and a grade 3 injury is a complete disruption of the three-ligament complex. More recent articles describe a more functional system: In this scheme, patients with grade 1 injuries have microscopic tears of the ligament, minimal swelling, normal findings on stress testing, and the ability to bear weight. Grade 2 injuries have a partial disruption of the ligament, significant swelling, indeterminant results on stress testing, and difficulty bearing weight. The ankle with a grade 3 injury has a ruptured ligament, swelling and ecchymosis, abnormal results on stress testing, and the inability to bear weight. These two classification systems are probably of little value to emergency physicians. A much more useful approach divides the injuries into two groups: stable, and potentially unstable or unstable.[17] If stress testing can be accomplished in the ED and the findings are normal, then the patient has a stable lateral ankle sprain and can be so treated. If results on stress testing are clearly abnormal or are indeterminate because of excessive swelling or pain, then the sprain should be treated as unstable.

Treatment of lateral ankle sprains has been equally controversial. A recent review of the English-language medical literature yielded 84 articles dealing primarily with soft tissue injuries of the ankle for a 30-year period.[18] The authors categorized the data to compare pharmacotherapy, surgical repair, active immobilization, cryotherapy, and diathermy. Although the average quality of the studies on a 10-point scale was 4 and no statistical analysis was performed, they made the following conclusions. Nonsteroidal anti-inflammatory drugs (NSAIDs) were associated with quicker recovery and less pain, active mobilization was the treatment of choice, and cryotherapy was useful. Unfortunately, only seven of the studies classified the degree of injury, and NSAIDs were compared with placebo rather than to acetaminophen. A review of more recent literature includes some fairly well performed prospective studies.[19,20 and 21] Most of these studies treated patients with grade 2 or 3 ankle sprains with compression, rest, and cryotherapy for 24 to 72 h. They then usually compared two treatment groups: (1) weight bearing with an ankle brace that allows plantar-dorsiflexion while resisting inversion and (2) eversion and plaster immobilization for up to 6 weeks. Patients in the early-mobilization groups returned to work or sport earlier than the immobilization groups, but at late follow-up there were no differences in outcomes. Additionally, direct comparisons of

operative repair with cast, cast alone, and early controlled mobilization of acute grade 3 ankle sprains suggest that there is no difference in long-term outcome. [22]

The data indicate that individuals with stable and unstable ankle sprains, who are unable to bear weight easily, should be treated with rest, ice, compression, and elevation (RICE) for 24 to 72 h, depending on the amount of swelling and degree of pain. Individuals who can easily bear weight and have a stable joint probably need no more than simple analgesics and an elastic bandage, near normal activity with no sports involvement or prolonged walking, and follow-up in 1 week if they still have discomfort. Patients who are unable to bear weight in the ED but appear to have a stable joint can be given an ankle brace and be told to apply it in 24 to 72 h and to follow with their primary care physician or orthopedist within 1 week for a repeat evaluation. Patients who clearly have an unstable joint should be referred to an orthopedic surgeon, with consideration of a posterior mold. Timing of consultation depends on local preferences, but it would be prudent to establish communication early, as the ultimate decision on the method of treatment lies with the orthopedic surgeon.

Medial Ligament Complex   An isolated sprain of the deltoid ligament is rare and is usually associated with a fibular fracture or significant tear of the tibial-fibular syndesmosis resulting from an eversion stress. When there is significant medial malleolus tenderness and swelling, Maisonneuve fracture is suspected and careful attention should be paid to the proximal fibula and fibular shaft. If the radiographs of the ankle and the fibula are negative, then a significant syndesmosis tear should be suspected. Patients with these type of injuries should be treated with RICE and early referral to an orthopedist.

Tibiofibular Syndesmotic Complex   These injuries are usually associated with a hyperdorsiflexion injury. The talus moves in a superior direction and separates the fibula and tibia resulting in a partial or complete rupture of the syndesmosis. Patients usually complain of pain just above the plafond. These are significant injuries with prolonged recovery and should be treated with RICE and early consultation.

An excellent review of deltoid ligament, syndesmosis, and other "atypical ankle sprains" can be found in the work by Clanton and Porter. [17]

PROGNOSIS OF LIGAMENTOUS INJURIES   The long-term complications of ankle sprains include functional instability (a subjective sensation of giving way without mechanical instability), mechanical instability (a demonstrable laxity), chronic pain, stiffness, and recurrent swelling. The documented incidence of complications is highly variable, and varies from 6 to 40 percent. [19,22] The long-term sequelae can be reduced with early rehabilitation. Physical therapy should be directed initially at active and passive range of motion exercises followed by early mobilization, strengthening exercises, proprioceptive training and, finally, restoration of normal activity.

STRAINS AND CONTUSIONS   Strains are injuries to muscles or tendons and usually are not associated with a specific injury but rather are due to repetitive stress. The stress can be due to overuse secondary to athletic activity or to poorly fitting footwear. Treatment includes simple analgesics (anti-inflammatory medications may be of benefit), rest, identification and correction of provocative factors, and specific rehabilitative exercises. Contusions are usually caused by direct trauma, typically from a baseball or a hockey puck. Fractures are rare and usually are of the bone cortex only. Treatment is symptomatic with simple analgesics and ice.

PERONEAL TENDON SUBLUXATIONS AND DISLOCATIONS   These injuries can be easily misdiagnosed as lateral ankle sprains. The mechanism is described by a sudden hyperdorsiflexion of the foot while the peroneal tendons are taut in eversion. This injury is most often associated with skiing. The superior retinaculum holding the peroneal tendons in place is stripped off the posterolateral malleolus. In more severe injuries, a small avulsion fracture will be noted on a radiograph, and the peroneal tendons dislocate or more often sublux anteriorly over the distal tip of the fibula. Consider this injury when tenderness and ecchymosis over the posterior edge of the lateral malleolus is noted in the absence of tenderness over the anterior talofibular ligament. It is important to consider this diagnosis in the acute setting: the treatment is frequently operative repair of the retinaculum. [17]

Fractures and Dislocations

CLASSIFICATION SCHEMES   There are multiple classifications of ankle fractures. The more complex utilize both the position of the foot at the time of injury and the deforming force. These classifications are useful in predicting associated injuries. In the Lauge-Hansen classification system, the first word refers to the position and the second word refers to the force. The Danis-Weber classification is based on the level of the fracture of the fibula. Proximal fractures of the fibula are associated with damage to the syndesmosis and the increased likelihood of an unstable fracture. There are three types of injury in this classification scheme: The type A (fracture of fibula below the syndesmosis) is a supination injury and corresponds to the Lauge-Hansen-type suppination-adduction injury. The type B injury (fibular fracture at level of syndesmosis) is associated with external rotation force and corresponds with the suppination-eversion injury of Lauge-Hansen. The type C injury (fibular fracture above the syndesmosis) is associated with an external rotation-abduction force and corresponds with the pronation-eversion or abduction Lauge-Hansen injuries. The AO classification system amplifies the Danis-Weber system by subdividing each classification type into three subtypes to better describe associated medial injuries (Fig. 268-3).
FIG. 268-3. The AO amplification of the Danis-Weber classification of ankle fractures.

Henderson described the simplest classification system based on radiographic appearance. This scheme is commonly utilized and uses the terms unimallelolar, bimalleolar, and trimallelolar to describe fractures of the ankle.

Although it is important to have a basic understanding of these classification systems, the most essential aspects of ankle injuries to appreciate is the stability of the injury and the exclusion of associated injuries (Table 268-1).

TABLE 268-1   Associated and Occult Injuries of the Ankle

TREATMENT   All fractures of the ankle, with the exception of fibular avulsion fractures, require immobilization by cast alone or surgical reduction with subsequent casting. Avulsion fractures are treated as stable ankle sprains if they are minimally displaced, less than 3 mm in diameter, and there is no indication of a medial ligamentous injury. The treatment goal with all other ankle fractures is to restore the anatomic relationship of the ankle, maintain reduction during the healing process, and institute early mobilization of the ankle. To ensure this, the talus has to be anatomically positioned in the mortise, the joint line has to be parallel to the ground, and the articular surface has to be smooth. The means to attain this goal is not only dependent on the type of fracture but also on the age and athletic expectations of the patient. Local preferences may also play a role in this decision. Most fractures, with the exception of unimalleolar injuries, require open reduction and fixation. The Maisonneuve fracture (AO type C2-3), although considered an unstable injury, can generally be treated with cast immobilization for 6 to 8 weeks, depending on the stability of the syndesmosis.[15] The Bosworth fracture, a rare variation of the Maisonneuve fracture where the proximal fibula gets trapped behind the tibia, usually requires operative reduction. The debate over the necessity of operative treatment for unimalleolar fractures with associated syndesmosis and deltoid ligamentous injuries is complex and beyond the scope of this text. Stable fibular fractures are treated with a short leg-walking cast for 6 weeks.

The timing of consultation is discussed below. In the interim, fractures should be splinted with a posterior mold and kept non-weight-bearing in all cases and elevated with application of ice in many. The analgesic need of the patient should be addressed. There is absolutely no basis for the practice of withholding analgesics until operative consent is obtained.

OSTEOCHONDRAL FRACTURES   Osteochondral fractures are due to acute trauma or repetitive stress. These injuries vary from a deformation of the cartilage overlying the talar dome to a free-floating avulsion fracture. The staging and treatment of these lesions are complex, and orthopedic consultation is required. Treatment can involve excision or cast immobilization for up to 6 weeks.[17]

PROGNOSIS OF ANKLE FRACTURES   Early complications and sequelae of ankle fractures are several and include skin necrosis and osteomyelitis in the short term and chronic pain, osteoarthritis, malunion, nonunion, and reflex sympathetic dystrophy in the long term. Although most of these problems are rare, postreduction arthritis can complicate up to 30 percent of fractures.

FRACTURE-DISLOCATIONS AND OPEN FRACTURES   Dislocations of the ankle joint can occur in one of four planes and are frequently associated with a fracture. The posterior dislocation is most common and happens usually when the foot is plantar flexed and a backward force is applied. The injury is usually associated with rupture of the tibiofibular ligaments or fracture of the lateral malleolus. The anterior dislocation occurs with a dorsiflexed foot and fracture of the anterior aspect of the tibia. Lateral displacement is accompanied by ligamentous disruption and fracture of either or both malleoli. Finally, the talus can be displaced upward with a significant impaction. There will be an associated fracture of the talar dome or tibial plafond and disruption of the syndesmosis.

Patients with fracture-dislocations of the ankle are at considerable risk of neurovascular compromise and conversion of a closed fracture to an open one. Under most circumstances, the reduction of fracture-dislocations is left to an orthopedic surgeon. However, if there is vascular compromise indicated by absent pulses and a cool dusky foot or tenting of the skin caused by fractured bone, the emergency physician should perform the reduction. Do not delay reduction in order to obtain radiographs. If possible, place the patient on the stretcher, with the affected foot hanging over the side with a flexed knee. This forces the leg into external rotation and the foot into internal rotation. It also gives the physician the advantage of gravity. Administer adequate intravenous analgesia with the appropriate cardiorespiratory monitoring. The heel and foot should be grasped with both hands (with an assistant stabilizing the proximal leg), and downward traction and rotation applied in the opposite direction of the mechanism of the injury. Little force is required. A splint is applied once distal perfusion is restored and the foot is again elevated. Irreducible fractures are quite rare and, of course, require open reduction.

Protect open fractures from further contamination by applying a wet, sterile dressing over the wound with a gauze roll. No studies substantiate the application of betadine-soaked gauze to the laceration site. Splint the injury until radiographs and definitive treatment are available. Tetanus-diphtheria toxoid is given as necessary, and tetanus immunglobulin considered if the wound is grossly contaminated. The antibiotic of choice is cephalexin, and an aminoglycoside is added if the wound is grossly contaminated. Consider clindamycin for patients with penicillin allergy.

PEDIATRIC INJURIES

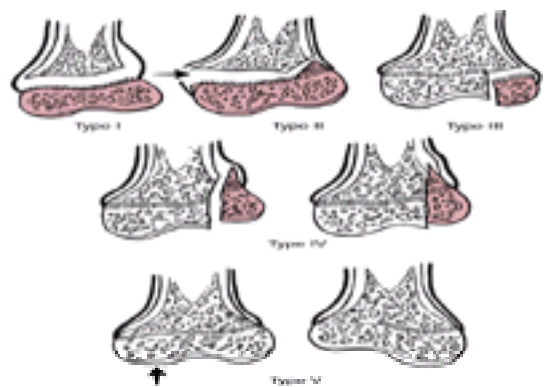
A different injury pattern has to be considered in the pediatric population. Patients with immature bones are more likely to have fractured the growth plate than to have sprained a ligament. The distal fibular and tibial growth plates are usually closed by the age of 16 and then the pattern of injury mimics that in adult patients. The Salter-Harris classification system describes the pattern of injury in skeletally immature individuals (Fig. 268-4).


FIG. 268-4. Salter-Harris classification of pediatric fractures.

Soft tissue injuries are rare in the pediatric population. Look for an anterior dislocation of the pernoneal tendon in young athletes who complain of lateral ankle pain. If the tendon is palpated anterior to the lateral malleolus, it can be relocated by pronating the foot while in dorsiflexion. A patient with a normal radiograph and tenderness over the growth plate of the lateral malleolus has a Salter I fracture.

The Salter type I and II fibular fractures are usually associated with an inversion injury and are treated with closed reduction and a walking cast for 4 weeks. Closed reduction with a short or long leg cast for 6 weeks is the treatment for a Salter type II tibial fracture (pronation-eversion force) with an associated greenstick fibular fracture. Salter type III and IV fractures (significant adduction force) of the distal tibia with an associated fibular shaft fracture often require open reduction and fixation. Type V fractures (axial force) are rare and are treated with closed reduction and non-weight-bearing. Unfortunately, type V fractures can result in bone growth retardation. The prognosis of other pediatric fractures, however, is excellent.

TIMING OF CONSULTATION

No set of rigid rules for the timing of orthopedic consultation exists to guide emergency physicians for each specific ankle injury. Although it may be reasonable to request an in-person orthopedic consultation in an academic center at 3 o'clock in the morning for a stable ankle fracture, this will not endear a community-based emergency physician to his orthopedic colleagues. Although it may be perfectly acceptable for an emergency physician in some countries to apply a circular short leg cast to an AO type A1 or a Salter type I or II fibular fracture and arrange follow-up, this approach would not be common practice in other locales (Table 268-2).

Immediate Consultation in Emergency Department	Delayed Consultation*	Within 1 Week
All open fractures	Stable unimalleolar fractures	Potentially unstable sprains
All fracture dislocations	Unstable ligamentous injuries	
All dislocations	Acute peroneal dislocations	
All trimalleolar fractures†	Pediatric Salter I, III	
All bimalleolar fractures†		
Unstable unimalleolar fractures†		
Pediatric Salter III, IV, V†		
Maissoneuve fractures†		

*Implies that communication is established at time of diagnosis and specific time of consultation has been set.
†Consultation can be delayed in the emergency department in fractures without neurovascular compromise and appropriate splinting.

TABLE 268-2   Timing of Consultation

EMERGENCY DEPARTMENT TREATMENT ISSUES

Pharmacotherapy

The need for analgesia should always be addressed. As individual perception of pain varies, a simple ankle sprain may only require an elastic bandage or acetaminophen in most patients, while some will require oral narcotics. Although some studies suggest that the anti-inflammatory effect of NSAIDs is useful in treating ligamentous injuries,[18] other studies suggest that there is no benefit.[23] Patients who are in significant distress or who should be kept NPO because of anticipated surgery require parenteral analgesia.

Immobilization

Noncircular cast immobilization can be accomplished with a Jones bandage or a posterior mold. A Jones bandage has more padding and probably is more comfortable for patients with severe bruising and swelling, but may not accomplish the same degree of immobilization as a posterior mold. The patient should be supine on a stretcher. Apply two to three layers of abdominal pads, extending from the distal foot to just below the knee, and hold them in place with 4-inch elastic bandages. A four-inch cotton cast padding can be applied, in place of the abdominal pads, in a circular fashion overlapping by at least 50 percent with a minimum of three complete layers. The Jones bandage should not be used for more than a couple of days.

A posterior mold is most easily applied if the patient is prone on a stretcher with the knee flexed to 90°. Most emergency departments have a prepackaged padded splint material available. For extra padding, apply a single layer of 4-inch cotton cast padding from the toes to the knee, followed by a 4-inch plaster or fiberglass splint. The wet splint should extend along the plantar surface of the foot and the calf from just distal of the first metatarsal-phalangeal joint to the fibular head (Fig. 268-5). Hold the splint in place with 4-inch elastic bandages. As the splint hardens, keep the ankle at a 90° angle and mold the splint about the instep and malleoli. Use three or four layers of cotton cast padding, if prepackaged splints are not available, followed by 15 to 20 layers of 4-inch plaster fashioned into a slab of appropriate length. If more support is required, especially in the setting of an unstable joint, another slab can be added to give additional medial-lateral support. Size the patient, if necessary, for crutches and instruct in their appropriate use. For a weight-bearing patient, a cast shoe can be applied.
FIG. 268-5. Short leg posterior splint with and without a stirrup splint.

Ankle Braces

Several different ankle braces (which allow dorsiplantar flexion but do not allow inversion or eversion of the ankle) are available. These devices vary from complex applications of athletic tape, to lace-up splints and inflatable plastic stirrup-type braces. Although few studies exist that compare these braces, it is clear that any device that speeds mobilization and weight bearing will promote early return to full function. [19,21]

Cryotherapy and Other Modalities

Ice packs have been shown to limit swelling and decrease pain.[18] The pack is applied directly to the ankle or the splint and is left on for 20 min at a time. It can be repeated every few hours. Ultrasound has not been shown to promote healing. [18,24]

269 FOOT INJURIES

John A. Michael
Ian G. Stiell

The foot is a complex, highly evolved structure that bears the weight of the body and acts as a lever to propel the body forward while walking or running. It is designed to carry the body over varied terrain with little apparent difficulty. Although most injuries are minor and heal with time, undertreated and unrecognized injuries can result in significant long-term pain and disability. Radiographs are sometimes difficult to interpret, and seemingly minor abnormalities can be associated with a significant injury.

ANATOMY

Chopart and Lisfranc joints divide the foot into three regions. The talus and the calcaneum comprise the hindfoot. The midfoot contains the cuneiforms, the cuboid, and the navicular. The metatarsals and the phalanges make up the forefoot (Fig. 269-1). There are a total of 28 bones and 57 articular surfaces. Numerous intrinsic muscles and ligaments contribute to the integrity of the foot's structure. The biomechanical specifics of the foot involved in ambulation are extremely complex. In general, eversion and inversion occur about the subtalar and calcaneotarsal joints, whereas adduction-abduction and flexion-extension occur about the metatarsophalangeal and interphalangeal joints.
FIG. 269-1. Bony anatomy of the foot.

The body weight when standing is distributed about the heel to the rear and the five metatarsal heads to the front. The curved shape of the foot is held in position by three arches. The shape of the bones, the arrangement of the ligaments, and the tone of the muscles maintain the position of the arches. The plantar aponeurosis covers the sole of the foot and is a strong band of fascia that originates on the medial side of the calcaneum and fuses with the fibrous sheaths of the phalanges.

The blood supply of the foot comes from branches of the popliteal artery. The anterior tibial artery serves the dorsum of the foot, and its branch, the dorsalis pedis, can be palpated over the dorsum of the midfoot. Branches of the posterior tibial and the peroneal arteries serve the sole. The motor and sensory nerves of the foot include branches of both the femoral and sciatic nerves and include branches of the saphenous, sural (sensory), and deep and superficial peroneal nerves (both sensory and motor).

The essential parts of the anatomy of concern include, but are not limited to, the following. The first metatarsal bears twice the weight as any other metatarsal, and injuries to this bone require a more conservative approach. The blood supply to the foot is tenuous, and major fractures of the talus and subtalar dislocations are complicated by avascular necrosis. The base of the second metatarsal is the "keystone" of the Lisfranc complex, and any injury to this area has to be treated with caution.

EVALUATION

History

As with all injuries, it is important to obtain an adequate history. Many injuries to the foot are associated with significant forces or falls from a height, and other injuries have to be sought. Generally, most foot injuries are caused by direct or twisting forces. Twisting forces are associated with avulsion-type injuries and are generally more minor than the injuries caused by direct trauma. Previous injuries, general medical condition, and repetitive mechanisms are all important to elicit from the patient. Increasing inability to ambulate after an injury and increasing pain may be suggestive of a minor sprain or of an impending vascular catastrophe. Special care should be paid to puncture wounds. Consider the type of shoes worn, the possibility of a foreign body, and the potential of tetanus.

Physical Examination

Elevation of the foot and the application of ice at triage will facilitate the physical examination. The patient should be examined on a stretcher. Examination of the foot includes an ankle examination (see Chap. 268, "Ankle Injuries"). The foot should be inspected for any loss of skin integrity, for deformity, and finally for swelling and ecchymosis. Passive range of motion should be assessed and compared with the uninjured foot. Palpate the achilles tendon, the calcaneum, the dorsum of the midfoot, and then the metatarsals and phalanges. Pay special attention to the base of the fifth metatarsal and the area over the base of the second metatarsal. Actively move the various joints of the foot through their range of motion. Next, grasp two adjacent metatarsal heads and move them in opposite dorsiplantar directions. Finally, if the foregoing exam does not suggest a specific injury, observe the patient ambulating. Normal findings on examination and the ability to complete several weight transfers to the injured foot essentially excludes a significant injury.

IMAGING

Patients with normal findings on examination of the hindfoot and forefoot and on examination of the ankle and midfoot (see Fig. 268-2, the Ottawa Ankle Rules, from the previous chapter) probably do not need radiographs. Clinical judgment should always prevail in the decision-making process. Abnormal findings on examination mandate a complete, three-view, standard foot series. If there is pain about the heel, an axial view of the calcaneum should be added. The lateral view of the foot and

the axial view of the calcaneum are important in excluding hindfoot injuries, while the anteroposterior (AP) and oblique projections are more useful in delineating midfoot and forefoot injuries.

Other plain radiographic views, bone scans, and computed tomographic (CT) scans are seldom utilized by emergency physicians in the evaluation of foot injuries. Emergency physicians, however, should occasionally order comparison weight-bearing AP radiographs of the foot to exclude a subtle diastasis (greater than 1 mm) at the Lisfranc joint. The criteria for a normal radiograph are detailed in Fig. 269-2.[1]

FIG. 269-2. Normal radiographic anatomy of the Lisfranc joint.

INJURIES AND TREATMENT

Acute Soft Tissue Injuries

Puncture Wounds are discussed in Chap. 43. Complicated foot infections, gunshot wounds to the foot, and many lawn mower injuries require consultation and/or operative debridement.[3,4] The latter two open injuries require a careful search for associated vascular and tendon injuries, radiographs to document foreign-body presence and bony involvement, consideration of tetanus vaccine and immunoglobulin administration, aggressive wound irrigation, analgesics, and antibiotics in most cases. Do not rely on the presence of fever, abnormal radiographs, or elevated white cell counts and erythrocyte sedimentation rates to exclude the diagnosis of osteomyelitis.[2,5]

TURF TOE   Forced hyperextension of the the first metatarsophalangeal causes a sprain or tear of the joint capsule. The injury is usually associated with a push-off mechanism from a hard surface. The treatment is conservative, with analgesics and with a supportive shoe to prevent further dorsiflexion.

PLANTAR FASCIA RUPTURE   This is a tear in the plantar fascia at the point of insertion on the calcaneum. Patients describe a sudden pop and pain that is usually associated with sudden plantar flexion of the foot. Treatment is nonoperative.

TENDON RUPTURES   Acute ruptures of the tendons of the foot are rare and are usually associated with penetrating or lacerating injuries. Extensor and flexor hallucis tendon injuries are repaired primarily. The treatment of other tendon transections is controversial.

CRUSH INJURIES AND COMPARTMENT SYNDROME   Injuries caused by crush-type mechanisms without associated skin or bone injuries may appear innocuous. These injuries, however, place the foot at risk for the development of compartment syndrome. Compartment syndrome should be suspected when there is pain out of proportion to the injury. Typically, the foot is tensely swollen, and the pain is not relieved by elevation and is increased by passive dorsiflexion of the big toe. Paresthesias may be present, but pedal pulses and capillary refill are often preserved. If compartment syndrome is suspected, intracompartmental pressures must be measured. There are multiple compartments in the foot. The measure of pressure in these small compartments is technically difficult, and orthopedic consultation may be necessary to exclude this diagnosis. Immediate fasciotomy is required once the diagnosis is confirmed.

DIFFERENTIAL DIAGNOSIS OF SUBACUTE AND CHRONIC FOOT PAIN   Patients frequently present to the ED with the complaint of foot pain of varying duration. Although several disorders that cause pain are obvious on inspection, including bunions, ingrown toenails, corns, hammertoes and blisters, other problems require a directed physical examination of the foot. The diagnosis and treatment of these disorders is described in Table 269-1.

TABLE 269-1   Differential Diagnosis of Subacute and Chronic Foot Pain

Fractures and Dislocations

HINDFOOT   Talar fractures are uncommon. Minor avulsion fractures of the neck, body, and lateral process are usually treated with a posterior slab, crutches, and orthopedic follow-up. Os trigonum and transchondral talar dome fractures are difficult to identify in the ED and are sometimes diagnosed in the follow-up of "ankle sprains." Major fractures of the talar neck and body are associated with severe dorsiflexion and axial forces. These injuries often require open reduction and merit immediate orthopedic consultation. These fractures are frequently complicated by avascular necrosis.

Peritalar or subtalar dislocations are rare. In this injury, the calcaneotalar and talonavicular joints are disrupted while the tibiotalar joint remains intact. Although the dislocation can occur in any direction, medial dislocation is by far the most common and is the result of a severe rotational-inversion force. These injuries require immediate orthopedic consultation and emergent reduction. Closed reduction can sometimes be accomplished using conscious sedation in the ED, although frequently a general or regional anaesthetic in the operating room is required.

An axial load to the heel, caused by a fall from a height, is the mechanism associated with most fractures of the calcaneum. These injuries are frequently associated with other injuries, most commonly vertebral column, forearm, and other lower extremity fractures. Fractures should be categorized as intraarticular or extraarticular.

Although the more common subtalar, intraarticular fractures are usually obvious on the lateral foot radiograph, some compression fractures may be subtle. When this injury is suspected by mechanism or examination, carefully examine the radiograph utilizing the measurement of Boehler's angle. If the angle is less than 20°, suspect a fracture (Fig. 269-3). The criterion for open reduction of these fractures is controversial, with CT scanning playing an important diagnostic and preoperative planning role. Seek immediate orthopedic consultation. In the interim, apply a well-padded posterior splint, elevate the foot, and address analgesic needs.

Comminuted fractures of the calcaneum can be extremely painful. The incidence of compartment syndrome with these fractures is high.
FIG. 269-3. Boehler's angle is formed by two lines, one between the posterior tuberosity **(A)** and the apex of the posterior facet **(B)**, and the other between the apex of the posterior facet **(B)** and the apex of the anterior process **(C)**. An angle less than 20 degrees suggests a calcaneal compression fracture.

Extraarticular fractures are less common and usually are associated with a rotational mechanism as well as an axial load. Included are fractures of the tuberosity, the sustentaculum tali, anterior process avulsion, and extraarticular oblique body fractures. Most nondisplaced fractures can be treated conservatively with a posterior slab, crutches, and early orthopedic consultation.

MIDFOOT   Isolated fractures of the navicular, cuboid, and cuneiforms are uncommon and are difficult to identify on radiograph. Fractures of the navicular are most common and can involve the tuberosity, the dorsal surface, and the body. Isolated fractures of the cuboid and cuneiforms are extremely rare, and an associated injury to the Lisfranc joint should be sought. Most isolated injuries of the tarsal bones are treated conservatively.

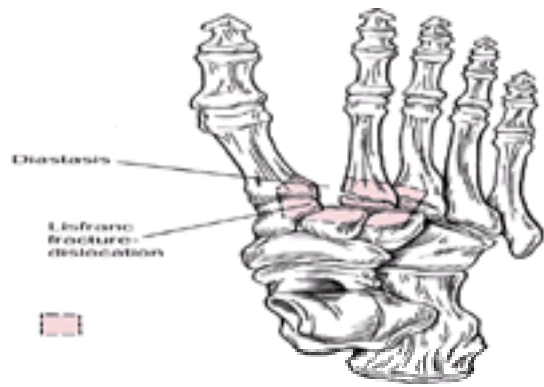
The six-bone tarsometatarsal complex is known as the Lisfranc joint. Injuries to this joint are not uncommon, and unfortunately up to 20 percent of these injuries are missed in the ED.[6] The force required and the mechanism of injury are varied and can range from a seemingly minor rotational force to severe axial load as seen in an automobile accident. The great majority of injuries to the Lisfranc joint are associated with fractures, usually of the metatarsals, the cuboid, or the cuneiforms. A fracture of the base of the second metatarsal is pathognomonic of a disruption of the ligamentous complex (Fig. 269-4). The Lisfranc injury is classified by the direction of the dislocation. A divergent dislocation describes metatarsals splayed in both medial and lateral directions, usually between the first and second metatarsals. In isolated dislocations, one or more metatarsals are displaced from the rest. In homolateral dislocations, all five metatarsals are displaced in the same direction, either laterally or medially. Suspect this injury if there is point tenderness over the midfoot or when there is laxity between the first and second metatarsals in a dorsal-plantar direction. Diagnosis is made radiographically on the AP view when there is more then a 1-mm gap between the bases of the first and second metatarsals. Weight-bearing radiographs may be required to make the diagnosis. Injuries to the Lisfranc joint frequently require open reduction and fixation or percutaneous placement of Kirschner wires and non-weight-bearing for several weeks. These injuries are complicated by pedal artery damage in the short term and degenerative arthritis and chronic pain in the long term.


FIG. 269-4. Fracture of the base of the second metatarsal.

FOREFOOT   Metatarsal fractures are most often associated with a crush or more occasionally with a twisting injury. Metatarsal fractures are divided into shaft and neck fractures. Nondisplaced shaft injuries are usually treated conservatively with either a walking cast or an orthopedic shoe. An exception is a fracture of the first metatarsal shaft. Keep this injury non-weight-bearing. Likewise, displaced shaft fractures of the middle metatarsals can be treated with closed reduction, followed by immobilization in a cast and non-weight-bearing for 6 weeks. A displaced first metatarsal fracture will often require an open reduction and fixation. Metatarsal neck fractures generally follow the treatment of shaft fractures, but postreduction instability of displaced neck fractures is not uncommon and open fixation is sometimes required.

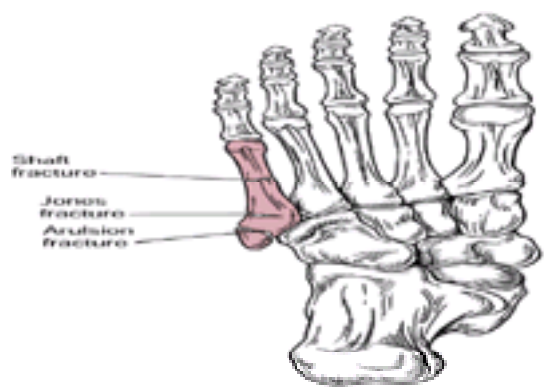
Fifth metatarsal fractures are the most common of the metatarsal fractures. Shaft fractures usually can be treated conservatively, as above. The Jones fracture is described as a transverse fracture through the base of the fifth metatarsal 15 to 31 mm distal to the proximal part of the metatarsal. This fracture is frequently complicated by nonunion or malunion and should be treated with a non-weight-bearing cast for 6 weeks. The "pseudo-Jones" is an avulsion fracture of the tuberosity of the base and can be treated with a cast shoe. (Fig. 269-5).


FIG. 269-5. Fractures of the fifth metatarsal.

Most nondisplaced phalangeal fractures can be treated conservatively with "buddy taping" and, occasionally, a cast shoe. Address the patient's analgesic need and arrange orthopedic consultation on a prn basis. Advise against prolonged ambulation or standing in the first week. Displaced fractures can be manipulated into position by using a digital block and manual traction. Some authors advocate open reduction of some displaced fractures, especially of the big toe.

Most dislocations of the forefoot involve the the distal interphalangeal and posterior interphalangeal joints of the second through fifth toes. These injuries can be

easily reduced by manual traction and treated with buddy taping as needed. Dislocations of the big toe are rare, occasionally difficult to reduce, and require walking-cast immobilization for 3 weeks.

OPEN FRACTURES   Open fractures of the foot require immediate orthopedic consultation. In the interim, protect open fractures from further contamination by applying a wet, sterile dressing over the wound with a gauze roll. Splint the injury until definitive treatment is available. Consider tetanus immunoglobulin if the wound is grossly contaminated. The antibiotic of choice is cephalexin, and add an aminoglycoside if the wound is grossly contaminated. Consider clindamycin for patients with a penicillin allergy. If there is going to be a significant delay to operative management, the wound should be irrigated.

PEDIATRIC INJURIES

Fractures of the foot are rare in children, presumably due to the flexibility of the immature bone and cartilage. Comparison radiographs may be of some benefit in the evaluation of these injuries. Generally, most fractures occur in the metatarsals, and these injuries are usually treated conservatively. Orthopedic consultation can be deferred, with the exception of injuries to the first metatarsal, and complications are usually minimal. Fractures of the calcaneum, talus, tarsals, and phalanges are rare. Injuries to the base of the second metatarsal suggest that a significant injury has occurred, and immediate orthopedic consultation is required. Crush injuries of the pediatric foot should be treated with care; compartment syndrome is more common in children than adults, even without fracture. [7]

TIMING OF CONSULTATION

Like ankle injuries, no set of rigid rules for the timing of orthopedic consultation exists to guide emergency physicians for each specific foot injury. In   Table 269-2   a general guideline is set forth. Timing of consultation will vary with local preferences.

Immediate Consultation in Emergency Department	Deferred Consultation*	Within 1 Week	Prn to Note
All open fractures	Extraarticular calcaneus fractures	Avulsion fractures calcaneus	Pseudo-Jones fracture
All fracture-dislocations	First metatarsal fractures	Avulsion fractures tarsal	Phalangeal fractures
Major talar neck and body fractures†	Displaced metatarsal shaft	Metatarsal fractures	Phalangeal dislocations
Intraarticular calcaneus fractures†	True Jones fractures	Pediatric metatarsal fractures	Soft tissue injuries
All Lisfranc injuries†	Tendon ruptures and lacerations	Ruptured plantar fascia	
Most puncture wounds	Retained foreign bodies		
Suspected compartment syndrome			

* Implies that communication is established at time of diagnosis and that the specific time of consultation has been set.
† Consultation can be delayed in the emergency department in fractures without neurovascular compromise and with synergistic splinting.

TABLE 269-2   Timing of Consultation for Foot Injuries

EMERGENCY DEPARTMENT TREATMENT ISSUES

Analgesia

The need for analgesia should always be addressed by the emergency physician. As individual perception of pain varies, a fifth metatarsal tuberosity fracture may require acetaminophen and a cast shoe in most patients, whereas others will require hydrocodone or oxycodone with acetominophen. Patients who are in significant distress, or who should be kept NPO because of anticipated surgery, require parenteral analgesia.

Immobilization

Most fractures of the foot can be splinted by a posterior slab or a Jones bandage (the appropriate method of application is discussed in   Chapter 268, "Ankle Injuries"). Cast shoes, variably called orthopedic, Reece, or post-op shoes, are useful in splinting minor foot fractures when the patient is allowed to bear weight on the injured extremity. Cast shoes can also be applied over a posterior splint to allow weight bearing. Apply an appropriately sized piece of felt or cotton padding between the two phalanges when they are being buddy taped.

Cryotherapy

Ice packs have been shown to limit swelling and decrease pain. [8]

270 COMPARTMENT SYNDROMES

Ernest Ruiz

Compartment syndromes are serious and often insidious problems that must be considered in the emergency department (ED) on a frequent basis. The incidence of compartment syndromes overall is unknown, but the conditions that can cause it are myriad and common. Early diagnosis and treatment are curative, whereas delay results in permanent and severe disability. An understanding of the pathophysiology and the early signs of the process is crucial if an emergency physician is to intercede appropriately. Compartment syndromes occurring in the limbs are the subject of this chapter.

PATHOPHYSIOLOGY

Compartment syndromes are due to increased pressure within closed tissue spaces that compromises the flow of blood through nutrient capillaries in muscles and nerves. The complex relationships between time, Starling forces, systemic and venous pressure, and reperfusion injury are not completely understood. The clinical variables of each case make a definitive explanation of how capillary blood flow is compromised a difficult exercise. However, a common factor is elevated tissue pressure. Normal tissue pressure is about zero and usually less than 10 mmHg. Capillary blood flow within the compartment is compromised at pressures greater than about 20 mmHg, and muscle and nerves are at risk for ischemic necrosis at pressures greater than about 30 to 40 mmHg. Of the tissues within the compartments, nerve is most sensitive, followed by muscle tissue. Blood flow through arteries, arterioles, and collaterals is not compromised significantly at these pressures. Nevertheless, tissues within the compartment that are dependent on the nutrient capillaries become ischemic and then necrotic if the compartment pressure is not reduced promptly. By the time that distal pulses are reduced, muscle necrosis has occurred. Ischemic muscles hurt, and this pain is exacerbated by active muscle contraction and by passive stretching of the muscle.

An increase in compartmental pressure can be caused by (1) compression of the compartment, for example, by burn eschar, a circumferential cast, or a pneumatic pressure garment; and (2) by a volume increase within the compartment due to hematoma and edema. Direct trauma with resulting bleeding and edema is probably the most common cause, but overexertion (shin splints) and limb compression during recumbency as a result of alcohol or drug overdose are also common causes. Mubarak and Hargens[1] developed a classification of the acute compartment syndromes (Table 270-1) listing the myriad of possible causes. Their text is highly recommended for readers wishing to learn more about this topic.

TABLE 270-1   Classification of Acute Compartment Syndromes

COMPARTMENTS AT RISK

Virtually any muscle mass invested in fascia is at risk, given the right conditions.

Upper Extremity

The upper arm has an anterior and a posterior compartment. The anterior compartment contains the biceps-brachialis muscle and the ulnar, median, and radial nerves (Fig. 270-1). The posterior compartment contains the triceps muscle. Fortunately, the compartments of the upper arm are relatively roomy, and compartment syndromes are uncommon in this location. The forearm has volar and dorsal compartments that are further subdivided into smaller compartments by investing fascia at mid-forearm (Fig. 270-2). The volar compartment contains wrist and finger flexors, and the dorsal compartment contains wrist and finger extenders. The hand has thenar and hypothenar compartments, containing the intrinsic muscles of the thumb and little finger, respectively. The interosseous muscles of the hand are contained in their own compartments (Fig. 270-3).

FIG. 270-1. The biceps-brachialis (anterior) and triceps (posterior) compartments of the right arm.

FIG. 270-2. Forearm compartments: transverse sections through the right forearm at various levels.

FIG. 270-3. Hand compartments: transverse section through the right hand.

Lower Extremity

There are three gluteal compartments of the buttocks. One contains the tensor muscle of the fascia lata, another the gluteus medius and minimus, and the third the gluteus maximus. The sciatic nerve lies adjacent to the gluteus maximus and can be compressed by it.

The thigh has three compartments: the anterior, medial, and posterior. The anterior compartment contains the vastus lateralis, the vastus intermedius, and the vastus medialis muscles, as well as the sartorius and rectus femoris muscles. The femoral artery and nerve also traverse the anterior thigh compartment. The medial compartment contains the adductor longus, the adductor brevis, and the adductor magnus muscles, plus the gracilis muscle. The posterior compartment contains the semimembranosus, the semitendinosus, and the biceps femoris muscles. The sciatic nerve also traverses the posterior compartment.

The leg has four compartments (Fig. 270-4). The anterior compartment, the compartment most frequently involved by this syndrome, contains the tibialis anterior muscle and the extensor muscles of the toes—the extensor hallucis longus and the extensor digitorum longus muscles. The anterior tibial artery and the deep peroneal nerve are also located in this compartment. The lateral compartment, which is frequently involved when the anterior compartment is involved, contains the peroneous longus and brevis muscles, as well as the superficial peroneal nerve. The deep posterior compartment contains the tibialis posterior muscle, the flexor digitorum longus muscle, and the flexor hallucis longus muscle. It also contains the posterior tibial artery and the tibial nerve. The superficial posterior compartment contains the gastrocnemius muscle, the soleus muscle, and the sural nerve.

FIG. 270-4. The four compartments of the leg.

DIAGNOSIS

The history, including mechanism of injury, is very important, since many patients at risk for the syndrome are severely ill or injured and cannot relate whether they are experiencing pain. Palpation of the compartments in question may or may not reveal tenseness and swelling; when in doubt, the resuscitating physician should measure tissue pressure.

Alert and intact patients will virtually always relate that they are experiencing severe and constant pain over the involved compartment. Palpation of the compartment will also elicit pain. Active contraction of the involved muscles will increase the pain, as will passive stretching of the muscles (Table 270-2). Hypoesthesia resulting from compromise of nerves traversing the involved compartment appears at about the same time as muscle weakness and pain.

TABLE 270-2   Symptomatology of Acute Compartment Syndromes

Possible compartment syndromes associated with injuries such as fractures or penetrating wounds should prompt an immediate surgical consultation, since the presence of a compartment syndrome may influence subsequent treatment choices.

Pressure Measurement

In patients without a clear need for surgical consultation, measuring the compartment pressures in the ED assures safe patient disposition and management. Compartment pressure can be quickly and easily measured using a commercially available battery-powered monitor [Stryker STIC Monitor (Stryker Instruments, Kalamazoo, MI) or Ace Intracompartmental Pressure Monitor (Ace Medical Company, Los Angeles, CA)] that has a self-contained pressure transducer and readout. Compartment pressure is measured after careful aseptic preparation, insertion of the side-ported 18-guage needle into the compartment, and injection of a small volume of sterile saline while keeping the apparatus level. There is a brief overshoot as resistance to flow and inertia is overcome, but within a second of time a plateau of pressure will be reached that is the compartment pressure in mmHg. Always check the accuracy of the transducer by filling the needle and transducer with saline and holding it level and open to the atmosphere. It should read zero. Measure the pressure twice, whether normal or high, to assure that the needle had not become lodged in fibrous tissue.

When an electronic pressure transducer and monitor, as is used for vascular pressure measurement, are available, they can be used as follows: (1) Attach a short length of intravenous (IV) extension tubing to a stopcock and then to a pressure transducer. (2) Fill the transducer and tubing with sterile saline. Adjust the height of the transducer to the level of the compartment in question. Zero the transducer with the tubing open to the atmosphere at the level of the compartment. (3) After antiseptic skin preparation, fill a 16-gauge catheter over needle with sterile saline. Insert it into the compartment and remove the metallic needle. Attach the IV tubing to the catheter. (4) Inject a small quantity (less than 1 mL) of saline through the transducer and into the compartment while observing the monitor. A small overshoot will be seen and then the pressure will plateau at true compartment pressure. Wilson and colleagues [2] found this system as accurate as the Stryker device. Uppal and coworkers[3] describe a system that uses the Intravenous Alarm Control (IVAC) pump as a monitor. EDs that use the IVAC pump may wish to study his report.

The technique of Whitesides and colleagues [4] for compartment pressure measurement had the advantage of requiring only basic materials available in every ED. Unfortunately, the required three-way stopcock is now hard to find, having been replaced by two-way stopcocks for most applications. Electronic pressure transducers have become standard pieces of equipment in the ED and are easier to use. However, those anticipating situations lacking electronic monitoring should obtain the supplies and be familiar with the Whitesides method. This requires a 20-mL syringe, a three-way stopcock, two IV extension tubes, a Luer male blood pressure cuff adaptor, a bedside mercury manometer, a small bottle of sterile saline, and an 18-gauge needle. Assemble the apparatus as shown in Fig. 270-5. The bottle of saline is vented with an 18-gauge needle, and the needle on the apparatus is then inserted into the saline and saline withdrawn until the IV extension is half-filled. When removing the needle from the saline bottle, it is important to avoid getting any air in the needle. The needle is then placed in the compartment and the apparatus kept at the level of the needle and the stopcock turned so that it is open in all three directions. Two people are required for this test. One watches the manometer while the other slowly and gently depresses the plunger in the syringe while watching the saline meniscus. When the meniscus moves toward the patient, the operator notifies the manometer watcher, who notes the reading at that instant. In this way, only a minute amount of saline is injected into the compartment. As with the other methods, measure the pressure twice.
FIG. 270-5. The Whitesides method. Tissue pressure is measured by determining the amount of pressure with this closed system that is required to overcome the pressure within the closed compartment while injecting only a minute quantity of saline.

Measure the patient's systolic and diastolic systemic pressure during the time that compartment pressure is measured, as some surgeons use the mean arterial pressure[5] or diastolic pressure[4] in combination with compartment pressure to decide when emergency fasciotomy is needed. Other surgeons prefer to operate on clinical grounds only. In general, a compartment pressure of 35 to 40 mmHg is considered grounds for emergency fasciotomy.

Needle Placement

In general, the needle is placed where the patient describes the most pain or in the location that is most tense to palpation on examination. If the compartment in question is in a deep position or is small, as in the intrinsic muscle compartments of the hand, many surgeons will opt to operate on purely clinical grounds. The forearm is another region that can be difficult because of nervous and vascular structures in the midst of muscle bellys and numerous fascial septa. An accepted technique when the patient has a forearm fracture is to make volar and dorsal punctures adjacent to the fracture, at the carpal tunnel, and a volar puncture proximal to the fracture.[6] Of course, surgical consultation would be in order. The deep posterior compartment of the leg is reached by inserting the needle behind the medial surface of the tibia and directing it horizontally to the center of the leg.

Complications

Injecting too much saline into the compartment can result in false high readings. Inserting the needle into an artery or vein in a hypocoagulable patient can result in the development of a compartment syndrome. Injecting air into the tissues can confuse x-ray interpretation, adding open fracture and gas-forming organism infection to the differential diagnosis.

MANAGEMENT

Compartment pressures between 15 and 20 mmHg are problematic. If the problem is acute and the patient is reliable, the patient can be told to return for repeat measurement if symptoms do not improve. A pressure of 20 mmHg can be damaging if it persists for several hours; therefore, admission or surgical consultation will be needed for unreliable patients. Pressures greater than 20 mmHg demand admission and surgical consultation. A pressure of 30 to 40 mmHg is generally considered grounds for emergent fasciotomy in the operating room. Fasciotomy is accomplished by making a longitudinal skin incision over the compartment. The underlying fascia is then split the length of the compartment, allowing the contained muscle to expand. Do not recommend ice cooling, because muscle perfusion may be decreased by it. Do not recommend elevation of the limb, because the resulting decrease in arterial perfusion pressure may also decrease muscle perfusion. Bed rest would provide the best chances for improvement when conservative management seems to be in order.

Francis L. Counselman

Rhabdomyolysis was first described in the Book of Numbers in the Old Testament. During the flight from Egypt, a number of Israelites experienced symptoms of rhabdomyolysis after eating hemlock-seed-fed quail.[1] In the early 1900s, the clinical syndrome of muscle pain, weakness, and dark urine became known as Meyer-Betz disease.[2] In the 1940s, Bywaters and Beall described acute renal failure as a complication of rhabdomyolysis observed in Londoners suffering from crush injuries during the German blitz.[3] Today, we realize rhabdomyolysis is a complication of a variety of disease processes and injury.

PATHOPHYSIOLOGY

Rhabdomyolysis is a syndrome characterized by injury to skeletal muscle with subsequent release of intracellular contents. These contents include myoglobin, creatine phosphokinase (CPK), aldolase, lactate dehydrogenase (LDH), serum glutamic-oxaloacetic transaminase, and potassium. Although numerous causes of rhabdomyolysis have been described, the common terminal event appears to involve the disruption of the Na^+,K^+-ATPase pump and calcium transport, resulting in increased intracellular calcium and subsequent muscle cell necrosis.

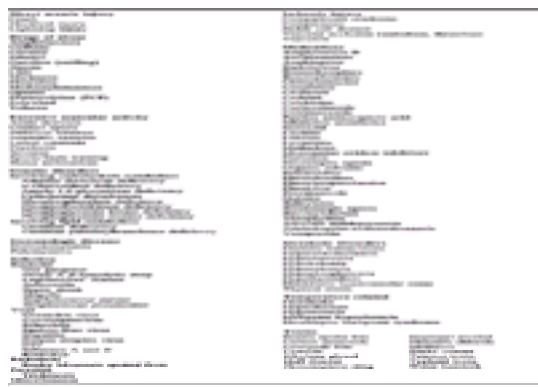
Several classifications systems have been developed to characterize the numerous causes of rhabdomyolysis. None of these systems are universally recognized, and each has its own limitations. In addition, many patients have multiple causes of rhabdomyolysis (e.g., alcohol abuse and hypokalemia). Table 271-1 lists the various causes. In general, the most common causes of rhabdomyolysis appear to be alcohol and drug abuse, toxin ingestion, trauma, infection, strenuous physical activity, and heat-related illness.


TABLE 271-1   Causes of Rhabdomyolysis

Consider hereditary causes in patients with a history of recurrent rhabdomyolysis and exercise intolerance. Patients in coma are at risk for development of rhabdomyolysis due to immobility from unrelieved pressure upon gravity-dependent body parts. In one study, the most common positions leading to rhabdomyolysis were the lateral decubitus, lithotomy, sitting, knee-chest, and prone positions.[4] Alcohol consumption can result in rhabdomyolysis secondary to coma-induced muscle compression and a direct toxic effect. Nutritional compromise and hypophosphatemia, both common in alcoholics, increase the risk of rhabdomyolysis. Alcohol is considered to be a causative or contributory factor in approximately 20 percent of all cases of rhabdomyolysis.[5] Drugs of abuse that have commonly been implicated in acute rhabomyolysis include cocaine, amphetamines, LSD, heroin, and phencyclidine (PCP). Common medications associated with the development of rhabdomyolysis include diuretics, narcotics, theophylline, corticosteroids, benzodiazepines, phenothiazines, and tricyclic antidepressants.

Viral and bacterial infections have been known to cause rhabdomyolysis. Strenuous physical activity, as seen in athletes, military recruits, and outdoor laborers, is a common cause of rhabdomyolysis. Factors that further increase the risk in this group of patients include poor physical conditioning, inadequate fluid intake, high ambient temperatures, and high humidity levels.[6]

CLINICAL FEATURES

The presenting symptoms of rhabdomyolysis are usually acute in onset and include myalgias, stiffness, weakness, malaise, low-grade fever, and dark (usually brown) urine. Symptoms relating to the musculoskeletal system, however, may be present in only 271 percent of cases.[7] Nausea, vomiting, abdominal pain, and tachycardia can occur in severe rhabdomyolysis. On occasion, mental-status changes are present secondary to urea induced encephalopathy. Swelling and tenderness of the involved muscle groups and hemorrhagic discoloration of overlying skin may be observed, but only in a minority of cases. Muscle swelling may not become apparent until after rehydration with intravenous (IV) fluids. The muscle groups involved may be localized or diffuse, depending on the etiology. Commonly, the postural muscles of the thighs, calves, and the lower back are involved. An important point to remember is that acute rhabdomyolysis may be present without any of these signs or symptoms, and the patient may have essentially normal findings on physical examination. For this reason, the diagnosis is often made only after soliciting a historical clue (e.g., recent cocaine use) or finding an elevated serum CPK or the presence of myoglobinuria on routine laboratory testing.

DIAGNOSIS

An elevated serum CPK level is the most sensitive and reliable indicator of muscle injury. The degree of CPK elevation correlates with the amount of muscle injury and the severity of illness, but not the development of renal failure or other morbidity. Most authors require a fivefold or greater increase in serum CPK, without cardiac or brain injury, as the requirement for making the diagnosis of rhabdomyolysis. In general, serum CPK begins to rise approximately 2 to 12 h after the onset of muscle injury, peaks in 24 to 72 h, and then declines at the relatively constant rate of 39 percent of the previous day's value. Ongoing muscle necrosis should be suspected in patients with elevated CPK values that fail to decrease in this manner. The isoenzyme CPK-MM (found in skeletal and cardiac muscle) is responsible for the majority of the elevation in serum CPK. The CPK-MB fraction (found primarily in cardiac, but also skeletal, muscle) may also be elevated, but should not exceed 5 percent of the total CPK level.

Myoglobin is an oxygen-binding protein found in skeletal and cardiac muscle and involved in oxidative metabolism. Myoglobin elevation occurs before CPK elevation following muscle injury and then is rapidly cleared from the plasma through renal excretion and metabolism to bilirubin. Myoglobin enters the urine when the plasma concentration exceeds 1.5 mg/dL and causes the typical reddish brown discoloration when urine myoglobin exceeds 100 mg/dL.[7] Since myoglobin contains heme, qualitative tests such as the dipstick (utilizing the orthotoluidine reaction) does not differentiate between hemoglobin and myoglobin. Therefore, suspect myoglobinuria when the urine dipstick is positive for blood, but no red blood cells are present on microscopic examination. Radioimmunoassay is only slightly more sensitive than the dipstick technique in identifying myoglobinuria, but usually not necessary. Since myoglobin levels may return to normal within 1 to 6 h after the onset of muscle necrosis, the absence of an elevated serum myoglobin or the absence of myoglobinuria does not exclude the diagnosis. In one study, 26 percent of patients with

rhabdomyolysis did not have myoglobinuria. [7]

Other laboratory studies may be useful to identify the common complications of rhabdomyolysis, as well as the underlying etiology. Electrolytes, calcium, phosphorus, and uric acid levels should be determined in order to identify hyperkalemia, abnormal calcium and phosphorus levels, and hyperuricemia. A urinalysis should be performed on all patients. Serum creatinine and blood urea nitrogen (BUN) are useful as a baseline and to identify acute renal failure. Since disseminated intravascular coagulation (DIC) is a complication, all patients suspected of rhabdomyolysis should have a baseline CBC and DIC screen (e.g., prothrombin time, partial thromboplastin time, fibrin split products, and fibrinogen). Other common laboratory findings in rhabdomyolysis include elevated levels of aldolase, LDH, urea, creatine, and aminotransferases. Magnetic resonance imaging (MRI) has recently been shown to be highly effective in localizing rhabdomyolysis and is more sensitive than computed tomography or ultrasound in detecting abnormal muscle. [8] The high intensity lesions on T2-weighted MRI are most likely due to edema and inflammation of the muscles, rather than to permanent histologic changes. [9] Further laboratory testing to identify the underlying cause(s) of rhabdomyolysis should be based on the medical history and clinical presentation.

COMPLICATIONS

The complications of rhabdomyolysis include acute renal failure (ARF), metabolic derangements, DIC, and mechanical complications (e.g., compartment syndrome or peripheral neuropathy) (see Table 271-2). ARF is the most serious complication of rhabdomyolysis. Although rhabdomyolysis is thought to account for 5 to 8 percent of all cases of ARF, [10] the incidence of this complication in rhabdomyolysis is less clear. It is estimated that between 0 [11] and 271 percent [12] of patients with rhabdomyolysis develop ARF, with 33 percent the most often quoted figure. [7] This wide range probably reflects the multifactorial etiology necessary for the development of ARF. Factors known to contribute to rhabdomyolysis-induced ARF include hypovolemia, acidosis/aciduria, tubular obstruction, and the nephrotoxic effects of myoglobin. Renal tubular obstruction occurs secondary to precipitation of uric acid and myoglobin. Ferrihemate, the breakdown product of myoglobin, is responsible for the direct toxic effect on the kidneys. This effect, however, appears to occur only in the presence of hypovolemia and aciduria (pH < 5.6). The ARF may be oliguric (most common) or nonoliguric. The need for dialysis, serum potassium and calcium levels, and mortality rates appear to be similar for both rhabdomyolysis-induced ARF and non-rhabdomyolysis-induced ARF. Patients with rhabdomyolysis-induced ARF, however, do have higher serum uric acid and anion gap levels. [7] Neither the presence of myoglobinuria nor the degree of CPK elevation is predictive of which patients are at risk for developing ARF.

Acute renal failure

Metabolic derangements
   Hypercalcemia (late)
   Hyperkalemia
   Hyperphosphatemia
   Hyperuricemia
   Hypocalcemia
   Hypophosphatemia (late)

Disseminated intravascular coagulation

Mechanical complications
   Compartment syndrome
   Peripheral neuropathy

TABLE 271-2   Complications of Rhabdomyolysis

The serum potassium level is elevated in 10 to 40 percent of cases, due to release of potassium from injured skeletal muscle. [7,13] Renal function, however, appears to be the most important determinant of the degree of elevation. Hyperkalemia can be a significant complication of rhabdomyolysis if acute renal failure occurs.

Elevated uric acid levels can occur, especially in crush injures, due to release of muscle adenosine nucleotides and subsequent conversion to uric acid by the liver. Uric acid levels usually correlate with serum CPK levels.

Initially in rhabdomyolysis, serum phosphorus levels may be elevated, due its leakage from injured muscle. Later in the disease course, mild hypophosphatemia may be seen, but rarely requires treatment. Hypocalcemia, the most common metabolic complication, occurs early in rhabdomyolysis and is usually asymptomatic. It has been attributed to the deposition of calcium salts in necrotic muscle, due to the hyperphosphatemia and decreased levels of 1,25-dihydroxycholecalciferol. These soft tissue calcifications can sometimes be observed on x-ray of the involved limb muscles. The hypocalcemia can occur, however, without elevated levels of phosphorus. Later, as calcium is mobilized from damaged muscle, serum calcium levels rise and symptomatic hypercalcemia may be observed.

Disseminated intravascular coagulation occurs in severe rhabdomyolysis and can result in hemorrhagic complications. The DIC usually resolves spontaneously within several days.

The mechanical complications of rhabdomyolysis consist of compartment syndrome and peripheral nerve injury. Compartment syndrome occurs secondary to marked swelling and edema of the involved muscle groups. This swelling will often not occur until after IV hydration. Characteristic signs and symptoms include pain, parasthesias, paralysis, pallor, and pulselessness. Of these, a sensory deficit is the most reliable physical finding. [14] If the intracompartmental pressures exceed 30 to 35 mmHg, fasciotomy is recommended. The associated muscle swelling may also cause pressure on peripheral nerves, resulting in neuronal ischemia and causing parasthesias or paralysis. Nerve injury is often proximal, and multiple nerves may be involved in the same extremity. [15] These peripheral neuropathies usually resolve within a few days or weeks, though, in a minority of patients, they can be permanent.

TREATMENT

Prehospital Care

For victims of crush injury, or patients strongly suspected of having rhabdomyolysis and prolonged extrication/transport times, IV rehydration with normal saline should be initiated as soon as possible. In one small series, aggressive infusion of crystalloids at a rate of approximately 1.5 L/h helped prevent the development of ARF in seven crush-injury victims. [16] The addition of sodium bicarbonate to each liter of crystalloid may be considered, but there are no controlled studies in the preshospital setting to confirm its benefit.

Emergency Department

Once in the emergency department, aggressive IV rehydration remains the mainstay of therapy. This should be continued for the first 24 to 72 h. Curry and colleagues recommend rapid correction of the fluid deficit with IV crystalloids followed by infusion of 2.5 (mL/kg)/h, with the goal of maintaining a minimum urine output of 2 (mL/kg)/h. [10] Others recommend a goal of 200 to 300 mL of urine output each hour. Sodium bicarbonate, 44 to 271 meq added to each liter of normal saline, or 1 mmol/kg administered as an IV bolus, has been recommended to maintain a urine pH of 6.5 or above to prevent the development of ARF. [10,16] Alkalinization is not without risks, however, since it can exacerbate the hypocalcemia observed in rhabdomyolysis.

To assist in diuresis, 20% mannitol is commonly recommended, although there are no prospective studies on its benefit. This may given as a single 1g/kg IV dose over 30 min, [10] or as 25 g IV initially, followed by 5 g/h IV, for a total of 120 g/day. Mannitol should only be given after volume replacement and avoided in patients with oliguria or with other causes of potential hypertension. Intravenous furosemide (40 to 200 mg) has also been used to assist in maintaining an adequate urine output following IV hydration. [13] Despite appropriate treatment however, dialysis may be necessary to treat rhabdomyolysis-induced ARF.

All patients should have a Foley catheter placed to monitor urine output. Patients should be placed on a cardiac monitor because of the risk of dysrhythmias secondary to metabolic complications. For patients with heart disease, comorbid conditions, or preexisting renal disease, or for elderly patients, hemodynamic monitoring may be necessary to avoid fluid overload. Serial measurements of urine pH, arterial pH, electrolytes, CPK, calcium, phosphorus, BUN, and creatinine

should be performed.

Hypocalcemia observed early in rhabdomyolysis usually requires no treatment. Calcium should only be given to treat hyperkalemia-induced cardiotoxicity or profound signs and symptoms of hypocalcemia. Hypercalcemia, on the other hand, is frequently symptomatic and normally responds to saline diuresis and IV furosemide. Hyperphosphatemia should be treated with oral phosphate binders when serum levels exceed 7 mg/dL. Similarly, the hypophosphatemia, which may occur late in rhabdomyolysis, only requires treatment when the serum level is less than 1 mg/dL. Hyperkalemia, which is usually most severe in the first 12 to 36 h following muscle injury, can be significant when associated with ARF. Treatment should be initiated to prevent cardiac complications. Traditional insulin and glucose therapy, though recommended, may not be as effective in rhabdomyolysis-induced hyperkalemia. The use of ion-exchange resins (e.g., sodium polystyrene sulfonate) is effective, as is dialysis.

Finally, avoid the use of prostaglandin inhibitors such as nonsteroidal anti-inflammatory agents because of their vasoconstrictive effects on the kidney. Most importantly, treat the underlying etiology of the rhabdomyolysis.

DISPOSITION

All patients with suspected rhabdomyolysis require admission for IV hydration, diuresis, management of complications, and treatment of the underlying etiology. For at least the initial 24 to 48 h, these patients should probably be admitted to a monitored bed to identify dysrhythmias secondary to the metabolic complications. The nephrology service should be consulted to evaluate the need for dialysis for all patients presenting with ARF or symptomatic hyperkalemia unresponsive to therapy.

Orthopedic surgery is unique in its abundant use of implants to reconstruct the musculoskeletal system. Implants may be used to replace a degenerated structure or simply to stabilize a bone or ligament while it heals. The goal is a painless, functioning spine or extremity. Implants are used in fractures, arthrodesis, arthroplasty, and ligament fixation.

This chapter reviews the common types of orthopedic implants. Postoperative complications that may be seen in an emergency department following implant use, including breakage, migration, and infection, are discussed.

COMMON ORTHOPEDIC IMPLANTS STABILIZING BONE TO BONE

Plates and Screws

Plates and their accompanying screws are commonly used to add stability while fractures, osteotomies, or arthrodeses fuse. They come in many different shapes and sizes because they have been designed to fit different areas of the skeleton. They all share the common function of stabilizing bone in an anatomically acceptable position while it heals to itself. To perform this function, the plate must be securely attached to bone with multiple screws to each fragment. When this method is used to manage fractures, the bones are placed in direct contact, and healing occurs without the large amount of callus formation seen with casting or intramedullary nailing (Fig. 272-1). Therefore, it is often difficult to determine when fracture union is complete, and it is not uncommon for the fracture line to be visible more than 1 year after surgery (Fig. 272-2).
FIG. 272-1. A. This clavicle fracture was rigidly fixed with a plate and screws. **B.** Note that the fracture is healing without significant callus formation.

FIG. 272-2. This femur fracture is rigidly healed at 1 year, but the fracture line (*arrow*) is still present.

COMPLICATIONS   Early complications include wound infections, either superficial and amenable to antibiotics or deep and requiring surgical débridement. Later complications include nonunion of the fracture. Plate-screw constructs are simply temporizing measures. If the bone does not heal, the plate will eventually bend or break or the screws will pull out of the bone (Fig. 272-3). Plates and screws are sometimes removed, and the bone is then at risk for refracture (often through a screw hole) for approximately 7 months.

FIG. 272-3. A. This severely comminuted, open distal femur fracture was fixed with a plate and screws. **B.** Despite bone grafting, the screws broke before the fracture healed.

Intramedullary Rods

Since their popularization during World War II, solid, single intramedullary rods have become the most common method of treating femoral and tibial fractures and, more recently, some humeral fractures (Fig. 272-4). They have also been used to stabilize osteotomies or arthrodeses. Over the last decade their application to fractures has been extended by the addition of proximal and distal interlocking screws that add rotational stability. Over the past 5 years open fractures have been treated with intramedullary nails that are placed with minimal reaming of the bones. All these advances have led to the greater number of emergency patients who have intramedullary rods or nails.

FIG. 272-4. This femur fracture was stabilized with an intramedullary rod.

Intramedullary rods are placed through an incision at the end of the bone, avoiding the joint surface. The intramedullary canal is then mechanically reamed to a slightly larger size than the nail. The nail is then inserted, and interlocking screws are added if needed for stability at the fracture or osteotomy. The immobilization of the fracture is less than that gained with plates and screws, and therefore the healing process involves visible callus formation at the fracture site (Fig. 272-5). In open fractures, minimal or no reaming, which retains the maximum blood supply to the injury, may be performed and requires a smaller-diameter rod. Although less popular today than single, solid rods, multiple, small, flexible rods are still sometimes used to gain fracture stability (see Fig. 272-6).

FIG. 272-5. Note the large callus formation at the fracture site.
FIG. 272-6. These Ender rods were chosen to stabilize this open tibia fracture.

COMPLICATIONS As with all surgery, infection is the most worrisome early complication and still occurs with a 1 to 2 percent incidence in closed fractures despite the use of perioperative antibiotics. Unreamed nails are commonly used for open fractures and have up to a 25 percent infection rate. The number of emergency department encounters for postoperative infectious complications will increase. Due to their central location, rods have a greater mechanical strength than plates and screws. They, however, will also fail (usually after 1 year) by breaking at an unhealed facture site (Fig. 272-7). With weight bearing, the interlocking screws may break, often without loss of fracture stability. Any noninterlocked nail may work its way back out of the bone and irritate surrounding soft tissue. Femoral rods may then cause trochanteric bursitis. The multiple, small, flexible rods are notorious for this problem and often become palpable under the skin (Fig. 272-8). Nonunion of the fracture occurs more frequently with open fractures, and therefore the small unreamed nails used for these fractures are at risk for breakage.
FIG. 272-7. This distal femoral intramedullary nail broke before fracture union occurred.
FIG. 272-8. The Ender rods have "backed out" of the bone and were prominent just under the skin.

External Fixators

External fixators have been widely used to stabilize open fractures. A fixator is preferred over cast immobilization because it allows the physician access to the soft-tissue injury. External fixators also may be used to temporarily stabilize an extremity while life- or limb-threatening surgery is performed. Certain types of closed fractures, such as distal radius fractures, may require an external fixator to maintain an adequate reduction of the fracture.

Nontraumatic uses of external fixators include stabilization of arthrodeses; special clamps may be used to add compression that enhances union. More recently, complex wire and ring (Ilizarov) fixators have been used to lengthen bones and correct deformities.

The external fixator is divided into two components: the fixation pins or wires and the external frame. The threaded pins or wires are inserted into each fragment at a distance from the fracture site. When connected to the frame, they are able to rigidly hold the bone so that union occurs (Fig. 272-9).
FIG. 272-9. This external fixator is used to stabilize the open tibia fracture while still allowing access to the soft tissue wound.

COMPLICATIONS   Because external fixation is usually chosen for severe open fractures, which have a higher rate of infection, emergency department visits are not uncommon. Patients present with increased redness, swelling, or drainage at the previous open wound site. The skin should be prepared and deep cultures obtained by aspiration or swab. The fixation pins and wires very commonly sustain pin tract infections, which may easily be treated by releasing the skin around the pin site with a no. 11 blade after adequate local anesthesia. Oral antibiotics may be given empirically. With time, the fixator pins may loosen in the bone. The clamps connecting the pins to the frame may also loosen. This may result in instability or loss of reduction at the fracture site. This will usually be detectable clinically (unstable fractures are painful when stressed) or by radiographs.

Fixation Wires and Pins

Small smooth or threaded percutaneous pins (Fig. 272-10) are often used in the small bones of the hand or foot to add stability while fracture union occurs. The hand and foot possess an excellent blood supply, which usually results in early union. The pins are cut off outside the skin so that they may be removed between 3 and 9 weeks postoperatively.
FIG. 272-10. This smooth pin was used to stabilize the fracture at the base of the thumb metacarpal.

Internal cerclage wires are often used to hold structures that have fractured under tension. Examples are tuberosity fractures of the proximal humerus (Fig. 272-11) or patella fractures. Cerclage wires may also be used with or without a plate to stabilize a fracture around a prosthetic joint implant (Fig. 272-12). They serve the same role as a screw, which cannot be placed through the implant.
FIG. 272-11. A. and **B.** This olecranon fracture was stabilized with two smooth pins and a cerclage wire, which allowed joint motion during healing.
FIG. 272-12. A. and **B.** This periprosthetic fracture is stabilized by a special plate designed for use with wires or screws.

COMPLICATIONS   As with external fixation pins, the most common complication of using percutaneous pins is pin-tract infection. Such infections can be treated by removing the pin, but this should only be done after consultation with an orthopedist. A course of oral antibiotics may also be indicated. Complications of cerclage wires include wire breakage prior to union or perforation of a wire through thin overlying skin.

Cervical Spine Implants

The cervical spine is unique from the rest of the vertebral column due to the common use of halo fixation. A halo is simply a ring external fixator that is rigidly attached to the outer skull table with pins. Usually, four rods are used to connect this ring to a well-molded plastic or plaster body jacket. The halo limits the motion of the cervical spine, allowing fractures to heal or arthrodesis to unite.

The most common cervical implant is a posterior cerclage wire (Fig. 272-13), which limits motion between adjacent vertebrae while fusion occurs. A bone block taken from the iliac crest is often used as a biologic implant in the anterior cervical spine to gain fusion. Special plates and screws have been developed for the anterior cervical spine. Their use is likely to accelerate in the future.
FIG. 272-13. This patient underwent posterior fusion of the entire cervical spine, with internal cerclage fixation supplemented by an external halo for 6 months.

COMPLICATIONS   As with other external fixators, the most common complication of halo fixation is pin-tract infection. Infected pins are usually removed and a new pin placed in an alternative site. Loose, noninfected pins should never be tightened because this risks penetration of the inner skull table and resultant meningitis. The internal implants will fail if the vertebrae fail to unite.

Anterior and Posterior Thoracolumbar Spine Implants

Although the number of spinal instrumentation systems is overwhelming, the basic concepts are simple. A rigid plate or rod is connected to the spine to limit motion between vertebral segments and allow healing or fusion to occur. There are three ways of connecting the rod or plate to the vertebrae: with a hook, a wire, or a screw. When reduced to these terms, the instrumentation is much simpler.

Most advances in spinal instrumentation arose from the treatment of childhood scoliosis. The first was the Harrington rod-hook system (Fig. 272-14), introduced in 1960 and still in use today. Two major lessons were learned in the development of this system: (1) extremely durable materials were needed to avoid breakage; and (2) no matter how rigid the instrumentation, failure was inevitable if fusion did not occur (Fig. 272-15). Over the years, many instrumentation systems have been developed with special hook designs that allow the basic Harrington rod concept to be used for a multitude of spinal problems.
FIG. 272-14. This patient's posterior spine fusion was stabilized by a Harrington rod on the left and a Luque rod on the right.

FIG. 272-15. This double Luque rod construct broke prior to fusion.

In the 1970s, Eduardo Luque developed a system in which smooth metal rods were laid along the spine and wired to each segment. This created an extremely rigid construct that did not require postoperative bracing. This system is still in use today with only slight modifications (Fig. 272-14). Current systems may use combinations of hooks, screws, and wire for improved fixation and correction of deformity.

The drawback of rod-hook and rod-wire systems is the need for the implant to immobilize over a large number of vertebral levels. This problem has been addressed by pedicle screws placed directly into the vertebral body. This technique dates back to 1949. Because the screw passes through both the posterior and anterior spinal elements, excellent fixation is obtained (Fig. 272-16). This allows the surgeon to greatly reduce the number of segments immobilized. The pedicle screws are then connected to a rigid rod or plate.
FIG. 272-16. The fracture has been reduced and stabilized with pedicle screws attached to posterior bars.

Posterior spinal instruments are more commonly used than anterior instrumentation, due in part to the ease and safety of the posterior approach. Numerous types of anterior instrumentation have been developed (Fig. 272-17) using same principal of connecting to the vertebrae with a screw that in turn connects to a bridging plate, rod, or cable system.
FIG. 272-17. An anterior spine plate and screws are used to stabilize this lumbar burst fracture. The numerous buckles are from the molded plastic jacket, which adds additional support.

COMPLICATIONS   Early emergency visits usually involve wound problems. Diagnosis of an infection is supported by the presence of severe pain and an elevated temperature, white blood cell count, and erythrocyte sedimentation rate. Painful acute implant failure is not common, but Harrington-type hook implants may disengage. The patient usually notes an acute "pop" and an immediate increase in pain. This is usually best demonstrated on the lateral radiograph because the hook will no longer be under the vertebral lamina (Fig. 272-18). Rod breakage is usually a late occurrence due to failure of the fusion to prevent motion. Patients greater than 3 months postoperative usually will not have instability. Rod breakage should be easily detectable on standard anteroposterior and lateral radiograph views. Pain complaints from spine surgery patients are commonly encountered in the emergency department. Narcotics should be given sparingly, and communication with the orthopedic surgeon is often helpful in the management of patients with chronic pain.
FIG. 272-18. A. This hook-and-rod system was used to stabilize a lumbar burst fracture. **B.** The patient noted a "pop" with forward bending, and the lateral radiograph confirms that the top hook was disengaged.

COMMON ORTHOPEDIC IMPLANTS STABILIZING SOFT TISSUE TO BONE

The fitness craze of the last 15 years has led to a greater number of sports-related injuries. This has also resulted in greater need for reliable methods of stabilizing avulsed ligaments or tendons to bone. Graft implants are also more commonly used and must be stabilized while they heal to the host bone. These type of implants are most commonly used in the knee.

Thousands of anterior cruciate reconstructions are performed each year in the United States. The ruptured cruciate ligament may be replaced with harvested hamstring tendons or one-third of the patella tendon still connected at each end to a bone block from the patella and the tibia. It may also be replaced by a cadaveric patella tendon graft. These reconstructions not only increase the knee's stability but also lower the risk of future meniscal injuries.

The graft may be stabilized by heavy sutures or directly stabilized to bone with a metalic implant. Hamstring tendon grafts have no bone; therefore, they are usually left attached to the tibia, threaded through the knee, and then stabilized by heavy permanent suture ties to a screw or staple. The free bone-patella-bone grafts may also be stabilized in this fashion but are more commonly held by "interference" screws that are placed parallel to the graft bone in the tunnel. The threads then engage and stabilize the graft bone to the host bone (Fig. 272-19).

FIG. 272-19. A. and **B.** These interference screws rigidly fix the anterior cruciate ligament graft.

It is difficult to suture directly to bone. Previously this was performed by drilling small holes through which the suture could be threaded. More recently, special sutures that are coupled to metallic implants that can be drilled into the bone have been developed. These are often seen around the shoulder and have greatly simplified surgical techniques (Fig. 272-20).

FIG. 272-20. These metal-anchored sutures were used to repair a ruptured pectoralis major insertion to the proximal humerus.

COMPLICATIONS   Although rare, postoperative infection (presenting as increased pain and fever) is a catastrophic early complication of knee reconstructions. Immediate surgical débridement is usually indicated. The most common complication of soft-tissue-stabilizing implants is loss of fixation. This may occur through failure of the suture or the bone-implant interface. Migration of anterior cruciate ligament metallic implants into the joint has not been a problem.

Often an athlete will present to an emergency department with an injury to a previously reconstructed knee. The reconstructed anterior cruciate ligament may be injured in the same manner as the original ligament, or the patient may simply have sustained a meniscal injury. Great psychological stress may accompany reinjury, and this diagnosis should therefore be deferred to an orthopedist. If surgery was performed less than 8 weeks previously, the knee examination should also be deferred to the treating orthopedist, since the graft itself may not have healed fully to bone. Placement of a knee immobilizer is usually a simple temporizing measure. The orthopedist is often unable to perform an optimal examination until 7 to 10 days after the injury, when inflammation has subsided. Patients will often not accept this long an interval, and earlier referral is probably indicated if the patient's anxiety is obvious. During the interim, cold therapy, gentle active range-of-motion exercises, and nonsteroidal anti-inflammatory drugs are beneficial.

TOTAL JOINT ARTHROPLASTY

Prosthetic replacement of joints is extremely common in the United States. The indication for arthroplasty is a painful degenerated joint that severely impairs the quality of life of the patient. Almost every joint of the upper and lower extremity has had prosthetic replacements designed for it. The weight-bearing joints of the lower extremity must tolerate much higher forces than the joints of the upper extremity. Fortunately, the bones of the lower extremity are much larger, which allows for better fixation of the prosthetic devices.

The elbow and knee arthroplasties function in a similar manner, in that they both control the length of the extremity. As they bend, the extremity shortens. The hip and shoulder also function similarly because they position the extremity in space and have free motion in three planes.

Prosthetic Types

There is a great deal of variation between the design of prostheses for different joints. The small joints of the hand and foot are often replaced with silicone interpositional arthroplasties. The joint surfaces are excised and a silicone spacer is inserted. A metal grommet may be placed in the bone first to allow for improved wear properties (Fig. 272-21). These implants will survive if the forces across them remain low. Silicone implants are also used for wrist arthroplasty.
FIG. 272-21. This patient with rheumatoid arthritis underwent MCP silastic implants with metal grommets.

Large-joint arthroplasties may be subdivided into total joint arthroplasty in which both sides of the joint are addressed and hemiarthroplasty in which only one side is replaced. Hemiarthroplasties are most often used in the ball and socket joints of the shoulder and hip with only the ball portion being replaced. It is attached to a stem that is inserted in the intramedullary canal. Hemiarthroplasty is most commonly used for fractures involving the proximal humerus and proximal femur.

Total joint arthroplasty was first popularized by Sir John Charnley for the hip. A metal femoral prosthesis articulates with a plastic pelvic cup. Often a metal backing is added to the cup. These metal-on-plastic total joints have been adapted to almost every other joint but are most commonly used in the knee followed by the hip, shoulder, elbow, wrist, ankle, and infrequently the small bones of the hand.

Total joints may also be divided into constrained or nonconstrained implants. The rate of loosening from the bone is much higher with constrained implants, which are designed with the two components locked together in a hingelike fashion that prevents dislocation. Constrained designs are used mostly with revision work where the amount of soft tissue loss leads to an unstable joint. The exception is the elbow, where primary (first time) constrained prostheses are often used, because this joint has very little inherent soft tissue stability.

Motion between the implant and the host bone will cause pain. Three methods of fixing the prosthesis to the bone may be used. The implant may be press-fit, allowing the gross bone structure to stabilize the implant. The implant may be seated in polymethylmethacrylate cement that bonds to both the bone and the implant in much the same manner mortar stabilizes a post in a hole or a tile on the floor. Implants with special coatings and surfaces that allow bone to grow directly into the implant were introduced in the 1980s.

The results of modern joint arthroplasty are excellent. The results are much better where the forces are low or the bones are large. Currently, total hip and total knee arthroplasty has a greater than 90 percent success rate at 15 to 20 years.

Complications

All of the joints are prone to similar complications such as dislocation, prosthetic breakage, periprosthetic fractures, infection, and loosening. It is possible for any nonconstrained implant to dislocate. The diagnosis is usually obvious, but should be confirmed by biplane radiographs, because one view may not clearly show the dislocation (Fig. 272-22). Because many of today's implants are modular (snap together in the operating room), relocation should not be attempted without discussion with an orthopedic surgeon. Disassembly of the prosthesis during attempted closed reduction has been reported. Consent for reduction under anesthesia should be obtained prior to any heavy sedation. It is safest to relocate modular implants under fluoroscopy.
FIG. 272-22. A. and **B.** This patient's total hip arthroplasty is dislocated. The slight asymmetry on the first view was not detected, and further radiographs were needed to diagnose the dislocation.

Modern alloys have greatly reduced the incidence of prosthetic breakage. More commonly the bone around the prosthesis fractures (Fig. 272-23). Other than making the diagnosis of a periprosthetic or prosthetic fracture the emergency medicine physician will generally not be involved in the treatment of these problems.

FIG. 272-23. This patient sustained a periprosthetic femur fracture during a fall.

Total joint arthroplasty should not be painful. Any time a patient presents with new onset of pain around a prosthesis, loosening of the prosthesis must be suspected. Loosening occurs in two ways: from infection or from the loss of implant fixation. Late loosening is usually characterized by insidious onset of pain and rarely presents to the emergency department. Many criteria for radiographic evidence of loosening have been presented in the orthopedic literature. Radiographic loosening is usually detected as migration of the implant over time with lytic destruction of bone around the prosthesis (Fig. 272-24).

FIG. 272-24. This right cemented total hip arthroplasty is obviously loose, with associated proximal femoral bone loss.

Infection of a total joint arthroplasty is a catastrophic event. In the first few weeks postoperatively the prosthesis may sometimes be salvaged by immediate surgical débridement and intravenous antibiotics. The most sensitive emergency screening tests are an erythrocyte sedimentation rate or C-reactive protein. Aspiration of any joint should be performed prior to administration of any antibiotics but should never be performed without a surgeon's approval. It is possible for an uninfected implant to be infected by a needle aspiration. Late infections of a prosthesis require removal of a prosthesis to clear the infection.

Some of the most serious complications involving total joint arthroplasties involve the soft tissue structures around the joint. Ligaments holding the joint together can disrupt causing instability of the joint. Tendons that pass around the joint can rupture leading to loss of function of the joint. If diagnosed early they can often be repaired with an excellent result.

COMPLICATIONS OF UPPER EXTREMITY ARTHROPLASTIES   The silicone interpositional arthroplasties may fail and create particles that cause an inflammatory response. This is differentiated from an infection by radiographs showing the radiolucent silicone "spacers" and aspiration of fluid for cell count, Gram stain, and culture.

The elbow joint has greater complications than any other commonly replaced joint. Even in the best centers infection rates of 10 percent or greater are not uncommon. This may be due to the thin soft tissue over the posterior elbow. Loosening rates at the elbow are also high due to the need for a constrained prosthesis and limited bone for fixation.

The shoulder's humeral component is extremely durable (Fig. 272-25). The glenoid component with its small bone surface area for fixation is prone to failure. Dislocation of the shoulder can only be diagnosed with a true anteroposterior and either axillary or transcapular lateral radiograph. Acute loss of motor power may be the result of a rotator cuff tear.

FIG. 272-25. This total shoulder arthroplasty has a well-fixed cemented humeral component.

COMPLICATIONS OF LOWER EXTREMITY ARTHROPLASTY   Silicone interpositional arthroplasty is also used in the feet, but the failure rates are much higher due to the higher forces. Ankle arthroplasty has had limited success because the small bones of the hind foot do not allow adequate fixation to withstand the high forces placed across the ankle joint.

The knee has excellent inherent ligamentous stability and therefore unconstrained implants (Fig. 272-26) are usually used today. It is possible for these implants to dislocate; however, it is not as common as in the shoulder or hip. Instability can develop in knee arthroplasties if a ligament is disrupted such as the medial collateral ligament or the posterior cruciate ligament. Diagnosis is by the same examination methods used on nonreplaced knees. Disruption of the quadriceps mechanism is a disastrous complication and must be considered if the patient is unable to straight leg raise. When the patella tendon ruptures, repair rates are extremely poor if not diagnosed and treated early.

FIG. 272-26. A. and **B.** This patient with osteoarthritis underwent a total knee arthroplasty, with all components cemented.

The hip, like the shoulder, may be addressed by hemi- or total arthroplasty. The acetabulum is usually not replaced in fracture management, but almost always replaced for arthritis. The acetabulum is replaced by a plastic shell that accepts the head of the femoral component. This plastic liner may also be metal backed which allows for bone ingrowth or more even stress transfer when cemented (Fig. 272-27). The hip is the most common joint to dislocate. This is confirmed by biplane radiographs and because these prostheses are often modular, great care and often fluoroscopy should be used during relocation. Reattachment of the trochanter after the transtrochanteric approach is usually performed with wire. These wires commonly break during the healing process but are not usually a problem.

FIG. 272-27. This "hybrid" total hip arthroplasty has a cemented femoral component and a noncemented acetabular component that is additionally fixed with screws.

273 NECK PAIN

Myron M. LaBan

Neck pain has an encyclopedic list of causes, including trauma, degenerative disease, infections, neoplasms, congenital variations, inflammatory arthritis, and psychic tension. An evaluation of neck pain requires an understanding of the anatomy of the cervical spine. The cervical spine consists of seven vertebrae; the fifth through the seventh are alike in shape and size, whereas the first cervical vertebra (atlas) and the second (axis) differ in structure. The lower third through seventh vertebral bodies articulate with each other via their superior and inferior articular processes, enabling limited rotation and lateral flexion. The atlas (C1) supports the occipital condyles and the axis (C2). Its inferior articulations resemble the other inferior vertebral articulations. The dens and its stabilizing horizontal ligament enable rotation between C1 and C2. The transverse processes of each of the cervical vertebrae are perforated by a foramen through which the vertebral vessels pass. Topographically, the first cervical vertebra is located immediately behind the angle of the mandible, the transverse process of the atlas is positioned between the angle of the mandible and the mastoid process, the hyoid bone is anterior to the level of C3, the thyroid cartilage is anterior to C4, and the cricoid cartilage is at the level of the sixth cervical vertebra.

The muscles of the neck are compartmentalized into seven fascial planes. These planes normally enable pain-free movement of one muscle group on the other. Following acute neck trauma, petechial hemorrhages and edema within these same fascial planes may produce limited motion associated with complaints of stiffness, pain, and swelling.

The stable but flexible cervical spine is linked by both ligaments and disks. Because of major structural differences, the cervical disks are less likely than lumbar disks to prolapse. The cervical spine is more mobile, the superincumbent weight is less, the nucleus pulposus is more anteriorly displaced and, unlike the lumbar spine, the annulus is reinforced posteriorly in its entire width by the posterior longitudinal ligament.

The eight paired cervical spinal roots exit the intervertebral foramina between the superior and inferior pedicles, except for the upper two cervical roots. Unique to the cervical spinal roots, in over half the cases the ventral and dorsal roots are separate at the neural foramina. In these cases, isolated irritation of the dorsal (sensory) root posteriorly by an osteophyte may produce only sensory complaints. Similarly, ventral root (motor) compromise by a degenerative or herniated disk may produce only painless, progressive weakness. Segmental motor or sensory signs associated with a root disorder are called *radiculopathies.* Signs and symptoms of spinal cord disease are called *myelopathies.*

The sinuvertebral nerves from the dorsal root reenter the intervertebral foramina supplying sensory innervation to the ligaments of the spinal canal. Anteriorly, they supply the posterior longitudinal ligament and posteriorly the ligamentum flavum, meninges, and associated vessels. Ascending and descending branches also supply the zygoapophyseal joints, providing position sense.

The cervical portion of the spinal cord surrounded by spinal fluid is suspended laterally to the enveloping dura by 20 dentate ligaments. The dura in turn is attached cephalad to the rim of the foramen magnum and within the vertebral spinal canal is cushioned from trauma by epidural fat.

CLINICAL FEATURES

The source of neck pain can often be determined by a thorough and searching history. In most cases, patients can identify the inciting event or an exacerbating maneuver or position that causes pain. Following trauma, note the exact nature of the impact with reference to positioning; accompanying lacerations of the head, neck, or face; the use of restraints; the use of protective sports equipment; associated limb or trunk fractures or contusions; and loss of consciousness or seizures. The date of injury, the patient's age and occupation, preexisting medical conditions, and other contributing factors should also be identified. Determine the character of pain and its distribution. Ask about specific neurogenic symptoms, including extremity weakness, incoordination, numbness or paresthesias, and sphincter and sexual dysfunction. Patients with visual, auditory-vestibular, and pharyngeal-laryngeal symptoms often require direct questioning to elicit complaints. The results of previous imaging studies and prior response to medication or physical treatment may be diagnostic.

The physical examination begins with an observation of a loss of neck flexibility, unless a mechanism of injury is present for possible cervical fracture or spinal cord injury. In such cases, the neck should remain immobilized until radiographs are obtained and reviewed by the emergency physician. Pain may cause splinting of the head on the shoulders during position change. Active and passive movement should be assessed, including rotation (chin to shoulder) and lateral flexion (ear to shoulder). When localized ipsilateral neck pain is experienced toward the side of head movement, zygoapophyseal joint irritability is suspected. When ipsilateral pain radiates to shoulder or arm (Spurling sign), a radicular component may be present. Contralateral neck pain suggests either a primary ligamentous or a muscular source of discomfort as these structures are stretched.

Palpate the posterior cervical triangle, the supraclavicular fossa, and carotid sheaths, and the anterior neck. Auscultation of the carotid and the subclavian arteries may demonstrate bruits, in the former associated with potential cerebral insufficiency and in the latter instance with a thoracic outlet or vascular steal syndrome. Symptomatic occipital neuralgia can be replicated by firm pressure over the occipital notch, producing scalp numbness or burning dysesthesias in the occipital nerve distribution. Various compression and distraction maneuvers of the cervical spine are also diagnostically useful. They include vertical skull compression or lateral flexion positions that replicate radicular symptoms and manual vertical distraction, a reverse Spurling maneuver, which "unloads" the spinal roots and adjacent cervical vertebral joints, thereby reducing pain.

An evaluation of neck discomfort is incomplete without shoulder, arm, and neurologic examination (Table 273-1), since cervical spinal radiculopathies can cause upper extremity pain, paresthesias, and weakness. Knowledge of the dermatome, sclerotome, and myotome referral distribution of spinal root irritation is also essential to diagnosis. Look for muscle atrophy or fasciculations. A loss of triceps reflex suggests C7 root pathology, whereas a loss of biceps reflex suggests a C5-C6 root syndrome. Motor strength is tested by the "break" maneuver, whereby the patient is given a maximal advantage of position and strength and the examiner "breaks" the muscle, comparing one side with the other. The triceps is tested by having the patient extend the elbow and maximally resist the examiner's efforts to flex the elbow. A smooth, asymmetric "give" rather than a "ratchety" break suggests C7-C8, posterior cord, or radial nerve involvement. Similarly, other muscle groups are tested and patterns of weakness are correlated with the clinical history and symptoms. Local nerve palpation also is a useful adjunct to the examination. C5-C6 root lesions often elicit tenderness over the brachial plexus at Erb's point in the supraclavicular fossa, whereas a C8-T1 root lesion can cause tenderness over the distal ulnar nerve at the elbow.

Disk Space	Cervical Root	Pain Complaint	Sensory Abnormality	Motor Weakness	Altered Reflex
C1-C2	C1-C2	Neck, scalp	Scalp		
C4-C5	C5	Neck, shoulder, upper arm	Shoulder, thumb	Spinati, deltoid, biceps	Reduced biceps reflex
C5-C6	C6	Neck, shoulder, upper medial, scapular area, proximal forearm, thumb	Thumb and index finger, lateral forearm	Deltoid, biceps, pronator teres, wrist extensors	Reduced biceps and brachioradialis reflex
C6-C7	C7	Neck, posterior arm, dorsum proximal forearm, chest, medial scapula, middle finger	Middle finger, forearm	Triceps, pronator teres	Reduced triceps reflex
C7-T1	C8	Neck, posterior arm, medial proximal forearm, medial inferior scapular border, medial hand, ring and little fingers	Ring and little fingers	Triceps, flexor carpi ulnaris, hand intrinsics	Reduced triceps reflex

TABLE 273-1 Signs and Symptoms of Cervical Radiculopathy

Sensory symptoms of pain or dysesthesias are difficult to evaluate, particularly when motor signs are absent. This is all too often the case in cervical spinal radiculopathies. The discrete separation of the motor and sensory roots at the cervical neural foramina is the explanation for motor sparing despite severe sensory symptoms. Marked C7 root irritability without motor weakness of the triceps (radial nerve C7-C8) or the pronator teres (median nerve C6-C7) can present only with aching at the medial, middle scapular border, or aching in the myotome distribution to the chest, axilla, or triceps. Numbness or tingling in the C7 dermatome distribution to the middle finger may be the only symptom of spinal root irritation.

Early cervical spinal myelopathies can only be recognized if the examiner looks for them, so a full neurologic examination that includes the lower extremities is needed to evaluate neck pain. Common signs and symptoms include hyperreflexia, a positive Babinski sign, gait disturbance, lower extremity weakness, impaired fine hand movement, or upper and lower extremity spasticity.

The need for radiographs depends on the clinical condition suspected. If degenerative disease is suspected, oblique views of the cervical spine can identify foraminal narrowing. Both the dens and the lowest cervical and upper thoracic vertebrae should also be visualized. Flexion-extension films are useful if instability is suspected. Magnetic resonance imaging is now the preferred test to evaluate the cervical cord.

Electromyographic (EMG) studies can diagnose neural structural abnormality, assess the level and the degree of severity, and provide a prognostic baseline and an objective means of reassessment. Both EMG and nerve conduction velocity testing are needed if there is progressive motor impairment or when confusion exists as to the level of neural compromise. Unfortunately, EMG findings lag 2 weeks behind a patient's actual clinical state. EMG is a test of motor dysfunction. If the sensory root is solely compromised and the motor root spared, the EMG findings may be normal.

CERVICAL SOFT TISSUE INJURIES

Hyperflexion-hyperextension injuries to the cervical spine result in stretching of soft tissues, intervertebral joints, nerve roots, and adjacent peripheral nerves. The most common precipitating events are motor vehicle accidents, falls, and sport injuries. Staged automobile accidents using cadavers have demonstrated injuries ranging from petechial hemorrhage and edema, muscle and ligament distraction, vertebral dislocations and fractures, to herniations of the intervertebral disk. The forces applied during motor vehicle crashes are multiple and depend on the position of the head and neck as well as the type of accident. Forces applied include flexion, extension, rotation, and vertical compression. A rear-end collision propels the trunk forward on the pelvis, throwing the head into hyperextension and stretching the anterior structures of the neck. Hyperextension injuries include hyperextension dislocation; atlas fractures including avulsions of the anterior arch, extension teardrop fractures, or fractures of the posterior arch; laminar fracture; traumatic spondylolisthesis; and other fracture dislocations. A head-on impact initially produces acute flexion, compressing the anterior neck structures. Hyperflexion injuries include anterior subluxation; unilateral or bilateral interfacet dislocations; vertebral compression fractures; avulsion fractures of the spinous processes; and complete subluxation with disruption of the posterior ligaments, facet capsule, and annular disk fibers. Both hyperextension and hyperflexion injuries are also associated with rebound flexion and extension, respectively. To compound the mechanism of injury further, a vertical component may be added as the cervical spine is compressed when the individual's trunk is lifted by the force of impact.

Passengers forewarned of an impending rear collision can potentially protect themselves by flexing the neck and tucking the chin against the chest. An extended head potentiates the risk of ligamentous rupture and articular dislocation. Areas of preexisting degenerative disease are most susceptible to injury.

Postinjury complaints are highly variable and, besides neck pain, may include headache, vertigo, dysesthesias, visual symptoms, dizziness, tinnitus, dysphagia, and hoarseness. Typically, pain is delayed for a number of hours following an accident. Restricted cervical range of motion can be associated with radicular patterns of myotome weakness suggesting cervical root compromise. Headache can occur from stretching and tearing of occipital muscles and the occipital nerve. The cause of vertigo is unknown but could be due to brainstem contusion, trauma to sympathetic fibers that accompany vertebral arteries, vertebral artery insufficiency secondary to atherosclerosis, or osteophytic compression of the vertebral arteries. Spatial instability affecting balance is not uncommon, and patients describe a feeling of "sliding" or "veering" with changes of direction rather than true vertigo. This rather unique description of spatial instability may be due to injury to the zygoapophyseal joints of the neck rather than the inner ear. Dysphagia can occur as a result of pharyngeal edema or a retropharyngeal hematoma. Vocal hoarseness can be attributed to stretching of the recurrent laryngeal nerve, often associated with marked edema of the sternocleidomastoid muscles and carotid sheaths, potentially increasing neck circumference by one collar size. In such a case, however, blunt neck or laryngeal injury should always be suspected and evaluated with computed tomography of the neck. The most devastating complication of hyperflexion-hyperextension injury is the central cord syndrome, which may occur in the presence of cervical spondylosis, spinal stenosis, ankylosing spondylitis, or disk herniation. There may be no radiographic evidence of spinal trauma. Findings of central cord syndrome include weakness of both upper and lower extremities with predominance of weakness in the former; or upper and lower extremity spasticity. (See Chap. 264, "Injuries to the Spine," for further discussion.)

Cervical spine x-ray films are of value to exclude fracture or subluxation, and flexion-extension views can demonstrate vertebral instability. Initial roentgenograms may reveal only an initial loss of the normal cervical lordosis, with subsequent studies possibly demonstrating evidence of new ligamentous ossification. Extension views of the cervical spine can demonstrate vacuum clefts in the anterior surface of the cervical disks, suggesting the presence of an avulsed disk.

Treatment initially consists of splinting of the neck with a fitted soft cervical collar fastened in slight flexion, and the use of topical ice packs for the first 24 h. Heat should be applied after 24 h. Early mobilization exercises starting at 72 h to restore flexibility should be combined with superficial moist heat and a gradual reduction in the use of the soft collar. Early in recovery, diathermy and/or cervical traction may aggravate symptoms. However, later these modalities are useful when ligamentous or articular pain persists or for treatment of radicular symptoms. In both instances treatment must be based on a specific diagnosis. Oral analgesics, including narcotics, initially are appropriate for pain relief. Muscle relaxants are not very effective. With chronic discomfort, oral nonsteroidal anti-inflammatory drugs are useful. Where occipital neuralgia or myofascial symptoms are sources of continuing pain, local injections of a mixture of long-acting steroid and 1% lidocaine followed by ice massage and ultrasound are useful.

CERVICAL DISK PATHOLOGY

Cervical disk herniations occur as the nucleus pulposus protrudes through the posterior annulus fibrosis, producing either an acute radiculopathy or occasionally a myelopathy. Cervical spondylosis and stenosis are associated with a subtle progression of symptoms, including neck stiffness or localized pain, occipital neuralgia, extremity-referred radicular pain, and occasionally clinical manifestations of a progressive myelopathy.

Acute Cervical Disk Herniations

Evidence of degeneration of the nucleus pulposus and the annulus fibrosis usually antecedes cervical disk herniation. These protrusions are usually confined by the posterior longitudinal ligament but can occasionally extrude through this ligament as free fragments. Direct posterior ruptures, although infrequent, can produce progressive myelopathy, whereas the more common posterolateral herniations precipitate the symptoms and signs of an acute cervical radiculopathy. Disk prolapse is $1\frac{1}{2}$ times more common in males, occurring most often in the fourth decade. The levels of most frequent involvement are C6-C7 (C7 root), usually left sided, and C5-C6 (C6 root), usually right sided.

The symptoms of an acute cervical disk prolapse include neck pain, headache, sclerotomal referral to the shoulder and along the medial scapular border, myotome pain in the spinal root distribution to the shoulder and arm, and dermatomal sensory dysesthesias of the appropriate finger. Motor signs include fasciculations, atrophy and weakness in the myotome distribution of the spinal root, loss of deep tendon reflexes; and, with cervical myelopathy, lower extremity hyperreflexia, Babinski sign and, rarely, loss of sphincter control. Cervical hyperextension and lateral flexion to the symptomatic side can replicate the symptoms, as can a Valsalva maneuver, whereas manual cervical distraction in flexion alleviates them. A thorough and searching examination, including muscle testing, easily delineates the level of root involvement (see Table 273-1).

Electroneuromyography can be complementary in diagnosis and will exclude occult peripheral mononeuropathies and acute brachial plexopathies. Cervical spine

x-ray films are often more useful in these syndromes for what they fail to reveal rather than what they demonstrate. The presence of degenerative disease may mask a soft cervical disk protrusion. In younger adults, x-ray films may be normal, failing to reveal even a large herniation. In this instance, magnetic resonance imaging is necessary for diagnosis.

Treatment consists of analgesics sufficient to control pain, a cervical soft collar and, without evidence of carotid bruits or myelopathy, a trial of intermittent cervical traction. If the symptoms and signs of acute cervical root compression fail to respond to conservative treatment or reoccur, surgery may be recommended if imaging demonstrates a prolapsed cervical disk with root compression. Indications for hospital admission include:

1. Intractable radicular pain unresponsive to treatment.
2. Progressive upper extremity weakness, especially in the C7 distribution.
3. Progressive lower extremity myelopathic signs, such as positive Babinski sign, hyperreflexia, motor weakness, and bladder or bowel dysfunction.

Cervical Spondylosis and Stenosis

Cervical spondylosis is a progressive condition that can present either as a loss of cervical flexibility or as neck pain. Neck pain is due to local zygoapophyseal joint degeneration. Degenerative disk disease predisposes individuals to progressive osteoarthrosis of the cervical zygoapophyseal joints. A loss of disk height associated with annulus bulging produces cervical segment instability, excessive facet weight bearing, and incongruous joint motion during neck movement, accelerating articular degeneration. Altered mechanical stresses produce traction osteogenesis with subsequent spur formation. Spurs can encroach posteriorly on the spinal canal, producing cervical myelopathy; laterally on the intervertebral foramen, producing cervical radiculopathy; and anteriorly on the esophagus, producing dysphagia.

The combination of a congenitally narrowed spinal canal further compromised by a vertebral osteophytic bar anteriorly, and a buckling ligamentum flavum posteriorly, increases the risk of myelopathy secondary to cervical spinal stenosis as the diameter of the spinal canal is reduced to less than 12 mm. Cervical spinal stenosis can also occur in about 20 percent of patients with lumbar spinal stenosis. Selective impingement of the dorsal spinal root by an osteophyte arising from the zygoapophyseal joint can present with complaints of digital numbness or vague myalgias, which on subsequent appraisal can be related to the known myotome distribution of a spinal root. The C6 nerve root emerges between the C5 and C6 vertebrae and is the earliest and most frequent site of a degenerative disk. Since the C6 myotome encompasses most of the major proximal shoulder muscles, a complaint of bilateral shoulder pain should raise suspicion of C6 radiculopathy. Spurious osteophytes can produce Horner syndrome, vertebral-basilar symptoms, severe radicular symptoms without associated neck pain, painless upper extremity myotome weakness, and chest pain mimicking angina. Radiographic studies demonstrating typical segmental degenerative changes may in fact bear no relation to the actual spinal root level of the presenting complaint. For example, foraminal encroachment visible on x-ray views may be more severe at C5-C6, with the patient presenting with both clinical and EMG evidence of a progressive C7 radiculopathy arising from the C6-C7 level.

Localized neck pain and stiffness attributable to arthritis at the zygoapophyseal joint can be treated with cervical collar support, superficial ice massage, ultrasound, flexibility exercises, and nonsteroidal anti-inflammatory drugs. Cervical traction therapy may aggravate pain due to arthritis. For cervical radicular pain, though, intermittent cervical traction initially in the formal setting of an outpatient physical therapy facility, followed by ongoing home cervical traction, is an effective approach. Myofascial pain can often be managed with topical ice, deep kneading massage, stretching exercises, and local injections of steroids and lidocaine. The prompt recognition and correction of aggravating factors, such as emotional stress or prolonged postural neck hyperextension related to overly soft seating or to the use of bifocal glasses during reading, may in itself be curative.

274 THORACIC AND LUMBAR PAIN SYNDROMES

Paul J.W. Tawney
Cara B. Siegel
Myron M. LaBan

THORACIC SPINE

Although spine pain complaints are more common at cervical and lumbar levels, thoracic complaints can be as disabling. This region of the spine is comparatively stable and protected both by the rib cage and the orientation of the facet joints. In this region, the spinal cord and paired segmental nerves traverse the narrowest of bony canals and any compromise of the available space can result in rapid and profound neurologic deficits.

Thoracic spine fractures occur most commonly at the T10–L2 levels and can occur from direct trauma as well as forced hyperflexion of the trunk, as in lap-belt injuries. Vertebral fractures resulting from spinal osteoporosis occur in 8 percent of women over 80 years of age. Such compression fractures are usually wedge-shaped and stable. The presenting symptom is usually severe pain, and accompanying myelopathy is rare. However, when long tract signs, such as hyperreflexia, Babinski's sign, and urinary incontinence are present, a malignancy metastatic to the spine must be suspected. An epidural metastasis may present similarly as an acute myelopathy with or without pain or abnormal x-rays. Myelography, computed tomography (CT), or magnetic resonance imaging (MRI) is needed to differentiate the relatively rare thoracic disk protrusion (1 percent of all disk herniations) from a spinal cord tumor. Pain from thoracic root lesions is usually worse while reclining at night and is relieved by assuming an erect position. Patients may sleep sitting up in a chair. They may on initial examination demonstrate Babinski reflexes that disappear after a brief period of rest. Slowed lumbar spinal evoked potentials can also be diagnostic in confirming thoracic spinal myelopathy. [1,2]

Localized paravertebral pain can be associated with an acute facet syndrome. Plica entrapped within the thoracic zygapophyseal joints can produce severe and disabling pain. Radicular pain and localized stiffness associated with osteoarthrosis of these same vertebral joints cause chronic pain and can result in narrowing of the neural and spinal canals. The latter can lead to signs and symptoms of thoracic spinal stenosis.

Rheumatoid spondylitis primarily affecting young men may initially present as thoracic spinal pain or stiffness. A loss of chest expansion to less than 1 in. at nipple line is suggestive and, with x-rays of the sacroiliac joints, is often diagnostic.

Herpes zoster neuralgia can also be associated with acute thoracic radiculopathy. It is difficult to diagnose before vesicles and bullae are evident.

Diabetic thoracic radiculopathy may present as abdominal pain. When this condition is suspected, electromyography (EMG) demonstrating thoracic paraspinal and abdominal muscle segmental denervation (T7–T12) can be diagnostic.

LUMBAR SPINE

Epidemiology

Low back pain is second only to the common cold as a cause of industrial absenteeism and is the primary cause of reduced working capacity. Sixty to 90 percent of the population will experience back pain in their lifetime. Fifty percent of people will have a recurrent episode. It is one of the most common reasons for a physician office visit. The yearly prevalence in working age adults is 50 percent. Over 5 million individuals are disabled with low back pain, making it the number one disability in workers less than 45 years old.[3,4] In 85 percent of cases, no definitive diagnosis or source of the pain can be given. The natural history of low back pain is that 90 to 95 percent of patients, even if they have sciatica, will be better within 2 months,[5] regardless of the type of treatment rendered.[6] Economic and psychosocial costs for this common disorder are substantial.[7]

Pathophysiology and Clinical Features

The causes of lumbosacral pain are as diverse and as complex as are the interrelated anatomic structures of the lumbar spine itself. Any innervated structure in the region can be a pain generator. The specific pain generator is rarely identified. Deep somatic pain due to mechanical irritation, inflammation, or even increased vascular pressure can emanate from the vertebral column, surrounding muscles, tendons, ligaments, or fascia. Discomfort of articular origin, either lumbar zygapophyseal or sacroiliac joints, can also be recognized by known sclerotome patterns of pain referral.[8] Pain due to nerve irritation can be perceived locally and distally. Nonspinal causes of low back pain must also be considered.

One rational approach to the diagnosis and treatment of low back pain or sciatica is predicated on an understanding of the process of spinal degeneration as described by Kirkaldy-Willis and Farfan.[9] Initially beginning with an alteration in the hydroscopic quality of the nucleus pulposus, it can progress from annular degeneration of a single disk to multilevel involvement. Sequential disk degeneration with associated zygapophyseal joint compromise can be associated with relatively infrequent disk prolapses. More often, progressive posterior facet disease is associated with foraminal or spinal canal encroachment, producing symptoms associated with lateral or central spinal stenosis.

Spinal Stenosis

Spinal stenosis can be a cause of back and lower extremity pain. It is defined as any narrowing of the lumbar spinal canal, nerve root canal, or intervertebral foramina, the predominant etiology being degenerative changes. Diagnosis is usually by CT or MRI. Incidence and prevalence as the primary source of pain is difficult to establish as it can also be found in asymptomatic individuals. The clinical presentation is usually that of an older individual with a long history of back pain. Ninety

percent also have leg pain, as the key sign is lower extremity pain exacerbated with walking and relieved with sitting (neurogenic claudication). However, this still has a broad differential, including osteoarthritis of the hip and vascular claudication due to peripheral vascular disease. Ambulation producing lumbar, gluteal, or calf pain may be a manifestation of peripheral vascular disease, but it is also indistinguishable from that of lumbar spinal stenosis. Both vascular insufficiency and spinal stenosis are aggravated by activity and relieved by rest. Vascular signs in the former case or neurologic abnormality in the latter instance can lead to the diagnosis, but arteriography or MRI or CT scan may be necessary for confirmation. Most helpful associations with spinal stenosis are age older than 65, absence of pain when seated, wide-based gait, and production of thigh pain with sustained lumbar extension of 30 s. Physical examination findings are not particularly helpful in ruling in or ruling out spinal stenosis. [10]

Three-Joint Complex Degeneration

The combined retrogressive and proliferative changes in the disk anteriorly and in the posterior joints present with both clinical symptoms and roentgenographic changes referred to as combined three-joint complex degeneration. The vertebra-disk-vertebra joint and the paired facet joints comprise the three-joint complex. Three distinct stages in the evolution of this process can be recognized clinically. The *stage of dysfunction* is associated with complaints of pain and stiffness, often without radiographic or clinical abnormality. The *stage of instability* is associated with evidence of spinal segment movement best exemplified by radiographic evidence of the presence of pseudospondylolisthesis, usually at the L4–L5 level, secondary to advanced degenerative disk disease with preservation of the stabilizing pars interarticularis. This phase of degeneration can be clinically recognized by the presence of limited spinal flexibility, reactive scoliosis, reduction in the lumbar lordosis, and, on occasion, the presence of neurologic abnormality, including alterations in deep tendon reflexes, reductions in muscle strength, and restricted straight leg raise (SLR) signs.

The final stage of stabilization is clinically associated with a marked loss of lumbar flexibility. "Stiffness" is a primary complaint that may supersede pain, particularly following periods of immobility. Prolonged standing or walking may precipitate symptoms of localized radicular pain, paresthetic complaints of numbness or tingling, and motor symptoms of "weakness" or "instability" with or without corroborative motor signs. Articular facet, laminar, and vertebral enlargement associated with osteophytic formation progressing to vertebral fusion are characteristic x-ray features of this stage.

The zygapophyseal (facet) joints are true synovial joints innervated by the medial branches of the dorsal rami. It has been estimated that 15 to 40 percent of chronic back pain is due to the zygapophyseal joints. The clinical presentation overlaps considerably with low back pain of other etiologies. The diagnosis remains one of exclusion and confirmation by analgesic injection. [11]

Sacroiliac Joint Disease

Mechanical dysfunction can occur within the sacroiliac (SI) joints. Sacroiliac joint pain is commonly referred to the inguinal and anterolateral thigh, as well as the lower abdominal quadrants, often simulating an acute appendicitis or ovarian cyst. Inflammatory processes can involve the SI joints, as in the seronegative spondyloarthropathies. Early in this process there may be little or no correlation between symptom severity and radiographic evidence of joint involvement. The pain is usually experienced over the joints themselves, radiating to the anterior lateral or posterior thighs. Usually worse at night, the pain may be bilateral, alternating from side to side. Prolonged standing or sitting, especially on long car trips, exacerbates the discomfort. "Weakness" or stiffness, primarily in the morning, is also a predominant symptom of sacroiliitis. When in young men, stiffness may be associated with new-onset rheumatoid spondylitis; the earliest complaint may be that of chest pain and stiffness rather than that of low back pain. The earliest sign may be that of restricted chest expansion of less than 1 in. at the nipple line. Unfortunately, chest expansion measurement, Schober test of lumbar range, and other sacroiliac tests are poor for following disease progression. [12]

Radiculopathy

Radicular pain derives from irritation of the proximal portion of the spinal nerve as a result of ischemia, chemical irritation by contents of the nucleus pulposus, or mechanical compression. Kuslich,[13] performing progressive local anesthesia during spinal surgery, has observed that compressed or chemically irritated nerve roots are perceived as painful when stretched, while normal nerve roots do not reproduce pain. The outer annulus and posterior longitudinal ligament also could be stimulated to produce pain. [13] Ninety-five percent of disk herniations occur at L4–L5 or L5–S1. Without complaint of sciatica, or pain below the knee in a dermatomal distribution, the chance of a herniated nucleus pulposus is 1 in 1000. Complaints of muscular pain in the myotome and sensory dysesthesias in the dermatome distribution of a spinal root may be accompanied by referred pain in the sclerotome distribution. Compromise of L5 and S1 roots can be experienced, respectively, as muscular pain in the anterior tibial compartment simulating "shin splints," and muscular pain in the calf mimicking a thrombophlebitis. Proximal L5 and S1 root compression is suggested distally by the presence of pain to palpation over the peroneal nerve (L5) at the fibular head and the tibial nerve (S1) in the tarsal tunnel. Sensory complaints in the presence of radicular syndromes may be useful in localizing root levels of involvement. Paresthesias in the great toe suggest L5 root involvement, and in the little toe S1 radiculopathy.

Other Causes of Lumbar Pain

Neurogenic pain in the low back region can be associated with herpes zoster as manifest in shingles or in femoral nerve mononeuropathy that is often associated with diabetes. Pain is due to loss of the pain inhibitory system in the central or peripheral nervous system. It is described as burning, tingling, or skin crawling. It is intensified by what would otherwise be nonpainful sensory stimulation, such as light touch (allodynia). It may persist after cessation of the provoking stimulus (hyperpathia).

Additionally, pain of remote origin, even outside the spine itself, can present as lumbar pain. Lesions within the central nervous system, and in the spinal cord at or above the lumbar area, can also produce both low back pain and radicular leg discomfort. Parasagittal brain tumors and thoracic root lesions, including neurofibromata, can simulate lumbar root syndromes.

Distal nerve entrapment syndromes also can present with primary complaints of lumbosacral pain. The most notable example of this situation is tibial nerve entrapment (S1) in the tarsal tunnel behind the medial ankle malleolus.

Pain to direct palpation over the ischial tuberosities, greater trochanters, or sciatic notches may suggest localized abnormality, including a bursitis at the tuberosity or trochanter or an enthesitis; that is, inflammation at the tendinous attachment of muscle to bone, at the insertion of the hip abductor and extensor muscle groups. Trochanteric bursitis itself can mimic lumbar radiculopathy with distal pain referral along the iliotibial band to the lateral knee. Excessive lateral trunk sway to the stance leg during ambulation, a compensated Trendelenburg gait, suggests primary intraarticular hip abnormality. On examination, corroborative evidence of an initial loss of hip internal rotation may be associated with medial groin pain and a positive Patrick sign, which may radiate to the knee. Attempting to "walk around," primary hip disease produces excessive stress at both the ipsilateral sacroiliac joint and the greater trochanter. Each, singly or together, may initially appear to be the salient problem until the loss of hip mobility is identified as the progenitor of the other complaints.

Based on their shared segmental innervation, pain from visceral disorders, including those of kidney, pancreas, and gallbladder; duodenal ulcers; colonic diverticulitis; expanding abdominal aortic aneurysm; epidural hematoma or abscess; and endometriosis, can all mimic primary low back disorders. Pain from a leaking abdominal aortic aneurysm is constant and aching and may be referred to the lower abdomen and inguinal areas as well as the low back. In the evaluation of low back pain in the elderly, an abdominal aortic aneurysm must always be considered in the differential diagnosis. Costovertebral angle percussion pain is invariably associated with retroperitoneal pathology, most often kidney. Spinal cord compression can develop as a first sign of malignancy or as a complication. It is usually associated with back pain and should always be suspected if there are any neurologic signs or sphincter dysfunction. A history of associated systemic symptoms and a lack of therapeutic response to a trial of initial bedrest, combined with an abnormal abdominal, pelvic, neurologic, or rectal examination, are usually sufficient to redirect the examination to the appropriate extraspinal problem. [12]

Diagnosis

Due to the prevalence, cost, concern for suboptimal care, and a growing body of evidence on low back pain, the Agency for Health Care Policy and Research (AHCPR) commissioned guideline development for evaluation and treatment of acute low back pain. [14] The *Quick Reference Guide for Clinicians* is a distilled version of the *Clinical Practice Guideline*, with summary points for ready reference on a day-to-day basis. [15] Text, figures, and tables from the *Quick Reference* are referenced throughout this chapter.

The AHCPR guideline defines acute low back problems as activity intolerance due to lower back or back-related leg symptoms of less than 3 months' duration. This includes new episodes in patients with recurrent low back problems. A focused medical history and physical examination are sufficient to assess the patient with an acute or recurrent limitation due to low back symptoms of less than 4 weeks' duration. Patient responses and findings on the history and physical examination, referred to as "red flags" (Table 274-1), raise suspicion of serious underlying spinal conditions. The medical history and physical examination can also alert the clinician to nonspinal pathology (abdominal, pelvic, and thoracic) that can present as low back symptoms. [15]

From Medical History		
Fracture	Tumor	Cauda Equina
Major trauma, such as vehicle accident or fall from height. Minor trauma or even strenuous lifting (in older or potentially osteoporotic patient).	Age over 50 or under 20. History of cancer. Constitutional symptoms, such as recent fever or chills or unexplained weight loss. Risk factors for spinal infection: recent bacterial infection (e.g., urinary tract infection); IV drug abuse; or immune suppression (from steroids, transplant, or HIV). Pain that worsens when supine; severe nighttime pain.	Saddle anesthesia. Recent onset of bladder dysfunction, such as urinary retention, increased frequency, or overflow incontinence. Severe or progressive neurologic deficit in the lower extremity.
From Physical Examination for any Potentially Serious Conditions		
Unexpected laxity of the anal sphincter. Perianal/perineal sensory loss. Major motor weakness: quadriceps (knee extension weakness); ankle plantar flexion, eversion, and dorsiflexors (foot drop).		

TABLE 274-1   Red Flags for Potentially Serious Conditions

AHCPR classifies low back problems into working categories:

Potentially serious spinal condition—tumor, infection, spinal fracture, or a major neurologic compromise, such as cauda equina syndrome, suggested by a red flag.

Sciatica—back-related lower limb symptoms suggesting lumbosacral nerve root compromise.

Nonspecific back symptoms—occurring primarily in the back and suggesting neither nerve root compromise nor a serious spinal condition.

Objectives of the diagnostic process are to rule out a serious systemic disease and neurologic compromise by searching for "red flags" for spine fracture, tumor, infection, cauda equina syndrome, or nonspinal pathology. Given the many variables impacting onset and persistence of back problems, one must also assess social or psychological distress (nonphysical factors) that may amplify or prolong pain. [16]

If a potentially dangerous problem is not present, diagnostic testing in the first 4 weeks of symptoms is not helpful. Ultimately, the treatment goal is to improve activity tolerance rather than focus on pain. Evaluation and treatment algorithms and tables are provided within the guideline to assist in initial and follow-up assessment of patients. A patient's estimate of personal activity intolerance due to low back symptoms contributes to the clinical assessment of the severity of the back problem, guides treatment, and establishes a baseline for recommending daily activities and evaluating progress. [15]

Spinal fracture may be suspected in major trauma, such as motor vehicle accident or fall from height, or minor trauma, or even strenuous lifting in an older or potentially osteoporotic patient. The examiner must give credence to the history, age, and circumstances of onset in establishing a diagnosis. For example, an elderly woman with acute onset, severe midthoracic pain, without a history of trauma, can be presumed to have an osteoporotic vertebral compression fracture until proved otherwise. Sacral insufficiency fractures may also be considered in elderly women. [17] Compression fracture is increasingly likely in patients over age 50 and more so for those over 70 years old. History of trauma or steroid use also supports this in the differential diagnosis (see Table 274-1).

Less than 1 percent of patients presenting to a general medical clinic with low back pain (LBP) had cancer. [16] All patients with cancer-related LBP had at least one of the following: age ³50 (80 percent); previous history of breast, lung, or prostate cancer (33 percent); unexplained weight loss, fever, chills; failure of conservative therapy; no relief with bedrest or supine position; and pain duration >1 month. Percussion pain over the bony spine itself supports the presence of an osseous abnormality, such as compression fracture, metastasis, or disk or vertebral infection. [18]

In patients found to have a spinal infection, fever was only associated 27 percent of the time. Other factors that raise the suspicion of infection are IV drug use, urinary tract infection, skin infection, and immune suppression due to steroids, transplant, or HIV. Disk space infections are relatively uncommon and are most often associated with recent disk surgery. However, they can also occur in association with a remote infection, that is, kidney, skin, distal trauma to a bursa, or in the drug addicted, or can also arise spontaneously in rare cases. [18]

The onset of lumbosacral pain associated with bilateral leg pain radiation and a sudden loss of bladder control should be presumed to be a midline herniated disk with the threat of paraparesis (cauda equina syndrome). This demands careful neurologic exam including rectal examination for sensory changes ("saddle anesthesia"), examination for motor and reflex function, and examination for possible immediate consultation for emergent imaging and possibly surgical intervention.

Physical Examination

Guided by the medical history, the physical examination includes: general observation of the patient; a regional back examination; neurologic screening; and testing for sciatic nerve root tension. The examination is mostly subjective because patient response or interpretation is required for all parts except reflex testing and circumferential measurements for atrophy.

Addressing Red Flags

Physical examination evidence of severe neurologic compromise that correlates with the medical history may indicate a need for immediate consultation. The examination may further modify suspicions of tumor, infection, or significant trauma. [15] If it does, then the physical examination must include abdominal, vascular, neurologic, and lower extremity evaluation. Abdominal visceral palpation and auscultation over the aorta and renal arteries, as well as an assessment of peripheral pulses, color, and temperature, should be routine.

Observation and Regional Back Examination

With the patient disrobed, the spine and pelvis should be observed for abnormal spinal curves, pelvic tilts, or the presence of spinal-pelvic lists, all suggesting splinting or guarding in response to pain. Each vertebra should be palpated to identify point tenderness that suggests bony involvement. The gait should be observed for a loss of normal, symmetric spinal-pelvic rhythm. Asymmetric posturing suggests pain or weakness to which the patient is biomechanically accommodating. Guarding or splinting can best be demonstrated at slower cadences and can be dramatically accentuated by spinal extension and flexion maneuvers.

Extension and lateral flexion toward the painful side of the lumbar spine on the pelvis narrows the neural foramina and loads the zygapophyseal joints on the ipsilateral side and aggravates local articular pain. Similarly, extension and lateral flexion to the opposite side reduce the load on the symptomatic joints and open the neural foramina, reducing pain. Flexion maneuvers can demonstrate painful limitations of spinal-pelvic range of motion as measured from fingertips to toes; adjacent spinal segments may be visualized to move as a singular unit in response to localized guarding.

Palpation of the paraspinal muscles and the spinal vertebral processes in relation to their relative excursion to each other vividly dramatizes this loss of spinal segment mobility.

The presence of an acute lumbar radiculopathy associated with a "tethered" root or prefixed spinal root syndrome initiates a precipitous sequence of maneuvers on

the painful side in an effort to unload the root, which includes a lateral thrust of the spine, elevation, and forward thrust of the pelvis, as well as acute flexion of the hip and knee to reduce tension on the inflamed nerve root.

With mechanical dysfunction of posture or the presence of neurologic signs such as alteration of deep tendon reflexes, weakness, atrophy, restricted or crossed straight leg–raising (CSLR) signs, and the presence of long tract signs or sphincter dysfunction, the diagnosis of primary spinal-neural pathology becomes self-evident.

Establishing a diagnosis in the absence of neurologic signs is more difficult. The examiner must rely to a greater extent on the details of the history and the ability to replicate and alleviate symptoms by anatomic maneuvers.[19]

Neurologic Screening

The neurologic examination can focus on a few tests that seek evidence of nerve root impairment, peripheral neuropathy, or spinal cord dysfunction. As noted, over 90 percent of all clinically significant lower extremity radiculopathy due to disk herniation involves the L5 or S1 nerve root at the L4–L5 or L5–S1 disc level. The clinical features of nerve root compression are summarized in Fig. 274-1.

FIG. 274-1. Testing for lumbar nerve root compromise.

Testing for Muscle Strength

An inability to walk on either the heels or the toes because of weakness in the foot dorsiflexors or plantar flexors, respectively, suggests an L5 radiculopathy in the former case and S1 root involvement in the latter instance. Similarly, difficulty in assuming or arising from a squatting position may indicate quadriceps weakness associated with L4 root compromise. Muscle atrophy can be detected by circumferential measurements of the calf and thigh bilaterally. Differences of less than 2 cm in measurements of the two limbs at the same level may be a normal variation.[15] Weakness of the hip flexors suggests L3 compromise, of the quadriceps L4, the foot dorsiflexors and great toe extensors L5, and the calf S1 radiculopathy. Deep tendon reflexes are tested and compared one side with the other. An absent or reduced knee jerk suggests an L4 radiculopathy, biceps femoris jerk L5, and an asymmetric Achilles reflex an S1 root compression syndrome.[15] Up-going toes in response to stroking the plantar footpad (Babinski or plantar response) may indicate upper motor neuron abnormalities (such as myelopathy or demyelinating disease), rather than a common low back problem. Testing light touch or pressure in the medial (L4), dorsal (L5), and lateral (S1) aspects of the foot (see Fig. 274-1) is usually sufficient for sensory screening.[15]

Clinical Tests for Sciatic Tension

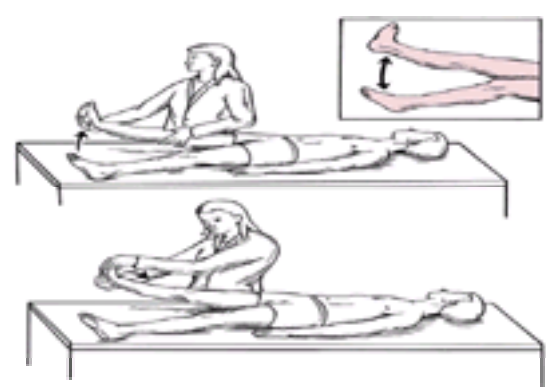
Straight leg–raising testing can be both confusing and diagnostic. The SLR test (Fig. 274-2) can detect tension on the L5 and/or S1 nerve root. SLR may reproduce leg pain by stretching nerve roots irritated by a disk herniation. Pain below the knee at less than 70° of straight leg raising, aggravated by dorsiflexion of the ankle and relieved by ankle plantar flexion or external limb rotation, is most suggestive of tension on the L5 or S1 nerve root related to disk herniation. Reproducing back pain alone with SLR testing does not indicate significant nerve root tension.[15] A CSLR sign occurs when contralateral leg elevation produces sciatic pain in the symptomatic leg. Crossover pain is a stronger indication of nerve root compression than pain elicited from raising the straight painful limb. A markedly positive SLR in the younger patient is more likely associated with a prolapsed intervertebral disk than in an older patient, particularly when it is associated with a positive CSLR.


FIG. 274-2. Instructions for the straight leg–raising (SLR) test. 1. Ask the patient to lie as straight as possible on a table in the supine position. 2. With one hand placed above the knee of the leg being examined, exert enough firm pressure to keep the knee fully extended. Ask the patient to relax. 3. With the other hand cupped under the heel, slowly raise the straight limb. Tell the patient, "If this bothers you, let me know, and I will stop." 4. Monitor for any movement of the pelvis before complaints are elicited. True sciatic tension should elicit complaints before the hamstrings are stretched enough to move the pelvis. 5. Estimate the degree of leg elevation that elicits complaint from the patient. Then determine the most distal area of discomfort: back, hip, thigh, knee, or below the knee. 6. While holding the leg at the limit of straight leg raising, dorsiflex the ankle. Note whether this aggravates the pain. Internal rotation of the limb can also increase the tension on the sciatic nerve roots.

Additional confirmatory maneuvers include an exacerbation of pain with foot dorsiflexion or with the addition of head flexion with the SLR maneuver held at the symptomatic limit of sciatic pain tolerance. In the older patient, positive SLR or CSLR tests are less specific as to pain etiology but do suggest a radicular component of involvement.[15] Sitting knee extension (Fig. 274-3) can also test sciatic tension. The patient with significant nerve root irritation tends to complain or lean backward to reduce tension on the nerve.[15]

FIG. 274-3. Instructions for sitting knee extension test. With the patient sitting on a table, both hip and knees flexed at 90 degrees, slowly extend the knee as if evaluating the patella or bottom of the foot. This maneuver stretches nerve roots as much as a moderate degree of supine SLR.

Inconsistent Findings and Pain Behavior

The patient who embellishes a medical history, exaggerates pain perception, or provides responses on physical examination inconsistent with known physiology can be particularly challenging.[15] This condition can be objectified in the physical exam with the use of Waddell's nonorganic physical signs.[20] Tests can be included in the flow of the general physical exam for the back. Testing includes tenderness to superficial skin rolling; report of low back pain with axial loading or when the whole body is rotated as one; the "flip test," in which the patient does not report pain with seated straight leg raise (often using distraction of manual muscle testing the quadriceps or ankle dorsiflexors) but reports pain at a low angle on the supine SLR; weakness or sensory loss in a nonanatomic distribution; and overreaction with "pain behaviors." If three or more of these signs are present, it represents increased psychological distress on the part of the patient to their condition. While it can be frustrating to the clinician, it is usually not purposeful, nor is it evidence of malingering or a mental disorder. Considering it a "cry for help" on the part of the patient allows the clinician to offer appropriate support and psychological intervention as follow-up. In patients with recurrent back problems, inconsistencies and amplifications may simply be habits learned during previous medical evaluations. In working with these patients, the clinician should attempt to identify any psychological or socioeconomic pressures that might be influenced in a positive manner. The overall goal should always be to facilitate the patient's recovery and avoid the development of chronic low back disability.[15] In the emergency department, one must also be aware of the patient demonstrating drug-seeking behavior.

In patients with pain, further diagnostic studies are often considered, especially given the difficulty of establishing a definitive anatomic structure to account for the patient's condition.

Diagnostic Studies

Prior to ordering imaging studies the clinician should have noted either the emergence of a red flag or physiologic evidence of tissue insult or neurologic dysfunction.[15]

Plain x-rays of the lumbar spine are recommended for ruling out fractures in patients with acute low back problems when any of these red flags are present: recent significant trauma (any age), recent mild trauma (patient age over 50), history of prolonged steroid use, osteoporosis, or patient age over 70. Oblique views are not necessary.[14] Laboratory tests such as erythrocyte sedimentation rate (ESR), complete blood count (CBC), and urinalysis (UA) can be useful to screen for nonspecific medical diseases (especially infection and tumor) of the low back.[15] Plain x-rays in combination with CBC and ESR may be useful for ruling out tumor or infection in patients with acute low back problems when any of these red flags are present: prior cancer or recent infection, fever over 100°F, IV drug abuse, prolonged steroid use, low back pain worse with rest, or unexplained weight loss. If tumor or infection is suspected, CT or MRI may be considered in the presence of red flags, even if plain films are negative. In the presence of red flags suggesting cauda equina syndrome or progressive major motor weakness, prompt use of CT, MRI, myelography, or CT-myelography is recommended. Because these conditions may require timely surgical intervention, planning and choice of study is best carried out in consultation with a surgeon. In patients with acute back problems who have had prior back surgery, MRI with contrast is the imaging test of choice because it can help distinguish disk herniation from scar tissue from previous surgery.[14] A bone scan can detect physiologic reactions to suspected spinal tumor, infection, or occult fracture.[15]

When the neurologic examination is less clear, however, further physiologic evidence of nerve root dysfunction should be considered before ordering an imaging study. Electromyography (EMG), including H-reflex tests, may be useful to identify subtle focal neurologic dysfunction in patients with leg symptoms lasting longer than 3 to 4 weeks. Sensory evoked potentials (SEPs) may be added to the assessment if spinal stenosis or spinal cord myelopathy is suspected.[15]

There is a 20 to 40 percent false-positive rate with plain films, CT, MRI, and myelogram. The altered anatomic structures identified may not be responsible for the patient's pain. Most findings on these studies are consistent with normal degenerative changes and are also found in asymptomatic individuals. Any imaging abnormalities must correlate with the patient's symptoms and signs to be of value in guiding treatment.

Treatment

In the evaluation of back syndromes, the examiner's goal is to discriminate between pain of neurogenic origin and pain of musculoskeletal origin, as well as to rule out nonspinal pathology. Although the potential for surgical intervention is by far greater with neurologic than with musculoskeletal involvement, in both instances surgery is indicated in less than 1 percent of all cases. If no red flags are identified that would require diagnostic imaging or immediate consultation, symptomatic treatment may be initiated. Fortunately, the majority of all lumbosacral syndromes respond to routine symptomatic treatment, including relative rest, progressive activity, simple comfort measures such as superficial heat, and oral analgesics.[19]

Patient Education

If the initial assessment detects no serious condition, assure the patient that there is "no hint of a dangerous problem" and that "a rapid recovery can be expected." The need for education varies among patients and during various stages of care. An obviously apprehensive patient may require a more detailed explanation. Patients with sciatica may have a longer expected recovery time than patients with nonspecific back symptoms and thus may need more education and reassurance. Any patient who does not recover within a few weeks may need more extensive education about back problems and the reassurance that special studies may be considered if recovery is slow.[15] This points out the necessity of follow-up referral in this patient population.[19]

Medication

Comfort is often a patient's first concern. Nonprescription analgesics will provide sufficient pain relief for most patients with acute low back symptoms. If treatment response is inadequate, as evidenced by continued symptoms and activity limitations, prescribed pharmaceuticals or physical methods may be added. Table 274-2 summarizes comfort options.[15] Muscle relaxants seem no more effective than NSAIDs for treating patients with low back symptoms, and using them in combination with NSAIDs seems to have no demonstrated benefit. Side effects including drowsiness have been reported in up to 30 percent of patients taking muscle relaxants.[15]

Recommended		
Nonprescription analgesics Acetaminophen (safest) NSAIDs (Aspirin,* Ibuprofen*)		
Prescribed Pharmaceutical NAeRxols	Prescribed Physical NAeRxols	
Nonspecific low back symptoms and/or sciatica Other NSAIDs*	Nonspecific low back symptoms Manipulation (in place of medication or a shorter trial of combined with NSAIDs)	
Options		
Nonspecific low back symptoms and/or sciatica Muscle relaxant‡,§ Opioids†,‡,§	Nonspecific low back symptoms Physical agents and modalities‖ (heat or cold modalities for home program only) Shoe insoles‖	Sciatica Manipulation (in place of medication or a shorter trial of combined with NSAIDs) Physical agents and modalities‖ (heat or cold modalities for home program only) Few days' rest‖ Shoe insoles‖

*Aspirin and other NSAIDs are not recommended for use in combination with one another due to the risk of GI complications.
†Equivocal efficacy.
‡Significant potential for producing drowsiness and debilitation; potential for dependence.
§Short course (few days only) for severe symptoms.

TABLE 274-2 Symptom Control Methods

Opioids appear no more effective than safer analgesics for managing low back symptoms. Opioids should be avoided if possible and, when chosen, used only for a short time. Poor patient tolerance and risks of drowsiness, decreased reaction time, clouded judgment, and potential misuse/dependence have been reported in up to 35 percent of patients. Patients should be warned of these potentially debilitating problems. [15]

Physical Methods

Manipulation, which is defined as manual loading of the spine using short- or long-leverage methods, is safe and effective for patients in the first month of acute low back symptoms without radiculopathy. For patients with symptoms lasting longer than 1 month, manipulation is probably safe, but its efficacy is unproved. If manipulation has not resulted in symptomatic and functional improvement after 4 weeks, it should be stopped and the patient reevaluated. [15,16]

Other interventions, including traction, massage, diathermy, ultrasound, cutaneous laser application, biofeedback, application of shoe lifts, and transcutaneous electrical nerve stimulation (TENS), have not yet been found to provide any lasting benefit. Instruction in self-application of heat or cold may be provided for temporary symptom relief. Additionally, invasive techniques such as needle acupuncture and injection procedures (injection of trigger points in the back; injection of facet joints; injection of steroids, lidocaine, or opioids in the epidural space) have no proven benefit. [15]

AHCPR Guidelines for Activity Limitations

To avoid both undue back irritation and debilitation from inactivity, recommendations for alternate activity can be helpful. Bedrest is reserved for patients with the most severe limitations (due primarily to leg pain). [15] This should not exceed 2 days. In general, especially if no red flags have arisen, patients should be instructed to return to their usual daily activities including work as soon as able. The AHCPR guidelines outline the approach described below to activity limitations.

AVOIDING UNDUE BACK IRRITATION Activities and postures that increase stress on the back also tend to aggravate back symptoms. Patients limited by back symptoms can minimize the stress of lifting by keeping any lifted object close to the body at the level of the navel. Twisting, bending, and reaching while lifting also increase stress on the back. Sitting, although safe, may aggravate symptoms for some patients. Advise these patients to avoid prolonged sitting and to change position often. A soft support placed at the small of the back, armrests to support some body weight, and a slight recline of the chair back may make required sitting more comfortable. [15]

AVOIDING DEBILITATION Until the patient returns to normal activity, aerobic (endurance) conditioning exercise such as walking, stationary biking, swimming, and even light jogging may be recommended to help avoid debilitation from inactivity. An incremental, gradually increasing regimen of aerobic exercise (up to 20 to 30 minutes daily) can usually be started within the first 2 weeks of symptoms. Such conditioning activities have been found to stress the back no more than sitting for an equal time period on the side of the bed. Patients should be informed that exercise may increase pain slightly at first. If intolerable, some exercise alteration is usually helpful. [15]

Conditioning exercises for trunk muscles are more mechanically stressful to the back than aerobic exercise. Such exercises are not recommended during the first few weeks of symptoms, although they may later help patients regain and maintain activity tolerance. [15]

There is no evidence to indicate that back-specific exercise machines are effective for treating acute low back problems. Neither is there evidence that stretching of the back helps patients with acute symptoms. [15]

WORK ACTIVITIES When requested, clinicians may choose to offer specific instructions about activity at work for patients with acute limitations due to low back symptoms. The patient's age, general health, and perceptions of safe limits of sitting, standing, walking, or lifting (noted on initial history) can provide reasonable starting points for activity recommendations. Table 274-3 provides a guide for recommendations about sitting and lifting. The clinician should make clear to patients and employers that even moderately heavy unassisted lifting may aggravate back symptoms. Any restrictions are intended to allow for spontaneous recovery or time to build activity tolerance through exercise. Activity restrictions are prescribed for a short time period only, depending upon work requirements (no benefits are apparent beyond 3 months' restriction). [15]

Symptoms	Severe	→	Moderate	→	Mild	→	None
Sitting*	20 min	→	→	→	→	→	50 min
Unassisted lifting†							
Men	20 lb	→	20 lb	→	60 lb	→	80 lb
Women	20 lb	→	20 lb	→	35 lb	→	40 lb

*Without getting up and moving around.
†Modification of NIOSH Lifting Guidelines, 1981, 1993. Gradually increase unassisted lifting limits to 60 lbs (men) and 35 lbs (women) by 3 months, even with continued symptoms. Instruct patient to limit twisting, bending, reaching while lifting and to hold lifted object as close to umbilicus as possible.

TABLE 274-3 Guidelines for Sitting and Unassisted Lifting

REFERRAL

Referral for continuing outpatient care is absolutely critical. When seen on a one-time basis in the emergency center, each patient should be provided with an opportunity for follow-up in the event that the problem fails to respond to initial treatment. No matter how searching the physical examination, and notwithstanding the experience of the examiner, clinical manifestations can change rapidly, often dramatically, for example, the blossoming of the skin manifestations of herpes zoster 2 days after pain onset, to be recognized only by subsequent evaluations and further diagnostic studies such as MRI or EMG. Also, if the patient is given activity limitations and work restrictions, the limitations and restrictions require reevaluation to further substantiate need for these limits and to instruct patients in progressive return to activity. Referral to a specialist in physical medicine and rehabilitation for conservative spine care, a spine surgeon, or a multidisciplinary spine center offers the patient comprehensive management that would hopefully reduce future emergency department visits, especially as the patient's condition becomes more complex and perhaps less acute.

275 SHOULDER PAIN

D. Monte Hunter

Shoulder pain is one of the most common musculoskeletal complaints of patients over age 40. Work, recreation, and normal daily activities all place great demands on the shoulder. Of all adult patients presenting for evaluation of shoulder pain, one-third related their pain to work, one-third related their pain to athletic activity, and one-third could not identify any one specific precipitating event or factor.

Injuries involving the rotator cuff are the most common cause of shoulder pain. While these injuries can be acute, they more commonly occur from chronic overuse. Overuse can produce pathologic changes in the rotator cuff structures that progress along the continuum starting with subacromial bursitis from mechanical irritation, progressing to rotator cuff tendinitis, and eventually leading to partial and full thickness rotator cuff tears. Laborers who work with their arms above the horizontal and athletes of all ages, especially throwers, swimmers, and racquet sports enthusiasts, are the most susceptible to chronic overuse injuries. Acute injuries to the rotator cuff usually require significant trauma such as extreme forced hyperabduction or hyperextension of the upper extremity.

While disorders of the rotator cuff are the most common cause of shoulder pain, conditions affecting other intrinsic structures of the shoulder complex also can cause pain. Additionally, extrinsic disorders can refer pain to the shoulder and must be considered in the differential diagnosis. A focused history and physical examination carried out with an understanding of the complex anatomy and function of the shoulder are essential in determining the source of shoulder pain. Establishing the proper diagnosis, initiating the appropriate treatment, and making timely referrals for follow-up are critical in preserving the function and mobility of the shoulder.

FUNCTIONAL ANATOMY

The shoulder is the most versatile and yet the most vulnerable joint in the body. With range of motion greater than any other joint in the body, the shoulder is designed for mobility rather than stability. The ultimate function of the shoulder is to help position the hand and upper extremity for accurate and efficient use. The shoulder is also designed to provide strength and power to upper extremity movements. To meet the many demands placed on it, the shoulder uses three bones, four joints, and a specialized set of soft tissues consisting of muscles, tendons, ligaments, and bursae.

Bones and Joints

The humerus, clavicle, and scapula make up the bony structures of the shoulder complex. The scapula has two bony extensions, the coracoid and the acromion, which help protect the rotator cuff and play important roles in shoulder function.

The four joints of the shoulder include the glenohumeral, acromioclavicular, sternoclavicular, and scapulothoracic. All of these must work together to provide full shoulder motion and function. The *glenohumeral joint* is the most prominent and complex joint of the shoulder. This ball-and-socket joint is the central axis of motion of the shoulder. While the glenohumeral joint enjoys great freedom of motion, it is also recognized as the least stable joint in the body. To help improve its stability, this joint relies on three components. The first is the labrum, a fibrous band of tissue lining the glenoid cavity, analogous to the meniscus of the knee. The labrum increases the surface contact area of the humeral head within the glenoid. The second component consists of three glenohumeral ligaments, which aid stability by

reinforcing the joint capsule. Finally, four specialized muscles known as the rotator cuff encompass the glenohumeral joint and provide stability during motion.

The *sternoclavicular* and *acromioclavicular joints* work together to contribute to glenohumeral motion. Rotation at the acromioclavicular joint and elevation at the sternoclavicular allow complete arm elevation. The *scapulothoracic joint* represents the articulation of the scapula on the posterior wall of the thorax. Scapular motion is essential for overall shoulder motion: every degree of scapulothoracic motion allows two degrees of glenohumeral motion.

Muscles

The muscles of the shoulder complex not only generate motion and power for the upper extremity but also provide significant stability for the glenohumeral joint. The deltoid, which drapes the shoulder complex and forms its contour, acts as a powerful and independent elevator of the arm. Along with the pectoralis, the deltoid is the major mover of the upper extremity.

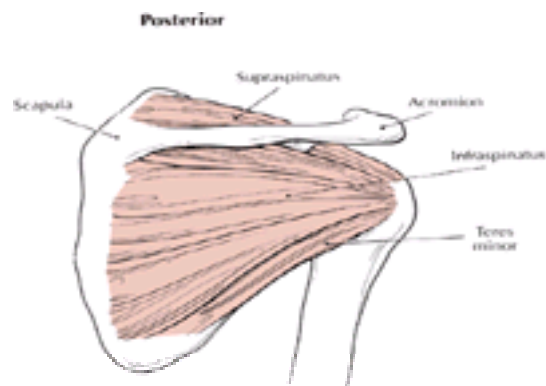
The rotator cuff consists of four muscles: the supraspinatus, the infraspinatus, the teres minor, and the subscapularis. All originate on the scapula, traverse the glenohumeral joint, and insert on the proximal humerus. The rotator cuff functions primarily as a dynamic stabilizer of the glenohumeral joint. The rotator cuff muscles also contribute significantly to the power of the upper extremity, providing 30 to 50 percent of the power in abduction and 90 percent in external rotation (Fig. 275-1, Fig. 275-2).


FIG. 275-1. Posterior view of shoulder illustrating rotator cuff muscles.
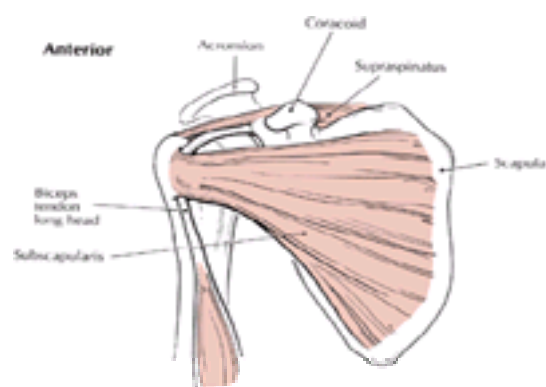

FIG. 275-2. Anterior view of shoulder illustrating supraspinatus and long head of biceps.

The *supraspinatus* originates on the posterior and superior aspect of the scapula, passes beneath the acromion, and inserts on the great tuberosity of the humerus. It initiates arm elevation and abducts the shoulder. It also balances the power of the deltoid, keeping the humerus centered in the glenoid during deltoid contraction.

The *infraspinatus* originates on the posterior scapula just inferior to the scapular spine. It inserts on the posterior aspect of the greater tuberosity and acts primarily as an external rotator of the arm (Fig. 275-1).

The *teres minor* originates on the lateral border of the scapula just inferior to the infraspinatus and inserts on the posterior aspect of the humerus. It works with the infraspinatus to provide external rotation (Fig. 275-1).

The *subscapularis* is the only rotator cuff muscle that arises from the anterior aspect of the scapula. It attaches to the lesser tuberosity of the humerus and provides internal rotation of the arm (Fig. 275-2).

The *long head of the biceps tendon*, although not formally considered part of the rotator cuff, assists in rotator cuff function. This tendon courses superiorly in the bicipital groove of the humerus between the greater and lesser tuberosities, passes between the subscapularis and supraspinatus tendons, and penetrates the glenohumeral joint to insert on the labrum (Fig. 275-2). During arm elevation, the tendon of the long head of the biceps depresses the humeral head, helping it remain centered in the glenoid.

Bursae

The bursae facilitate motion between the components of the shoulder. There are eight identifiable bursae in the shoulder complex. However, only one, the large subacromial bursa, also known as the subdeltoid bursa, is clinically significant. The subacromial bursa is extraarticular; its roof adheres to the undersurface of the deltoid, and its floor to the underlying rotator cuff. A thick layer of synovial fluid between the roof and the floor normally allows smooth frictionless motion between the rotator cuff and adjacent structures.

Coracoacromial Arch

The coracoacromial arch is an important anatomic concept in understanding shoulder pathology. The arch is formed by the coracoid posteriorly, by the acromion anteriorly, and by the coracoacromial ligament, which forms the anterior roof of the arch (Fig. 275-3). The humeral head provides the floor of the arch. This arch defines the space within which the muscles of the rotator cuff, the tendon of the long head of the biceps, and the subacromial bursa must fit and function. The coracoacromial ligament is considered vestigial; however, by virtue of its position it can contribute to compression or impingement of the rotator cuff.
FIG. 275-3. Lateral view of shoulder illustrating coracoacromial arch with rotator cuff and subacromial bursa.

IMPINGEMENT SYNDROME

Repetitive use of the arm overhead or above the horizontal compresses the rotator cuff and related structures between the humeral head and coracoacromial arch (Fig. 275-4). The *impingement syndrome* refers to the pathologic changes that occur in the structures of the rotator cuff due to this repetitive compression. Also referred to as *painful arc syndrome*, *cuffitis*, *supraspinatus syndrome*, and *bursitis*, impingement syndrome is the leading cause of shoulder pain and dysfunction. A basic understanding of this concept is essential for the proper evaluation and treatment of the patient with shoulder pain.
FIG. 275-4. Impingement of subacromial bursa and rotator cuff.

Pathophysiology

Repetitive impingement of the bursa, rotator cuff, and biceps tendon produces pathologic changes in these structures that progress in a predictable pattern. Early on, repetitive motion produces mechanical inflammation of the subacromial bursa and underlying rotator cuff. As activities that cause impingement continue, inflammation of the rotator cuff tendons worsens. Chronic inflammation in time leads to degeneration and eventual tearing of the rotator cuff. Degeneration of the rotator cuff exposes the biceps tendon, making it susceptible to degeneration and rupture. As the soft tissue restraints of the shoulder wear out, degenerative disease sets in and is typical of the advanced stages of the impingement syndrome.

Most of the pathologic changes in the rotator cuff due to impingement occur near the humeral insertion of the tendon. This area is referred to as the *critical zone* and has been identified as relatively avascular. Repetitive compression causes relative ischemia in this area. Over time this area degenerates and ultimately fails. The critical zone is the most common site of all rotator cuff abnormalities. The supraspinatus, due to its location in the coracoacromial arch, is the most commonly affected muscle of the rotator cuff.

Three stages of impingement are identifiable. Stage 1 is characterized by local inflammation, edema, and hemorrhage and is most commonly associated with subacromial bursitis and early rotator cuff tendinitis. These changes are considered reversible. Stage 2 is characterized by inflammation, thickening, and fibrosis of the rotator cuff tendons. Stage 3 is characterized by degeneration and rupture of the rotator cuff tendon. Degenerative changes in the bony structures of the shoulder usually accompany stage 3. Stages 2 and 3 are considered to be irreversible.

Clinical Features

Specific maneuvers on physical examination test for signs of impingement by compressing the rotator cuff and bursa between the humeral head and coracoacromial arch. Neer's impingement test requires the examiner to move the patient's straightened arm smoothly but forcibly to full abduction. This compresses the cuff and bursa against the undersurface of the acromion. A second test, Hawkins' impingement test, requires the examiner to position the patient's arm in 90° of abduction and 90° of elbow flexion. Rotation of the arm inwardly across the front of the patient's body compresses the cuff and bursa between the humeral head and coracoacromial ligament. These tests are considered positive if they reproduce pain.

Emergency Department Treatment

The goals of treatment of impingement lesions are twofold: to reduce pain and inflammation and, more importantly, to prevent progression of the process. Regardless of the stage of impingement identified, a conservative treatment program initiated by the emergency physician should include the following:

1. *Relative rest and modification of activities.* However, immobilization should be avoided whenever possible. Brief periods of support with a sling may be prescribed.
2. *Medication to reduce pain and inflammation.* Often analgesics are required to control pain during stage 2 and 3 impingement. Nonsteroidal anti-inflammatory agents can be prescribed for a 7- to 10-day course.
3. *Cryotherapy.* The application of ice to the affected shoulder for 10 to 15 min two to three times per day can have analgesic effects and is thought to reduce local inflammation and edema.
4. *Gentle range of motion.* Two simple exercises can help the patient maintain glenohumeral motion. Pendulum swings are done with the patient slightly bent at the waist with the arm hanging freely in front of the body. Gentle arcs of motion to the level of pain tolerance can be carried out for 5 to 10 min daily. The size of the arcs should increase daily as symptoms allow. Also, having the patient walk his or her fingers up the wall to the level of pain tolerance can also help preserve glenohumeral motion.
5. *Stretching and strengthening.* During stage 1 impingement, stretching and strengthening may be initiated early on. Entering stage 2 and 3 impingement, stretching and strengthening are most effectively carried out under the supervision of a physical therapist. This is an important part of the treatment of impingement and is usually prescribed by the primary care physician or orthopaedist, who can monitor the patient's response to therapy.
6. *Corticosteroid injections.* While local corticosteroid injections into the subacromial space can be effective for pain relief, their deleterious effects on soft tissues have been well documented. These include muscular atrophy, weakness, and further tissue degeneration. Injection directly into the substance of the tendon can lead to necrosis and rupture. Even in the primary clinician's office setting, the judicious use of corticosteroids is advised, with no more than two to three injections being recommended in one specific area. While a single injection is not believed to be harmful, caution is still advised for use in the emergency department because of the potential harmful effects of repeated injections and difficulty in ensuring reliable follow-up.

Follow-up

Timely referral for all stages of impingement is crucial to help preserve function and mobility in the shoulder. Clinical follow-up is usually recommended after 7 to 14 days for stage 1 and 2 lesions. For stage 3 lesions, associated with chronic disability or other concern for rotator cuff tears, more acute follow-up is recommended.

If symptoms have diminished at the time of follow-up, a supervised course of therapy with emphasis on rotator cuff stretching and strengthening may be prescribed. If the symptoms persist or have worsened, the clinical physician may attempt a subacromial injection of glucocorticoid to help arrest the inflammatory response. If symptoms persist despite full conservative measures after 6 to 12 weeks of treatment, further workup with arthrography, magnetic resonance imaging (MRI), or arthroscopy to rule out rotator cuff tearing may be carried out at the discretion of the primary clinical provider.

SUBACROMIAL BURSITIS

Pathophysiology

Subacromial bursitis is associated with stage 1 impingement and is typically characterized by localized edema and inflammation in the subacromial bursa. More importantly, an early inflammation of the rotator cuff tendon usually coexists. Subacromial bursitis typically is seen in patients under 25 years of age and usually results from mechanical irritation from repetitive overhand activities. It is important that this condition be recognized because it is reversible. If left unrecognized and untreated, it progresses to the irreversible conditions associated with stage 2 and stage 3 impingement.

Primary subacromial bursitis is rare but should be considered in patients with shoulder pain who have rheumatoid arthritis, tuberculosis, gout, or pyogenic infections.

Clinical Features

Patients usually describe the pain of subacromial bursitis as a dull aching sensation deep within the shoulder, frequently following activity and usually improving with rest. Patients seek medical attention only when the symptoms affect their work, performance, or ability to compete. On physical examination, no muscular atrophy or asymmetry is present unless the symptoms have been chronic. Little if any tenderness is elicited on palpation; however, when tenderness is present it typically will be found on the lateral aspect of the proximal humerus or on deep palpation in the subacromial space. Full range of motion in the shoulder is usually preserved but may be painful, especially between 60° and 100° of abduction. The pain is worse when resistance is applied to the arm in 90° of abduction. Muscle strength in the deltoid and rotator cuff muscles is usually not affected. Impingement signs and impingement injection tests are usually positive.

Radiographic Findings

Most often radiographs are normal in the early stages of impingement associated with bursitis.

Emergency Department Treatment

The goals of treatment of subacromial bursitis and early rotator cuff tendinitis are twofold: to reduce pain and inflammation and, more importantly, to prevent progression of this reversible process to the irreversible stages of rotator cuff tendinitis and degeneration.

More than 90 percent of patients with subacromial bursitis respond to conservative measures. An effective conservative treatment plan has been outlined previously in this section. Since inflammation of the bursa is typically due to overuse, a short period of relative rest is indicated. Immobilization is not indicated and, in fact, can be detrimental, leading to adhesions and loss of motion. Total inactivity usually is not necessary. *Relative rest* implies avoidance of those activities that reproduce symptoms; e.g., a tennis player should avoid serving but can continue to hit ground strokes, and a laborer should avoid working with his or her arms over the head. Nonsteroidal anti-inflammatory agents are effective in reducing pain and inflammation. Analgesics are rarely needed to control pain. Localized ice treatment for 10 to 15 min two to three times per day will help reduce pain and inflammation. As pain diminishes, the patient should begin gentle range of motion, stretching, and strengthening exercises.

Follow-up

Clinical follow-up is recommended in 7 to 14 days. To simply diagnose "bursitis" and treat the symptoms does the patient a disservice and places the patient's shoulder at risk for future dysfunction. At the time of follow-up, if the patient's symptoms have diminished, a supervised course of therapy with emphasis on rotator cuff strengthening may be prescribed. If symptoms persist or have worsened, a subacromial injection of a glucocorticoid may help arrest the inflammatory response. If symptoms persist despite full conservative measures after 6 to 12 weeks of treatment, further workup with arthrography or MRI to rule out rotator cuff disease may be initiated at the discretion of the patient's primary clinician.

ROTATOR CUFF TENDINITIS

Pathophysiology

Inflammation of the rotator cuff tendons occurs initially in stage 1 of impingement. Continued repetitive mechanical impingement leads to irreversible fibrosis and thickening of the tendons of the rotator cuff, the hallmark of rotator cuff tendinitis. These findings are thought to represent the second stage of impingement. The supraspinatus is the tendon most commonly affected; however, any of the rotator cuff tendons may be involved.

Clinical Features

Patients with rotator cuff tendinitis are typically between the ages of 25 and 40 years, but the duration of the symptoms is more useful than age in making this diagnosis. The patient will report prior episodes of shoulder pain or a long duration of pain before seeking treatment. Since the lesion is not reversible, time and activity modification alone will not improve the symptoms. Patient describe the pain as a deep, aching discomfort that interferes with work and normal daily activities. Night pain, especially sleeping on the affected arm or with the arms above the head, will interfere with sleep. On examination, disuse atrophy of the shoulder musculature may be present if symptoms have been chronic. Palpation of the rotator cuff insertion at the lateral aspect of the proximal humerus will usually produce pain and tenderness. During range-of-motion maneuvers, fibrosis and scarring within the tendon can cause crepitus. A sensation of catching also may be present if scar tissue is trapped beneath the acromion. Both active and passive motion may be limited due to the scarring. Rotator cuff strength testing will reveal mild to moderate weakness. Pain will usually be present when resistance is applied. The individual muscles of the rotator cuff can be isolated and tested individually. To test the supraspinatus, abduct the arm to 90° and place it forward 30° with the thumb pointed down in the so-called empty beer can position. Pain or weakness against resistance in this position suggests injury to the supraspinatus. External rotation tests the infraspinatus and the teres minor. To test external rotation, place the patient's arm against the body with the elbow bent to 90° and the forearm in neutral position. Stabilize the elbow against the patient's waist and instruct the patient to rotate the arm outward. In this same position, with the elbow flexed and fixed against the patient's body, have the patient rotate the arm inward around the front of the body against resistance. This internal rotation tests subscapularis function.

The impingement sign is usually positive because the inflamed tendons are compressed beneath the coracoacromial arch. Injection of subacromial anesthetic may diminish pain but generally does not improve motion or strength significantly.

Radiographic Findings

Radiographs are most often normal but may yield helpful diagnostic clues. The presence of osteophytes off the inferior clavicle or acromion represents a long-standing process. These osteophytes can contribute to further injury to the underlying tendons. The soft tissues of the subacromial space should be inspected for evidence of calcification.

Emergency Department Treatment

Treatment of tendinitis emphasizes controlling symptoms, preserving motion, and improving strength and flexibility. Immobilization should be avoided, although an arm sling may be provided for comfort and support during acute symptoms. Nonsteroidal anti-inflammatory agents can help reduce pain and inflammation, and occasionally analgesics are necessary. Gentle range-of-motion exercises are recommended as early as symptoms allow to prevent further contraction and scarring.

Follow-up

Referral for follow-up is recommended in 7 to 14 days. Early physical therapy with treatment to reduce inflammation along with a supervised stretching and strengthening program are an integral part of treatment. Most patients with tendinitis respond to conservative management, experiencing no significant dysfunction. However, if symptoms persist despite conservative measures, further investigation for a possible degenerative rotator cuff tear may be pursued by the patient's primary physician.

ROTATOR CUFF TEARS

Tears in the rotator cuff muscles can occur from acute trauma, chronic overuse, or a combination of the two. Acute rotator cuff tears account for approximately 10 percent of all rotator cuff tears and usually occur as a result of significant trauma. Traumatic causes typically involve a fall on an outstretched arm, causing extreme hyperabduction or hyperextension. Lifting a heavy object or catching a heavy object as it falls can also cause acute rotator cuff tears. Chronic rotator cuff tears account for 90 percent of all rotator cuff tears and are usually due to progressive degeneration. Stage 3 impingement is associated with 95 percent of all chronic tears. If a degenerative tear is present, it is prone to extension with acute trauma.

Rotator cuff tears can be further classified as full thickness or partial thickness. Full thickness tears, as the name implies, involve the full extent of the tendon. Partial thickness tears, on the other hand, can exist on either the superior or inferior surface of the tendon or in the mid substance of the tendon. Partial thickness tears are twice as common as full thickness tears and most commonly occur on the inferior aspect of the tendon. Acute full thickness rotator cuff tears from a single injury are rare. Partial thickness rotator cuff tears are more likely to occur from an acute injury, especially in younger patients.

The type and extent of the tear have significant implications for the ultimate treatment and prognosis. Full thickness tears usually require surgical treatment, whereas partial thickness tears often respond to conservative management. In the emergency department it may be impossible to distinguish a full thickness tear from a partial thickness tear or even from an acute flare-up of rotator cuff tendinitis. However, it is important for the emergency physician to understand the pathophysiology of these conditions and their implications to shoulder function. Proper recognition, early intervention, and proper referral can preserve shoulder motion and function.

Pathophysiology

The critical zone of the rotator cuff is an area of relative avascularity near the humeral insertion of the tendon. Repetitive compression and impingement cause ischemia in this area. With time this area degenerates and ultimately tears. The critical zone is the most common site of all rotator cuff tears. The supraspinatus, due to its location within the coracoacromial arch, is the most commonly injured rotator cuff muscle (Fig. 275-5).
FIG. 275-5. Rotator cuff tear. MRI coronal image of shoulder reveals tear in supraspinatus tendon at the critical zone (arrow) with edema (point).

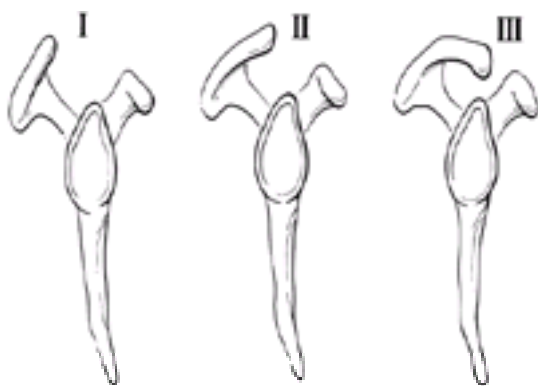
The bony structures of the shoulder can also contribute to rotator cuff tears. The acromion, which forms part of the roof of the coracoacromial arch, may be described as flat, curved, or hooked (Fig. 275-6). One clinical study associated a hooked acromion with 80 percent of rotator cuff tears, whereas a flat acromion was associated with fewer than 3 percent of tears.


FIG. 275-6. Acromial morphology. I. Flat. II. Curved. III. Hooked.

Acute traumatic rotator cuff tears, which account for 10 percent of all rotator cuff tears, require a significant force. For a single traumatic event to cause a rotator cuff tear, the force must overcome the tensile strength of the tendon. However, the tensile strength of the tendon is greater than that of bone; therefore, a bony avulsion injury of the humerus is much more common than an isolated rotator cuff tear following acute trauma (Fig. 275-7).
FIG. 275-7. Tensile strength of rotator cuff tendon is greater than bone. The patient suffered acute hyperabduction injury to arm causing extreme shoulder pain and dysfunction. Initially, radiographs (*A*) were interpreted as normal. MRI (*B*) of shoulder revealed avulsion fracture of humerus at site of supraspinatus tendon insertion.

Clinical Features

Patients with rotator cuff tears are almost always more than 40 years of age; rotator cuff tears in the young are rare. In general, the older the patient with shoulder pain, the more likely the presence of a rotator cuff tear. The clinical features of a chronic rotator cuff tear differ from those of an acute tear. Approximately one-half of all patients with chronic rotator cuff tears recall a specific trauma or an event associated with the onset of pain; however, the trauma is usually not significant. Patients more commonly report a history of gradual and progressive pain, which initially is described as worse at night. The pain eventually becomes persistent. The pain may be described as diffuse but is commonly localized to the lateral aspect of the upper arm. The patient typically reports flares of bursitis and tendinitis that initially responded to rest, anti-inflammatory agents, and glucocorticoid injections. However, as the rotator cuff weakens, the frequency, intensity, and duration of the symptoms increase and are less responsive to the usual treatments. Shoulder dysfunction progressively worsens and interferes with work, recreation, and normal daily activities. Arm elevation, external rotation, and lifting even light objects worsen the symptoms.

On examination, disuse atrophy may be present in patients with chronic rotator cuff tears. Palpation may produce discomfort at the lateral aspect of the upper arm or in the subacromial region. Active motion is variably limited by pain and weakness. Muscle strength is compromised, especially in abduction and external rotation. In fact, one study directly correlated the size of a rotator cuff tear with the strength of external rotation. The "drop arm test" is positive if the patient is unable to hold or lower a fully extended arm without dropping it. Crepitus and pain are usually present on range-of-motion testing. Injection of anesthetic into the subacromial space may diminish pain but will not improve motion or strength.

With acute injuries, such as a fall or catching a heavy object as it falls, the patient may report a sensation of "tearing in the shoulder" followed by severe pain and inability to raise the arm. An acute rotator cuff tear will produce immediate significant pain and disability. Asymmetry may be noted due to significant local swelling. A rotator cuff defect from the tear may be palpable overlying the humeral head. Active motion will be limited, with inability to abduct or externally rotate the arm against even minimal resistance. The drop arm test is positive and impingement signs are typically positive, but testing for them may not be practical after an acute injury. Injection of anesthetic into the subacromial space will not improve motion or strength.

Radiographic Findings

Radiographic findings may be supportive but are rarely diagnostic, yielding few specific clues unique to rotator cuff tears. With a large tear, the humeral head can "button hole" through the defect of the rotator cuff and assume a superior position to the glenoid. However, this is rarely appreciated. More often, radiographs will reveal findings associated with chronic rotator cuff pathology: sclerosis of the humeral head, degenerative joint disease at the acromioclavicular joint, osteophytes off the undersurface of the acromion and/or clavicle, and a hooked acromion.

Emergency Department Care

It may be clinically impossible to differentiate an acute rotator cuff strain from a partial-thickness or full-thickness rotator cuff tear. The immediate goal of emergency care for suspected rotator cuff injuries is to provide support, protection, pain relief, and most important, to help prevent further dysfunction and disability. An arm sling can be provided for support and comfort until acute symptoms subside. However, the perils of prolonged immobilization—stiffness, weakness, and loss of motion—should be emphasized to the patient. Appropriate analgesia should be provided, as should instruction in the proper use of ice two to three times per day to reduce pain and inflammation. When symptoms allow, gentle range-of-motion exercises such as pendulum swings and walking the fingers up the wall should be started.

Follow-up

Any patient with a suspected acute rotator cuff tear or with significant disability should receive prompt referral to an orthopaedist within 7 days. Young patients with full-thickness rotator cuff tears usually require surgical repair. Functional results are better if repair is carried out within 3 weeks of injury, before retraction, fibrosis, tendon degeneration, and muscular atrophy have occurred. Partial thickness or chronic tears may respond to conservative measures; however, early referral is warranted. If symptoms are improving at follow-up, conservative measures with physical therapy may be initiated. If significant symptoms and dysfunction persist, additional evaluation by MRI or CT arthrography may be pursued to determine the full extent of injury.

Following acute injuries, any evidence or suspicion of neurovascular compromise requires immediate orthopaedic consultation.

CALCIFIC TENDINITIS

Pathophysiology

Calcific tendinitis is considered a unique and still poorly understood disease process. It is characterized by the deposition of calcium hydroxyapatite crystals within one or more tendons of the rotator cuff. In time, the calcium deposition undergoes spontaneous resorption, with subsequent healing of the tendon. Calcific tendinitis does not appear to be related to any generalized disease process nor does its presence correlate with episodes of trauma or incidence of rotator cuff tears.

Primary tendon degeneration as a result of chronic repetitive microtrauma, age, or tissue hypoxia is considered to be the primary cause of this disorder. The supraspinatus is by far the most commonly affected tendon, with calcium deposition usually occurring 1 to 2 cm proximal to the insertion on the humerus; however, any of the rotator cuff tendons as well as the tendon of the long head of the biceps may be affected. After a variable period following the deposition of the calcium, spontaneous resorption occurs. The factors triggering resorption are unclear. With resorption of the calcium, the defect in the tendon remodels and heals.

The initial formation of the deposit is associated with few, if any, symptoms and little dysfunction. However, significant pain is associated with the resorption of the calcium deposit. This pain is thought to be due to the relative increase in pressure and volume within the tendon caused by vascular proliferation and the formation of granulation tissue.

Clinical Features

Patients in their thirties and forties are most commonly affected. This process is rarely seen in patients over 70. Of patients older than age 30 with shoulder pain, calcification in the rotator cuff tendons is found in approximately 7 percent. However, in asymptomatic patients between 31 and 40, 10 to 20 percent demonstrate rotator cuff calcification on routine radiographs. Of these patients, 35 to 45 percent will eventually become symptomatic. Females are affected more commonly than males, and calcification is often present bilaterally.

The onset of pain typically coincides with the resorption of the calcium deposit rather than the formation of it. Symptomatic patients experience sudden onset of shoulder pain, usually at rest. Any shoulder motion reproduces significant pain. The pain is often worse at night and interferes with sleep. The symptoms are usually self-limited, lasting 1 to 2 weeks in most cases. However, occasionally symptoms may be more indolent, producing less acute pain but lasting several weeks.

During an acute attack with intense pain, patients hold their arm across their body and often are reluctant to move it. Often a point of maximum tenderness can be palpated, usually over the proximal humerus near the tendinous insertion of the rotator cuff. Active and passive motion both are limited due to pain. Patients often report a sensation of catching when they move their shoulder through an arc of motion. Crepitus is frequently present with motion.

Radiographic Findings

Routine shoulder radiographs will reveal the calcific deposits. Deposits in the supraspinatus are readily visible on films in neutral rotation. Internal rotation of the humeral head best reveals deposits in the infraspinatus and teres minor. In patients with acute pain where resorption is actively occurring, calacium deposition may be ill defined or barely visible. However, during the formative phase, the deposit is usually dense, well defined, and easily visualized.

Emergency Department Treatment

The emergency department management of calcific tendinitis should be tailored to reduce the patient's symptoms and help protect shoulder function. During an acute attack, analgesics are usually necessary to calm the intense pain. A sling for brief periods of immobilization may be provided, but prolonged immobilization should be avoided to prevent loss of motion. The patient should be instructed to rest the shoulder in abduction on the back of a chair as often as is tolerable. Sleeping with a pillow beneath the axilla can also help prevent restricted motion. Gentle and progressive range-of-motion exercises should be emphasized and encouraged. In the acute phase, local application of ice for 10 to 15 min, two to three times per day, may provide analgesia and help control inflammation and edema. Local heat application may be used once acute symptoms have diminished.

Local needling of the calcific deposits in the emergency department has been described for the patient in acute pain. A point of maximum tenderness on palpation can be isolated, and the presence of calcification can be confirmed with radiographs. A local anesthetic, such as 2 percent xylocaine or bupivacaine without epinephrine, is used to anesthetize subcutaneous tissues corresponding to the anticipated site of needle placement. An 18-gauge needle can then be placed at the site of calcification. This may decompress the tendon and ease the pain acutely and may speed ultimate resorption of the deposit. Following this procedure, analgesics should be prescribed. Nonsteroidal anti-inflammatory agents for 7 to 10 days may also be helpful.

Follow-up

The patient should follow up with an orthopaedist within a week, regardless of whether he or she has undergone acute needling of the calcium deposit in the emergency department. Conservative measures such as physical therapy, local needling, and injection of local anesthetics at the site of the deposit may be prescribed. Surgical removal of the calcium deposit is usually considered only after all conservative measures have been exhausted.

ADHESIVE CAPSULITIS

Adhesive capsulitis, commonly referred to as the *frozen shoulder syndrome*, causes significant discomfort and dysfunction. It is characterized by markedly restricted joint motion and pain. This condition usually occurs in middle-aged patients and is uncommon in patients younger than 40 years of age and in those older than 70 years. It is more common in women, particularly postmenopausal women. The incidence in the general population is 2 to 5 percent; this increases to 10 to 20 percent in patients with diabetes. An increased incidence is also associated with patients with a history of trauma, cervical disc disease, thyroid disease, intracranial lesions, and personality disorders. It is rarely associated with the presence of rotator cuff tears.

Pathophysiology

The exact etiology of adhesive capsulitis remains unclear, and the pathophysiology remains poorly understood. Following injury or with chronic inflammation, the shoulder joint capsule becomes thickened and contracted. Pain initially limits motion. Decresed motion allows additional inflammation. Fibrosis and scarring between the capsule, rotator cuff, subacromial bursa, and deltoid progress, further restrict motion. The joint capsule normally has an inferior pouch or "axillary fold," which stretches to accomodate the humeral head during progressive elevation and external rotation of the shoulder. With fibrosis and thickening, the capsule is drawn tightly around the humeral head and the axillary fold is obliterated, restricting shoulder motion.

Autoimmune mechanisms as well as autonomic nerve dysfunction also have been implicated as causes of adhesive capsulitis, but the mechanism remains unclear.

Clinical Features

A period of shoulder immobilization following an injury or failure to mobilize the shoulder following a stroke are considered predisposing factors in the development of adhesive capsulitis. Frequently, however, no precipitating cause can be identified. Symptoms may develop insidiously over several months. Pain is described typically as diffuse and aching, is poorly localized, and often extends down the upper arm. The pain is often described as worse at night.

A painful stiffened shoulder is the hallmark finding on examination. Active and passive range of motion are limited, especially in abduction and in internal and external rotation. Disuse atrophy may be present. Pain is not usually reproducible by palpation but is present at the limits of motion as the fibrosed capsule is stretched. Impingement testing is difficult due to restricted motion. Posterior glenohumeral dislocation must always be considered in the patient with restricted motion of the shoulder.

Radiographic Findings

X-rays should be obtained to rule out a posterior glenohumeral dislocation. These should include three views at right angles to each other, typically an anteroposterior view of the humerus in internal and external rotation and an axillary or "y" view of the scapula. Adhesive capsulitis yields few specific diagnostic radiographic clues. Glenohumeral joint volume is described, but may be difficult to appreciate.

Emergency Department Treatment

The goal of treatment is to reduce pain and initiate restoration of motion and function. In the emergency department, this treatment consists of administering analgesics and anti-inflammatory agents and instructing the patient in the proper use of heat and ice to reduce discomfort. The patient should be instructed in general progressive range-of-motion exercises, such as pendulum swings and walking the fingers up the wall using the affected arm. A sling may be provided for comfort, but its long-term use should be discouraged to prevent further loss of motion.

Follow-up

Prompt orthopedic referral, at least within 1 to 2 weeks, is warranted. If conservative measures fail, arthroscopy and manipulation of the shoulder under general anesthesia to break up adhesions may be considered by the orthopaedist.

Prevention is the best treatment, and the emergency physician plays a vital role. Prolonged immobilization of the shoulder or upper extremity following injury should be avoided. Prompt referral to the patient's primary care provider or orthopaedist following shoulder injuries is indicated. It allows the patient to begin early progressive motion and physical therapy, where indicated.

DISORDERS OF THE BICEPS TENDON

Pathophysiology

The tendon of the long head of the biceps, by virtue of its position, can be a common cause of shoulder pain. Disorders of the biceps tendon can result from progressive impingement or may occur due to isolated inflammation or injury. The tendon of the long head of the biceps courses through the bicipital groove on the anterior aspect of the proximal humerus and inserts on the superior aspect of the labrum in the glenohumeral joint. The tendon may become inflamed or partially dislocated, sublux out of the bicipital groove, or rupture altogether.

Clinical Features

Patients with bicipital tendinitis present with acute, intense, localized pain at the anterior aspect of the shoulder. Palpation of the tendon within the bicipital groove reproduces the intense pain. Forearm supination, one of the main actions of the biceps, will also reproduce pain, especially when resistance is applied.

The tendon may sublux or momentarily dislocate from the bicipital groove if the transhumeral ligament, which forms the roof of the groove, tears from degeneration or acute trauma. Resisted forearm supination may cause subluxation that is palpable and accompanied by a painful popping sensation as the tendon subluxes.

In younger patients, mild trauma may cause complete rupture of the biceps tendon. In older patients, chronic impingement and degeneration may lead to rupture. On examination, the classic finding is described as a "popeye" deformity caused by contraction of the muscle from the side of the tear proximally.

Emergency Department Treatment

Supportive care and pain relief are the mainstays of emergency department care. Tendinitis and subluxation are managed conservatively. The emergency physician may provide a sling for brief use as needed for support and comfort. Analgesics and anti-inflammatory agents may be used in conjunction with prescription of relative rest, use of ice for 10 to 15 min two to three times per day, and elevation to reduce swelling.

Follow-up

For complete tears, referral to an orthopedist is recommended for surgical consideration, although frequently complete tears of the proximal biceps are managed conservatively. Conservative treatment will usually result in a 10 to 15 percent loss of strength in the muscle and will leave a cosmetic deformity.

OSTEOARTHRITIS

Since the glenohumeral joint is non-weight-bearing, primary osteoarthritis is rare. When it does occur, presentation is similar to that of degenerative disease in other joints; the patient experiences gradual and progressive onset of pain, which is worse with motion and better with rest. This usually occurs concurrently with degenerative disease of the acromioclavicular joint.

Secondary osteoarthritis is usually more common and usually associated with a previous fracture, recurrent dislocations, or with an underlying rheumatologic, metabolic, or endocrinologic disorder. Emergency department care of both primary and secondary arthritis includes analgesics, anti-inflammatory agents, and gentle exercises to preserve range of motion. Prompt referral should be made for further evaluation of possible underlying rheumatologic or inflammatory conditions.

DIFFERENTIAL DIAGNOSIS

Aches and pains in the shoulder are not always due to bursitis or tendinitis. Although disorders of the rotator cuff and other intrinsic structures of the shoulder are the most common cause of pain, extrinsic conditions outside the shoulder complex can refer pain to the shoulder. It is critical and can be life preserving to distinguish extrinsic causes from intrinsic causes of shoulder pain.

The Neck

The neck is the most common source of pain referred to the shoulder. Degenerative disease of the cervical spine, degenerative disc disease, and herniated nucleus pulposus can all refer pain to the shoulder. These symptoms may occur acutely or gradually. The pain is usually worse during daytime activities and better at night when activities cease. The patient with a C5–C6 herniated disk may present with pain very similar to that due to rotator cuff disease. Careful and thorough examination of the cervical spine and a complete neurovascular examination should be included in the evaluation of any patient with shoulder pain. On examination, range of motion in the neck may be restricted and may reproduce symptoms in the shoulder. Axial loading may especially cause referred pain. If a cervical condition is considered to be the source of pain, cervical radiographs including oblique views should be obtained. In the absence of neurologic findings, conservative measures may be inititiated. In the emergency department, the patient may be fitted with a soft cervical collar and provided with analgesics and anti-inflammatory agents as needed for comfort.

The Brachial Plexus

An injury to the brachial plexus can cause pain referred to the shoulder and can produce weakness and atrophy in the muscles of the shoulder within weeks of injury. Radiographic evaluation of the cervical spine should be included in the emergency department evaluation of patients with suspected brachial plexus injury or involvement.

Brachial plexus neuritis is uncommon but can be very painful. It is usually determined to be of viral origin. The inflammation of the brachial plexus can lead to weakness and atrophy of the muscles of the shoulder complex within weeks following the onset of pain. Cervical spine radiographs should be included in the workup. Brachial plexus neuritis is usually self-limiting. Referral to a neurologist should be arranged if a patient is suspected of having this disorder.

Vascular Injuries

Injuries to the blood vessels also can cause shoulder pain. The most serious recognized vascular injury is acute thrombosis of the axillary artery. Repetitive mechanical trauma or explosive stress from lifting heavy objects can compress and contuse the intimal lining of the axillary artery. This predisposes the artery to thrombosis. Acute thrombosis requires primary thrombolytic therapy.

Neurologic Injury

The most common neurologic injury about the shoulder involves compression of the suprascapular nerve. This nerve originates from the brachial plexus distal C5–C6 nerve roots and courses posteriorly to the suprascapular notch. Not uncommonly, this nerve becomes entrapped beneath the transverse ligament at the level of the notch. Traction injuries from explosive movements can also injure the nerve. On examination, infraspinatus atrophy and associated weakness and external rotation will typically be found. The initial treatment is conservative. Electromyographic and nerve conduction velocity studies will reveal the extent and location of nerve injury. Surgery for decompression is considered if conservative measures fail.

Thoracic Outlet Syndrome

Compression of the brachial plexus and blood vessels proximal to the shoulder can cause shoulder pain. Women in the child-bearing years are affected three times more commonly than men. The medial trunk of the brachial plexus is most commonly affected, and the symptoms usually involve pain that radiates through the shoulder to the medial forearm and occasionally to the small and ring ringers. Patients can usually identify motions that reproduce the symptoms. Fatigue often prevents the use of the arms above shoulder level.

Radiographic evaluation may reveal evidence of a prior clavicle fracture with malunion or the presence of a cervical rib band, which are associated with compression

of the brachial plexus. Treatment is generally conservative, although surgical decompression may be considered if the symptoms become debilitating or refractory to conservative measures.

Pancoast's Tumor

This tumor, when present in the superior sulcus of the lung, may compress the brachial plexus against the chest wall and cause shoulder pain. The patient may experience local or radicular shoulder pain or sense a fullness in the supraclavicular fossa.

Thoraco-Abdominal Disorders

Finally, a large number of cardiothoracic disorders can cause shoulder pain. These include myocardial ischemia and infarction, pneumonia, and pulmonary embolism and infarction. Any thoracic or abdominal disorder that irritates the diaphragm can also cause referred shoulder pain. Finally, abdominal disorders that can cause shoulder pain include biliary tract disease, splenic injury or inflammation, perforated viscus, or ruptured ectopic pregnancy.

Complaints related to the musculoskeletal system account for 1 of 7 visits to the primary care provider and an abundance of emergency room visits. Evaluating the patient with musculoskeletal problems requires a thorough, thoughtful history and examination to determine whether the symptom is a local problem or a manifestation of a systemic disease, and whether a local problem is potentially catastrophic, as in the case of an unrecognized septic joint in a rheumatoid arthritis patient.

Life-threatening manifestations of rheumatic disease are infrequent. They most often result directly from internal organ involvement from systemic conditions such as systemic lupus erythematosus (SLE) or other vasculitides; examples include alveolar hemorrhage in SLE and aortic arch dissection in temporal arteritis. Alternatively, they may be a complication of treatment itself, such as infection in the setting of immunosuppression, or gastrointestinal hemorrhage complicating nonsteroidal anti-inflammatory drug (NSAID) use. Either can lead to serious morbidity and increased mortality if not recognized and managed promptly.

Table 276-1 highlights common presenting musculoskeletal complaints that warrant prompt evaluation and a fundamental differential diagnosis for each. Before diagnostic tests are obtained, an accurate clinical assessment is imperative.

TABLE 276-1   Emergent Musculoskeletal Clinical Signs and Symptoms

This chapter provides an overview of emergencies in rheumatology, with a focus on systemic rheumatic disease.

RHEUMATIC EMERGENCIES ASSOCIATED WITH RISK OF MORTALITY

The Airway and Respiratory System

Life-threatening respiratory compromise occurs by two major mechanisms in rheumatic diseases: difficulty ventilating due to airway obstruction and impaired ventilation due to weakness (Table 276-2). Relapsing polychondritis is an inflammatory disease affecting cartilage and usually begins with the abrupt onset of pain, redness, and swelling of the ears or the nose. The airway is affected in roughly 50 percent of patients, causing inflammation, destruction, and ultimate collapse of tracheobronchial cartilage. Patients report throat tenderness over cartilaginous structures and hoarseness. Less commonly they experience shortness of breath, cough, or stridor. Repeated exacerbations ultimately may cause asphyxiation. Pulmonary function studies with flow-volume loops detect airway obstruction more reliably than bronchoscopy. Emergency tracheostomy may be helpful, depending on the level and extent of airway compromise. Hospitalization for careful observation and high dose corticosteroids is necessary during acute exacerbations.

TABLE 276-2   Respiratory Manifestations of Rheumatic Diseases

Rheumatoid arthritis (RA) may cause cricoarytenoid dysfunction. RA patients with cricoarytenoid arthritis may complain of pain with speaking or swallowing, hoarseness, or stridor. If the joints become fixed in a closed position, airway compromise mandates emergency tracheostomy. Presentation with the above signs is an urgent indication for fiberoptic laryngoscopy.

The respiratory muscles may be impaired by inflammatory muscle disease. In dermatomyositis and polymyositis, respiratory insufficiency is uncommon at presentation but complicates poorly controlled or chronic disease. Patients should be observed for nasal flaring, as they may be too weak to generate intercostal retractions. Chest x-rays are normal or show "high-riding" diaphragms unless pulmonary involvement or an aspiration pneumonitis coexists. Admission for disease control and stabilization is indicated in any patient with inflammatory muscle disease and respiratory impairment. Patients with active or advanced disease may require intubation and ventilation for respiratory support. The clinical course can be followed at bedside with measurements of peak inspiratory and expiratory forces. Respiratory failure is predictable with peak inspiratory effort of less than 30 percent of predicted or vital capacity of less than 50 percent of predicted.

Pleurisy is common in RA and systemic lupus erythematosus (SLE). It may be asymptomatic in RA, but roughly half of lupus patients have signs and symptoms of pleurisy during the course of their disease. All effusions in rheumatic disease patients should be aspirated for diagnosis. Rheumatoid pulmonary effusions

characteristically have very low glucose levels, but so do effusions associated with indolent infections such as tuberculosis. Rheumatic, infectious, and malignant effusions are often exudative and either polymorphonuclear or mononuclear cells may predominate. In the patient without lupus nephritis, nonsteroidal anti-inflammatory drugs (NSAIDs) (e.g., indomethacin, 25 to 50 mg tid) usually suffice. Prednisone in moderate doses 10 mg po tid is reserved for patients failing this regimen.

Pulmonary hemorrhage can complicate Goodpasture's disease, SLE, hypersensitivity vasculitis, and Wegener's granulomatosis due to vasculopathic or vasculitic lung involvement. Ankylosing spondylitis (upper lobes), scleroderma, and, rarely, RA and other rheumatic diseases can lead to pulmonary fibrosis. Patients may present with abrupt decompensation with a history of a well-tolerated slow decline. In myositis, however, interstitial pneumonitis may become apparent with quiescent muscle disease, progress rapidly, and result in fulminant respiratory failure; these patients should be hospitalized to rule out infection and be treated with aggressive immunosuppression.

Cardiac Diseases

The heart is affected in many rheumatic diseases, with potential involvement extending from the pericardium to the endocardium. Of the rheumatic diseases, RA and juvenile rheumatoid arthritis (JRA) are most often associated with pericarditis. Pericarditis is usually asymptomatic, but occasional patients with chest pain attributed to costochondritis may have symptomatic pericarditis. Chest pain is characteristically positional, and a pericardial rub is usually heard. SLE often causes symptomatic pericarditis, particularly in the elderly. Patients also report symptoms typical of a flare, such as rash, oral ulcers, or joint pain. Symptoms tend to be consistent from one flare to the next, and therefore a thorough review of systems is key. When symptomatic pericarditis is diagnosed, malignancy and infection must be considered and excluded if clinically indicated. Treatment is similar to that for pleurisy above. Pericardial tamponade and constrictive pericarditis from either RA or SLE are uncommon.

While therapy has greatly improved long-term survival in SLE, late mortality from premature atherosclerotic disease is being recognized. Precordial chest pain in SLE is not always due to serositis or costochondritis, particularly with long-standing disease, and angina should be considered. Other causes of precordial pain are listed in Table 276-3.

Pericarditis, pancarditis
Angina, myocardial infarction
Dermatomal herpes zoster
Costochondritis
Vertebral compression fracture (thoracic radiculopathy)
Rib fracture
Pulmonary embolus
Gastroesophageal reflux

TABLE 276-3   Precordial Chest Pain in Rheumatic Diseases

Myocardial infarction (MI) in rheumatic diseases is not usually related to underlying disease. The noteworthy exceptions are Kawasaki disease (see Chap. 132, "Musculoskeletal Disorders in Children") and polyarteritis nodosa (PAN). PAN is a form of vasculitis affecting small- and medium-caliber arteries of the skin (nodular, urticarial, or multiform rashes), gut (abdominal angina), and kidneys (hypertension, hematuria). Coronary arteries are commonly involved. MI and PAN are usually clinically silent, but when MI occurs it can occur at any age.

Mortality in SLE from premature atherosclerosis is well recognized. Angina always should be considered in SLE patients with chest complaints, especially with long-standing disease and in those on steroids.

Acute rheumatic fever (ARF) remains an important cause of pancarditis. ARF follows streptococcal pharyngitis within a few weeks. It is heralded by rapid development of fever and acute polyarthritis (in adults) or migratory arthritis (in children). A few patients have a more insidious onset. Supportive clinical clues are the presence of subcutaneous nodules, chorea, or erythema marginatum, but only a third of patients will have one of the latter major manifestations. Diagnosis is based on documenting the clinical involvement and antecedent streptococcal infection. The throat should be cultured and antistreptolysin O (ASO) or streptozyme titers determined at intervals to document a fourfold change in titer over a month. Other baseline tests include serial chest x-rays, echocardiography and ECGs to monitor the carditis; and acute phase reactants (erythrocyte sedimentation rate, C-reactive protein). The fever and arthritis respond rapidly and completely to salicylate therapy, but salicylates should be held until the diagnosis is clear. Patients should be placed at bedrest until clinical and laboratory parameters begin to normalize.

Rheumatic fever is only one disease associated with migratory arthritis (Table 276-4). Bacterial endocarditis or septicemia due to common bacterial pathogens and the prodromal phase of pulmonary mycoplasma or fungal infections must be considered. Children with Henoch-Schoenlein purpura and cefaclor (Ceclor) serum sickness often have migratory articular and periarticular involvement. Stage II Lyme disease can be manifested by migratory articular involvement, with individual joints resolving over hours to days. Often young adults with polyarthritis are empirically treated with intravenous penicillin for disseminated gonococcus (GC) until a streptococcal infection is confirmed. The arthritis of ARF does not respond to antibiotic therapy; therefore prompt improvement suggests the diagnosis of GC.

Rheumatic fever
Subacute bacterial endocarditis
Henoch-Schönlein purpura
Cefaclor hypersensitivity (children)
Septicemia: staphylococcal, streptococcal, meningococcal, gonococcal
Pulmonary infection: Mycoplasma, histoplasmosis, coccidioidomycosis
Lyme disease

TABLE 276-4   Conditions Associated with Migratory Arthritis

Valvular heart disease is a recognized extraarticular manifestation of the seronegative spondyloarthropathies, particularly ankylosing spondylitis. Fibrotic changes of the aortic valve are usually asymptomatic, with dysfunction occurring more often in patients with long-standing, severe disease. Scar tissue also may impair cardiac conduction, leading to drop attacks. Relapsing polychondritis can affect the valves, causing aortic insufficiency and aneurysm. This may develop early after diagnosis and is a grave development. Table 276-5 summarizes cardiac involvement in rheumatic diseases.

Disease	Common	Infrequent	Rare
SLE	Pericarditis	Angina, myocarditis	Tamponade, constrictive pericarditis
Ankylosing spondylitis		Aortic stenosis/ insufficiency, dissection	Drop attacks
Relapsing polychondritis		Aortic insufficiency, dissection	
Polymyositis and dermatomyositis		Arrhythmias, myocarditis	
Scleroderma		Myocardial fibrosis, arrhythmias	Cor pulmonale
Vasculitides		Angina, myocardial infarction	

TABLE 276-5 Cardiac Manifestations of Rheumatic Diseases

ADRENAL INSUFFICIENCY

Rheumatic disease patients on glucocorticoids are usually instructed to seek medical care urgently if an illness like gastroenteritis prevents taking or absorption of prednisone. In general, the course of a rheumatic disease is not worsened by administration of stress glucocorticoids for a day during an acute illness, even if the dose is much larger than the usual daily dose. A large dose of glucocorticoid may cause labile hyperglycemia in diabetic patients, but no more so than the underlying acute condition. Other medications used to treat rheumatic diseases can be held safely for a brief bout of gastroenteritis. These include NSAIDs, cyclophosphamide or chlorambucil, methotrexate, hydroxychloroquine (Plaquenil), and calcium channel blockers, if they are only used to treat Raynaud phenomenon.

Rarely, patients treated with steroids in the past 18 months develop adrenal insufficiency. They may have early symptoms of weakness, depression, fatigue, and postural dizziness, or late life-threatening vomiting. The serum chemistries usually do not reveal hyponatremia or hyperkalemia in patients with adrenal insufficiency after prednisone withdrawal because that steroid has no mineralocorticoid activity. If adrenal insufficiency is a remote possibility, stress steroids should be administered. Dexamethasone is preferable, as that steroid will not interfere with assays of other adrenal steroids during subsequent diagnostic testing. Prior to the administration of stress steroids, a cortisol level should be drawn in the emergency room. Under stress, normally functioning adrenal glands generate a level in excess of 20 μg/dL.

RHEUMATIC PRESENTATIONS WITH HIGH RISK OF MORBIDITY

The Cervical Spine and Spinal Cord

Cervical spine disease and its neurologic risk is well recognized in rheumatoid arthritis and ankylosing spondylitis. In RA, pannus formation and destruction of ligamentous supporting structures may lead to atlantoaxial subluxation; an atlantodental distance in excess of the normal 3.5 mm seen in a lateral flexion view suggests instability (in children under 12, 4 mm of widening is normal). Cord compression may occur acutely following a trivial injury or be more insidious. Subtle clues include a change in bowel or bladder function, new weakness, numbness, or paresthesias. Instability may lead to cranial migration of the odontoid. Complaints relating to vertebral insufficiency (e.g., vertigo) may be reported. Lhermitte sign, an electric shock sensation radiating down the back on neck flexion, is a classic indication of cervical spine instability. Strength may be difficult to assess in an RA patient, so subtle differences in reflexes are particularly informative. Lateral cervical spine films in flexion are essential for evaluation. Neck flexion should not be forced, but rather studied at a degree considered comfortable by the patient.

The ankylosed, inflexible cervical spine in a patient with a seronegative spondyloarthropathy (e.g., ankylosing spondylitis) is susceptible to fracture with minor trauma. A whiplash-type injury or a blow from behind may result in new neck pain in an ankylosed area. The complaint of new neck pain requires a careful history and examination, with attention to possible trauma to the neck and evidence of peripheral nerve damage. Fractures are most commonly transverse through a disc space, leading to greater risk of dislocation and cord compression.

Intubation of patients with rheumatic cervical spine disease is best addressed in an elective, controlled situation after the cervical spine has been assessed. In an emergency, a patient with a stiff or arthritic neck should be intubated by the most experienced operator available. Atlantoaxial instability should be assumed, and extremes of head manipulation avoided.

The spinal cord can be affected by transverse myelitis in SLE, or a number of factors can induce an anterior spinal artery syndrome in patients with rheumatic diseases. The anterior spinal artery is a direct branch of the aorta; dissection of the aorta, vasculitis, or embolism can impair blood supply to the anterior cord and produce a clinical picture distinct from transverse myelitis or metastatic tumor by sparing of posterior column function (position sense and vibration).

The Eye

Temporal arteritis (TA) often causes sudden blindness, usually before the condition is diagnosed. Blindness can be prevented, however, if prodromal visual changes and coexistent symptomatology are recognized. Prodromal changes in vision almost always precede blindness.

TA is a granulomatous arteritis of the thoracic aorta and its branches; the vasculitis and ischemia in this distribution induce characteristic signs and symptoms: new headache, tender scalp, fluctuating vision, diminution or loss of a brachial pulse, pain in the jaw or tongue while chewing or talking, and constitutional symptoms. An elevated Westergren sedimentation rate (>50 mm/h), elevated liver function studies (particularly the alkaline phosphatase), and unexplained anemia are common laboratory abnormalities.

TA affects the middle-aged and elderly. Polymyalgia rheumatica (PMR), with proximal shoulder and hip girdle morning stiffness and aching, coexists in 10 to 30 percent of these patients. Prodromal changes in vision almost always precede blindness. A high index of suspicion is critical when evaluating anyone older than 50 with a new headache, fluctuating vision, or jaw, tongue, or upper extremity claudication. Diagnosis is established on temporal artery biopsy. If the clinical diagnosis is reasonably certain, steroid therapy should be initiated at a prednisone dosage of 60 mg/day to prevent blindness; this will not obscure pathologic findings if the biopsy is obtained within a week. Symptoms of PMR are easily controlled with prednisone, 5 to 7.5 mg po tid, and those patients without signs and symptoms of TA should not be unnecessarily treated with high-dose steroids.

Sjögren's syndrome, a lymphocytic infiltration of the lacrimal and salivary glands causing dry eyes and dry mouth, may complicate many rheumatic diseases or occur independently. It predisposes the patient to corneal irritation, ulceration, and superimposed infection.

In RA, a red eye requires careful evaluation. Under bright natural light, examination can reveal the difference between episcleritis, which is self-limiting, and scleritis, which is an emergency. Episcleritis is a painless injection of the episcleral vessels giving the eye a pink-red appearance; it rarely impairs vision. As it is self-limiting, no therapy is indicated. Scleritis causes exquisite ocular tenderness. The eye has a deep purplish discoloration. Visual impairment and scleral thinning with rupture are feared outcomes. High-dose steroids and intensive ophthalmologic management are required.

Hypertension

While hypertension can complicate PAN or SLE with renal involvement or RA with drug-induced renal toxicity (fluid retention, nephritis, or renal papillary necrosis), hypertension is a feared complication of systemic sclerosis (scleroderma). Hypertensive renal crisis was the leading cause of death in scleroderma until the advent of angiotensin-converting enzyme (ACE) inhibitors. The most susceptible patients have rapidly progressive skin changes and present within the first few years of diagnosis with complaints related to hypertension. Laboratory studies reveal rapidly progressive renal insufficiency and frequently a microangiopathic hemolytic anemia and thrombocytopenia. The hypertension results from sclerosis and impaired renal glomerular perfusion causing hyperreninemia. Dehydration from gastroenteritis or diuretics may precipitate the crisis. These patients should be hospitalized and promptly treated with captopril. Any intervention such as diuretics that

might exacerbate volume contraction and the underlying pathophysiology should be avoided.

Other rheumatic diseases may affect the kidneys but are not acutely life-threatening. Renal involvement in SLE, PAN, or Wegener's granulomatosis may result in hypertension. Drug-induced nephrotoxicity (hypertension, fluid retention, nephritis, or renal papillary necrosis) is seen in rheumatic disease patients using nonsteroidal anti-inflammatory agents, usually with preexisting hypertension or renal disease.

The Kidney

Most systemic rheumatic diseases may affect kidney function. Glomerulonephritis is a major determinant of morbidity in patients with lupus and Wegener's granulomatosis. Urinalysis abnormalities (hematuria, proteinuria) and hypertension are apparent before serum creatinine rises. Patients with lupus and nephrotic syndrome can develop renal vein thrombosis due to urinary loss of antithrombin III; they present with flank pain and proteinuria. In diffuse scleroderma, renal dysfunction secondary to hypertension and microangiopathy typically develops rapidly over days to a few weeks.

Occasionally, a patient with active polymyositis or metabolic muscle disease develops acute renal insufficiency due to rhabdomyolysis. In metabolic muscle disease, myalgias and muscle breakdown can be triggered by exercise. Myoglobinuria should be suspected when the urine is brown and the dipstick shows blood but no red blood cells. In contrast to a hemolytic state, the serum is clear, creative phosphokinase is elevated, and haptoglobin is normal. Patients should be hydrated with normal saline to restore intravascular loss that accompanies muscle necrosis. Lasix and mannitol also are indicated to preserve urinary output.

A final consideration is medication nephrotoxicity. Patients, particularly the elderly, treated with nonsteroidal anti-inflammatory drugs can develop renal insufficiency and fluid retention on the basis of alteration in renal blood flow; this is mediated by prostaglandin inhibition. A decline in renal function in any rheumatic disease patient should prompt a search for remediable causes of renal dysfunction, either related to drug therapy or to the rheumatic disease itself. See Chap. 271, "Rhabdomyolysis."

277 HAND INFECTIONS

Mark W. Fourre

Patients with hand infections routinely use the emergency department (ED) as their initial site of care. It is important for the emergency physician to accurately diagnose and treat the infection because failure to do so will likely cause long-term morbidity and disability. The hand is one of the most elegant and complex features of the human body, and the emergency physician must understand the basic anatomy and functions of the hand in order to appropriately manage the patient.

Infection is most commonly introduced by an injury to the dermis. The infection initially may remain superficial, as a cellulitis, or localized, as a paronychia or felon. Left untreated, these infections ultimately will spread along anatomic planes or to adjacent compartments in the hand. Deeper injuries may directly seed underlying structures, giving rise to rapidly spreading infections such as seen with closed-fist injuries or cat bites. Rarely, hematogenous spread may be the source of hand infections.[1]

A directed history must be obtained to delineate a likely cause of the infection. Patients who present with systemic symptoms secondary to a hand infection are seriously ill, and parenteral antibiotics with inpatient management is indicated. A history of chronic illness or immunodeficiency must alert the physician to the possibility of atypical pathogens.[2,3]

Since hand infections tend to disseminate along anatomic compartments and planes, the physical examination should be directed at defining the anatomic limits of the infection. The examiner should document if the process involves the skin, subcutaneous tissues, fascial spaces, tendon, joint, or bone.[4] If deep structures of the hand are involved, emergent consultation with a hand specialist is indicated because treatment likely will involve inpatient care and drainage in the operating room.

With the exception of superficial cellulitis, hand infections are surgical problems that must be managed using accepted surgical principles.[5] First, if there is pus, drain it. Superficial and discrete infections, such as paronychia and felons, can be drained in the ED. All other infections involving deep structures in the hand should be treated in the operating room by a hand surgeon. Second, immobilize and elevate the extremity. This will rest the hand, reduce inflammation, avoid secondary injury, and limit anatomic extension of the infection. Immobilization is accomplished by applying a bulky hand dressing and splinting the hand in a position of function: the wrist at 15 to 30° of extension, the metacarpophalangeal (MCP) joints at 50 to 90° of flexion, and the interphalangeal (IP) joints at 5 to 15° of flexion (Fig. 277-1). The hand may be elevated on pillows or suspended using stockinet. Third, broad-spectrum antibiotics should be initiated (Table 277-1). Finally, serial examinations should be performed to ensure that an effective management plan has been instituted. If the patient is not admitted to the hospital, timely and appropriate follow-up must be arranged by the emergency physician.
FIG. 277-1. Positioning the hand during immobilization. Top position is used when splints are applied in fractures or severe sprains. Bottom position is position of function used when applying a soft bond dressing.

TABLE 277-1   Initial Antibiotic Coverage for Common Hand Infections

MICROBIOLOGY

The bacterial etiology of hand infections depends on the source of the offending inoculum. Since *Staphylococcus* and *Streptococcus* species routinely colonize the skin, they are the bacteria most frequently isolated from hand infections.[1,6] Polymicrobial infections, including anaerobes, are the rule rather than the exception, and antibiotic coverage must be chosen accordingly.

Intravenous drug abusers typically present with abscesses or deep space infections secondary to *Staphylococcus aureus.* Although most commonly caused by direct introduction of a contaminated needle through inadequately cleaned skin, the infection may have spread hematoginously from a previously established bacterial endocarditis.[1] Paronychia and felons are commonly caused by minor trauma associated with chewing fingernails or exposing minor injuries to saliva. Most of these

infections are polymicrobial in origin, with most harboring anaerobic bacteria. [7]

Bacteria found in infections caused by animal bites reflect the oral flora of the involved species. This encompasses a broad range of bacteria, including gram-positive, anaerobic, and gram-negative organisms. In human bites, *Eikenella corrodens* is a common pathogen. Although sensitive to penicillin and ampicillin, *Eikenella* is relatively resistant to numerous antibiotics, including first-generation cephalosporins, nafcillin, and clindamycin. Therefore, a b-lactamase inhibitor drug alone or a first-generation cephalosporin in combination with penicillin is required for prophylactic antibiotic coverage for human bites and for treatment of hand infections caused by human bites. Cat and dog bites may harbor *Pasteurella multicida*,[5,8] which typically produces an aggressive, rapidly spreading cellulitis that quickly becomes suppurative. *Pasteurella* is also sensitive to penicillin and ampicillin, and antibiotic coverage is the same as is indicated in human bites. Initial antibiotic coverage is reviewed in Table 277-1. For a complete discussion on animal bites, see Chap. 43, "Puncture Wounds and Animal Bites."

Care must be exercised when managing patients with diabetes or acquired immunodeficiency syndrome (AIDS) because they may harbor atypical infections caused by *Mycobacterium* or *Candida albicans*.[2,3] Patients who are immunocompromised or asplenic may be at risk for rapidly progressive and fatal infections. Aggressive intervention is indicated in these settings.

CELLULITIS

Cellulitis is the most superficial of hand infections and may be treated definitively with antibiotics if diagnosed early enough in its course. Diagnosis is made by documenting erythema, warmth, and edema to the affected portion of the hand. The examiner must document lack of involvement of any deeper structures in the hand. Specifically, range of motion of the digits, hand, or wrist should not be uncomfortable for the patient, and palpation of the deeper structures of the hand should not produce any tenderness.

The most common offending organism is *Streptococcus pyogenes,* although *S. aureus* and other pathogens are identified occasionally. An antistaphylococcal penicillin or first-generation cephalosporin is recommended for initial treatment. [4] For more extensive involvement, parenteral antibiotics should be instituted. Inpatient management should be reserved for patients who are immunocompromised or systemically ill and for rapidly spreading infections.

The hand should be immobilized in a position of function, and the patient should keep the hand elevated at all times. Finally, close follow-up should be arranged, with reexamination occurring within the next 24 h.

FLEXOR TENOSYNOVITIS

Flexor tenosynovitis is a surgical emergency that must be diagnosed promptly by the examining physician and managed aggressively by both the emergency physician and the hand surgeon. Failure to accurately diagnose and manage a flexor tenosynovitis will lead to loss of function of the digit and eventually loss of function of the entire hand. Diagnosis is made by recognizing the classic clinical findings described by Kanavel. The four cardinal signs are tenderness over the flexor tendon sheath, symmetric swelling of the finger, pain with passive extension, and a flexed posture of the involved digit at rest. [9,10]

The infection usually is associated with penetrating trauma of the affected area, although the patient may be unaware of this injury. *Staphylococcus* is the most common bacteria isolated; however, infections often harbor anaerobes and are routinely polymicrobial in origin. [5,6,11] One should suspect disseminated *Neisseria gonorrhoeae* in any patient who has a recent history consistent with a sexually transmitted disease.

The emergency physician should initiate treatment with parenteral antibiotics. This should include a b-lactamase inhibitor or first-generation cephalosporin and penicillin. Vancomycin should be considered for patients who abuse drugs intravenously because they may harbor methicillin-resistant *S. aureus* (MRSA).[1] Any spontaneous exudate from the infection should be sent for Gram stain and culture with sensitivities.

The hand should be immobilized and elevated, and a hand surgeon should be consulted on an emergent basis. If the infection is identified early in its course, conservative therapy may be indicated initially. The patient would then be treated with parenteral antibiotics, immobilization, elevation, and reevaluation within 24 h. The decision to manage the patient without operative intervention must be made with involvement of the hand surgeon.

DEEP SPACE INFECTIONS

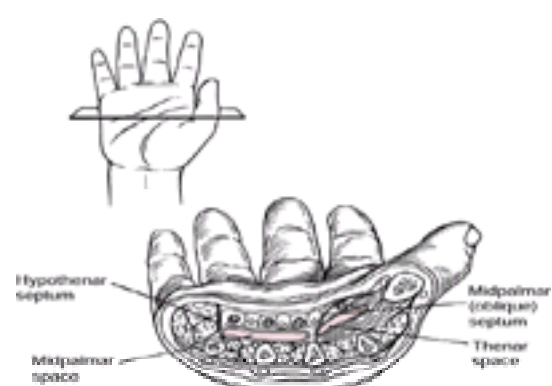
The hand offers numerous compartments in which infections may propagate and migrate. The volar surface of the hand encompasses many potential spaces that may become infected by direct inoculation or spread from surrounding structures. These include the thenar space, the midpalmer space, the radial bursa, and the ulna bursar (Fig. 277-2 and Fig. 277-3).
FIG. 277-2. Anatomy. Flexor tendon infections may travel quickly along established anatomic planes and spread quickly to the ulnar and radial bursae.


FIG. 277-3. Deep palmar spaces. The midpalmar and thenar spaces are deep in the structures of the hand. The proximity to vital structures necessitates an aggressive management course including parenteral antibiotics and referral to a hand surgeon for drainage.

The volar aspect of the hand is covered by the tough and relatively fixed tissues of the palm; the veins and lymphatics course through the softer tissues on the dorsum of the hand; thus, regardless of the precise anatomic site of infection or inflammation, the dorsum of the hand always will swell whenever there is an inflammatory

process. For this reason, a deep space infection initially may be misdiagnosed as a cellulitis over the dorsum of the hand if the practitioner does not obtain a thorough history and conduct a complete examination including palpation of the volar surface of the hand to elicit tenderness, induration, or fluctuance. Since these compartments are contiguous with the flexor tendons of the hand, range of motion of the digits often produces significant pain for the patient.

Occasionally, infections will arise in the web space. These "collar button" abscesses present with pain and swelling of the web space causing separation of the affected digits. Examination reveals induration or fluctuance in the dorsal and/or volar web space along with erythema, warmth, and tenderness. *S. aureus* and *Streptococcus* species are the most common organisms isolated.[9,10]

The emergency physician should initiate parenteral antibiotics (see Table 277-1), and the hand should be immobilized and elevated. The patient likely will require analgesia while in the ED. Emergent evaluation by a hand surgeon is required because drainage of the infection should be undertaken in the operating room.

INFECTIONS FROM CLOSED-FIST INJURIES

The most common "human bite" infection of the hand is actually the result of a patient striking another individual's teeth with a clenched fist. Because of the force associated with the contact and the penetrating nature of the human incisor, these infections tend to occur on multiple planes, and infection spreads rapidly to adjacent compartments. Skin, extensor tendons, joint space, bone, and surrounding deep spaces often are involved because the inoculum of saliva may traverse all these structures.

The physical examination should document the extent of the infection. Hand x-rays are indicated because closed-fist injuries are often associated with fractures. Since most of these wounds are open, a Gram stain and culture with sensitivities should be obtained for both aerobic and anaerobic bacteria.

The most common organisms reflect the natural flora of the mouth and include *Streptococcus* species, *S. aureus*, anaerobes, *E. corrodens,* and *Neisseria* species.[5,8] Antibiotics should be initiated immediately (see Table 277-1). The wound should be cleansed, irrigated, and left open. The hand should be immobilized in the position of function and elevated. Disposition should be arranged in consultation with the hand surgeon.

PARONYCHIA

A paronychia is an infection of the lateral nail fold or paronychium (Greek: *para,* "beside" + Greek: *onyx,* "nail"). Occasionally this may extend to the cuticle or eponychium (Greek: *epi,* "upon" + *onyx*). These common conditions are usually caused by minor trauma such as nail biting, manicures, or hang nails. The infection starts as a small area of induration that may be erythematous and tender.[4]

Most paronychia contain both aerobic and anaerobic bacteria. *S. aureus* and *Streptococcus* species are the most common aerobic bacteria cultured from these abscesses.[7] Chronic peronychium may occur, particularly in patients who are immunocompromised. Atypical bacterial or fungal infections such as *C. albicans* have been identified in these cases.

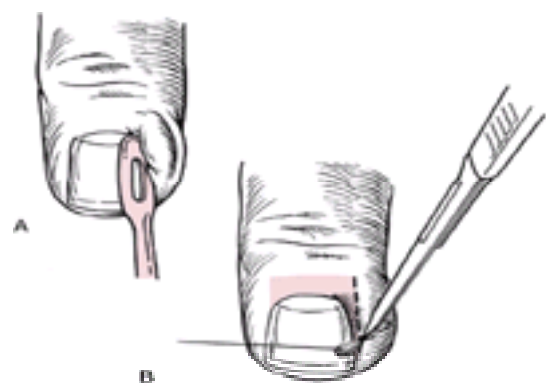
If no fluctuance is identified, the paronychia may be treated with warm soaks, elevation, and antibiotics (see Table 277-1). Early intervention may prevent the need for surgical drainage. After suppuration has occurred, the infection will exhibit either fluctuance or identifiable pus that will necessitate drainage. Minor infections can be treated with elevation of the paronychium or epionychium with a flat probe or no. 11 blade (Fig. 277-4). This procedure sometimes can be performed without placing a digital block or providing analgesia.


FIG. 277-4. Paronychia. **A.** The eponychial fold is elevated using a flat probe or no. 11 blade in order to allow the wound to drain. **B.** Alternately, a no. 11 blade may be used to incise the area of greatest fluctuation directly into the epionychium. The wound may then be gently probed with a small clamp to ensure drainage.

More extensive infections that do not communicate directly with the nail fold may require incision directly into the area of greatest fluctuance. A digital block should be performed using lidocaine or bupivicaine prior to these more invasive procedures. Severe infections with pus beneath the nail require removal of a portion of the lateral or proximal nail to ensure adequate drainage.[9] Rarely, a free-floating nail will be encountered on a bed of pus, necessitating removal of the entire nail.

Following incision and drainage, the patient should be instructed to keep the hand elevated and immobilized. Warm soaks may be initiated to keep the wound open and clean. The patient should be scheduled for reevaluation in 24 to 48 h. If significant cellulitis is present, a short course of antibiotics should be prescribed.

FELON

A felon is a subcutaneous pyogenic infection of the pulp space of the distal finger or thumb. The septa of the finger pad produce multiple individual compartments and confine the infection under pressure. The patient presents with marked throbbing pain and a red, tense distal pulp space. Infection typically begins with minor trauma to the dermis overlying the finger pad. With time, the bacterial infection gradually spreads between septa forming multiple compartmentalized abscesses. Left untreated, the infection may spread to the flexor tendon sheath and the interphalangeal joints, or eventually, osteomyelitis may develop.

S. aureus is the most common organism; however, *Streptococcus* species, anaerobes, and gram-negative organisms are encountered frequently. A Gram stain and culture should be obtained because these infections may be difficult to eradicate, and chronic infections may be caused by atypical organisms. [1,4] If osteomyelitis has developed, positive identification of the offending organism is necessary because long-term antibiotic therapy will be indicated.

If the finger pad is swollen and tense, or if there is any palpable fluctuance, drainage must be undertaken for healing to begin. A digital block must be performed because the procedure would be extremely painful without adequate anesthesia. A long-acting anesthetic such as bupivacaine should be used because postoperative discomfort is considerable. Most felons can be drained adequately with a limited incision and drainage procedure. A unilateral longitudinal approach is the most frequently used technique because it spares the sensate volar pad and achieves adequate drainage (see Fig. 277-5 *A*).
FIG. 277-5. Felon. **A.** The unilateral longitudinal approach is the most frequently used method for draining felons. This approach minimizes interference with sensate areas of the finger pad. **B.** If the felon is pointing on the volar surface of the finger pad, the longitudinal volar approach may be used.

A no. 11 blade is introduced lateral to the paronychium and is directed in a volar direction until pus is encountered. The incision should be extended to ensure adequate drainage, although it should not extend to the distal interphalangeal (DIP) flexor crease. Likewise, the incision should not carry through the distal end of the finger pad because this would likely cause instability and loss of sensation to the distal fingertip. A small clamp may be used to bluntly dissect septa to ensure complete drainage. If the wound is large enough, a small wick may be placed to encourage continued drainage. [9,10]

If the felon is pointing toward the volar fat pad, a longitudinal volar approach may be used, as depicted in Fig. 277-5*B*. Care should be exercised to avoid extending the incision to the flexor crease of the DIP joint. More extensive incisions such as the fishmouth, hockey stick, and through-and-through incisions are rarely, if ever, indicated. These incisions are routinely associated with loss of sensation to the fingertip and instability of the finger pad. [9,10]

Following drainage, the wound should be irrigated and then dressed with a dry, sterile dressing. The patient should be instructed to keep the extremity elevated, and the wound should be reevaluated in 24 to 48 h. Warm soaks may be initiated to keep the wound clean and promote continued drainage.

Most felons have significant associated cellulitis that should be treated with oral antibiotics. [12] A first-generation cephalosporin or antistaphylococcal penicillin should be prescribed for 7 to 10 days or until the infection has abated. Felons not responding to treatments outlined earlier should be referred to a hand specialist for more definitive management and long-term follow-up.

HERPETIC WHITLOW

Herpetic whitlow is a viral infection of the distal finger caused by the herpes simplex virus. Infection typically occurs when the dermis has come in contact with oral herpetic infections. Herpetic whitlow in children tends to be associated with gingivostomatitis and herpes simplex type 1 (HSV-1), whereas adults most commonly harbor herpes simplex type 2 (HSV-2).[13] Health care professionals historically have been at risk for this infection, although the incidence appears to have diminished with the advent of latex gloves.

The patient will present with a burning, pruritic sensation similar to all herpes simplex infections. On examination, the lesion is erythematous and tender, with vesicular bullae being the hallmark of herpetic whitlow (Fig. 277-6). Although indurated, the infection is not tense, as is seen in a felon. It is important that a herpetic whitlow not be misidentified as a felon because incision and drainage may result in increased morbidity and prolonged failure to heal. If there is any question concerning the diagnosis of herpetic whitlow, a vesicle may be unroofed, and the drainage may be used for a Tzanck smear to confirm the diagnosis.

FIG. 277-6. Herpetic whitlow is shown.(From Domonkos AN: Clinical dermatology, in *Andrews' Diseases of the Skin*. Philadelphia: Saunders, 1971).

Treatment consists of immobilization, elevation, and pain medication. Antiviral agents such as acyclovir may shorten the course of duration and have been shown to prevent recurrent infections.[14,15] The patient must be instructed in the management of the infection, and the finger should be kept in a clean dressing to prevent autoinoculation or spread of the herpes infection to other individuals.

NONINFECTIOUS INFLAMMATORY STATES OF THE HAND

General Principles

Patients with noninfectious inflammatory states of the hand often present to the ED for diagnosis and relief of their symptoms. Most often the patient has experienced an acute exacerbation of the symptoms related to recent overuse, either in the workplace or at home. Chronic conditions are also frequently encountered in the ED when patients are unable to access a primary care provider or when their symptoms persist despite previous evaluations.

Inflammatory states of joints and tendons can be markedly painful, with classic signs of inflammation being present. It is critical that the emergency physician not mistake an acute bacterial infection for an inflammatory condition. In severe cases of inflammatory tendinitis or arthritis, the physical examination may be identical to that found in conditions caused by acute septic arthritis or suppurative tenosynovitis. If there is any question concerning the diagnosis, the patient must be managed aggressively for infection, and an appropriate hand specialist should be consulted.

If an inflammatory state is confidently diagnosed, the patient initially should be treated with conservative measures. These include rest, immobilization, elevation, and initiation of anti-inflammatory agents.

Tendinitis and Tenosynovitis

Inflammatory tendinitis may involve the flexor or extensor tendons of the hand. Most commonly the patient is able to relay a history of repetitive motion directly affecting the inflamed tendon. Palpation of the tendon produces tenderness. Active or passive movement of the tendon produces significant pain.

Treatment involves placing the patient in a splint in the position of function with instructions for rest and elevation of the affected area. Effective doses of anti-inflammatory agents should be prescribed on a scheduled basis. In patients with simple synovitis, injection of a depot steroid (such as 40 mg/mL triamcinolone

mixed with 0.5% bupivacaine) into the synovial sheath is useful but should be done only when one is absolutely certain there is not infection. Accurate injection is important and may be challenging. One technique is to impale the tendon, as confirmed by distal motion on manipulation of the needle, and then to withdraw the needle while applying very gentle pressure to the plunger. When loss of resistance is felt, the needle is in the tendon sheath.

Patients should be referred to their primary care physician or a qualified hand surgeon for prompt follow-up. The patient also should be directed to return to the ED for worsening pain, increased swelling, or any signs of infection, including fever and erythema.

Trigger Finger

Tenosynovitis can develop in the flexor sheaths of the fingers and thumb. Scarring or inflammation may cause the tendon to become nodular which results in friction and catching between the tendon and its sheath, usually in the vicinity of the A1 pulley. This is referred to as *stenosing tenosynovitis*, or *trigger finger.* The patient experiences binding of the tendon, usually as the finger extends, relieved by a painful "snap" as the tendon clears the obstruction. Occasionally, this condition may progress to the point that the finger locks, usually in flexion. Early stages of trigger finger have been treated successfully with depot steroid injection into the tendon sheath, although there may be recurrence. Surgical division of the A1 pulley is usually curative.

DeQuervain's Stenosing Tenosynovitis

DeQueirvain's tenosynovitis is a common condition that occurs in patients who have experienced excessive use of the thumb. Often no good cause can be found. This is a tenosynovitis of the extensor pollicis brevis and abductor pollicis tendons, where they lie in the groove of the radial styloid.

The patient presents with pain along the radial aspect of the wrist that extends into the forearm. The definitive examination that confirms the diagnosis is Finkelstein's test (Fig. 277-7), in which the patient grasps the thumb in the palm of the hand and the examiner ulnar deviates the thumb and hand. This produces sharp pain along the involved tendons.

FIG. 277-7. The Finkelstein test is shown. The thumb is cupped in the closed fist and ulnar deviation reproduces pain along the extensor pollicis and abductor pollicis.

DeQuervain's tenosynovitis can be treated with injection into the tendon sheath of 1 mL of 0.5% bupivacaine mixed with 40 mg (1 mL) triamcinolone. This is accomplished by palpating the tendon with the thumb in hyperextension, and injecting 1 cm proximal to the tip of the radial styloid. Distention of the tendon sheath should be seen distal to the retinacular ligament. The tendon itself must not be injected, and care must be taken to avoid subcutaneous or intradermal injection of steroid because this may cause cutaneous thinning and depigmentation. A thumb spica splint should be applied to keep the thumb in a neutral position for 3 weeks. Instruct the patient to remove the splint briefly each day and perform range of motion exercises to prevent joint stiffness. Anti-inflammatory medication should be prescribed for 10 to 14 days. Recurrence of this condition is not uncommon, particularly when related to occupational stress. Persistent cases should be referred to a hand surgeon.

Carpal Tunnel Syndrome

Carpal tunnel syndrome is a peripheral mononeuropathy that involves entrapment of the median nerve in the carpal canal or tunnel, which is covered by the tense transverse carpal ligament. Whenever a condition causes swelling in the carpal tunnel, the median nerve is compressed, causing parasthesias that extend into the index and long fingers and the radial aspect of the ring finger and along the palmar aspect of the thumb. [16] The patient often complains of awakening at night with pain in the hand. In addition, patients often complain of numbness when driving a car or maintaining the hand in an extended position for a prolonged period of time.

Direct trauma to the wrist may exacerbate symptoms; however, a more common scenario involves overuse syndromes where the patient relays a history of repeated flexion and extension of the wrist that results in edema in the carpal tunnel. Other edematous conditions such as pregnancy and congestive heart failure may acutely exacerbate symptoms in patients with a predisposition for carpal tunnel syndrome. [17] It is also more common in diabetes and rheumatoid arthritis. [16]

Tinel's sign may support the diagnosis and involves tapping the volar aspect of the wrist over the median nerve. A positive sign produces paresthesias that extend into the index and long finger. Phalen's sign is more sensitive (50 percent) and specific (75 percent) and involves flexing the wrist maximally and holding it in this position for at least 1 min. The patient complains of tingling and numbness along the median nerve distribution. Both signs are subject to false-positive and false-negative results and electrodiagnostic techniques may be required to confirm the diagnosis. [18]

Initial treatment of carpal tunnel syndrome involves placing a volar splint to maintain the wrist in neutral position and giving the patient anti-inflammatory agents. Infiltration of the carpal tunnel with a mixture of 1 mL of 0.5% bupivacaine and 40 mg (1 mL) of triamcinolone may be beneficial, if the physician is experienced in the procedure. Unfortunately, this technique often provides only temporary relief. If this does not improve the condition, or if symptoms recur, surgical intervention is necessary to release the entrapment.

This condition may have a relapsing course, and permanent deficits of the median nerve occasionally are seen. Carpal tunnel syndrome should be diagnosed early, and the patient should be referred to a hand surgeon in a timely fashion.

Dupuytren's Contracture

Dupuytren's contracture is a poorly understood disorder resulting in fibroplastic changes of the subcutaneous tissues of the palm and volar aspect of the fingers. There appears to be a genetic component, and the condition is found most commonly in men of northern European descent. [19] This process eventually may lead to tethering and joint contracture. Firm longitudinal thickening and nodularity of the superficial tissues usually are readily appreciated. The diagnosis is made by identifying a nodule in the palm, usually at the distal palmar crease of the ring or small finger, which is held in the classic flexion contracture. [20] This condition should be referred to a skilled hand specialist because surgical excision of the fibrotic bands is usually palliative.

EPIDEMIOLOGY

Acute disorders of the joints affect a collection of patients with diseases that span a vast spectrum of age, acuity, and etiologies. A young child with an acute septic arthropathy may reside at one end of this spectrum, whereas an elderly patient with an acute exacerbation of osteoarthritis may lie at the other, both patients unified by an acutely painful hip. Emergency physicians must differentiate conditions that require immediate attention from those that require less urgent therapy. A careful, methodical process utilizing certain unifying approaches within the clinical history, physical examination, laboratory evaluation, and radiographic assessment will lead to appropriate diagnosis, treatment, and disposition.

CLINICAL FEATURES

Many pathways provoke acute joint complaints: degradation and degeneration of articular cartilage (osteoarthritis), deposition of immune complexes or immune-system-related phenomena (rheumatoid arthritis, rheumatic fever, and gonococcal arthritis), crystal-induced inflammation (gout and pseudogout), seronegative spondylarthropathies (ankylosing spondylitis and Reiter's syndrome), and bacterial invasion (septic or Lyme arthritis) or viral invasion (viral arthritis). These processes impact joint capsules and surfaces, resulting in a cascade of reactive and inflammatory events.

The most useful tool for evaluation of joint disorders is evaluation of synovial fluid. Table 278-1 lists the diagnostic characteristics of synovial fluid. However, joint aspiration may be difficult or impossible in smaller joints or those with minimal effusions. Identifying the distribution and number of affected joints is also necessary for diagnosis (Table 278-2). A migratory pattern of joint involvement may be helpful as well (Table 278-3).[1,2]

TABLE 278-1   Examination of Synovial Fluid

TABLE 278-2   Classification of Arthritis by Number of Affected Joints

TABLE 278-3   Common Joint Disorders Displaying a Migratory Distribution Pattern

Age and gender are also aids to diagnosis. Although no clinical pattern is diagnostic, certain general observations are helpful. Septic arthritis is important in infants and children,[3] with typical affecting organisms characteristic of age and development (Table 278-4). Additionally, a number of infectious and inflammatory processes are unique to childhood (Table 278-5).[3] In teen and adult years, sexual activity results in an increase in prevalence of gonococcal arthritis and Reiter syndrome associated with chlamydial urethritis.[4]

Patient/Condition	Expected Organisms	Antibiotic Considerations
Neonates and infants	Staphylococcus, gram-negative bacteria, group B Streptococcus, Candida	Nafcillin* plus aminoglycoside or third-generation cephalosporin, ampicillin-sulbactam
Children <5 years	Staphylococcus, Haemophilus influenzae	Nafcillin* plus cefuroxime, ampicillin-sulbactam
Older children and healthy adults	Staphylococcus, Gonococcus, Streptococcus	Nafcillin* plus third-generation cephalosporin, ampicillin-sulbactam
Involvement of the foot	Staphylococcus, Pseudomonas	Nafcillin* plus ceftazidime or aminoglycoside
Intravenous drug users	Staphylococcus, gram-negative bacilli	Nafcillin* plus aminoglycoside, ampicillin-sulbactam
Sickle-cell patients	Salmonella	Ciprofloxacin, ofloxacin, or ceftriaxone

*First-generation cephalosporin may be substituted for penicillinase-resistant penicillin. Vancomycin should be employed for treatment of suspected methicillin-resistant staphylococci.

TABLE 278-4   Commonly Encountered Organisms in the Septic Arthritis Patient

TABLE 278-5   Differential Considerations for the Acutely Inflamed Pediatric Joint

Crystal-induced arthritides commonly affect middle-aged adults. Gout is the commonest inflammatory joint disease in men over age 40.[5] The classic gout patient is a middle-aged man with an acute monoarthritis. Women, however, are generally spared the onset of gout until later middle age and can develop polyarticular involvement.[5]

As age progresses, the incidence of rheumatoid and osteoarthritis increases. Whereas osteoarthritis is a disease of older adults (over age 60), rheumatoid arthritis tends to strike earlier with a predilection for women three to four times that of men.[1] Additionally, rheumatoid arthritis classically demonstrates a progressive course with additive, polyarticular involvement of symmetric joints.[6]

DIAGNOSIS

Examination of Synovial Fluid

Joint fluid should routinely be analyzed for culture, Gram stain, leukocyte count with differential, and a wet preparation for crystals.[7] Glucose and lactate levels may be assessed as well. Cultures should include those for gonococci and anaerobes, when appropriate. Certain disease mechanisms are associated with classic joint aspirate findings (Table 278-1).

Laboratory Tests

In the acute setting, few tests other than the joint aspirate contribute meaningfully to the diagnostic evaluation. Although the erythrocyte sedimentation rate (ESR) is frequently elevated in a number of acute inflammatory and reactive arthritides (septic, gonococcal, crystal-induced, spondyloarthropathies, and rheumatoid and Lyme arthritis),[8] the ESR is neither specific nor sufficiently sensitive for disease or as a marker for disease progression. The most promising and applicable levels of ESR sensitivity have been reported as 90 percent in children and young infants with septic arthritis.[2,9]

The white blood cell count (WBC) also has poor sensitivity and specificity. Notably, in pediatric septic arthritis, the total WBC is reported as 30 to 60 percent sensitive, with a left shift of the differential approaching 66 percent sensitivity.[2,9] Similar findings have been described in the adult population as well.[10]

Although routine (as in the case of WBC and ESR) in the consideration of a potentially infected joint, blood cultures have limited utility as well. Cultures should be drawn prior to antibiotic therapy. Blood cultures, in the setting of acute septic arthritis in adult and pediatric patients, have demonstrated sensitivities of 23 and 40 percent, respectively.[10,11]

Additional laboratory assessment may be required for follow-up, including rheumatoid factor, antinuclear antibodies, antineutrophil cytoplasmic antibodies, HLA-B27 tissue typing, lupus anticoagulant, and repeat synovial fluid analysis.[12]

Radiology

Radiographs of an inflamed joint should be obtained when trauma, tumor, ankylosing spondylitis, avascular necrosis, or osteomyelitis are in the differential diagnosis. Radiographic evidence of osteomyelitis has been noted to follow infection by 7 to 14 days. [1,2] Radioisotope scanning is not usually required for emergency department diagnosis[3] but can be useful to detect osteomyelitis, occult fracture, avascular necrosis, or tumor.

ARTHROCENTESIS

Accurate diagnosis of articular problems often depends on aspiration and examination of synovial fluid from the affected joint(s) (Table 278-1).

Technique for Preparation of Selected Arthrocentesis Site

The skin overlying the affected joint should be free of cellulitis or impetigo in order to avoid contamination of the joint space during arthrocentesis. Other relative contraindications to joint aspiration are coagulopathy, hemarthrosis in hemophiliac patients, and the presence of a prosthetic joint. However, if the concern for septic arthritis is high, arthrocentesis may be performed in these settings after consultation.

The technique for preparation of any selected joint begins with overlying skin preparation and proper anesthesia. A large area overlying and adjacent to the affected joint is cleansed with povidone-iodine solution. After air drying, the skin is cleaned with an alcohol wipe to remove the povidone-iodine solution from the skin surface. This prevents the introduction of the povidone-iodine antiseptic into the joint, which can result in chemical irritation, or sterilization of the aspiration sample. Sterile drapes are then placed over the site.

Anesthesia is accomplished with infiltration of a local anesthetic by using a 25- to 30-gauge needle. Intraarticular injection of anesthetic should be avoided, because it can inhibit bacterial growth and may result in a spuriously negative culture in an early septic joint. [10]

A large-bore needle (18 or 19 gauge) should be used for aspiration of the joint. Smaller joints may require a smaller-bore needle to enter the joint space. The anticipated volume of fluid within the joint space should direct the selection of syringe size. As much synovial fluid should be removed as possible to optimize diagnosis and relieve pain from joint capsule distention. Aspirated fluid should promptly be sent for appropriate studies, including culture, Gram stain, leukocyte count with differential, and crystal analysis.

Shoulder

ANTERIOR APPROACH   Insert the needle just lateral to the coracoid process. This technique is performed with the patient sitting in an upright position, facing the examiner. The needle is directed posteriorly between the coracoid process and the humeral head. Because of the difficulty in locating the coracoid process, a posterior approach to the glenohumeral joint may be preferable in some patients.

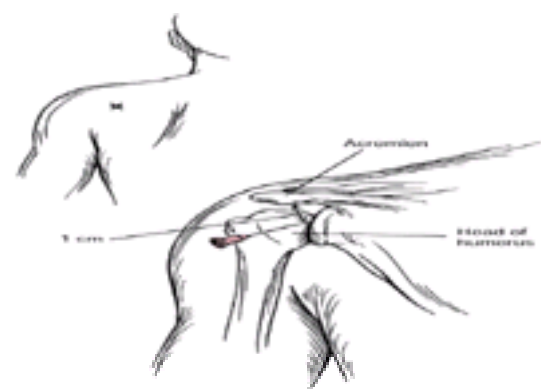
POSTERIOR APPROACH   Sit the patient upright with his or her back toward you. The spine of the scapula is palpated to its lateral limit: the acromion. The posterolateral corner of the acromion is located. The point for needle insertion lies 1 cm inferior and 1 cm medial to the posterolateral corner of the acromion (Fig. 278-1). A $1\frac{1}{2}$-in needle is directed anterior and medial toward the presumed position of the coracoid process. The glenohumeral joint is located at a depth of approximately 1 to $1\frac{1}{2}$ in.


FIG. 278-1. Arthrocentesis of the shoulder, posterior approach.

Elbow

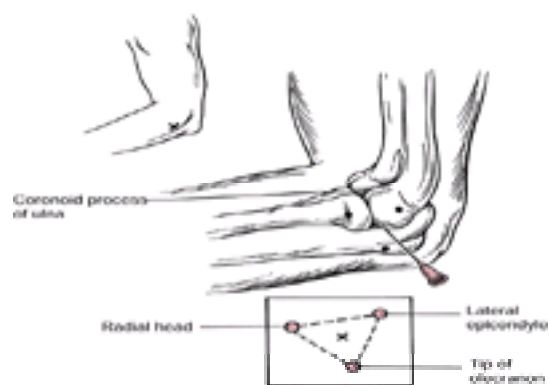
A lateral approach to the elbow is used. Place the elbow in 90 degree flexion, resting on a table, with the hand prone. Locate the radial head, lateral epicondyle of the distal humerus, and the lateral aspect of the olecranon tip. These three landmarks form the anconeus triangle. The center of this triangle is the site for needle entry into the skin. The needle should be directed medial and perpendicular to the radius (Fig. 278-2).


FIG. 278-2. Arthrocentesis of the elbow.

Wrist

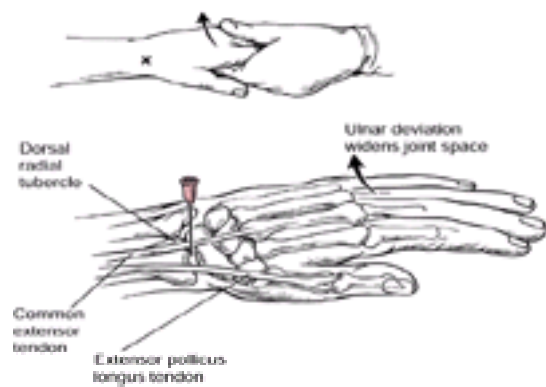
Landmarks for wrist arthrocentesis are palpable with the wrist in a neutral position. Noted landmarks are the radial tubercle of the distal radius, the anatomic snuff-box, the extensor pollicis longus tendon, and the common extensor tendon of the index finger (Fig. 278-3). The needle should be inserted perpendicular to the skin slightly ulnar to the radial tubercle and the anatomic snuff-box between the extensor pollicis longus and the common extensor tendons.


FIG. 278-3. Arthrocentesis of the wrist.

Hip

Hip arthrocentesis may be performed by either an anterior or a medial approach. Due to the belief that patients, particularly children, with a septic hip should undergo open surgical assessment and drainage, an orthopedic consultant performs this procedure. [3] Controversy exists regarding the utility of ultrasound, bone scan, or magnetic resonance imaging as a screening test prior to open surgical evaluation. [13,14] Immediate consultation with orthopedics is therefore desirable when a diagnosis of septic hip is considered.

Knee

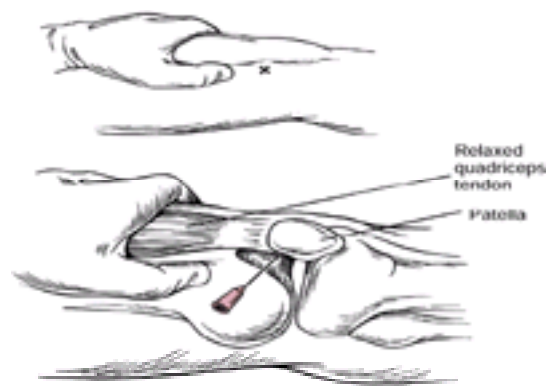
The knee joint can be entered either medial or lateral to the patella. With the patient supine, the knee should be fully extended and the quadriceps muscle relaxed. The midpoint of the patella is identified. The insertion point of the needle is located approximately 1 cm inferior to the patellar edge, either lateral (Fig. 278-4) or medial (Fig. 278-5) to the middle of the patella. The needle should be directed posterior to the patella and horizontally toward the joint space. Compression applied over the joint space or "milking" of the bursae, on the patellar side opposite of the needle insertion site, may facilitate aspiration.


FIG. 278-4. Arthrocentesis of the knee, lateral approach.
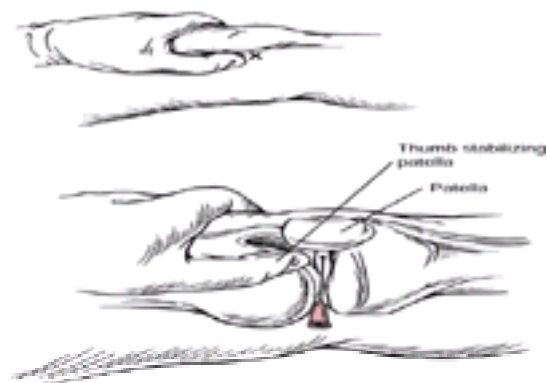

FIG. 278-5. Arthrocentesis of the knee, medial approach.

Ankle

Ankle arthrocentesis may be performed at either the subtalar joint (lateral approach) or the tibiotalar joint (medial approach). The subtalar joint is entered just below the tip of the lateral malleolus with the foot perpendicular to the leg (Fig. 278-6). The needle should be directed medially toward the joint space.
FIG. 278-6. Arthrocentesis of the ankle, lateral approach.

The tibiotalar joint is approached with the patient supine and the foot initially perpendicular to the leg. This position facilitates the location of a sulcus lateral to the medial malleolus and medial to the tibialis anterior and extensor hallucis longus tendons (Fig. 278-7). The foot is then plantar flexed with the needle entering the skin overlying the sulcus. The needle should be angled slightly cephalad as it passes between the medial malleolus and the tibialis anterior tendon.
FIG. 278-7. Arthrocentesis of the ankle, medial approach.

SPECIFIC CONDITIONS

Traumatic Arthritis

Traumatic hemarthrosis has a high association with ligamentous injury or an intraarticular fracture. Effusions following trauma may range from small to large painful ones that impede range of motion. Aspiration of very large traumatic effusions will provide pain relief and increase range of motion. Treatment of traumatic hemarthrosis consists of immobilization, ice, and elevation of the affected joint. In the absence of a fracture or significantly unstable joint requiring immediate orthopedic evaluation, follow-up is needed for possible ligamentous and articular injuries.

Spontaneous hemarthrosis usually indicates underlying systemic illness and should trigger a search for primary or secondary coagulopathies. Hemophiliacs should receive specific clotting factor replacement (see Chap. 212), and their joints should generally not be aspirated. Follow-up should be provided with hematology and orthopedics.

Nongonococcal Septic Arthritis

Three mechanisms can lead to septic arthritis: (1) hematogenous spread of bacteria, (2) migration of bacteria from a focus contiguous to a joint, and (3) direct inoculation of bacteria into the joint.

Septic arthritis is a medical emergency. A rampant bacterial infection with a normal inflammatory response can destroy a joint within hours to days. The involved joint can become exquisitely painful over a few hours. On examination, effusions may be scant, with significant splinting and resistance to movement.

Although the classic bacterial arthritis patient is described as febrile with chills and rigors, a 10-year retrospective review of 43 adult patients noted presence of fever or rigors in only 40 and 21 percent of patients, respectively. [10] Thus, the absence of constitutional symptoms should not preclude a septic arthritis diagnosis. A suspicion for a bacterial infection should always guide clinical decision making when approaching patients with monoarthritis.

After joint aspiration, if septic arthritis cannot be excluded, the patient should be admitted for pain control and parenteral antibiotics until synovial culture results are available. Consultation with the orthopedics or infectious disease departments is desirable. Repeat closed needle aspiration, arthroscopy, or open surgical drainage may be required, depending on a number of factors, including consultant preference, patient age, affected joint, and likelihood of septic source.

Gonococcal Arthritis

Gonococcal arthritis is the most common cause of septic arthritis in adolescents and young adults. [3] Joint infection will typically have a prodromal phase where migratory arthritis and tenosynovitis predominate before pain and swelling settle on one or more septic joints. Vesiculopustular lesions, especially on the fingers, may be found.

Synovial fluid cultures are often negative in gonococcal arthritis, with only 25 to 50 percent of cases yielding positive identification of the organism. Cultures of the posterior pharynx, urethra, cervix, and rectum, prior to antibiotic treatment, may increase the culture yield. [3]

Treatment for gonococcal arthritis follows the same principles as treatment for nongonococcal septic arthritis. *Neisseria gonorrhoeae,* in the setting of arthritis, remains sensitive to penicillin, and extended antibiotic coverage is typically not required following identification of the organism.

Crystal-Induced Synovitis (Gout and Pseudogout)

Crystal-induced synovitis is primarily an illness of middle-aged and elderly adults. Uric acid (gout) and calcium pyrophosphate (pseudogout) are the two most common crystalline agents, with gout representing the most common form of inflammatory joint disease in men older than age 40. [5] Patients typically present with joint pain that acutely evolves over hours, as in acute gout attack, or over a single day, as in pseudogout. An acute gout or pseudogout attack often follows trauma, surgery, a significant illness, or change in medications that results in an abrupt change in uric acid levels. Crystalline involvement of joints has a predilection for the lower extremities. Although the first metatarsophalangeal joint is a classic focus for acute gout, no joint is the exclusive site of involvement for either crystal.

The diagnosis of a crystal-induced synovitis is by joint aspiration and identification of crystals through a polarizing microscope. Uric acid crystals appear needle shaped and blue when the source of light is perpendicular to the crystal. Calcium pyrophosphate is yellow in this alignment, with a rhomboid shape. Crystals should be located within phagocytes from aspirates of synovial fluid or inflamed tissues adjacent to the affected joint.

Serum uric acid levels have limited utility in diagnosis, as up to 30 percent of patients will have normal uric acid levels during an acute attack. [5] The joint aspirate WBC is often high with gout, approaching 100,000/mm^3 in some cases. [5] However, the presence of crystals, absence of findings on Gram stain/culture and, frequently, the dramatic response to nonsteroidal anti-inflammatory drugs (NSAIDs) will clarify the diagnosis. When the diagnosis of a septic joint cannot be excluded, hospital admission until cultures and/or clinical response clarify the diagnosis is the safest course of action.

When the diagnosis of gout or pseudogout is established, a NSAID, such as indomethacin, is standard first-line therapy. All NSAID dosing should be adjusted for renal function and continue for approximately 1 week. For patients with normal renal function, the initial dose of indomethacin is 50 mg. Therapy is continued three times a day for 3 to 5 days. Substantial pain relief typically occurs within 2 h of NSAID administration. [15] Additional treatment for pseudogout is typically not required.

Colchicine, although uncommonly necessary, may also be employed as an alternative in the treatment of acute gout. Oral colchicine is typically administered at a dose of 0.6 mg/h until intolerable side effects (vomiting or diarrhea) or efficacy ensue. Intravenous administration of colchicine, particularly at toxic levels, can be associated with serious side effects, with risks such as bone marrow suppression, neuropathy, myopathy, and death. Consequently, intravenous colchicine is rarely used.

Patient disposition is determined by consideration of effective analgesia and the inclusion or elimination of septic arthritis as a diagnosis in the patient evaluation. Once the symptoms of an acute crystal-induced synovitis episode have resolved, long-term control may be achieved with reduction or elimination of gout-inducing agents (diuretics, aspirin, or cyclosporine) and treatment with prophylactic drugs, such as allopurinol or probenecid.

Lyme Disease

The arthritic manifestations associated with Lyme disease occur in the weeks, months, or years following the primary, stage I infection. Typically, a monoarticular or oligoarticular, asymmetric involvement of joints is noted, with brief exacerbations followed by complete remission. Large joints are most often affected. A migratory pattern of oligoarthritis may be noted, in addition to brief attacks of bursitis and tendonitis.

Arthrocentesis yields an inflammatory synovial fluid with cultures uncommonly positive. The diagnosis of Lyme arthritis is initially suspected in patients residing in, or with a recent visit to, an endemic area. A history of tick bite or erythema chronicum migrans (ECM) rash is helpful but often absent. In patients with no history of rash, tick bite, or endemic location, a constellation of characteristic stage II and stage III findings—such as fatigue, neurologic abnormalities, and/or cardiac conduction disturbances—may be helpful in establishing the diagnosis. Ultimately, definitive diagnosis requires the history or presence of the ECM rash, multiorgan system involvement, or laboratory confirmation through enzyme-linked immunosorbent assay, immunofluorescent antibody titer, or isolation of the *Borrelia burgdorferi* spirochete from a clinical specimen.

Given the difficulty of making a definitive diagnosis in many patients, treatment of suspected Lyme arthritis is often initiated on the grounds of high clinical suspicion. Treatment is administered for 3 to 4 weeks with a number of antibiotics recognized as effective, including doxycycline, penicillin G, amoxicillin, or ceftriaxone. Intravenous antibiotic therapy is reserved for those patients with more severe presentations.

Rheumatoid Arthritis

Rheumatoid arthritis is distinguished by its symmetric, polyarticular involvement, with noted sparing of the distal interphalangeal (DIP) joints. Patients will describe stiffness of the joints occurring after prolonged periods of inactivity (morning stiffness). Multisystem involvement is characteristic, and depression, fatigue, and generalized myalgias are also common. Extraarticular symptoms and signs include pericarditis, myocarditis, pleural effusion, pneumonitis, and mononeuritis multiplex syndrome.

Articular involvement is noted for symmetric, painful, tender joints. A "boggy," slightly edematous synovium may be palpated. Sparing of the DIP joints is the rule, with an additive involvement of affected joints during the course of the illness. Arthrocentesis of synovial fluid is typically noted for an inflammatory profile.

Treatment during an acute exacerbation is directed at reducing pain and inflammation. Salicylates or other NSAIDs are the cornerstone of treatment, with immobilization providing added relief from joint movement pain. Corticosteroids may be utilized for brief periods with long-term therapy using agents such as antimalarials, gold, and methotrexate.

Osteoarthritis

Osteoarthritis is distinguished from rheumatoid arthritis by a lack of constitutional symptoms and/or multisystem involvement. Destruction of joints in osteoarthritis may involve the DIP joints, with less dramatic symmetric, polyarticular exacerbations. Although osteoarthritis is a chronic, polyarticular disease, patients may present with an acute monoarthritis exacerbation, typically of the knee. Effusions are small and difficult to aspirate. When analyzed, however, synovial fluid is noted to be noninflammatory.

Radiographs contribute to the diagnosis of osteoarthritis, demonstrating characteristic joint space narrowing due to destruction of articular cartilage. Treatment, as in rheumatoid arthritis, involves rest of affected joints and the use of salicylates or NSAIDs. Because of the noninflammatory and destructive nature of osteoarthritis, corticosteroids are not used in the disease. Disease progression often necessitates total joint replacement.

Reiter's Syndrome

Reiter's syndrome, or reactive arthritis, is a seronegative spondyloar thropathy characterized by an acute, asymmetric oligoarthritis preceded 2 to 6 weeks by an infectious illness. The classic triad of Reiter's syndrome is arthritis, urethritis, and conjunctivitis. A history of all three components is not necessary for diagnosis. *Chlamydia* or ureaplasma are common inciting infectious agents, particularly with regard to a precipitating urethritis. Diarrhea has also become recognized as an entity that may precipitate a reactive arthritis. A history of recent diarrhea or enteric infection while traveling abroad may suggest a recent *Salmonella* or *Shigella* infection as an inciting factor for the disease.[4]

Joint involvement is typically found in the lower extremities, particularly the heels of the feet. A diffuse swelling of an entire digit (sausage digit) may be found as well but is not specific to Reiter's syndrome alone.[1] Synovial fluid aspirates demonstrate an inflammatory profile. Treatment is supportive with emphasis on pain control and NSAID therapy. Antibiotics have not been found to contribute to treatment of Reiter's syndrome patients.

Ankylosing Spondylitis

Another of the seronegative spondyloarthropathies—ankylosing spondylitis—demonstrates an arthritic predilection for the spine and pelvis. Ankylosing spondylitis is similar to rheumatoid arthritis in its association with morning stiffness and multisystem involvement with constitutional symptoms such as malaise, weakness, and fatigue. However, ankylosing spondylitis is clearly differentiated in its association with hereditary factors, particularly the HLA-B27 antigen and negative rheumatoid factor.

Ankylosing spondylitis is suspected in individuals younger than age 40 who note insidious onset of symptoms that improve with exercise, are associated with morning stiffness, and last longer than 3 months.[16] Radiographic findings, in addition to genetic predisposition, are helpful in the diagnosis of ankylosing spondylitis. Squaring of the vertebral bodies (bamboo spine) and sacroiliitis are some of the more classic findings. Treatment consists of pain control with short-term and long-term management with NSAIDs.

BURSITIS

The term *bursitis* refers to any acute or chronic inflammatory process involving one of the more than 150 bursae identified throughout the human body. [17] Bursitis is classified by etiology, body location, and presence of infection. Etiologic entities include trauma, crystal-induced, rheumatoid, and idiopathic forms. Presence of infection is noted by classification as septic or nonseptic. *Staphylococcus aureus* accounts for the majority of identified infectious agents, but *Staphylococcus epidermis* and *Streptococcus* species are also encountered.

Bursitis is a relatively common condition, due to the number of bursae and the minimal trauma required to initiate a clinically evident process. The affected site is determined by the activity precipitating the event and/or the relatively superficial location of many bursae. Certain entities are frequently associated with occupations or activities that precipitate their occurrence: "carpet layer's knee" (prepatellar bursitis) or "student's elbow" (olecranon bursitis).

General principles of management include restraint from further trauma/injury, elevation, and a compressive dressing. Drug therapy with NSAIDs is the primary pharmacotherapeutic intervention. Injection of the affected bursa with steroids is controversial and should be avoided when septic bursitis cannot be excluded. Specifically, olecranon and prepatellar bursitis are not uncommonly complicated by infection.

Septic bursitis generally responds well to oral antibiotics, with emphasis on coverage of *Staphylococcus* and *Streptococcus* species. Selected patients will require more aggressive interventions, including admission to hospital, administration of parenteral antibiotics, incision and debridement, and open irrigation. These patients typically have more advanced, purulent infection within the bursa, extensive spread of infection/cellulitis to surrounding soft tissues, suspected joint involvement, or failure to respond to oral antibiotics and outpatient interventions.

Specific Conditions

OLECRANON BURSITIS   The olecranon bursa overlies the olecranon process on the extensor surface of the elbow. Patients with olecranon bursitis present with a tense, edematous bursa that is often tender to palpation. Pain elicited with range of motion at the elbow is minor until the motion tightens and compresses the

distended overlying bursa. The bursa is frequently erythematous and warm.

Distinguishing nonseptic bursitis from the septic and crystal-induced forms is a clinical challenge. Patients with crystal-induced bursitis will often demonstrate gouty tophi overlying the elbow extensor surface. Presence of crystals in bursal fluid analysis is diagnostic.

Septic bursitis and nonseptic bursitis are difficult to distinguish. No definitive conclusion can be reached solely on the basis of physical exam findings or history, although one report has noted the utility of a comparison of surface temperature of the affected bursa with the unaffected side. [17] These authors reported a temperature difference exceeding 2.1°C to be highly predictive of a septic bursal fluid aspirate.

Most authors advocate the importance of aspirating bursal fluid, [17,18,19 and 20] which is performed both for diagnostic and therapeutic purposes. Bursal fluid, like joint aspirates, demonstrates characteristic findings (Table 278-6). The utility of any one finding is limited, however, and the culture represents the definitive test for presence or absence of infection.

	Septic	Traumatic and Idiopathic	Crystal Induced
Appearance	Purulent; may be straw colored or serosanguineous	Straw colored, serosanguineous, or bloody	Straw colored to bloody
Leukocytes/µL	1500–300,000; mean 75,000	50–11,000; mean 1100	1000–6000; mean 2900
Differential count	Predominantly PMNs	Predominantly mononuclear	Highly variable
Ratio bursal fluid to serum glucose	<50%	>50%	Unknown
Gram stain	Positive in 70%	Negative	Negative
Crystals present	No	No	Yes
Culture results	Positive	Negative	Negative

TABLE 278-6   Characteristics of Bursal Fluid in Patients with Septic and Nonseptic Olecranon and Prepatellar Bursitis

Aspiration of olecranon bursitis fluid is undertaken by means of a lateral approach to the affected bursa. As in joint aspirates, a sterile technique should be utilized, with evacuation of as large amount of fluid as possible.

Management of patients with olecranon bursitis follows the aforementioned general bursitis management principles. When a septic bursitis is definitively excluded, a steroid injected into the bursa may expedite resolution of inflammation. [20] However, a septic process usually cannot be excluded during the initial evaluation of an acute olecranon bursitis. As a consequence, utilization of steroid injection should be approached with caution.

Antibiotic treatment is usually effective with a 14-day course of oral antibiotic therapy. [17,19] Selected patients who may require parenteral therapy or operative management are generally distinguished by their toxic appearance, systemic signs of infection, extensive cellulitis to surrounding tissues, failure of outpatient interventions, or immunocompromised host status.

PREPATELLAR BURSITIS   Prepatellar bursitis may affect any of the four bursae surrounding the extensor aspect of the knee. As in other bursitis conditions, a history of overuse or trauma to the prepatellar area is often elicited. Clinical findings are consistent with those of olecranon bursitis.

Aspiration of prepatellar bursal fluid should be approached by either a medial or lateral approach to the affected bursa. The incidence of prepatellar septic bursitis is much less than that of olecranon bursitis (approximately 75 percent less). [17] Treatment emphasizes conservative management and occasionally requires antibiotic therapy or admission following the same approach as already outlined for patients with septic olecranon bursitis.

Frantz R. Melio

In 1990 the National Center for Health Statistics conducted a National Health Interview Survey that included a list of the three most common podiatric problems: bunions, corns and calluses, and ingrown toenails. In response, 13.2 out of 1000 people reported being afflicted by bunions, 24.5 per 1000 with ingrown toenails, and 20 per 1000 with corns or calluses. Advanced age, poverty, and female gender were associated with increased risk for these diseases. It is thus apparent that chronic foot problems play an important role in U.S. health care.[1] Patients with chronic or complicated foot problems generally should be referred to a dermatolgist, orthopedist, general surgeon, or podiatrist, depending on disease and local resources.

CORNS AND CALLUSES

Pressure or irritation causes focal hyperkeratotic lesions of the skin of the foot. The cause of these lesions can be external (poorly fitted shoe) or internal (bunion). These areas of epidermal accumulation are defined as *calluses.* Calluses serve a protective function and should not be treated if they are not painful. Calluses grow outward but are soon pushed inward by continued pressure and become corns. Corns also develop in areas of scarring and between toes. Corns are classified as hard or soft. Hard corns are seen over bony protuberances where the skin is dry. Soft corns are seen between toes where the skin is moist. Corns may be painful or painless, but pressure on the corn usually produces pain. Corns interrupt the normal dermal lines and can thus be differentiated from calluses. Hard corns may resemble warts; however, when pared, warts bleed and corns do not. Soft corns resemble tinea, which often leads to misdiagnosis and mistreatment.[2,3 and 4]

Treatment of symptomatic lesions consists of paring with a no. 15 blade scalpel and application of a pad on or around the lesion to relieve pressure. Avoiding constrictive footwear is also important. Keratolytic agents are advocated by some authors but are thought to be too toxic and better avoided by others. Patients should be referred to a podiatrist, since therapy includes repeated paring and possibly surgery to correct any underlying source of pressure.[2,3 and 4]

Keratotic lesions may be an indication of more severe underlying disease, deformity, local foot disorder, or mechanical problem. Other causes of keratotic lesions include syphilis, psoriasis, arsenic poisoning, rosacea, lichen planus, basal cell nevus syndrome, and, rarely, malignancies.[3]

PLANTAR WARTS

Plantar warts are caused by the human papillomavirus. These warts are fairly common and contagious. They may be painful and are usually found over bony prominences. Single lesions are endophytic and hyperkeratotic. A mother-daughter wart is similar to a single lesion except for a small vesicular satellite lesion. Mosaic warts are often painless, closely grouped, and may coalesce. Diagnosis is usually made clinically. There are many therapeutic options. Treatment is complicated by the fact that many of these lesions will resorb spontaneously within 2 years. These patients may require prolonged treatment in resistant cases and should be referred.[3,5]

TINEA PEDIS

The incidence of tinea pedis in industrialized countries has been estimated at 10 percent of the population. It has been estimated that in high-risk patients as many as 70 percent are affected. In the United States, $240 million per year is spent on products used to treat tinea pedis. Factors that predispose to infection include hot and humid climate, occlusive footwear, infrequent changes of socks or shoes, hyperhidrosis of the feet, conditions that lead to maceration of the feet, and repeated exposure of the feet to fungi combined with some form of minimal trauma. In high-risk groups, such as the elderly and immunocompromised patients, infections can become chronic and resistant to treatment and can disseminate. Tinea pedis can usually be prevented with proper hygiene. These measures include daily bathing and drying of feet, wearing absorbent socks and changing them daily, wearing shoes that "breathe" and changing them daily, wearing different footwear for sporting activities, and using drying agents and antifungals for prophylaxis in high-risk groups.[6]

The causative fungal organisms of tinea pedis usually belong to the dermatophytes, with *Trichophyton rubrum* being the most frequently responsible, accounting for approximately 60 percent of cases. The *Microsporum* species, *Candida,* and saprophytic fungi also account for many occurrences.[6]

Clinically, tinea pedis appears in a variety of forms, ranging from mild scaling to acute inflammation. The most common form is interdigital infection. Interdigital presentation may be as benign as a fissure in the toe web, usually between the fourth and fifth toes. More commonly, the affected interspaces appear white, macerated, and soggy as a result of multiple simultaneous infections (dermatophyte and bacteria). These complex infections usually begin with dermatophyte infection of the toe web. The fungi produce antibiotics that select for an antibiotic-resistant bacterial population (both gram-positive and gram-negative). These bacteria induce further inflammation and damage to the epithelium. The bacteria also produce anifungal by-products and quickly predominate. It has now been recognized that these bacteria alone are also etiologic agents of tinea pedis. The more severe the infection, the more likely that other organisms such as yeast and saprophytic fungi are also involved. These lesions are pruritic and may become painful when the patient wears a closed shoe or exercises.[6,7]

A second form of tinea pedis is the hyperkeratotic or moccasin-type infection. This is a chronic form of tinea that is characterized by scaly eruptions, fissuring, pruritus, erythema, and the absence of vesicles and pustules. It is usually limited to the weight-bearing surfaces of the feet and spares the intertriginous areas. *T. rubrum* is the most frequent causative organism.[6,7]

The vesicular form is another common presentation of tinea pedis. This infection is characterized by vesicles and vesicopustules and is most commonly caused by *T. mentagrophytes, Epidermophyton floccosum,* and rarely, *Microsporum.* The lesions usually begin on the non-weight-bearing areas of the soles and can extend along the entire plantar surface, to the intertriginous areas, up over the toes, and onto the dorsum of the foot. Patients experience a burning pain and pruritus. An ulcerative form of tinea may be the result of secondary pyogenic bacterial infection involving these vesicles.[6,7]

Tinea infections must be differentiated from other lesions that affect the foot. Juvenile plantar dermatosis is a lesion frequently confused with tinea. Affected children have dry, cracked, red scaly patches on the toe pads and anterior plantar surface of the feet; the toe webs and insteps are spared. Treatment consists of lubricants and occlusion, with socks at night. Contact dermatitis is characterized by involvement of the dorsal surface of the feet, with well-demarcated, red patches that may contain tiny vesicles. Psoriasis presents as thick scaly lesions that spare the web spaces and affect the heel. Erythrasma is a low-grade chronic infection that may involve the web spaces. Symmetric patches are also present in the groin and axillae. These lesions fluoresce bright "coral red" under Wood's lamp examination. Pitted keratolysis is a diphtheroid bacterial infection which produces marked hyperkeratosis with multiple 1- to 3-mm punched-out pits on the plantar surface of the foot. Id reactions, which are immunologic reactions to antigenic products of fungal infections, may present as sterile vesicles.[3,6,7]

Diagnosis of tinea pedis is made clinically. Fungal cultures, due to bacterial overgrowth and fungal suppression, are usually very low yield. [6]

Due to the complexity of these infections, the ideal medication must be antifungal, antibacterial, and have local drying as well as anti-inflammatory properties. The imidazole group of antifungals (miconazole, clotrimazole, econazole, ketoconazole, oxiconazole, sulconazole and thoconazole) meet all these criteria and are also effective against *Candida.* Remember to avoid simultaneous treatment with erythromycins. These agents are an excellent choice for initial, empiric treatment of tinea pedis. Some of these medications are available in over-the-counter preparations. These topical antifungals generally should be applied for 2 to 3 weeks. Topical terbinafine and butenafine, applied for 1 to 2 weeks, may be used as an alternative. [8]

Creams and solutions are most often appropriate when treating tinea. Ointments hold the active ingredient at the site longer but should not be used on oozing or moist lesions. Sprays may also be helpful; they evaporate quickly, leaving the medication on the surface for absorption. [6]

Oral therapy with itraconazole, fluconazole, or terbinafine has recently been advocated. These medications are generally well tolerated, have been shown to be as effective as topical therapy, and require only a one week duration of treatment. [9,10]

The role of topical glucocorticoids is controversial. While the anti-inflammatory properties are advocated, the inhibition of cellular defenses may prolong the duration of infection. More important, the low level of anti-inflammatory action that the imidazoles possess is usually sufficient. [6]

Other aspects of therapy include proper hygiene such as daily foot cleaning, drying, and changes in socks and footwear. Application of drying agents such as aluminum chloride (Drysol) or aluminum acetate (Burow's solution and Domeboro) may assist in preventing hyperhidrosis and help control infection. Tight occlusive shoes should be avoided, and soft absorbent socks should be worn. High-risk patients should be told not to walk barefoot. [3,6,7]

Most patients respond to the measures outlined above. However, some infections are resistant to conservative therapy and require prolonged oral antifungal medication. These patients would benefit from appropriate referral. [3,6,7]

ONYCHOMYCOSIS

Dermatophyte fungi are the most frequent cause of nail plate invasion, with *T. rubrum* being the most common organism. Other organisms that can lead to nail infection include *Scopulariopsis brevicaulis, Scytalidium* species, *Aspergillus* species, *Acremonium* species, and *Candida.* The elderly, patients with psoriasis, diabetics, and immunocompromised individuals are more prone to developing onychomycosis. [11,12,13 and 14] Nail infections usually spread from surrounding infected skin. The infection can be either under or within the nail plate. If allowed to progress, these infections lead to severe disturbances in nail growth. The affected toenails appear opaque, discolored, and, at times, hyperkeratotic. Treatment of this disease process is complicated by the fact that topical antifungals are poorly absorbed through the nail. Newer oral antifungals (itraconazole, terbinafine, and fluconazole) have become the preferred first-line agents used in the treatment of onychomycosis. Continuous (daily for 12 weeks) and pulse (daily therapy for 1 week a month for 3 to 4 months) therapies have been studied. Pulse therapy appears to be as effective and have fewer side effects than continuous therapy. Oral terbinafine appears to be the most cost-effective of these agents. [11,15,16,17,18 and 19]

Surgical or chemical debridement of the nail matrix may play a role as adjunctive therapy to the preceding oral antifungals. Patients should be referred to a podiatrist or other appropriate practitioner for continued care because these lesions often require prolonged care. Even with optimal treatment there is a very high recurrence rate. Autoavulsion and traumatic avulsion of involved toenails is common. [4,11,19]

ONYCHOCRYPTOSIS (INGROWN TOENAIL)

Ingrown toenails occur when a segment of the nail plate penetrates the nail sulcus and subcutaneous tissue. Curvature of the nail plate is the most common predisposing factor. The lesion usually occurs as a result of external trauma or self-treatment. Onychocryptosis is characterized by inflammation, swelling, and infection of the medial or lateral aspect of the toenail. The great toe is the most commonly affected. Protracted infection may result in periungual ulcerative granulation. In patients with underlying diabetes or arterial insufficiency, cellulitis, ulceration, and necrosis may lead to amputation if treatment is delayed. If infection is not present at the time of presentation, simple elevation of the nail with placement of a wisp of cotton between the nail plate and the skin, daily foot soaks, and avoidance of pressure on the nail is usually sufficient treatment. Another option, if no infection is present, is to remove a small spicule of the offending nail. A digital block is placed as described below. The area is cleaned, and the skin is prepared for surgical procedure. An oblique portion of the affected nail is trimmed about one- to two-thirds of the way back to the posterior nail fold. The nail groove should then be debrided, and a nonadherent dressing placed [3,4,20] (Fig. 279-1).

FIG. 279-1. Partial toenail removal.

If granulation or infection is present, then partial removal of the nail plate is indicated. This is performed by placing a digital block and preparing the area for a surgical procedure. The entire affected area, one-quarter or less of the nail plate, is cut longitudinally (anterior to posterior), including the portion of the nail beneath the cuticle. English anvil scissors or a nail splitter are the optimal instruments for cutting the nail. The affected cut portion of the nail is then grasped with a hemostat and, using a rocking motion, removed from the nail groove. The nail groove is then debrided and a dressing is placed [20] (Fig. 279-2).
FIG. 279-2. Partial toenail removal (infection present).

One may also cauterize the exposed nail plate. However, cauterization should only be performed by those with appropriate experience with this procedure. [20] An 88% phenol mixture can be applied for 30 s with a cotton-tipped applicator. The phenol is then rinsed with an alcohol solution. Any phenol that comes in contact with healthy tissues must be removed immediately. Silver nitrate also may be used to cauterize the area and should be left on the nail matrix for 1 min. Cauterization is not without risk, as these chemicals may cause extensive tissue destruction. Hemostasis is also extremely important in order to avoid inadvertent absorption of these toxins.

Once the procedure is completed, a nonadherent gauze or antibiotic ointment should be placed on the wound. A bulky dressing should then be placed on the toe. The wound should be checked in 24 to 48 h. [20]

OTHER NAIL LESIONS

Other common toenail afflictions include paronychia and subungual hematoma, which are treated similarly to when they occur in the fingers. Hyperkeratotic toenails can be a problem in the elderly. These may become so severe as to affect gait and cause ulcerations and infections. Patients with these lesions require referral for repeated trimming or nail plate removal. [3,4]

BURSITIS

There are many bursae in the foot, all of which may become a source of pain. Pathologic bursae can be divided into noninflammatory, inflammatory, suppurative, and calcified. Noninflammatory bursae are usually pressure-induced and are found over bony prominences. Inflammatory bursae are commonly due to gout, syphilis, or rheumatoid arthritis. Suppurative bursitis is due to the invasion of the bursae, usually from adjacent wounds, by pyogenic organisms (primarily staphylococcal species). Acute bursitis can lead to the formation of a hygroma or calcified bursae. In severe cases, pressure on bursae can lead to fistula and ulcer formation. Diagnosis of these lesions is dependent on analysis of bursal fluid, which can be obtained by large-bore needle aspiration. Fluid should be sent for cell count; protein, glucose, and lactate (elevated in septic bursitis) levels; crystal analysis; and Gram stain as well as culture (since initial Gram stains are often negative). Treatment of the bursitis depends on its cause. In all cases one should avoid further pressure to the area by instructing the patients to be non-weight-bearing. Septic bursitis should be initially treated with a penicillinase-resistant semisynthetic penicillin while awaiting culture results. Repeated aspiration or incision and drainage may become necessary. [21,22 and 23]

PLANTAR FASCIITIS

Plantar fasciitis is an inflammation of the plantar aponeurosis. The plantar fascia's main function is to anchor the plantar skin to the bone, thus protecting the longitudinal arch of the foot. The cause of plantar fasciitis is usually overuse in the physically active patient or in the patient unaccustomed to activity. Other causes include abnormal joint mechanics, tightness of the Achilles tendon, shoes with poor cushioning, abnormal foot position and anatomy, and obesity. In the younger patient, collagen vascular diseases and rheumatic diseases can lead to this entity. Patients present with pain on the plantar surface of the foot that is worse on arising and after physical activity. Examination usually reveals a point of deep tenderness at the anterior medial aspect of the calcaneus, the point of attachment of the plantar fascia. Plantar fasciitis is generally a self-limiting disease. Short-term treatment consists of rest, ice, nonsteroidal anti-inflammatory agents, heel and arch support shoe inserts, and dorsiflexion night splints (molded ankle-foot orthosis that holds the plantar fascia and Achilles tendon stretched.) Patients should be taught Achilles tendon stretching exercises and be told to avoid walking barefoot on hard surfaces. In severe cases, a short-leg walking cast may be applied to unload and rest the plantar fascia. Glucocorticoid and local anesthetic injections may be helpful. Glucocorticoid injections are associated with plantar fascia rupture and potentially serious sequelae. Only those with appropriate experience should perform this procedure. [24,25,26 and 27]

Long-term therapy consists of proper foot support, stretching, and strengthening exercises. Surgical intervention may be required in refractory cases. Patients should be referred to a podiatrist, orthopedist, or other appropriate practitioner. [25]

TARSAL TUNNEL SYNDROME

This compression neuropathy of the posterior tibial nerve has recently received greater recognition as a cause of foot and heel pain. After coursing inferiorly to the medial malleolus, the posterior tibial nerve enters the tarsal tunnel. The plantar aspect of the tarsal tunnel is bound by the talus and calcaneus bones and by the tibialis posterior, flexor hallucis longus, and flexor digitorum longus. The dorsal aspect is bound by the inelastic flexor retinaculum, which extends from the medial malleolus to the calcaneus to the abductor hallucis muscle.

In the setting of overuse, running and activities requiring restrictive footwear (e.g., ski boots, skates) have been implicated. The edema of pregnancy may also be a precipitant. Hyperpronation while running makes the nerve more vulnerable both to direct trauma from stretch and to indirect trauma from inflammation of the surrounding structures resulting in compression.

Pain is noted at the medial malleolus, the heel (calcaneal branch), and sole (medial or lateral plantar branch), depending on the site and severity of compression. Distal calf pain may result due to retrograde radiation (Valleix phenomenon). Similiar to carpal tunnel syndrome, the pain is often worse at night. More advanced compression may result in weak toe flexion. Tinel's sign is positive inferior to the medial malleolus. Simultaneous dorsiflexion and eversion of the ankle exacerbates symptoms.

The differential diagnosis includes plantar fasciitis and, if limited to the heel, Achilles tendinitis. Plantar fasciitis will cause point tenderness over the plantar heel and worse pain upon morning standing. Tarsal tunnel syndrome causes greater medial heel and arch pain due to involvement of the abductor hallucis muscle. Fasciitis pain may improve with gradual ambulation throughout the day, whereas tarsal tunnel worsens. In addition, tarsal tunnel syndrome may produce distal calf pain, whereas fasciitis does not.

Initial treatment includes avoidance of the exacerbating activities and use of NSAIDs. If there is no improvement or symptoms recur after a few weeks, then orthopaedic evaluation and treatment, which include electromyographic studies, steriod injection, orthotic devices, or surgery, are recommended.

GANGLIONS

A ganglion is a common benign synovial cyst. Ganglia are 1.5 to 2.5 cm in diameter and are often attached to a joint capsule or tendon sheath. Although ganglions typically occur in the wrist, they may also occur in the foot. These lesions typically arise in the anterolateral aspect of the ankle but can occur in many areas of the foot. The pathogenesis of these lesions is unknown. The two most popular theories are (1) that they are produced by herniation of the tendon sheath, and (2) that they arise from focal myxomatous degeneration of collagenous tissues caused by trauma. Ganglions may appear suddenly or gradually, may enlarge and diminish in size, and may be painful or asymptomatic. On examination one notes a firm, usually nontender, cystic lesion. Diagnosis is usually made clinically, although ultrasound and MRI are useful if there is any question of the diagnosis. Aspiration and instillation of glucocorticoids leads to the complete resolution of ganglions in some cases. Most ganglions require complete surgical excision. [28,29]

TENDON LESIONS

Tendon lesions usually require referral and/or consultation with a podiatrist or orthopedist to aid in treatment decisions (Fig. 279-3 and Fig. 279-4). Tenosynovitis and tendinitis may occur in the foot, usually due to overuse. Patients present with pain over the involved tendon. The flexor hallucis longus, posterior tibialis, and Achilles tendon are most commonly involved. Treatment consists of rest, ice, and oral anti-inflammatory agents. [30,31]
FIG. 279-3. Tendons of the foot.

FIG. 279-4. Tendons of the foot.

Tendon lacerations are usually traumatic. The usual mechanism of injury is a cut to the dorsal or plantar aspect of the foot. Tendon lacerations should be explored and repaired if the ends of the tendon are visible in the wound. The foot should be casted in dorsiflexion after the repair of extensor tendons, and in equinus after repair of flexor tendons. Unfortunately, tendon repairs in the foot have a relatively high complication and disability rate. Specialty consultation is appropriate. [3C,31]

Spontaneous rupture of the Achilles, tibialis anterior, and posterior tibialis tendons is fairly common. Diagnosis and proper treatment of tendon ruptures is aided by ultrasound, CT scanning, and MRI studies. Orthopedic consultation should be obtained to aid in proper therapeutic decisions. Achilles tendon ruptures are usually due to forceful dorsiflexion and occur more commonly in males. Patients present with pain, a palpable defect in the area of the tendon, and inability to stand on tiptoes. Squeezing the calf of the prone patient whose knee is flexed at 90° will normally cause the foot to plantar flex. This response will be absent in patients with Achilles tendon ruptures. Treatment is generally surgical in younger patients and conservative (casting in equinus) in older patients. [3C,31]

Ruptures of the anterior tibialis tendon are rare. These usually occur after the fourth decade and are not excessively painful. Patients present with varying degrees of foot drop and a palpable defect distal to the ankle joint in the area of the tendon. In most cases, disability is minimal and surgery is not necessary. [30,31]

Spontaneous ruptures of the posterior tibialis tendon also occur after the fourth decade. Two-thirds of these cases occur in women. The presentation is usually chronic and insidious. Patients notice a gradual flattening of their arch, with modest discomfort and swelling over the medial ankle. Examination reveals absence of the tendon's normal prominence and weakness on inversion of the foot. Patients find it impossible to stand on tiptoes. Treatment may be conservative or surgical, depending on the duration of the tear and activity of the patient. [3C,31]

Another tendon rupture of note is rupture of the flexor hallucis longus, which presents as a loss of plantar flexion of the great toe. This lesion must be repaired in ballet dancers but not in the nonathlete. [3C,31]

Disruption of the peroneal retinaculum can occur as a result of a blow during dorsiflexion of the foot. Besides pain localized to the peroneal tendon behind the lateral maleoles, the patient complains of a clicking when walking as the tendon subluxes. Treatment is generally surgical repair.

PLANTAR INTERDIGITAL NEUROMA (MORTON'S NEUROMA)

Neuromas may form in a plantar digital nerve, usually proximal to its bifurcation. These neuromas may occur in any of the digital nerves but are most common in the third interspace. The cause of these lesions is thought to be local irritation of the nerve due to entrapment, usually from tight-fitting shoes. Women between the ages of 25 and 50 years are the most commonly affected group. Patients present with pain located in the area of the metatarsal head. The pain is described as burning, cramping, or aching. Pain is worsened by ambulation and resolved by rest and removal of shoes. The pain may radiate to the affected toes, and patients may note numbness in the toes. Pain is usually easily reproduced upon palpation of the area, and at times a mass is felt. Diagnosis is usually made clinically, but nerve conduction studies, electromyograms, ultrasound studies, and MRI may be helpful at times. Conservative treatment consists of wearing wide shoes with good metatarsal head supports and metatarsal head off-loading inserts. Local glucocorticoid injections can be curative. Conservative therapy is often unsuccessful, and patients may ultimately require neurolysis or surgical intervention. [24,32]

COMPARTMENT SYNDROME

Compartment syndromes have been more commonly described to affect the arms and legs. Nine compartments have been identified in the foot. Compartment syndrome occurs when an elevation of tissue pressure within one of these nonyielding fascial compartments impedes vascular flow. In the foot, the cause of compartment syndrome is usually a high-energy injury associated with multiple fractures. Crush injuries are more likely to cause compartment syndrome. Compartment syndromes have been reported in association with midfoot fractures and rearfoot fractures, burns, contusions, bleeding disorders, postischemic swelling after arterial injury or thrombosis, venous obstruction, exercise, and prolonged pressure to the affected area. There have also been reports of chronic compartment syndromes due to overuse. Patients typically present with severe acute pain that is worsened on active or passive movement, swelling, paresthesias, and neurovascular deficits. The only reliable method to diagnose compartment syndrome is by obtaining intracompartmental pressures. Once the diagnosis is made, fasciotomy should be performed emergently. The sequelae of compartment syndrome range from transient neurologic compromise to complete myoneural necrosis, fibrosis, and ischemic contractures. The prognosis of compartment syndrome is directly related to the time delay in diagnosis and treatment. [33,34]

IMMERSION FOOT (TRENCH FOOT)

Immersion foot is the result of prolonged exposure of the foot to a moist, nonfreezing (but below 60°F, 15.56°C), occlusive environment. Immersion foot is classically seen in military operations, but the homeless civilian population is also particularly at risk. Prolonged cooling of the extremities produces direct soft tissue injury, with the peripheral nerves being most affected. Wet conditions accelerate the injury, as do factors that reduce circulation to the extremities. These factors include constrictive footwear, prolonged immobilization, hypothermia, smoking, dehydration, nutritional deficiencies, trauma, and underlying disease. When first seen, the injured area is pale, anesthetic, pulseless, immobile, but not frozen. After several hours of rewarming, a vigorous hypermia develops associated with severe burning pain and reappearance of proximal sensation. Edema and bullae, at times sanguinous, may develop as perfusion increases. This hyperemic phase may last weeks, and hyperhidrosis is a prominent late feature. Patients may develop fever and lymphadenopathy. The injury evolves slowly, and anesthesia may be permanent. Differential diagnosis includes cellulitis and fungal infections. Treatment is conservative and includes admission for bedrest, leg elevation, and air drying of feet at

room temperature. Antibiotics play little or no role in the recovery process but should be given if superinfection is present. [35,36]

PLANTAR FIBROMATOSIS

Plantar fibromatosis, or Dupuytren's contracture of the plantar fascia, does not occur as commonly as in the hand. Plantar fibromatosis is a disorder of fibrous tissue proliferation, which slowly invades the skin and soft tissues. Presentation is generally in adolescence or young adulthood. Patients present with small (0.5 to 1.0 cm), asymptomatic, palpable, slowly enlarging, fixed, firm masses on the plantar aspect of one or both feet. These lesions tend to be in the non-weight-bearing areas of the foot. Toe contractures do not occur. These lesions have a tendency to reabsorb spontaneously. Treatment is conservative, and only rarely is surgery indicated. These patients should be referred to the appropriate consultant for continued care. [23,29,37]

FOOT ULCERS

Foot ulcers can generally be classified as neuropathic or ischemic by the predominant etiologic factor and clinical features. Infection can be a complicating factor in either type of ulcer. Diabetics are prone to both types of ulcers and in addition are more apt to develop infections. It has been estimated that proper foot care in diabetics (including prophylaxis and treatment of foot ulcers) could reduce the number of lower limb amputations by 44 to 80 percent. [38,39]

Ischemic ulcers are secondary to vascular compromise, usually due to atherosclerosis of larger vessels. Ulcers rarely develop due to problems with the microcirculation in an area. These ulcers are seen in the setting of a cool foot, dependent rubor, pallor on elevation, atrophic shiny skin, and diminished pulses. Patients may complain of symptoms of intermittent claudication and leg pain in the supine position, relieved by dependency. If the underlying vascular disease is corrected, these ulcers usually heal quickly. Without reconstructive surgery, the prognosis is poor and amputation is often inevitable. [40,41 and 42]

Neuropathic ulcers are essentially pressure ulcers. Patients at risk are those with absent or distorted foot sensation. These include patients with diabetes, leprosy, tabes dorsalis, and other congenital or acquired neuropathies. Their feet are prone to ischemia from pressure by ill-fitting shoes, foreign bodies, abnormal bony prominences, and most commonly from the daily stresses of walking. The ulcers are usually well circumscribed with surrounding white calluslike material. The foot (if there is no underlying vascular disease) has normal temperature, color, and pulses. Defects in touch, pressure, or proprioception are noted on examination. Motor weakness and muscular atrophy may also be present. These changes can lead to abnormal gait and foot anatomy. [38,39 and 40]

Once an ulcer becomes infected, two aspects of therapy are essential for healing: thorough debridement and complete pressure relief. Debridement must be aggressive; wet-to-dry dressing changes are not sufficient. Once debridement is completed, the role of wet-to-dry dressing is controversial. These dressings may prevent drying of the ulcer and eschar formation. To date, no topical agents or foot soak has been conclusively found to be beneficial for the healing of diabetic ulcers. Relief of pressure is accomplished by either complete bed rest or by total contact casting. [38,39 and 40]

Antibiotics and often admission are warranted for the treatment of infected ulcers. Infections are usually polymicrobial. The most common organisms are *Staphylococcus aureus* and beta-hemolytic streptococci. Other organisms found in diabetic foot ulcers are various species of Enterobacteriaceae and anaerobes, enterococci, and *P. aeruginosa.* Superficial cultures of infected ulcers are unreliable. Cultures should be obtained of any purulent drainage and of aspirates from fluctuant areas. Antibiotics should initially be broad spectrum to cover the wide variety of possible infective organisms. Choices depend on the severity of infection (Table 279-1). Cellulitis and signs of deep soft tissue infection require hospitalization for antibiotics and strict bed rest. Abscesses should be incised and drained. X-rays should be considered if there is any suspicion of subcutaneous gas, foreign body, osteomyelitis, and Charcot foot. MRI and bone scan may be indicated to determine the presence of osteomyelitis. Palpation of bone in the depths of infected pedal ulcers has been shown to strongly correlate with osteomyelitis. With diabetics, a serum glucose level should be obtained, as it is often elevated. Patients with nonhealing foot ulcers should undergo evaluation to determine the underlying etiology of the ulcer (vascular, diabetic, or other systemic disease, including malignancies). Hyperbaric oxygen has been advocated by some as beneficial in the treatment of both infected and noninfected foot ulcers. [38,39 and 40,43,44,45,46 and 47]

TABLE 279-1   Selected Empirical Antimicrobial Regimens for Foot Infections in Patients with Diabetes Mellitus*

MALIGNANT MELANOMA

The incidence of malignant melanoma is increasing, thus making consideration of this disease process important. Malignant melanoma of the foot accounts for up to 15 percent of all cutaneous melanomas. Melanomas can present as an atypical, pigmented, or nonhealing lesion of the foot, including the nail. These malignancies often imitate more common foot disorders such as fungal infections and plantar warts. Since prognosis is directly related to early diagnosis, a high index of suspicion must be maintained. All skin lesions that are either atypical or not healing despite treatment should be referred for biopsy. [29,48]

FOOT LESIONS INDICATIVE OF DISSEMINATED DISEASE

Many disease processes may be manifest by foot lesions. Acquired immunodeficiency syndrome may present with a variety of foot lesions, including Kaposi's sarcoma and nonhealing ulcers and those caused by bacterial and fungal infections such as histoplasmosis (which can present as maculopapular eruptions or depressed pits of the soles). [49] These patients may develop neuropathies presenting as both paresthesias and dysesthesias. Secondary syphilis presents as a nonitching polymorphic rash that affects both the soles and palms. The rash of Rocky Mountain spotted fever, which is initially discrete, macular, and later petechial, is also found on the palms and soles. Cutaneous forms of tuberculosis have also been described that affect the feet. Hand-foot-and-mouth disease causes small vesicular lesions on the soles, palms, buttocks, and in the mouth. This entity is caused by coxsackievirus and occurs in the late summer and fall.

280 BEHAVIORAL DISORDERS: CLINICAL FEATURES

Douglas A. Rund

Psychiatric disorders are common in the emergency department patient population. Estimates of the proportion of emergency department patients who present with a psychiatric disorder range from a few percent to more than a third. This variability is partly due to differences in patient population and utilization of alternatives for psychiatric crisis intervention. When patients are screened for mental disorders including substance abuse, many patients have unrecognized psychopathology that is relevant to their assessment and treatment in the emergency setting. Subgroups of the emergency patient population at higher risk for psychiatric disorders include those who are self-referred for nonurgent problems, patients with chest pain, and the "after midnight" group of emergency department patients, who had more psychiatric illness (56 percent) than the daytime group (20 percent). Sometimes, psychiatric disorders clearly make up the primary reason for an individual's presentation to an emergency department. In other cases, psychiatric disorders lead to injury and illness. Such conditions create the need for emergency care. As screening studies have shown, psychiatric disorders may form part of the current or past medical history of a patient, yet possess little importance for the immediate clinical condition.

In studies that report categories of psychiatric illness seen in the emergency department, the most prominent diagnoses are substance abuse, affective disorders, anxiety disorders, antisocial personality disorder, and severe cognitive impairment. Among repeat users of the emergency department, persons with schizophrenia are overrepresented.

Psychiatric disorders can cause substantial impairment in social or occupational functioning or marked distress. Patients or their families are often unwilling to seek psychiatric care because of the stigma of mental illness. Their evaluation in the emergency department is their point of entry into the health care system. Also, due to poor judgment, financial considerations, or cognitive impairment, many psychiatric patients do not regularly seek medical attention until an emergency intervenes. They then seek emergency treatment for their medical needs. The most serious manifestations of mental illness (suicide, psychosis, and violent behavior) are medical emergencies and consequently are appropriately dealt with in the emergency department. Emergency physicians require substantial knowledge and skill to be able to recognize psychiatric disorders, perform crisis intervention and stabilization, and refer the patient for psychiatric hospitalization or outpatient care as needed.

DIAGNOSIS

In the assessment of patients presenting with psychiatric symptoms, as with other medical conditions encountered in the emergency department, it is crucial to promptly stabilize the patient's acute condition and evaluate the major complaint immediately. Formulating a specific diagnosis must necessarily follow initial stabilization procedures in this clinical process. The determination that an individual is suicidal and in need of hospitalization, for instance, is more important than deciding whether that person suffers from schizophrenia or psychotic depression.

Nevertheless, provisional psychiatric diagnoses can be made in the emergency department. Recognition of specific behavioral syndromes can assist in evaluating the presenting complaint, pursuing associated symptoms, and determining treatment and disposition. Emergency physicians should be sufficiently familiar with commonly seen psychiatric illnesses to describe their predominant clinical features.

Structured Diagnostic Criteria

Over the past 15 years, awareness of the earlier unreliability of psychiatric diagnosis guided the development of operational criteria for separate and distinct mental disorders. These rules allow researchers and clinicians to agree on the presence or absence of a particular disorder. In addition, the criteria are based on observable signs and the patient's report of symptoms, not on unconscious psychic mechanisms. This simplifies the task of diagnosis for emergency physicians and other nonpsychiatrists because extensive knowledge of pathophysiology and unconscious mental processes is not essential.

The current official diagnostic nomenclature, published in 1994 by the American Psychiatric Association, is the *Diagnostic and Statistical Manual of Mental Disorders,* fourth edition, commonly known as DSM-IV. A copy of DSM-IV should be available for reference in the emergency department because it contains both the list of criteria for each disorder, and additional material on demographics, associated symptoms and syndromes, and differential diagnosis. Future revisions of DSM-IV will likely be based to a greater degree on biologic criteria as more is learned about biochemical, structural, and genetic features of various psychiatric illnesses.

Multiaxial Diagnostic System

The DSM-IV diagnoses are made on a multiaxial system in which each axis refers to a different domain of information. This system aids in making a comprehensive assessment, organizing complex clinical information, and communicating between professionals. Axis I disorders comprise the clinical syndromes of mental disorders. Conditions listed on Axis II are the personality disorders and developmental disorders, including mental retardation, which may underlie the more florid Axis I syndrome. Axis III notes general medical conditions. Axes IV and V record psychosocial stressors and adaptive functioning. It is generally unnecessary for the emergency physician to make a complete multiaxial diagnosis, but knowledge of this system may facilitate an understanding of medical records and psychiatric consultants' notes. For instance, a patient with previous medical records containing DSM-IV diagnoses of Axis I: alcohol intoxication; Axis II: antisocial personality disorder; and Axis III: scalp laceration, should be recognized as likely to display features of the Axis II personality disorder, although the patient's chief complaint may be a new problem.

PSYCHIATRIC SYNDROMES (AXIS I DISORDERS)

The organization and major categories of Axis I disorders covered here are listed in Table 280-1. A useful strategy for making a DSM-IV diagnosis is to classify the primary feature into a major category, consider possible nonpsychiatric etiologies for the complaint, and then use the decision trees in Appendix B of DSM-IV to identify the appropriate diagnosis. The decision trees guide the clinician who is unfamiliar with the intricacies of the criteria within a category to identify the features that distinguish closely related conditions.

TABLE 280-1 Axis I Disorders

Delirium, Dementia, Amnestic, and Other Cognitive Disorders

This group of syndromes is characterized by a clinically significant deficit in cognitive or memory function due to a general medical condition. There are several distinct and common causes of organic brain syndromes in which the causative factor is known; for example, vascular dementia and alcohol withdrawal delirium. In these cases, the specific diagnosis is listed in DSM-IV. In other cases, the etiologic factor should be specified using the descriptor "due to [general medical disorder or substance]" for example, "delirium due to hepatic encephalopathy."

DEMENTIA   The essential clinical feature of *dementia* is a pervasive disturbance of cognitive functioning in several areas including memory, abstract thinking, judgment, personality, and other higher cortical functions such as language. If clouding of consciousness is present, then the patient does not have solely a dementing illness, but has *delirium* or intoxication. The presence of global cognitive impairment may be detected by a bedside cognitive examination, such as the Mini Mental State Examination, and additional confirmatory history should be gathered from an informant, such as a family member. Memory disturbance is usually the earliest sign to be apparent to others, and unless it is very mild, it can be easily identified by examination.

Patients with dementia may be brought to the emergency department after having been found wandering away from home or an institution. Because the onset of most forms of dementia is slow and gradual, presentation to the emergency department often occurs only when some acute worsening of mental status occurs, which may be the result of a superimposed medical illness, adverse drug effect, or environmental change. The demented patient's diminished intellectual and physiologic resources allow abrupt worsening of function with the addition of such stressors.

Early in the course of dementia, anxiety, depression, or psychosis may dominate the clinical picture and obscure cognitive dysfunction. For this reason, a high degree of clinical suspicion of dementia should be maintained when evaluating an elderly patient with no prior psychiatric history who presents with new psychiatric problems. Demented persons are also prone to unrecognized physical illness because of inability to perceive or describe symptoms. Careful examination and appropriate laboratory testing are always indicated in the initial and ongoing evaluation of such patients.

It must be noted that dementia is not synonymous with the older designation of "chronic organic brain syndrome," which implies irreversiblity. Common causes of potentially reversible dementia include metabolic and endocrine disorders, polypharmacy, and depression. Often, especially in elderly patients, depression may present with prominent cognitive impairment, a condition erroneously labeled "pseudodementia," but more accurately called *dementia of depression.* The presence of a relatively acute onset, prominent mood changes, and vegetative disturbances such as loss of appetite and weight, sleep disturbance, or expressions of guilt or suicidal ideation all point to depression as the cause. In these situations, treatment of the mood disorder may lead to resolution of the cognitive impairment, although recent studies indicate that many such patients have evidence of brain dysfunction and only partial treatment response.

DELIRIUM   Like dementia, *delirium* is characterized by global impairment in cognitive function, but is distinguished from it in two major ways. In delirium, the patient has clouding of consciousness, a reduction in the awareness of the external environment (manifest as difficulty sustaining attention), varying degrees of alertness ranging from drowsiness to stupor, and sensory misperception.

The primary distinguishing feature of delirium is the course that is typically acute, with rapid deterioration in hours or days, rather than months as with dementia. Also, the severity of delirium fluctuates over the course of hours; the patient may appear normal at one time and wildly agitated a few hours later. Extreme changes in psychomotor activity, ranging from restlessness and hyperactivity to stupor, are frequent in delirium, but uncommon in dementia except in the later stages when a delirious state may be superimposed. Finally, hallucinations, often visual, are common in delirium. They typically have a vivid quality to which the patient reacts strongly. The hallucinations contrast with the visual hallucinations seen by psychotic patients, which are often described and experienced indifferently.

Substance-Induced Disorders

INTOXICATION   When recent ingestion of a specific exogenous substance produces maladaptive behavior and impairment of judgment, perception, attention, emotional control, or psychomotor activity, and the patient does not display features of delirium, hallucinosis, or other organic brain syndromes, a diagnosis of *intoxication* is made. When the offending substance is known, it should be specified (e.g., alcohol intoxication or amphetamine intoxication). The specific features of intoxication syndromes commonly seen in the emergency department are described in greater detail in the section on toxicology.

As a general rule, the diagnosis of intoxication can be rather easy when laboratory analysis reveals the type and amount of intoxicant circulating in the system. The clinical features of alcohol intoxication are familiar to experienced emergency physicians and range from impaired judgment and coordination through ataxia, lethargy, and coma. When repeated episodes of intoxication occur in a brief period of time, the individual by definition has a substance abuse disorder, and the additional diagnosis is made.

WITHDRAWAL   *Withdrawal* can follow cessation or reduction in use of a substance of abuse. The category signifies a syndrome characteristic of withdrawal from that particular drug, when the clinical syndrome does not satisfy the criteria for delirium or another organic brain syndrome. For example, mild forms of alcohol withdrawal would be classified here, but if the patient is confused, hallucinating, and agitated, a diagnosis of alcohol withdrawal delirium is indicated. The diagnosis is made by identification of the withdrawal syndrome along with evidence of recent use of the substance in a pattern sufficient to produce withdrawal when the amount ingested is decreased. Specific withdrawal patterns depend on the agent customarily used.

Alcohol withdrawal, for instance, includes up to four stages: autonomic hyperactivity (6 to 8 h after cessation of drinking); hallucinations (24 h after withdrawal); major motor seizures (1 to 2 days); and global confusion (3 to 5 days after last use of alcohol). Some withdrawal syndromes, particularly from alcohol or barbiturates, can be life threatening.

Mental Disorders Due to a General Medical Condition

DSM-IV has implemented a major change in the classification of psychiatric symptoms caused by medical conditions. The previous terminology of "organic brain syndrome" and the subtypes organic mood disorder, organic delusional disorder, for example, have been eliminated because of the implication that the "functional" mental disorders were unrelated to biologic changes in brain function. Using DSM-IV, where there is evidence that a psychiatric disturbance is a direct physiologic consequence of a general medical condition or substance, the mental disorder is specified as "... due to" the medical problem; for example, "major depression due to hypothyroidism." Common medical causes of psychotic and mood disorders are covered in Chap. 281.

Schizophrenia and Other Psychotic Disorders

Schizophrenia and related disorders are marked by the presence of psychotic symptoms, primarily delusions and hallucinations. *Delusions* are defined as fixed false beliefs that are not amenable to arguments or facts to the contrary and that are not shared by others of similar cultural background. Common delusions are of several types. *Persecutory delusions* are those in which one believes that one is being attacked, followed, harassed, or conspired against. *Grandiose delusions* are those that

involve themes of special powers or abilities. *Bizarre delusions* are those with patently absurd content, such as believing that one's thoughts are controlled by extraterrestrial beings. *Hallucinations* are false perceptions experienced in a sensory modality and occurring in clear consciousness. Auditory hallucinations are the most common, followed in order of prevalence by visual, tactile, olfactory, and gustatory. The most prevalent psychosis is *schizophrenia,* described in detail in the next section. The other psychotic disorders, discussed briefly, are less common. A decision tree helpful in evaluating psychotic symptoms is presented in <u>Fig. 280-1.</u>

FIG. 280-1. Decision tree for evaluating psychosis.

SCHIZOPHRENIA   Schizophrenia is one of the most serious public health problems in the world and accounts for 25 percent of all hospitalized patients. The essential features are a deterioration in functioning, the presence of active-phase symptoms (hallucinations, delusions, disorganized speech or behavior, catatonic behavior, or negative symptoms) for at least one month, and the relative absence of a mood syndrome. Research has established the importance of genetic factors in its cause, and schizophrenia is most likely a group of disorders of varying etiology that share a final common pathway, much as is the case with mental retardation. It is a brain disease, and there is no evidence that psychosocial stressors or poor parenting are responsible for the cause of the illness, although these may have a profound effect on the patient's adaptation to this usually chronic disorder.

Schizophrenia usually starts in late adolescence or early adulthood, although the onset can occur at any age. The childhood history of schizophrenics often is marked by shyness, oddness or eccentric behavior, school difficulties, or paranoid behaviors, but such features are not always present. A prodromal phase, in which a gradual deterioration of function is noted, usually precedes the development of active delusions or hallucinations. Such deterioration usually includes the worsening of social withdrawal or the new onset of social withdrawal, odd behavior or speech, and difficulty in functioning in school or work. Patients or their families rarely seek care until the onset of the active phase of psychosis. Schizophrenics seldom seek care at all because they lack insight; they do not realize that their perception, thoughts, and behavior are abnormal.

Antipsychotic drugs usually reduce the severity of delusions and hallucinations. Other manifestations of schizophrenia less responsive to antipsychotics include negative symptoms (lack of volition, blunting of emotion, anhedonia, and inattention). Such symptoms result in lasting impairment in self-care, work, and social relations.

Disorganization of thinking and behavior characterizes schizophrenia. Disheveled appearance and grooming, bizarre behavior, poor judgment, and loosening of associations indicate such disorganization. *Loosening of associations* refers to a loss of the normal logical connections between one thought and the next; the schizophrenic's speech is often vague, rambling, disjointed, or nonsensical. Fantastic experiences and bizarre ideas are described in an indifferent manner and unchanging facial expression.

Common reasons for persons with schizophrenia to come to the emergency department include worsening of psychosis resulting from stress or noncompliance with medication, suicidal behavior, assaultiveness (often as a result of paranoid thinking), and extrapyramidal side effects of neuroleptic drugs. Schizophrenics constitute a large share of the chronic homeless population and may be brought in, by authorities, in a confused state, obviously unable to attend to their basic needs. Their poor judgment and disorganization may lead to disregard for medical problems, so attention must be given to their physical status as well as the psychiatric problem.

SCHIZOPHRENIFORM DISORDER   *Schizophreniform disorder* is diagnosed when the patient meets the criteria for schizophrenia but the symptoms have been continuously present for less than six months. A rapid onset over a few days and good premorbid functioning are more common than in schizophrenia.

BRIEF PSYCHOTIC DISORDER   Some individuals may become acutely psychotic after exposure to an extremely traumatic life experience. If such a pyschosis lasts for less than four weeks, it is termed a *brief psychotic disorder*. Precipitants of the psychosis include the death of a loved one or a life-threatening situation such as combat or a natural disaster. Emotional turmoil, confusion, and extremely bizarre behavior and speech are common.

DELUSIONAL DISORDER   *Delusional disorder* is a syndrome distinct from schizophrenia characterized by persistent nonbizarre delusions. Unlike schizophrenia, delusional disorder is rarely characterized by impairment in daily functioning, and the patient may appear outwardly normal aside from the strange ideas expressed. The onset is in middle or late adulthood, and the delusions develop over months or years. Several subtypes have been identified, the most common of which is the persecutory type, in which the delusions follow themes of being conspired against, cheated, followed, poisoned, or harassed. Other types of delusional disorder include delusional jealousy, in which the patient has an unsubstantiated conviction that one's partner is unfaithful, and the somatic type, in which patients believe they emit a foul odor or are infected with parasites.

Emergency medical evaluation may be occasioned by threats or acts of violence directed at the alleged persecutors, by suicidal behavior, or by involuntary commitment. Delusional disorders are uncommon, and more likely causes of this syndrome are psychotic depression or chronic stimulant abuse.

Mood Disorders

The mood disorders are the most prevalent of the major psychiatric disorders, affecting about 10 to 15 percent of the general population at some time in their lives. Depressive disorders are the major cause of completed suicide. An unsuccessful attempt may bring the patient to the emergency department. Mood disorders, substance abuse, and anxiety disorders are the most common psychiatric diagnoses in emergency patients.

Mood, or *affective,* disorders differ from the normal extremes of sadness and happiness in that characteristic clusters of psychological and vegetative symptoms (depressive or manic syndrome) are present, and functioning is impaired. Any of the features of schizophrenia such as delusions, hallucinations, or disorganization may be present, but if a full depressive or manic syndrome exists, a diagnosis of a psychotic mood disorder is required. Another important characteristic of affective disorders is that they tend to be episodic, with periods of remission and normal function.

MAJOR DEPRESSION   The essential features of *major depression* are a persistent dysphoric (sad) mood or pervasive loss of interest in usual activities, lasting for at least two weeks. Associated psychologic symptoms include guilt over past deeds, self-reproach, feelings of worthlessness or hopelessness, inability to experience pleasure, and recurrent thought of death or suicide. "Vegetative symptoms" involve physiologic functioning and include loss of appetite and weight, sleep disturbance, fatigue, inability to concentrate, and psychomotor agitation or retardation. The depression may begin gradually or rapidly but usually will have been present for several weeks before the patient comes for treatment.

When the patient complains of the full spectrum of depression symptoms, the diagnosis of major depression is easy to make, but when the chief complaint is a single symptom such as insomnia or fatigue, it will be necessary to elicit the other symptoms of major depression to make the diagnosis. Somatic complaints such as vague pain or weakness may be part of major depression, as may generalized anxiety. A useful screening mnemonic is presented in <u>Fig. 280-2.</u>

In	Interest
S	Sleep
A	Appetite
D	Depressed mood
C	Concentration
A	Activity
G	Guilt
E	Energy
S	Suicide

FIG. 280-2. *In SAD CAGES.* A screening mnemonic for major depression. (From Rund DA, Hutzler JC: *Emergency Psychiatry.* St. Louis: Mosby, 1983, with permission.)

Major depression is more common in women, persons with a family history of depression or suicide, and individuals with medical or other psychiatric illnesses. When a medical disorder or drug produces a depressive syndrome through a presumed biologic effect on the brain, the diagnosis should be "depression due to (the offending condition)." Major depression is often superimposed on other mental disorders such as substance abuse, personality disorders, and anxiety disorders. Depression in the elderly may go unrecognized by the emergency physician. Screening tools for depression recognition in the geriatric population can be helpful in diagnosis.

Primary mood disorders tend to display more biologic features, are more familial, and respond better to somatic antidepressant treatment than do mood disorders due to medical disorders. The lifetime risk of suicide is 15 percent, so prompt and aggressive treatment is strongly indicated. Major depression is often recurrent, so certain patients must be maintained on long-term treatment to prevent relapse.

BIPOLAR DISORDER   Bipolar disorder, previously termed *manicdepressive illness,* is characterized by the ocurrence of mania. A full manic syndrome is one of the most striking and distinctive conditions in clinical practice. The essential disturbance in mood is one of elation or irritability. Manics feel "on top of the world," expansive, energetic, and precarious but may quickly become argumentative, hostile, and sarcastic, especially when their plans are thwarted.

The vegetative signs of mania are a decreased need for sleep, increased activity, rapid pressured speech, and racing thoughts. Manics may have grandiose ideas, such as unrealistic plans to start a business or run for public office, and if the grandiosity reaches delusional proportions, such patients may believe themselves to be famous, fabulously wealthy, or blessed with special powers and abilities. Poor judgment in spending money and sexual behavior may lead to problems that prompt manics' families to seek treatment for them, because manics usually lack insight into their abnormal condition and deny that anything is wrong. For this reason, reports from informants such as relatives often reveal important information to substantiate the diagnosis. Because patients who have had a manic episode almost invariably have depressions at some time (the other "pole" of bipolar disorder), a past history of depression may also help in diagnosis.

The disorder is equally common in men and women, and the onset is usually in the third and fourth decades. Complications include suicide, substance abuse (excessive alcohol use is common during the manic phase), and marital and occupational disruption. The course of bipolar disorder is episodic, with the duration, frequency, and regularity of the episodes varying greatly. Depressive episodes are more frequent than manic episodes.

DYSTHYMIC DISORDER   *Dysthymic disorder* is a more chronic and less severe form of depressive illness and was previously termed depressive neurosis. Depressed mood must have been present most of the day, more days than not, for at least two years. Psychotic features are not seen, and these patients often have a life-long gloomy, pessimistic outlook. Women are more often affected, and the onset is in childhood, adolescence, or early adulthood. Associated personality disorders and substance abuse are common. When vegetative symptoms are present, they are usually less severe than with major depression. Major depression may be superimposed on dysthymia, often in association with stressful life events. When major depression complicates dysthymia, the patient may be brought in for evaluation because of the severity of symptoms or treatment following a suicide attempt.

Anxiety Disorders

The anxiety disorders are mental disorders in which apprehension, fears, and excessive worry dominate the psychological life of the individual. Pathologic degrees of anxiety are accompanied by varying degrees of autonomic activity out of proportion to any real danger or threat. Because anxiety is a ubiquitous condition and frequently is associated with medical illness, depression, neurologic syndromes, and psychoses, a diagnosis of a primary anxiety disorder should be made by exclusion of other causes.

Anxiety disorders are diagnosed in 4 to 8 percent of the general population, and are more often diagnosed in women than men. Because of the physical nature of certain symptoms associated with anxiety disorders, patients often seek treatment and evaluation in medical rather than psychiatric settings.

PANIC DISORDER   Patients who experience recurrent attacks of severe anxiety are said to suffer from *panic disorder.* A panic attack consists of a sudden extreme surge of anxiety and dread accompanied by autonomic signs, including palpitations, tachycardia, shortness of breath, chest tightness, dizziness, sweating, and tremulousness. The symptoms develop over a few minutes at most and may either be unprovoked or occur with a phobic stimulus, such as a crowded store. After the attacks begin, some patients start to avoid situations that seem to precipitate the panic (phobic avoidance). Such behavior can severely impair their functioning. When activities are severely limited, the complication of *agoraphobia* is diagnosed. In agoraphobia, the patient tends to avoid situations where ready escape or assistance during an attack are not possible. The frequency and severity of panic attacks wax and wane, but the illness is generally chronic. Unless agoraphobia is severe, most patients are married, employed, and seldom require psychiatric hospitalization unless depression is superimposed on the anxiety disorder.

Because of the very real and frightening nature of the panic attack and its unexpected occurrence, the emergency department is a frequent initial source of medical attention. The presenting complaints may mimic a variety of medical emergencies and careful exclusion of an organic etiology is mandatory. History-taking should include questions about domestic violence and sexual abuse or assault because sometimes these experiences are the source of panic attacks.

GENERALIZED ANXIETY DISORDER   When anxiety attacks are absent, yet the patient complains of persistent worry, tension, or free-floating anxiety, a diagnosis of generalized anxiety disorder should be considered. This condition lasts at least six months and is characterized by apprehensive worrying, muscle tension, insomnia, irritability, restlessness, jumpiness, or distractibility. Muscle tension may be so severe that the patient actually experiences diffuse muscular pain. Associated autonomic symptoms include the cardiopulmonary, gastrointestinal, and neurologic symptoms seen in panic attacks. In generalized anxiety disorder, such symptoms occur more continuously and chronically than in panic disorder.

PHOBIC DISORDERS   Phobic disorders, other than agoraphobia, are an unusual cause of self-referral to the emergency department. In phobias, the anxiety symptoms are recognized as excessive and occur when the patient is exposed to, or anticipates exposure to, a specific situation, which then leads to avoidance of the stimulus to a degree that interferes with the patient's life. In social phobia, the situation involves having the attention of others drawn to the patient. Such activities as public speaking or meeting strangers create a fear that the patient will be embarrassed in some way. Specific phobia are quite common; they involve fear of a very specific stimulus such as animals, heights, dark, or flying.

OTHER ANXIETY DISORDERS   *Posttraumatic stress disorder* is an anxiety reaction to a severe psychosocial stressor, usually life-threatening, such as military combat, fire, rape, or natural disaster. Symptoms involve repetitive and intrusive memories of the event, nightmares, emotional numbing, survivor guilt, and varying degrees of depression and anxiety. Substance abuse appears to be a frequent complication.

Obsessive-compulsive disorder is a mental disorder in which the patient experiences intrusive thoughts or images that cannot be eliminated from the mind. Typical thoughts involve images of graphic violence to self or others, contamination, or perverse sexual behavior that the patient would not carry out but nevertheless obsessively fantasizes about. To control the obsessive thoughts, the individual may engage in compulsive behavior or rituals such as excessive washing, repetitive checking, or counting. When the obsessions and compulsions occupy a great deal of time, the patient may become significantly disabled and seek psychiatric

attention. The sense of helplessness and the impairment can lead to the development of depression, which also leads the patient to seek help.

Somatoform Disorders

Many patients have particular complaints or symptoms for which no medical explanation can be identified. When a physical cause has been clearly eliminated, and the complaint is not delusional or occurring in the context of a depression or anxiety disorder, somatoform disorders may be considered. When the complaint involves a loss of function, usually in the neurologic system (e.g., paralysis, blindness, numbness) and psychological factors are deemed etiologic, a *conversion disorder* may be present. The term conversion reflects Freud's hypothesis that unexpressed emotion associated with a traumatic event or situation could be "converted" into physical symptoms and signs. Conversion disorders are much more common in culturally and psychologically unsophisticated persons. This diagnosis should be made with extreme caution, if at all, in the emergency department because studies indicate that many patients diagnosed with conversion disorder eventually develop signs of a physical disorder explaining the symptom. Erroneous attribution to a mental disorder obviously deprives the patient of appropriate medical treatment.

Some patients have a wide variety of complaints and long complicated histories of medical problems that have no apparent medical cause. Such individuals may have *somatization disorder,* a disorder beginning in the teens and twenties, usually in women, and leading to considerable unnecessary diagnostic and surgical intervention. The prototypical patient is a middle-aged woman who describes a "positive review of systems" in a dramatic and confusing way. Conversion symptoms, menstrual complaints, multifocal pain, sexual and gastrointestinal symptoms, dizziness, and diverse psychiatric symptoms are common findings. The diagnosis is made when the patient has a history of a variety of medically unexplained symptoms involving multiple organ systems. As with conversion disorder, a firm diagnosis of somatization disorder should not be made on the basis of a single visit to the emergency department, but the identification of somatizing behavior is useful for future reference, because these patients frequently make repeated contacts.

Hypochondriasis may be diagnosed when the patient is preoccupied with fears of serious illness, fears that persist despite appropriate medical evaluation and reassurance.

Finally, when pain is the sole complaint and the intensity and secondary disability are unexplained by a known physical ailment, a diagnosis of *pain disorder* may be considered.

Identification of a somatoform disorder in the emergency department has such profound implications on future management that it is advisable to avoid making a firm diagnosis of these disorders unless a long history of prior similar complaints is documented and no organic disease has become apparent. This wisdom is tempered additionally because well-established conversion or other "psychogenic" complaints provide absolutely no protection against the development of a treatable medical disorder; new complaints always warrant careful examination for objective findings. When the physician is quite sure that no organic disease exists, the patient may be reassured that no serious physical illness is present. Avoid telling the patient that it is "all in your head" because this is not likely to be believed. Regular follow-up with a general internist or family physician is the best management for somatization disorder. Patients with this disorder notoriously resist psychiatric referral and treatment.

Dissociative Disorders

The dissociative disorders are a group of uncommon and poorly understood conditions where the central feature is a sudden alteration in the normal integration of identity and consciousness. The dissociation often occurs under severe stress and may or may not be recurrent, although it is rarely permanent. The forms of dissociative state relevant to emergency practice are *psychogenic amnesia,* a temporary loss of memory for important personal details that is not due to an organic cause, and *psychogenic fugue,* in which a similar loss of memory and assumption of new identity are accompanied by travel away from home. Dissociative disorders are difficult to distinguish from malingering, in which the individual in pursuit of a clear goal, such as avoiding incarceration or military duty, may consciously feign amnesia. As always, organic causes such as drug intoxication or loss of memory such as that resulting from transient global amnesia must be ruled out.

Other conditions in this category include *multiple personality disorder* and *depersonalization disorder.*

PERSONALITY (AXIS II) DISORDERS

Personality refers to an enduring pattern of perceiving, relating to, and reacting to one's environment and interpersonal relations. When a pattern of behavior is lifelong, not limited to periods of illness, and causes significant impairment in social and occupational functioning or considerable distress, a *personality disorder* is present. Some individuals are painfully aware of the consequences of their behavior but are unable to alter these fundamental ways of dealing with their world. Most of the patients who are seen clinically in medical and psychiatric settings who are diagnosed with a personality disorder lack a clear awareness of how their behavior alienates others or aggravates their own stress. Even when such insight is possible, actual personality change is unlikely.

The patient presenting with a personality disorder may often be recognized by the characteristic effect the interaction has on the physician and medical staff. Antisocial patients, for instance, are disliked immediately; they seem to be in control of their behavior unlike psychotic or depressed patients, but nonetheless have repeatedly engaged in maladaptive behavior. The patient may be seen as using the emergency department for some vague, or obvious, goal. These disorders are the most common secondary diagnosis in the malingerer.

The emergency physician seldom needs to decide which of the personality disorders relates appropriately to the patient. General categories of personality disorders are grouped in Table 280-2. When such features are present and seem to be interfering with some important aspect of the patient's life, personality disorder can be suspected. The presenting complaint should be evaluated appropriately, because patients with well-established character disorders still develop bona fide medical illnesses.

Behavior	Personality Disorder Group
Eccentric, odd, isolated, withdrawn, suspicious, inhibited, no friends, overly sensitive	Paranoid, schizoid, schizotypal
Emotional, dramatic, angry, seductive, impulsive, erratic	Antisocial, histrionic, borderline, narcissistic
Anxious, fearful, nervous, cautious	Dependent, avoidant, obsessive-compulsive

Source: Rund DA, Hutzler JC: *Emergency Psychiatry.* St. Louis: CV Mosby, 1983; DSM-IV, with permission.

TABLE 280-2 Behavioral Characteristics that Suggest Various Clusters of Personality Disorders

The personality disorder that constitutes a disproportionate share of emergency visits is *antisocial personality disorder.* The patient shows a continuous pattern of maladaptive behavior displaying disregard for the rights of others in a variety of ways: criminal behavior, fighting, lying, abuse and neglect of dependents and spouses, financial irresponsibility, recklessness, and inability to sustain enduring attachments to others.

The sociopathic behavior begins before the age of 15, but the diagnosis may not be made until after the age of 18. Sociopathy is much more frequent in males, in lower socioeconomic classes, and in relatives of alcoholics and sociopaths. Alcohol and drug abuse, imprisonment, multiple divorces, traumatic injury, accidental and violent deaths, and poor medical compliance are common complications.

Management of the antisocial patient in the emergency department is often frustrating, but anger toward the patient can be minimized and the interaction hastened along by setting firm limits on behavior, focusing on the chief complaint, and providing the patient with necessary information about the medical problem at hand. No effective psychiatric intervention can be forced on the patient, although certain patients may benefit from substance abuse treatment, psychotherapy, or organized

religion when motivated to make changes in their lives. Fortunately, the most violent and disruptive behavior of many antisocials seems to "burn out" in the late twenties or after, although their adjustment to society often continues to be marginal.

281 BEHAVIORAL DISORDERS: EMERGENCY ASSESSMENT AND STABILIZATION

Jeffery C. Hutzler
Douglas A. Rund

This chapter presents the principles of medical and psychiatric evaluation of patients with behavior disorders and reviews the management of suicidal and violent patients. The majority of psychiatric patient visits to emergency departments occur at night when psychiatric services are limited; therefore, the hospital must be staffed at off-hours with adequate personnel adept at handling patients who are suicidal, violent, or otherwise distraught or psychotic.

EMERGENCY APPROACH TO PSYCHIATRIC ASSESSMENT

Decision Making

A decision strategy for emergency psychiatric assessment should follow this sequence of questions: (1) Is the patient stable or unstable? (2) Does the patient have a serious medical condition that is causing abnormal behavior or thought processes? (3) If the cause of changes in behavior is not due to an underlying medical condition, it will be primarily *psychiatric* or *functional*. What is the diagnosis and severity? (4) Is a psychiatric consultation necessary? (5) When should the patient be forcibly detained for emergency evaluation?

Physical Restraint

Situations that require emergency stabilization, sometimes against a patient's wishes, involve a patient stating that he or she is potentially or actually violent, suicidal, or developing rapidly progressive medical conditions causing disturbed behavior (e.g., hypoglycemia, meningitis, or other causes of delirium). Disturbances involving actual or threatened violence are the most difficult for emergency department staff. The staff, of course, fear injury or that such patients will escape and hurt themselves or others. There are always limitations in security personnel and immediately available staff. There are often limitations in the physical facility itself in regard to restraining such patients.

Violent behavior demands immediate restraint. Hospital security forces and police are best equipped and best trained to subdue such patients with the least chance of staff or patient injury. Staff in the emergency department should not attempt to subdue a patient unless they are fully trained to do so. An initial show of force (four or five male attendants) may be sufficient to induce the patient to accept physical or chemical restraint without further resistance. Under ideal circumstances, the emergency department staff should organize themselves to be able to subdue a violent person if security personnel are not immediately available. This requires training and practice. The approach to the patient usually requires five team members with one member assigned to each limb and the leader assigned to the head. When approached from different directions and grabbed simultaneously, the violent person can usually be immobilized and restrained.

Potentially violent behavior requires the summoning of adequate force and the adoption of a nonthreatening attitude by a physician and staff. A physician should never have his or her hands out when approaching a patient or make other gestures that might be interpreted as an attack. The physician should also stay distant from the patient, avoid excessive eye contact, and maintain a somewhat submissive posture and tone of voice. Ideally, the physician should stand in a location that neither threatens the patient nor blocks his or her own retreat from the room. Allowing the patient to ventilate feelings verbally is important. Setting limits on acceptable behavior and making neutral comments may diffuse a potentially violent situation. Adequate force nearby should be visible to the patient, and the patient should clearly be told that certain kinds of behavior will result in restraint.

The decision to release a patient from physical restraints should be made jointly by medical and nursing personnel on the basis of a judgment regarding the patient's condition and behavior and not as a result of the patient's bargains or threats. Restraints should be removed in a stepwise fashion, from four limbs to two, to none.

Stabilization of an actively suicidal patient requires adequate suicide precautions. All dangerous objects are removed from the patient in the treatment room. Staff members should watch the patient closely and not allow the patient to leave the examining room unaccompanied by a staff member. Some institutions have members of the security staff available to provide supervision.

Patients who are threatening or demonstrate actual or potential violent behavior should be disrobed, gowned, and searched for weapons. Seemingly innocuous objects such as belts or belt buckles can be used by a patient to inflict self-injury or injury to others. Some emergency departments have installed metal detectors to prevent highly lethal weapons from entering the department. It has been determined that other patients do not resent the use of metal detectors because they feel safer themselves.

Initial Evaluation

The most effective tool available for the evaluation of behavioral disorders, particularly where "organic" mental disorders may be involved, is an excellent record of a patient's medical-psychiatric history. The history (including the use of medication, alcohol, or other drugs), physical examination, neurologic examination, and mental status examination should be incorporated into the early stages of evaluation of a person with disturbed behavior.

The changed behavior is a good starting point for inquiry. Sudden onset of major changes in behavior, mood, or thought in an individual who previously had functioned normally may be the result of an urgent medical disorder. Few "functional" or purely psychiatric behavioral disorders begin as abruptly as those caused by a medical condition. Behavioral disorders have resulted from all of the following life-threatening conditions:

Central nervous system (CNS) infection: meningitis or encephalitis
Intoxication
Alcohol or drug withdrawal
Hypoglycemia
Hypertensive encephalopathy
Hypoxia
Intracranial hemorrhage
Poisoning
CNS trauma
Seizure disorder
Acute organ system failure

A sudden change in behavior, especially in a patient over the age of 40, is a potentially important indicator of a new and correctable process. Neurologic symptoms associated with the behavioral changes should be explored. Such symptoms include fainting, dizziness, brief periods of disorientation, impairment of speech, confusion, loss of consciousness, headaches, and difficulty performing previous routine tasks.

The most important information about such behavioral changes will come from the patient's family. If the family is unavailable, friends or coworkers should be contacted and questioned. Third-party information may be the only source of information on a patient unable to give a cogent history. The source may be able to report substance abuse and can describe the level of previous functioning. Of course, it is important to get a history of any previous psychiatric illness or treatment. Similar previous change in behavior over past years weighs against the onset of a new "organic" process. However, it is important to weigh present information carefully to avoid a quick assumption that a patient's presentation is due to repeated occurrences of a preexisting disorder. In other words, psychiatric patients also develop medical illnesses producing change in behavior.

A medical history and review of systems is particularly important. The necessary questions can be addressed to the patient, or if he or she cannot answer these questions, a family member. Recent medical illnesses or symptoms such as infections, head trauma, fever, human immunodeficiency virus risk factors, difficulty in breathing, and dizziness should be investigated. A history of neurologic symptoms is particularly important. Any recent changes such as periods of confusion, speech difficulties, or syncope are suggestive of an organic disorder. A history of exposure to toxic substances such as heavy metals, organic solvents, or other occupational hazards may suggest a cause for newly disturbed behavior. To complete the investigation, family and social history may identify stressors in the patient's environment that are either a direct cause of changes in behavior or accentuate any responses to underlying disease.

Prescribed drugs, over-the-counter medications, illicit drugs, and alcohol can all create disturbed behavior. It is difficult to ask questions about drug use with certain patients such as the elderly,[1] the "important" patient, or those known personally by the emergency department personnel, but it is necessary. In particular, it is important to ask about the use of sedative-hypnotics, stimulants, psychotropic agents, anticonvulsants, anticholinergic agents, antiparkinsonian agents, cardiovascular drugs, diuretics, hormones, analgesics, anti-inflammatory drugs, anti-infective agents, and other categories of prescription drugs. Many of these medications cause changes in behavior when taken even in therapeutic doses. Ask specifically about over-the-counter drugs because patients rarely consider these "medications." Over-the-counter analgesics containing salicylates, anticholinergics, antihistamines, or bromides may produce delirium or toxic psychosis. Alcohol and street drugs such as phencyclidine, LSD, mescaline, amphetamines, or cocaine can produce a toxic psychosis similar to acute schizophrenia or mania. Hypnosedatives such as barbiturates or benzodiazepines may produce a confusional state or delirium both with intoxication and withdrawal.

Many emergency department patients meet diagnostic criteria for alcohol abuse, and patients with chronic mental illness have an even higher incidence of alcohol abuse than the general population. The many syndromes associated with alcohol abuse should be recognized by emergency physicians. These include intoxication, withdrawal, delirium, hallucinosis, alcohol amnestic disorder, paranoid behavior, and dementia. Alcohol screening tests are useful in disturbed patients even when the odor of ethanol is not present.

Detecting partner violence in the emergency department is an important aspect of the initial evaluation. In one study, [2] nearly 14 percent of emergency visits by women were associated with acute partner violence. Three brief questions will detect the majority of women with a history of physical or nonphysical violence in the past year. These three questions are

1. "Have you been hit, kicked, punched, or otherwise hurt by someone within the past year? If so, by whom?"
2. "Do you feel safe in your current relationship?"
3. "Is there a partner from a previous relationship who is making you feel unsafe now?"

Patients with positive screens should have this history documented in the medical record, and they should be offered counseling and referral to a safe shelter.

Mental Status Examination

The objective of the mental status examination is to distinguish functional from organic disorders. A great deal of the information obtained in mental status examinations becomes evident through patient observation and the initial patient interview (Table 281-1). Abnormal mental status examination findings suggest an organic basis for abnormal thought or behavior. Lability of affect, the necessity to repeat simple questions, irritability, disorientation, and lack of cooperation are some signs of organic dysfunction.

Behavior
  What is the patient doing?
Affect
  What feelings is the patient displaying?
Orientation
  Does the patient know what is happening, where, and when?
Language
  Is the patient understanding and being understood?
Memory
  Can the patient recall historical details, recent and remote?
Thought content
  Is the patient reporting beliefs that make little sense?
Perceptual abnormalities
  Is the patient experiencing unusual sensory phenomena?
Judgment
  Is the patient able to make rational decisions?

TABLE 281-1   Mental Status in the Emergency Department: An Outline

Important components of the mental status examination include level of consciousness, spontaneous speech, behavioral observation, physical appearance, the relaying of history information, attention, and language comprehension. This information is usually easily obtained during history taking. The more traditional mental status examination relies on specific assessment of orientation, memory, intellect, judgment, and affect.

The physician should compare his or her own direct observations of the patient's behavior with reports from the patient's family and friends. Documentation of the patient's orientation should include an assessment of attention, ability to concentrate on a specific task, and the traditional evaluation of person, place, and time. The patient should be asked the day, month, and year and place where he or she is presently being examined. Impaired language performance, including difficulty with speech, reading, writing, and word finding, may indicate a neurologic disorder. Memory is often divided into three categories: immediate, recent, and remote. Immediate memory is tested by asking a patient to repeat a series of digits (usually five) forward and backward. Recent memory can be tested by asking the patient to repeat three unrelated words immediately and then again after 3 to 5 min. The patient should be able to restate these after 3 to 5 min. The patient may also be asked about events that have occurred in the last few hours. Remote memory can be tested by asking about previous addresses, occupations, or historical events from an early period in the patient's life. Tests of memory should include details of significant personal, national, and international historical events. All history should be corroborated.

Investigation of higher cognitive functions includes assessment of a patient's general command of information; mental calculation, especially subtraction, such as serial sevens; and spelling of words forward and backward (such as world). Patients with organic disease often have difficulty spelling backward or performing serial calculation. The patient's affect or outward display of emotion should be evaluated for sadness, euphoria, and anxiety. This may help distinguish between cognitive disturbance induced by depressive disorders and dementia due to significant cerebral pathology. An examiner can draw some conclusions regarding a patient's thought processes during the patient's own telling of his or her history.

Disordered thought processes include paranoid or grandiose delusions, fixed false beliefs, and delusional denial of illness. Such beliefs should be compared with reports from family and friends.

Visual hallucinations do occur in functional psychotic illnesses (schizophrenia or affective disorder), but most often result from organic disease. A patient with visual

hallucinations should always be assumed to have organic pathology until proven otherwise.

Judgment may be impaired in organic disease, and historical evidence of faulty judgment should be elicited. Insight about judgment can be gained by asking a patient how he or she would deal with day-to-day problems, such as finding the way home from the hospital.

Finally, the examiner should test for specific focal neurologic deficits, including apraxias, agnosias, right-left disorientation, aphasias, and inability to follow complex spoken and written commands. Such signs may or may not occur in association with other localizing neurologic signs, such as asymmetric reflexes, paresthesia, or hemiparesis.

Ask the patient to "draw a clock face." The physician can draw a circle on a piece of paper and ask the patient to fill in the numbers on the paper to look like a clock face. If the patient can put in the numbers correctly in a clock face, he or she should then be asked to put the hands at the position to read a specific time. If the patient cannot do these tasks, organic disease is present.

Accurately diagnosing and understanding behavioral emergencies in the elderly is difficult but important. Syndromes include confusion, agitation, psychosis, and behavioral regression. Diagnoses that cause emergency syndromes such as this in the elderly are listed in Table 281-2.

Delirium
Medications (especially anticholinergic agents), physical illness (especially infectious and metabolic diseases), and drug withdrawal states (especially alcohol).

Dementia
Alzheimer's disease and multi-infarct dementia account for 75 percent. However, treatable causes include drugs, depression, endocrine diseases, normal pressure hydrocephalus, subdural hematomas, and alcohol dependency.

Medications
Psychotropic drugs, digitalis, cimetidine, and anticonvulsant medications.

Physical illnesses
Renal and hepatic failure, chronic obstructive pulmonary disease, cardiovascular illnesses, and electrolyte imbalance.

Depression
Bipolar disorder, major depression, melancholia, psychotic depression.

Alcohol intoxication/dependency
Alcoholism, alcohol abuse secondary to chronic depression, decreased tolerance/increased sensitivity to alcohol.

TABLE 281-2   Diagnoses That Cause Emergency Behavioral Syndromes in the Elderly[1]

Physical Examination

The objectives of physical examination are to identify disorders that may cause or have an impact on the behavior disorder and identify the presence of medical problems that may need special care in, or are inappropriate for, management in a psychiatric setting.

A physical examination should be conducted on every patient. Vital signs are a simple physical screening test of patients with altered behavior. Abnormal vital signs, when observed, must not automatically be dismissed as secondary to anxiety or stress. Bradycardia can be seen in patients with hypothyroidism, Stokes-Adams syndrome, or elevated intracranial pressure. Tachycardia may be apparent in patients suffering from hyperthyroidism, infection, heart failure, pulmonary embolus, or alcohol withdrawal. Fever is often associated with extreme hyperthyroidism or thyroid storm, vasculitis, alcohol withdrawal, sedative-hypnotic withdrawal, meningitis, or various inflammatory processes. Hypothermia is observed in sepsis, dermal disease, hypoendocrine status, CNS dysfunction, and intoxication. Hypotension may be an indicator of shock, Addison's disease, hypothyroidism, or medication side effects. Hypertension may be associated with hypertensive encephalopathy or stimulant abuse. Tachypnea is seen in patients with metabolic acidosis, pulmonary embolism, pneumonia, cardiac failure, or fever. Any such disorders may result in a secondary behavioral disturbance. The limited expense of, and useful information provided by, vital signs justifies their use in all patients.

A general physical examination should ideally be conducted with the patient completely disrobed and gowned. The patient should be carefully checked for signs of trauma. Contusions or abrasions of the head, face, and neck may be common if the patient is bellicose and may suggest the possibility of otherwise unsuspected head injuries. Extremities should be checked for frostbite or other evidence of exposure-related injury. If trauma is demonstrated or suggested by history, the mechanism of injury should be carefully reconstructed. For a variety of reasons, patients may omit or underreport the extent and cause of trauma.

Chest, cardiac, and abdominal examinations should be carefully performed and a careful neurologic examination should be specific for features that suggest organic disease. Other neurologic signs, such as bilateral asterixis or multifocal myoclonus, are often associated with delirium.

Laboratory Evaluation

The selection of particular laboratory tests emerges from diagnostic needs suggested by the history and by the findings of mental status examination and physical examination. Fluid and electrolyte disorders are common in elderly patients. Hypoglycemia can precipitate aggressive or agitated behavior, and an elevated white blood cell count may signify infection in patients with acute changes in mental status. Tests that can be helpful when a patient presents with agitation are listed in Table 281-3.

TABLE 281-3   Laboratory Tests to Help Identify Causes of Agitation

EMERGENCY SITUATIONS REQUIRING EMERGENCY INTERVENTION

Suicide

The annual rate of suicide in the United States is about 11/100,000 accounting for at least 31,000 deaths annually. [3] There seem to be epidemiologic differences between suicide attempters and suicide completers. Suicide completers, for instance, are more likely than attempters to be older, male, living alone, or physically ill. These are high-risk patients who need to be carefully assessed. The ratio of attempted suicides to completed suicide is estimated to be about 40:1.

A suicide attempt is not a common accompaniment of the "downward" portion of the normal mood swings occasionally experienced by everyone. Only about 2 percent of the general population have seriously considered taking their lives and only about 1 percent have actually attempted suicide. Therefore, suicide attempters must be taken seriously. The attitude of the staff should be empathic; suicide precautions should be instituted; and, following medical management, the assessment of suicide

risk should be carefully evaluated and documented. The decision to hold and hospitalize such patients should be given serious consideration.

Suicidal thinking is more frequent among women than among men and is associated with a clinical depression, social isolation, undesirable life events, and early parental loss. Suicidal thinking may precede an actual attempt by many months and may persist long after improvement in mental status and personal relationships.

Negative attitudes toward the suicide attempter have been documented among all types of emergency personnel: paramedics, nurses, and emergency physicians. A negative attitude intensifies a patient's already low self-esteem, thus increasing the risk of subsequent suicide and making it difficult to establish a therapeutic relationship.

Schizophrenia, substance abuse, and depression are psychiatric diagnoses that place a suicidal patient at relatively high risk. [3] Personality disorder and adjustment disorder implying a transient situational disturbance are frequent diagnoses in suicide attempters and are generally associated with relatively lower completion risk than the major psychiatric illnesses noted previously. Patients with these disorders still show a higher risk of completed suicide than the general population.

Drug overdose accounts for the overwhelming majority of all contemporary suicide attempts. Drugs used for suicide attempts tend to parallel prevailing prescribing patterns. Toxicity of the agent and the lethal intent of the patient help assess the relative risk. A patient taking a large dose of amitriptyline would be considered at greater risk than someone taking a few antihistamine tablets. Some patients may be relatively unaware of a drug's potential toxicity, however, and such knowledge and their continuing intent to die must be assessed by questions such as "Were you surprised to find yourself alive after taking the overdose?"

Violent attempts (shooting, jumping, hanging) are generally considered serious and a high-risk factor for a future attempt. A number of reports have described a "wrist-cutting syndrome" in young, unmarried women whose self-mutilation, although repetitive, has seldom been thought to be serious in intent. These acts usually have been carried out in a state of mounting tension with depersonalization followed by relief after self-mutilation. A significant number of "wrist slashers," or self-mutilators, however, whose cases have been followed for 5 to 6 years, have committed suicide.

In determining suicide risk, a general rule is that the risk of a successful suicide rises with advancing age. Men are two to three times more likely than women to complete suicide, whereas women are two or three times more likely than men to attempt suicide. Patients who are single, divorced, separated, widowed, or unemployed are at higher risk than those who are married and employed.

A psychotic patient who attempts suicide requires careful observation, whatever restraint necessary, and evaluation by a psychiatrist. A psychotic patient may respond unpredictably to distorted perceptions in a fearful or driven manner.

Secondary gain is a term that indicates that while the primary motive for a suicide attempt appears to be death, the attempt may meet another need such as attention or a plea for emotional help. When such needs are met by the attempt, a secondary gain is achieved and the risk of subsequent suicide attempt is lessened momentarily. It is dangerous, however, to assume that secondary gain is the cause of a suicide attempt with an initial evaluation in an emergency department. All suicide behaviors should be taken seriously.

Perhaps the most important part of the assessment of the suicide attempter is a determination of the patient's feelings and thoughts at the time of the interview. The patient who experiences helplessness, exhaustion, overwhelming depression, and a clear expression of intent to die certainly remains at high risk. If a patient expresses continuation of such feelings at the time of the interview, the physician has sufficient evidence that the patient needs psychiatric consultation immediately. Some patients, however, seem to equate self-injury with other forms of emotional discharge such as crying, talking to a friend, or becoming inebriated. They do not perceive the event as an attempt to end their life. When asked about their feeling at the time of the attempt, such patients may indicate that they were angry or vengeful. Attitudes and affect that generally indicate a good prognosis at the time of the interview are anger, remorse, or embarrassment. A patient who sits quietly, refusing to provide additional information to an examiner, should be considered at high risk. Feelings of hopelessness, helplessness, or exhaustion seem to be among the clearest indicators of long-term suicidal risk in patients hospitalized at one time for depression.

Patient disposition can be aided by estimating the lethality of the attempt and the likelihood of rescue. When there is a high likelihood of rescue and low lethality, a patient is considered at lower risk than in the reverse situation. A patient who makes a hanging attempt in a desolate wooded area is at greater risk than a person who takes a handful of relatively nontoxic pills in front of witnesses.

Patients who have made previous suicide attempts have traditionally been considered to be at greater risk for future suicide. Prior attempts seem a particularly ominous sign, particularly if the intensity and apparent lethality of the suicide attempts escalate with each subsequent attempt.

A "No Harm Contract"[4] is very useful in the emergency department in evaluating suicidal risk. The "No Harm Contract" [4] is a verbal or written agreement, initiated by the emergency room physician or psychiatrist, in which the suicidal patient is asked to agree not to harm or kill himself or herself for a particular period of time. This can be therapeutic, helping to reveal the intent of the patient and reduce it. It can also be diagnostic in assessing the nature and severity of a patient's suicidality. It can uncover specific issues precipitating suicidal thoughts and the ability of the patient to contract for safety.

A very difficult decision in the emergency department is when to discharge a child or adolescent patient who has expressed suicidal thoughts or behavior. Consideration of the following criteria is suggested before discharging a child or adolescent patient with suicidal ideation or behavior from the emergency department:[5]

1. The patient must not be imminently suicidal.
2. The patient must be medically stable.
3. The patient and the parents agree to return to the emergency department if suicidal intent recurs.
4. The patient must not be intoxicated, delirious, or demented.
5. Potentially lethal means of self-harm have been removed.
6. Treatment of underlying psychiatric diagnoses has been arranged.
7. Acute precipitants to the crisis have been addressed and attempts been undertaken to resolve them.
8. The physician believes that the patient and family will follow through on treatment recommendations.
9. The patient's caregivers and social supports are in agreement with the discharge plans.

Adolescents who complete suicide are more likely to have had histories of substance or drug abuse, disruptive disorders, anxiety, mood disorder, or schizophrenia. Precipitating events are usually stressors such as disciplinary crises, being in trouble with the law or at school, or the loss of a relationship. [6]

A summary of high-risk and low-risk suicide profiles is presented in Table 281-4.

TABLE 281-4 Evaluation of Suicide Risk in Adults and Adolescents

Clinical Management

High-risk patients whose suicide intent is strong and immediate require immediate psychiatric hospitalization. Moderate-risk patients are those who present in a serious suicidal crisis, but who, because of a positive response to initial intervention and favorable social support, are not judged to be in immediate danger. Hospitalization can often be avoided with such patients, provided practical outpatient treatment can be established immediately. Such determinations are most often made in concert with a psychiatric consultant. Available means of suicide, such as firearms or drug caches, should be removed, and any psychotropic medication should be used judiciously and prescribed conservatively. It is important to have a family member take charge of a patient's medications.

Before discharging a patient, the physician must be certain that the patient has a good social support system and there is an absence of clearly pathologic features that predispose the patient to subsequent suicide. The support system usually includes a place to live and family or friends who will support the patient emotionally.

Low-risk patients frequently present with suicidal threats or minor attempts that occur in the context of a clearly definable external crisis. Social support is usually available and responsive. However, because many attempts that appear trivial on first glance are found to have more serious implications on closer examination, all patients presenting following a suicide attempt should be carefully assessed. If there is any question about the safety of discharging a suicidal patient, and psychiatric consultation is not immediately available, the patient should be hospitalized.

Chemical Restraint

Chemical restraint should be administered after gathering as much information as possible to enable provisional diagnostic assessment. Once initial medical history, physical examination, and laboratory information have been obtained, if a patient continues to chafe against restraints and to show uncontrolled behavior, the use of a pharmacologic intervention to assist in behavioral control might be considered. Although a variety of medications can be used, the only one with a clear advantage over the rest is lorazepam (Ativan), a potent benzodiazepine that has the advantages of the wide therapeutic index of the class, rapid onset of action, and the ease of administration by parenteral or oral routes. Lorazepam is the only benzodiazepine that can be reliably administered intramuscularly (IM), and its oral and parenteral potencies do not greatly differ, allowing for ease in dosage calculation. Alternative medications such as short-acting barbiturates have a much narrower therapeutic index, and sedating neuroleptic medications such as the phenothiazines have the disadvantage that those which are most sedating also cause the greatest difficulty with orthostatic hypotension. Useful dosage levels of lorazepam would be 1 to 2 mg orally (PO) or IM every half-hour until an adequate level of sedation is achieved. If this is insufficient, haloperidol can be used. The dose is 5 mg IM in younger adults and 1 to 2 mg IM in the elderly. However, haloperidol should not be given to those with Parkinson's disease or other movement disorder. The combination of haloperidol (5 mg) and lorazepam (2 mg) is sometimes given initially to calm agitated behavior, especially if psychotic features are present. Droperidol (Inapsine), 2.5 to 5 mg intravenously (IV), ensures rapid onset of tranquilization. Hypotension from droperidol occurs in a number of patients and is generally treated with a 250 to 500 mL crystalloid infusion.

Consultation and Referral

In the ideal setting, all emergency departments would have psychiatric consultation available at all times. However, in many instances, the physician in the emergency department will be forced to rely on more limited resources. Many psychiatric problems leading to emergency department presentation do not require immediate definitive treatment. In many instances, disposition following initial screening can be made to a variety of secondary sources of evaluation and treatment. Judgments regarding referral depend on assessment of a patient's likelihood of becoming violent toward self or others. Clues that suggest potential violence include hostile behavior, verbal aggressiveness, or statements about violent intent. Such patients need immediate hospitalization. Marked disorientation and confusion require evaluation for organic components. In the absence of such indications, referral can be made to a psychiatrist or a psychiatric facility. Results of the emergency department medical and psychiatric evaluation should be summarized in writing and provided to the consultant. The patient should receive clear discharge instructions and should have a follow-up interval for any medical or surgical disorders that were identified.

282 PSYCHOTROPIC MEDICATIONS

Richard A. Nockowitz
Douglas A. Rund

The emergency physician must be able to administer certain selected psychotropic medications appropriately and recognize and manage side effects, toxicities, and adverse interactions with other medications.

There are four major classes of psychotropic medications dealt with here: antipsychotics, anxiolytics/sedative-hypnotics, antidepressants, and mood stabilizers such as lithium and anticonvulsants. There are multiple indications for several of these medications, particularly the antidepressants and anticonvulsants. However, only the antipsychotic and anxiolytic classes have undisputed utility on an emergency basis. Antidepressants and lithium are rarely prescribed by the emergency physician, primarily because they have long latencies of action and multiple side effects and require careful long-term monitoring. Only in exceptional circumstances, in consultation with a psychiatrist who agrees to provide follow-up care, might the emergency physician elect to initiate antidepressant or lithium therapy. Extensive pretreatment evaluation and detailed patient education weigh heavily against prescribing lithium, MAOIs, or heterocyclic antidepressants in the emergency department.

The emergency physician should be familiar with the emergency indications, common side effects, toxic reactions, and common interactions of the psychotropic medications. Caution in prescribing is the rule. Certain cases are bound to be complex, requiring detailed psychiatric evaluation, and serious medical disorders may coexist with psychiatric disorders. Patients with medical disorders, a history of serious side effects with psychotropic medication, or apparent need for more than one psychoactive medication usually require psychiatric consultation.

ANTIPSYCHOTICS (NEUROLEPTICS)

Indications

Because antipsychotic medications are symptom-specific (not disease-specific), they are useful in nearly all psychoses, whether primary (due to psychiatric illness) or secondary (substance-induced or due to a general medical condition). In the emergency setting, they are most often indicated to control agitated or psychotic behavior that constitutes an imminent danger to the patient or others.

A known allergy to a specific antipsychotic medication is a contraindication to its use and to use of other antipsychotic medications of the same class. Most patients who claim to be allergic to antipsychotic medications, however, actually describe a history of acute dystonic reactions when questioned more carefully.

Guidelines

Low-potency antipsychotics (Table 282-1) such as chlorpromazine (Thorazine) and thioridazine (Mellaril) may cause significant hypotension and thus are rarely used in emergency medicine. High-potency antipsychotics such as haloperidol (Haldol) and fluphenazine (Prolixin) have relatively few anticholinergic and alpha-blocking effects and are remarkably safe, even at high doses. They are the emergency antipsychotic agents of choice.

Generic Name	Brand Name	Approximate Equivalent Dose, mg	Relative Potency
Phenothiazines			
Aliphatic			
Chlorpromazine	Thorazine	100	Low
Triflupromazine	Vesprine	30	Low
Piperidines			
Mesoridazine	Serentil	50	Intermediate
Thioridazine	Mellaril	100	Intermediate
Piperazines			
Acetophenazine	Tindal	15	Intermediate
Perphenazine	Trilafon	10	Intermediate
Trifluoperazine	Stelazine	5	High
Fluphenazine	Prolixin, Permitil	2	High
Thioxanthenes			
Aliphatic			
Chlorprothixene	Taractan	100	Low
Piperazine			
Thiothixene	Navane	4	High
Dibenzazepine			
Loxapine	Loxitane, Daxolin	15	Intermediate
Dihydroindolones			
Molindone	Moban	10	Intermediate
Butyrophenones			
Haloperidol	Haldol	2	High
Droperidol	Inapsine (for injection)	2	High

TABLE 282-1   Commonly Used Antipsychotic Agents

Optimal pharmacologic management of acute agitation or psychosis is to use a high-potency neuroleptic such as haloperidol intravenously. Oral or intramuscular dosing is also acceptable if intravenous administration is not possible. In most patients, the initial drug is haloperidol. The initial dosage of 2 mg is doubled every 45 min until the symptoms are controlled, the patient is calmed, or the behavior is stabilized. The best approach is not to think of the dosages as cumulative but rather to find the one single dosage that effectively treats the symptoms. Once this is accomplished, use this particular effective dose on an "as needed" basis each time the

patient's symptoms reappear. Some clinicians augment this strategy with a dose or two of a benzodiazepine (e.g., 1 or 2 mg lorazepam) to control the symptoms. This proves useful in certain circumstances, such as with an agitated psychotic or manic patient, because there is a synergistic effect between the two medications. Additionally, the benzodiazepine may prevent potential extrapyramidal problems that occasionally occur with neuroleptic use. These are easily managed if they do occur, however, as discussed in the following section. One advantage to using haloperidol intravenously is an exceptionally low incidence of extrapyramidal side effects compared with the incidence seen with intramuscular or oral routes of administration. Dosages may need to be half those described or less if the patient is elderly, debilitated, brain-injured, or has AIDS.

Side Effects

Antipsychotics block dopamine receptors throughout the central nervous system (CNS). Dopamine receptor blockade in the mesolimbic areas accounts for their antipsychotic properties. Dopamine blockade in the nigrostriatal tract is responsible for the majority of motor side effects, including acute dystonias, akathisia, and Parkinson's syndrome.

Acute dystonias, which usually occur in young males during the trial phase of antipsychotic treatment, are probably the most common side effect of antipsychotic medications seen in the emergency department. Muscle spasms of the neck, face, and back are the most common dystonias, but oculogyric crisis and even laryngospasm may also occur. When a drug history is not carefully obtained, dystonias are often misdiagnosed as primary neurologic illnesses (seizures, meningitis, tetanus, etc.). Treatment with either 1 to 2 mg of benztropine IV or 50 to 100 mg of diphenhydramine IV rapidly corrects the dystonia. Dystonias often recur, even if the antipsychotic is decreased or discontinued, however, unless an antiparkinsonian drug such as benztropine, 1 mg PO two to four times daily, is administered over the next several days.

Akathisia, a sensation of motor restlessness with a subjective desire to move, can begin several days to several weeks after initiation of antipsychotic treatment. Often misdiagnosed as anxiety or exacerbation of psychiatric illness, akathisia is aggravated by subsequent increases in antipsychotic dosage. Other coexisting extrapyramidal effects, such as cogwheel rigidity and shuffling gait, suggest antipsychotic effect, but these signs are not invariably present. Management can be difficult, but some useful strategies are known. If possible, the dosage of the antipsychotic should be decreased. The best treatment is probably administration of beta blockers. Propanolol 30 to 60 mg per day is a good starting dose. Some patients need 90 to 180 mg per day as blood pressure and heart rate allow. Antiparkinsonian or anticholinergic drugs such as benztropine, 1 mg PO two to four times daily, may also afford some relief. In refractory cases, the antipsychotic may need to be changed to an atypical agent, as discussed below.

Antipsychotic-induced *Parkinson's syndrome* is particularly common in the elderly and usually begins in the first month of treatment. A complete Parkinson's syndrome, including bradykinesia, resting tremor, cogwheel rigidity, shuffling gait, masked facies, and drooling can occur, but often only one or two features of the syndrome are obvious. Antipsychotic dosage reduction and/or anticholinergic medication is usually effective.

Whereas antidopaminergic extrapyramidal side effects (EPS) such as acute dystonia, akathisia, and Parkinsonism occur more often with high-potency neuroleptics, anticholinergic and anti-adrenergic effects are more commonly seen with low-potency neuroleptics. Both anticholinergic and alpha-blocking effects are dose-related and much more common in the elderly.

Anticholinergic effects range from mild sedation to delirium. Peripheral manifestations may include dry mouth and skin, blurred vision, urinary retention, constipation, paralytic ileus, cardiac dysrhythmias, and exacerbation of narrow-angle glaucoma. The central anticholinergic syndrome is characterized by dilated pupils, dysarthria, and an agitated delirium. Discontinuation of the antipsychotic and institution of supportive measures is the most prudent therapy. Physostigmine, 1 to 2 mg administered slowly IV may temporarily reverse the syndrome but may be very toxic and should be reserved for life-threatening situations.

Cardiovascular side effects are seen almost exclusively with low-potency antipsychotics. The exception to this is the rare occurrence of torsades de pointes caused by high dosages of high-potency neuroleptics such as haloperidol and droperidol. Alpha-adrenergic blockade and a negative inotropic effect on the myocardium may cause pronounced orthostatic hypotension and, rarely, cardiovascular collapse. Usually the hypotension can be easily managed with IV fluid. In severe cases, agonists, such as metaraminol (Aramine) or norepinephrine (Levophed), may be required.

Neuroleptic malignant syndrome (NMS) is an uncommon idiosyncratic reaction to neuroleptic drugs manifested by rigidity, fever, autonomic instability (tachycardia, diaphoresis, and blood pressure abnormalities), and a confusional state. Elevation of muscle enzymes, such as creatinine phosphokinase (CPK) and aldolase, the white blood cell count, and liver function tests are often seen. While high-potency antipsychotics may be more likely to cause the disorder, all antipsychotics are potential offenders. NMS is a medical emergency and has a mortality rate as high as 20 percent. Management includes immediate discontinuation of the antipsychotic medication, hydration, and meticulous supportive treatment in an intensive care setting. Anticholinergic medications are not helpful and may worsen the condition by further impairing centrally mediated temperature regulation. Medications such as dantrolene sodium or bromocriptine are sometimes used to relieve the rigidity. See Chap. 153 for a detailed discussion.

Overdose

While antipsychotics are rarely fatal when taken alone, overdose can present some unique management problems. With the exception of thioridazine (Mellaril), antipsychotics are potent antiemetics. The antiemetic effect may interfere with pharmacologic induction of emesis, and gastric lavage is often required. Agents with beta-agonist activity such as isoproterenol are contraindicated for cardiovascular support because beta-stimulated vasodilatation may worsen hypotension. Extrapyramidal effects may also be prominent in antipsychotic overdosage and are best treated with 50 to 100 mg IV of diphenhydramine (Benadryl).

ATYPICAL AGENTS

Clozapine

Clozapine (Clozaril) is an "atypical" antipsychotic medication in that it is preferentially more active at limbic than at striatal dopamine receptors and causes few or no EPS. Unfortunately, it may produce agranulocytosis, so its use is reserved for patients with schizophrenia unresponsive to standard agents and for those suffering from severe EPS or tardive dyskinesia with the standard agents. Use of clozapine requires weekly complete blood counts (CBC) the first 6 months of use and then every 2 weeks after that. Any white blood cell count less than 3500 requires closer monitoring, whereas a white blood cell count less than 2000 or absolute granulocyte count less than 1000 mandates immediate discontinuation of the drug and consultation with a hematologist. Fever may be a side effect during the first few weeks of therapy and should prompt an immediate CBC. If the CBC is normal, the fever will typically reverse. Clozapine is strongly sedating, strongly anticholinergic, and has considerable hypotensive effects. It also poses a substantial risk for inducing seizures, particularly when higher doses are used. Respiratory depression and arrest have been reported rarely, and there is a suggestion that coprescription of a benzodiazepine may increase the risk for this side effect.

Commonly reported features of overdose include altered sensorium (drowsiness, delirium, and coma), tachycardia, hypotension, respiratory depression and failure, hypersalivation, and seizures. Management, in addition to administration of activated charcoal, is symptomatic and supportive. Epinephrine and its derivatives should be avoided, as should antidysrythmics such as procainamide and quinidine. Close surveillance, including cardiac and vital sign monitoring, should continue for several days because of risk of delayed toxic effects. Fatal overdosages have been reported, usually at dosages over 2500 mg.

Risperidone

Risperidone is another "atypical" antipsychotic medication whose pharmacologic profile of potent serotonin (5-HT $_2$) antagonism and moderate dopamine (D$_2$) antagonism probably accounts for its relatively lower risk of EPS. Unlike clozapine, it does not have increased risk of agranulocytosis. Common side effects include sedation, insomnia, constipation, and weight gain. Cardiovascular effects may include small, short-term increases in heart rate, accompanied by reduced systolic/diastolic blood pressure, orthostatic hypotension, and QT-interval prolongation. Seizures have been reported in 0.3 percent of patients.

Features of overdose generally reflect exaggerated pharmacologic effects: drowsiness, sedation, tachycardia, hypotension, EPS, prolonged QT, widened QRS and, in several instances, seizure. Management is basically supportive. Cardiovascular monitoring is imperative. Should antidysrhythmic therapy be required, agents such as disopyramide, procainamide, and quinidine, which have the potential for QT-prolonging effects, should be avoided. As with more traditional antipsychotics, agents that

may worsen effects of b-adrenergic blockade, such as bretylium, epinephrine, and dopamine, should also be avoided.

Olanzapine

Olanzapine (Zyprexa) has a chemical profile very similar to that of clozapine and thus causes little or no EPS. It also has the advantage of not being known to cause agranulocytosis and thus does not require monitoring of the white blood count. Its main adverse effects can include considerable weight gain, sedation, and mild anticholinergic activity. Little is known at this time about effects of overdose, but exacerbation of brain side effects such as somnolence and anticholinergic signs would be expected.

Quetiapine

Quetiapine (Seroquel) is the newest atypical antipsychotic agent and, like the others, is characterized by a high 5-HT/D $_2$ binding ratio, responsible for its low incidence of EPS, while maintaining its antipsychotic effect. It has a high affinity for histaminic and a-adrenergic receptors, however, causing prominent adverse effects of sedation, orthostatic hypotension, and some dizziness. Little is known about effects of quetiapine in overdose.

ANXIOLYTICS

Indications

Severe emotional distress may indicate a need for psychotropic medication, even if the patient is not psychotic or an imminent threat to him- or herself or others. While not a substitute for psychotherapy, short-term anxiolytic therapy may be particularly beneficial in the anxious, agitated patient during a psychosocial crisis. Anxiolytics are also indicated for acute panic reactions unresponsive to reassurance.

Anxiolytics have utility in medical and surgical emergencies as well. Nonpsychiatric uses include facilitation of cooperation and muscle relaxation during painful procedures; controlling seizures; treating alcohol, sedative, or hypnotic withdrawal; and allaying anxiety when a painful procedure such as surgery has been delayed.

Benzodiazepines are contraindicated in patients with known hypersensitivity to benzodiazepines and in acute, narrow-angle glaucoma. Pregnancy, particularly in the first trimester, is a relative contraindication.

Guidelines

Before prescribing anxiolytics, the emergency physician should try to rule out any serious underlying psychiatric illness. Because agitation and anxiety may indicate incipient psychosis or major affective disorder, anxiolytics should be used with extreme caution in patients with a history of major psychiatric illness. The possibility that a patient may be feigning illness to procure controlled substances should also be considered.

Benzodiazepines are very effective anxiolytics with a high therapeutic index. Nonbenzodiazepine anxiolytics (e.g., barbiturates and propanediols) have low therapeutic indices and high addiction potential. Except in the rare case of an allergy to benzodiazepines, non-benzodiazepine anxiolytics have little use in modern psychopharmacology. Buspirone hydrochloride (BuSpar), an atypical anxiolytic medication that does not interact with the benzodiazepine-GABA receptor complex, has a delayed onset of action of days to weeks, which makes it impractical for use in emergent situations. Since it does not have cross-tolerance with other sedative/hypnotics or alcohol, it is not useful in treatment of sedative/hypnotic or alcohol withdrawal.

Certain benzodiazepines have relatively long half-lives (Table 282-2), including diazepam (Valium), chlordiazepoxide (Librium), flurazepam (Dalmane), and prazepam (Centrax). Agents with long half-lives gradually accumulate in the body and thus have a greater potential for causing sedation and confusion, particularly in the elderly. For short-term use, these agents may benefit the young, healthy person in crisis who complains of insomnia but is also anxious during the day. A single bedtime dose both induces sleep and has a mild anxiolytic effect the following day. For the most part, however, with the exception of the use of diazepam in seizures, short-acting benzodiazepines such as lorazepam (Ativan), oxazepam (Serax), and alprazolam (Xanax) are the preferred agents in emergency medicine. Alprazolam (Xanax), 0.25 to 0.50 mg PO, is a particularly effective treatment in acute panic attack. Lorazepam, an agent with very low cardiopulmonary toxicity, is particularly well suited for emergency use. Dosages of 1 to 2 mg PO or IM are usually effective. Only midazolam (Versed), a very short-acting agent, and lorazepam (Ativan) have reliable intramuscular absorption. As with all benzodiazepines, dosage adjustments may be necessary: higher dosages may be required in patients with histories of alcohol or sedative/hypnotic abuse; lower dosages in patients with hepatic disease or severe debilitation. Because they potentiate other CNS depressants, benzodiazepines should be used with extreme caution in intoxicated patients. Benzodiazepines particularly suppress hypoxic respiratory drive and should be used with caution in patients with hypercarbia, especially if the patient is also receiving supplemental oxygen.

Generic Name	Brand Name	Approximate Half-life, h	Usual Total Oral Dose, mg
		ANXIOLYTICS*	
Alprazolam	Xanax	12	1–6
Chlorazepate	Tranxene	48	15–60
Chlordiazepoxide	Librium	20	15–60
Diazepam	Valium	35	15–60
Lorazepam	Ativan	16	2–6
Midazolam	Versed	2	—‡
Oxazepam	Serax	15	20–60
Prazepam	Centrax	15†, 100†	20–60
		HYPNOTICS	
Flurazepam	Dalmane	2†, 72†	15–30 qhs
Temazepam	Restoril	15	15–30 qhs
Triazolam	Halcion	2	0.125–0.5 qhs

*Anxiolytics are administered in divided doses, usually three or four times daily.
†Flurazepam and prazepam have active metabolites with long half-lives.
‡Midazolam is available for parenteral use only.

TABLE 282-2   Commonly Used Benzodiazepines

Side Effects

Benzodiazepine side effects are usually mild and easily treated. Drowsiness, decreased mental alertness, sedation, and ataxia are the most common side effects. Such effects can usually be managed conservatively by decreasing the dose and advising the patient to avoid potentially hazardous activities, such as driving or operating dangerous machinery. Excessive sedation and overdose can be reversed with flumazenil by giving 0.2 mg IV over 15 to 30 s and then 0.2 to 0.4 mg every 30 to 60 s up to 1 to 3 mg total dose depending on the circumstances. This is contraindicated, however, in mixed overdoses and chronic benzodiazepine use. Infrequent paradoxical responses to benzodiazepines of insomnia and agitation are more common in the elderly and require discontinuation of the medication. Because benzodiazepines have abuse potential and high street value, the emergency physician should never prescribe more than a week's supply.

HETEROCYCLIC ANTIDEPRESSANTS (HCAs)

Although tricyclic antidepressants (named for their three-ring structure) were first synthesized in the nineteenth century, their antidepressant properties were not recognized until the late 1950s. Since that time, other "cyclic" antidepressant agents have been formulated thus creating need for the more general term *heterocyclic* (Table 282-3). The therapeutic effect of HCAs is believed to be related to secondary downregulation of norepinephrine and serotonin postsynaptic receptors after initial blockade of presynaptic reuptake of norepinephrine and serotonin. HCAs are primarily indicated for major depression but may also be effective for dysthymic disorder, panic disorder, agoraphobia, obsessive compulsive disorder, enuresis, and school phobia. As previously advised, initiation of HCA therapy in the emergency department is not routinely recommended.

Generic Name	Brand Name	Usual Dose mg/day
TRICYCLICS		
Amitriptyline	Amitril, Elavil, Endep	75–200
Amoxapine	Asendin	100–300
Desipramine	Norpramin, Pertofrane	75–200
Doxepin	Adapin, Curetin, Sinequan	75–200
Imipramine	Janimine, Presamine, SK-Pramine, Trofranil	75–200
Nortriptyline	Aventyl, Pamelor	40–150
Pritriptyline	Vivactil	15–40
Trimipramine	Surmontil	75–200
OTHERS		
Maprotiline	Ludiomil	100–150
Trazodone	Desyrel	100–200

TABLE 282-3 Commonly Used Heterocyclic Antidepressants

Side Effects

HCAs have low therapeutic indices. Side effects are common and often occur with customary dosages, even though serum levels may be within the designated therapeutic range. The majority of side effects are either anticholinergic or cardiotoxic.

Anticholinergic side effects are the most common. They are particularly likely to occur with concomitant use of other drugs with anticholinergic properties, such as low-potency antipsychotics, antiparkinsonian agents, antihistamines, and over-the-counter sleeping remedies. Both peripheral and central effects may occur. Peripheral effects include dry mouth, metallic taste, blurred vision, constipation, paralytic ileus, urinary retention, tachycardia, and exacerbation of narrow-angle glaucoma. Central effects include sedation, mydriasis, agitation, and delirium. Mild to moderately severe anticholinergic effects may be managed by dosage reduction, change to a medication with fewer anticholinergic properties, or addition of urecoline, 10 to 25 mg PO three times daily. For acute urinary retention, urecoline, 2.5 to 5 mg may be given subcutaneously. When anticholinergic effects become life-threatening, physostigmine, 1 to 2 mg administered *very slowly* IV, may be used. If physostigmine toxicities ensue, the effects can be reversed with IV atropine sulfate, 0.5 mg for each 1.0 mg of physostigmine administered.

Cardiac side effects of HCAs may include nonspecific T-wave changes, prolonged QT interval, varying degrees of AV block, and atrial and ventricular dysrhythmias. Orthostatic hypotension from a-adrenergic blockade may be significant, particularly in the elderly.

HCA therapy may also be complicated by allergic obstructive jaundice; decreased seizure threshold (especially with maprotiline, clomipramine, and amoxapine); and, very rarely, agranulocytosis.

Trazodone has little in common with other HCAs. It lacks significant anticholinergic or cardiac conduction effects but may be associated with marked sedation, ventricular dysrhythmias, and significant orthostatic hypotension. It may also cause priapism, a urologic emergency.

MONOAMINE OXIDASE INHIBITORS (MAOIs)

MAO catalyzes the oxidation of biogenic amines (tyramine, serotonin, dopamine, and norepinephrine) throughout the body. The therapeutic effect of MAOIs is probably related to their ability to increase norepinephrine and serotonin in the CNS. They are recommended for atypical major depressive episodes, characterized by hyperphagia, hypersomnolence, reversed diurnal variation (worse in the evening), emotional lability, so-called leaden paralysis (heavy leaden feelings in arms or legs), and rejection hypersensitivity. They are also occasionally useful in selected cases of HCA-refractory major depression and panic disorder. Only two agents in this class, phenelzine (Nardil) and tranylcypromine (Parnate), are commonly used in the United States. As with HCAs, initiation of therapy in the emergency department is not recommended. The physician who initiates MAOI therapy must have firmly established an appropriate indication for use and provided the patient with extensive counseling about toxic interactions with numerous medications and foods.

Side Effects

In general, MAOIs have fewer side effects than do HCAs. *Orthostatic hypotension,* although occasionally severe, usually responds to supportive therapy. *CNS irritability,* including agitation, motor restlessness, and insomnia, is managed by dosage reduction or addition of a benzodiazepine. Occasionally, MAOIs, like other antidepressant medications, actually precipitate a manic episode. *Autonomic side effects,* such as dry mouth, constipation, urinary retention, and delayed ejaculation, sometimes occur but are usually mild.

MAOIs block oxidative deamination of tyramine and may precipitate a *hypertensive crisis* when certain drugs, such as sympathomimetic amines, L-dopa, narcotics, or HCAs, or tyramine-containing foods are ingested. Common tyramine-containing foods include aged cheese, beer, wine, pickled herring, yeast extracts, chopped liver, yogurt, sour cream, and fava beans. The onset of the crisis is usually heralded by a severe headache. While hypertension is potentially the most serious effect, cardiac dysrhythmias, restlessness, diaphoresis, mydriasis, and vomiting may also occur. Beta-blocking agents are contraindicated, since they may intensify vasoconstriction and worsen hypertension. Although death may occur from hypertensive intracranial hemorrhage, the vast majority of patients recover completely from the hypertensive episode within a few hours. The MAOI can be restarted the following day after dietary counseling is reinforced.

Drug-drug interactions often complicate MAOI therapy. MAOIs potentiate the actions of sympathomimetics, anticholinergics, and oral hypoglycemics. They also inhibit metabolic degradation of alcohol, barbiturates, and narcotics. When combined with meperidine (Demerol), MAOIs may cause a variety of adverse effects, including hypotension, hypertension, fever, and neuromuscular irritability. While the interactions listed are among the most common, the list is far from exhaustive. More comprehensive accounts may be found in standard references.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS (SSRIs)

Since the introduction of fluoxetine (Prozac) in 1988, the SSRIs have become the most commonly prescribed antidepressants in the United States. Other SSRIs currently available include sertraline (Zoloft), paroxetine (Paxil), fluvoxamine (Luvox), and citalopram (Celexa). SSRIs are primarily indicated for treatment of major depressive episodes but also have utility in dysthymia and anxiety disorders including generalized anxiety disorder, panic disorder, and obsessive compulsive disorder. Because of their favorable side effect profile and relative safety in overdose, some have argued that institution of an SSRI by an emergency department physician may occasionally be appropriate if (1) the patient can be assessed to rule out general medical causes for the depression, (2) ongoing substance abuse can be ruled out, and (3) the patient can be followed in the emergency setting until picked up by another health care provider. However, this rationale has rightly been questioned because of the concern over SSRIs and other antidepressants precipitating mania. The detection of bipolar disorder, because of its many variations and subtle forms, requires evaluation by an experienced psychiatrist. All antidepressants carry some degree of risk for precipitating a manic or mixed episode in a patient predisposed to bipolar illness.

Side Effects

SSRIs lack the anticholinergic and cardiac effects typical of the HCAs, although there have been several reports of symptomatic bradycardia with fluoxetine. The side effect profile of SSRIs reflect their potent serotonin antagonism. Among the most common side effects are headaches, dizziness, sexual dysfunction, nausea, diarrhea, insomnia, and agitation. Less common side effects are akithisia and apathy syndrome. A significant advantage of SSRIs is their high therapeutic index and associated low lethality, even when large quantities are ingested acutely.

An SSRI discontinuation syndrome has become apparent, more commonly with agents having a shorter half-life (e.g., sertralene, paroxetelene). It typically presents several days after cessation of one drug and is characterized by a flulike syndrome including nausea, vomiting, fatigue, myalgias, vertigo, headache, insomnia, and sometimes parathesias. Treatment is to reinstate SSRI therapy and taper more gradually.

A serotonin syndrome with SSRIs can occur when SSRIs are combined with other serotonergic medications such as the MAOIs. The syndrome is manifest by both CNS (restlessness, tremor, myoclonus, hyperreflexia, and seizures) and gastrointestinal (nausea, vomiting, diarrhea) irritability. Consequently, SSRIs or any medication that enhances serotonin levels should not be combined with MAOIs. Treatment of the serotonin syndrome consists of discontinuing the serotonergic agents and providing supportive care.

NEWER "COMBINATION" ANTIDEPRESSANTS

Whereas most tricyclic antidepressants enhance norepinephrine levels, SSRIs enhance serotonin levels, and psychostimulants (a category not discussed here) enhance dopamine levels. The newer antidepressants evidence "combinations" of these effects through various mechanisms. Examples of this include venlafaxine, bupropion, nefazodone, and mirtazapine.

Venlafaxine (Effexor)

Venlafaxine, which is structurally distinct from other antidepressants, is conceptually a combination of a tricyclic and an SSRI in that it enhances both serotonin and norepinephrine (as well as dopamine slightly) through reuptake blockade. It's advantages are relative freedom from medication interactions and no significant affinity for muscarinic, histaminic, and a-adrenergic receptors. Although lack of blockade for various receptors improves its side-effect profile somewhat, common complaints include agitation and insomnia, nausea, occasional dizziness, constipation, and sweating. Potential problems associated with venlafaxine include dose-related, sustained hypertension and the growing awareness of a significant discontinuation syndrome requiring very slow tapering of the drug. The hypertension needs to be monitored and may require lowering of the medication. The discontinuation syndrome can be significant. It usually occurs within days to 2 weeks after lowering or stopping the drug and is similar to SSRI discontinuation symptoms. It can be treated with an SSRI or by increasing the venlafaxine and tapering it more slowly. Venlafaxine should not be used in combination with an MAOI.

Bupropion (Wellbutrin)

Bupropion is also structurally unique and works by initiating reuptake inhibition of both norepinephrine and dopamine, the former more than the latter. It also interacts with few other medications and has a favorable side-effect profile due to its minimal anticholinergic and antihistaminic effects. It is being used also to aid in smoking cessation.

Common side effects include some initial restlessness and insomnia that typically resolves within 2 weeks. It is noted for having the lowest incidence of sexual side effects, which are common with other antidepressants, including SSRIs. In fact, when bupropion is added for SSRI-induced sexual dysfunction, sexual functioning improves in many patients. One concern with this drug had been a dose-related increase in the incidence of seizures. However, further study has shown no higher incidence at usual therapeutic dosages compared with other antidepressants. Caution should be taken when using this drug in patients with bulimia or metabolic disturbances predisposing to seizures. Likewise, individual doses greater than 200 mg and daily dosages greater than 400 mg should be avoided. Combination with an MAOI is to be avoided as well. Bupropion may be the least likely of all antidepressants to precipitate a switch into mania.

Nefazodone (Serzone)

Nefazodone inhibits serotonin reuptake inhibitors and blocks postsynaptic serotonin receptors (5-HT $_2$) at the same time. It is similar chemically to trazodone but possesses less a-adrenergic blockade. Common side effects are dizziness, headache, dry mouth, and nausea. Some patients also have problems with orthostatic hypotension and drowsiness. Anxiety is less of a problem with this drug compared with SSRIs, and sexual side effects are less common. It may be particularly useful for depression-associated insomnia.

Mirtazapine (Remeron)

Mirtazapine antagonizes inhibitory norepinephrine autoreceptors and heteroreceptors, causing increased release of norepinephrine and serotonin. The main side effects are somnolence, increased appetite, weight gain, and dizziness. Although serotonin enhancement is one of this drug's end results, it is via a very different mechanism, and the typical SSRI side effects are usually minimal. Given the limited clinical experience with this relatively new medication, effects of overdose are not well known.

MOOD STABILIZERS

Although lithium has been the mainstay of bipolar disorder (manic-depression) treatment for years, anticonvulsants such as carbamazepine, valproic acid, and now gabapentin and lamotrigine have come to play an increasingly important role in the management of this and other neuropsychiatric disturbances.

Lithium

Lithium carbonate is indicated for both acute mania and maintenance therapy in bipolar disorder. It also has utility in some cases of major depression (both unipolar and bipolar) and in some disorders characterized by episodic explosive outbursts or self-mutilation. Its mechanism of action is not exactly known, although it may relate to reducing dopaminergic function, enhancing serotonergic function, or reducing "excessive signaling" by the phosphytidylinositol system. The extensive pretreatment evaluation and long latency of action preclude the use of lithium as an emergency psychotropic medication. The emergency physician should be aware, however, of its side effects and signs of toxicity.

Side Effects

Patients vary widely in susceptibility to lithium side effects. While most of the serious adverse effects are associated with toxic serum levels, mild side effects such as gastrointestinal distress, dry mouth, excessive thirst, fine tremors, mild polyuria, and peripheral edema are often seen even when serum levels lie within the designated therapeutic range. This is particularly common during the first few weeks of therapy. Many of the more chronic side effects, including polyuria, nephrogenic diabetes insipidus, benign diffuse goiter, hypothyroidism, skin rashes and ulcerations, psoriasis, and leukocytosis without a left shift, appear unrelated to serum lithium levels. Underlying neurologic illness, dehydration, salt-restricted diets, and childbirth predispose to both minor and major side effects.

Toxicity and Overdose

The severity of lithium toxicity is related to both the serum lithium level and the duration of the elevated level. Even in acute overdose, symptoms may not be fully apparent for up to 48 h. As a general rule, lithium toxicity is rare at serum levels of less than 2 mEq/L. Early signs of toxicity include nausea and vomiting, dysarthria, lethargy, and a coarse hand tremor. As toxicity worsens, neurologic symptoms increase. Ataxia, myasthenia, incoordination, hyperreflexia, muscle fasciculation, blurred vision, and scotomas may develop. Eventually, confusion, choreoathetosis, myoclonus, and seizures occur, and the patient may finally become comatose. Cardiovascular toxicity is unusual at serum levels of less than 4 mEq/L. In addition to nonspecific T-wave changes, high lithium levels may be associated with hypotension, AV conduction defects, ventricular tachydysrhythmias, and eventually complete cardiovascular collapse.

Because lithium toxicity may result in permanent neurologic sequelae, it should be considered a medical emergency. General supportive care, with particular attention to fluid and electrolyte balance, is the foundation of therapy. Lithium excretion may be facilitated by forced saline diuresis and alkalinization of the urine with IV sodium lactate. Mannitol, 50 to 100 mg IV, may also be added to promote osmotic diuresis. Aminophylline, 500 mg given slowly IV, also promotes lithium clearance by both suppressing renal tubular reabsorption of lithium and increasing renal blood flow. If the serum level exceeds a 4 mEq/L, the patient should be dialyzed immediately. Dialysis may also be required for serum levels in the range of 2 to 4 mEq/L if the patient's clinical condition is poor.

Anticonvulsants

These drugs all act through different mechanisms to cause either enhanced GABA inhibitory function or decreased glutamate and aspartate excitatory release, both of which ultimately result in neuronal relaxation or stabilization. They have come to be used for mood stabilization in rapid-cycling, cyclothymic, and mixed states of

bipolar illness. Recent studies have demonstrated their superiority over lithium for such indications. Other uses are for impulsive aggression, behavioral disturbances in head-injured patients and patients exhibiting self-injurious behavior, and even for the irritability commonly seen in severe personality disorders. The side effects of carbamazepine and valproic acid are well known from their use as anticonvulsants.

Gabapentin is well tolerated, has few drug interactions, and does not need blood level monitoring. It may be titrated quickly and may be useful for patients already on multiple medications or with hepatic impairment. The main disadvantages are drowsiness, ataxia, and nausea at high dosages.

Lamotrigine is also well tolerated, with few adverse behavioral or cognitive effects. It does have some drug interactions (carbamazepine, valproate) and risk of potentially severe and fatal rash such as Stevens-Johnson and toxic epidermal necrolysis. The rash is more common in children and seems to be related to starting at too high a dosage, titrating too rapidly, and concomitant valproate therapy. Such a rash dictates immediate cessation of the medication in almost all circumstances. There may be additive toxicity with carbamazepine as well, causing more ataxia and dizziness than when used alone.

283 ANOREXIA NERVOSA AND BULIMIA NERVOSA

Alexander H. Sackeyfio
Susan J. Gottlieb

Anorexia nervosa and bulimia nervosa have reached epidemic proportions in the last 15 years. These diseases were once viewed as purely psychological in nature. However, increasing evidence has confirmed that both disorders involve physical complications, and knowledge of and ability to treat the medical complications of eating disorders are crucial for the patient's well-being.

Eating disorders affect between 5 and 10 percent of adolescent girls and young women, and up to 0.10 percent of males. Originally regarded as rich girls' diseases, they are now recognized across all socioeconomic and racial groups and in patients between the ages of 8 and 80. The onset of anorexia is usually between 12 years of age and the mid-thirties, with a bimodal distribution at ages 13 to 14 and 17 to 18. Bulimia usually begins between the ages of 17 and 25. The onset of both disorders has been reported in older persons. [1,2]

Anorexia, with its resulting starvation syndrome, is more likely to be recognized than is the commoner bulimia, which is frequently concealed from both family and physician. Table 283-1 lists the signs and symptoms that suggest a diagnosis of anorexia, and Table 283-2 lists the signs and symptoms of bulimia.

Unexplained growth retardation

Unexplained primary amenorrhea

Weight loss of unknown origin

Unexplained hypercholesterolemia or carotenemia in a thin person

Exercise abuse

Membership in a vulnerable vocational group (see last item in Table 283-2)

TABLE 283-1 Clues to Undiagnosed Anorexia Nervosa

Hypokalemia of unknown cause or complications of hypokalemia (cardiac, renal, central nervous system)
Metabolic acidosis related to laxative abuse or excessive exercise
Parotid gland or submandibular gland enlargement, esophagitis, esophageal bleeding or rupture
Large unexplained weight fluctuations or weight loss
Unexplained elevations of serum amylase level
Unexplained secondary amenorrhea
Extensive loss of dental enamel or onset of many new caries
Scars on the knuckles of the hand (from induced vomiting)
Presence of juvenile diabetes mellitus
Other disorders of impulse control (alcoholism, drug abuse, borderline personality disorder)
Member of predisposed vocational group (models, ballet students or professionals, wrestlers, jockeys)

TABLE 283-2 Signs and Symptoms of Bulimia in Adolescents and Young Adults

Anorexic patients[3] may present with one or all of the following:

1. Refusal to maintain body weight over a minimum normal weight for age and height; for example, weight loss or failure to make expected weight gain during a period of growth, leading to body weight 15 percent below normal
2. Intense fear of becoming obese even when underweight
3. Disturbance in the way in which body weight, shape, or size is perceived; for example, an obviously underweight or even emaciated patient's complaining of being fat or believing that one area of the body is "too fat"
4. Absence of at least three consecutive expected menstrual cycles (primary or secondary amenorrhea)

A diagnosis of bulimia[3] is suggested by the following:

1. A minimum average of two episodes of binge eating (rapid consumption of a large amount of food in a short period of time) per week for at least 3 months
2. A feeling of lack of control over the eating behavior during the eating binges
3. Regular engagement in self-induced vomiting, use of laxatives, strict dieting, fasting, or vigorous exercising in order to prevent weight gain
4. Persistent overconcern with body shape and weight

A third diagnosis[3] to be considered is eating disorder not otherwise specified. It is characterized by

1. For females, all criteria for anorexia except still menstruating
2. All criteria for anorexia except normal weight
3. All criteria for bulimia but lower frequency or duration
4. Regular use of compensatory weight control measures after small amount of food
5. Chewing and spitting out but not swallowing large amounts of food
6. Binge-eating disorder

The diagnosis of an eating disorder should be considered in a premenarchal patient who engages in potentially unhealthy weight-control practices and/or demonstrates obsessive thinking about food, weight, and height, especially if there is a delay in the maturation for gender and age. Families of patients with eating disorders tend to be outwardly orderly, respectable, and conventional. However, the inner dynamics of the family involve a rigid adherence to secret obligations and stifling prohibitions. Honesty and spontaneity are discouraged, and true autonomy and self-gratification are submerged beneath the adolescent's desire to please and gain approval from other family members.

ETIOLOGY

The onset of anorexia most often occurs during adolescence.[1] Normal physiologic changes that are preparation for the reproductive function, namely, an increase in total body fat (up to 200 percent in adolescent females) as well as the accumulation of fat around the chest and hips, are perceived as "fatness," and the adolescent begins to diet to lose the unwanted weight. Various reasons have been proposed for the progression of "normal" dieting into an eating disorder. Some feel that, for the anorexic, restriction of eating serves as a part of a general need to control impulses and disturbing feelings. Others have suggested that the central problems might be an avoidance of adulthood, an emergent panic related to the challenge of late adolescence, and the loss of the security enjoyed by the child and early adolescent.[1,2]

Bulimics have an intense need for approval, a high self-expectation, and a poor body image. Bingeing provides escape from boredom, anger, and loneliness and is sometimes a preferred social experience, especially when interpersonal intimacy has been elusive. Purging adds to an already negative self-image. Binge eating in bulimics almost always begins as a response to hunger from dieting and weight loss. Late in the syndrome, binge eating becomes generalized to deal with emotional distress.[1,2]

DIAGNOSIS

The differential diagnosis includes both psychiatric and medical disorders. Schizophrenics can present with an aversion to eating and sometimes with eating and purging. In depressive illness, anorexia and hyperphagia can be part of the presenting symptoms. Hysterics, patients with inadequate personality disorders, and patients with borderline personality disorders may also exhibit eating disorders.

A number of medical disorders should be considered, including superior mesenteric artery syndrome, inflammatory bowel disease, chronic hepatitis, Addison disease, diabetes, hyperthyroidism, hyperemesis gravidarum, tuberculosis, and malignancy. About 20 percent of teenage diabetics also have an eating disorder.[1] Extremely thin people in professions requiring low weight (e.g., ballet dancers, models, and jockeys) and runners may or may not have an eating disorder.[2]

PATHOPHYSIOLOGY

Eating disorders are associated with a number of physiologic changes (Table 283-3). Cachectic patients are relatively well adapted to their chronically deprived, mildly catabolic state. The hypothalamus is affected by low fat intake, which disturbs the reproductive, metabolic, growth, and neurohypophyseal hormones. There is an associated fall in metabolic rate, protein levels are preserved, and cell-mediated immunity tends to be normal.[4]

TABLE 283-3 Physiologic Changes Associated with Eating Disorders

Self-induced vomiting results in various disorders. Dental problems are caused by gastric acid regurgitation into the oral cavity. In addition, the oral hygiene of most anorexics is poor, and the vigorous brushing often done by bulimics aggravates dental problems. This poor oral hygiene, together with dietary deficiencies and dehydration of the soft tissue of the mouth, can cause gingivitis and dental erosion.

Parotid and submandibular gland enlargement is often seen. Oral lacerations and contusions, and callus formations on knuckles from stimulating the gag reflex, are common. Dysphagia, hematemesis, and, rarely, rupture of the esophagus, subcutaneous emphysema, or pneumomediastinum can occur following excessive purging. Easy bruising due to loss of bile salts and poor absorption of vitamin K is another complication. Severe hypokalemia and hypovolemia often accompany recurrent vomiting. Ipecac abuse can cause a dermatomyositis-like syndrome and cardiomyopathy. Hyperamylasemia, probably of salivary gland origin, is associated with purging episodes.

Laxative abuse produces weight loss mainly by dehydration and hypokalemia. Common nonspecific complaints of laxative abuse include constipation, diarrhea, abdominal cramping, and bloating. Severe potassium depletion due to chronic laxative abuse and intense physical exercise may contribute to myonecrosis. Specific effects include melanosis coli and cathartic colon. In cathartic colon, the colon is converted into an inert tube incapable of propelling the fecal stream without large doses of laxatives. This condition is not entirely reversible and may require colectomy. Brownish gray hyperpigmented areas on the skin are reported as complications of phenolphthalein-containing laxatives (e.g., Correctol and Ex-Lax).

Diuretic abuse results in dehydration and multiple serum abnormalities, including hypokalemia, hypercalcemia, hyperuricemia, hypomagnesemia, and hyponatremia.

Binge eating after a period of starvation can result in acute gastric distention and/or pancreatitis. Postbinge pancreatitis has a reported 10 percent mortality rate.

Periods of starvation result in hypoglycemia, which is a poor prognostic indicator. Hypoglycemia is often associated with hypothermia, coma, and infections, and may be fatal. Starvation leads to low insulin levels that are insensitive to both glucose and amino acid infusion. Gastric distention and reduced gastric emptying produce enhanced satiation and prolonged intermeal intervals. Food has been demonstrated to remain in the stomachs of anorexics for up to 24 h.

Starvation causes decreased hypoxic ventilatory drive, vital capacity, tidal volume, and minute ventilation. In addition, the surfactant pool is reduced, resulting in "stiffer" lungs with a greater tendency to collapse. The muscles of ventilation are affected by starvation, causing reduced diaphragm mass and respiratory muscle weakness.

Cardiovascular changes include brady- and tachyarrhythmias due to cardiomyopathy or electrolyte abnormalities. ST-T wave changes and Q-T-interval prolongation may be evident. Decreased peripheral adrenergic activity with normal adrenomedullary function results in bradycardia and orthostatic hypotension.

Dermatologic changes include pedal or pretibial edema with or without hypoalbuminemia, excessive loss of subcutaneous fat, brittle hair and nails, pellagra or scurvy, and petechiae or purpura.

Peripheral neuropathy, most likely a product of chronic malnutrition, is a notable complication.[5] Localized compression neuropathies secondary to subcutaneous tissue loss can also develop. Some patients experience paresthesias of the fingers and toes. Deep tendon reflexes may be diminished, and gross motor coordination may be impaired.

Anorexics are especially likely to be compulsive exercisers. Stress fractures[6] in the feet, march hemoglobinuria, and various musculoskeletal overuse syndromes have been identified as complications of compulsive exercise.

Osteoporosis is common in anorexics. It usually affects the femur, radius, and spine, in order of decreasing frequency. Estrogen deficiency is not a major causative factor. Any patient with an eating disorder who has been amenorrheic and low in weight for more than a year should undergo bone-density studies. A femur fracture has been reported in a young anorexic who tripped on a rug. [6]

Adolescent diabetics induce ketosis by skipping insulin for a day or two to lose weight; sometimes they overeat and increase insulin in compensation. The abuse of insulin and food can lead to severe metabolic consequences. Young diabetics with frequent hospitalizations should be evaluated for a coexisting eating disorder.

PSYCHOLOGICAL PRESENTATIONS

In addition to the presenting physical symptoms, psychological manifestations may be detected on emergency evaluation. Depression, including suicidal ideation, is the primary psychological complication of eating disorders. Other psychological manifestations include obsessive-compulsive personality traits, with rumination about food, calories, and weight. Ritualistic eating and exercising behavior are also evident. Perfectionistic striving often results in deterioration of friendships and leisure activities.

Impulse-control disorder is a psychological complication of eating disorders more commonly seen in bulimics than in anorexics. Other behavioral manifestations include shoplifting and stealing, sexual promiscuity, drug and alcohol abuse, and self-mutilation.

PROGNOSIS

As with most mental illnesses, the earlier the onset, detection, and treatment, the better the prognosis. Eating disorders can have potentially irreversible effects on the physical and emotional growth of adolescents. There is evidence suggesting improved outcome with early treatment, and therefore the threshold for intervention should be lower than with adults. The prognosis for individuals who have engaged in maladaptive eating patterns for years is guarded. Behaviors may remain constant, or the patient may improve briefly and return to the eating disorder during stressful times. Psychological immaturity persists in about 50 percent of the patients, with difficulties in social adjustment, and one-third continue to have problems with eating. Chronicity increases the risk of morbidity.

Despite advances in the understanding of anorexia and bulimia nervosa, eating disorders are still associated with significant long-term rates of morbidity and mortality. Mortality figures range from 2 to 5 percent to a high of 18 percent. Abnormally low albumin levels and low body weight (<60 percent ideal body weight) best predict a lethal course. High creatinine and uric acid levels predict chronicity in anorexics. [7] Death may result from suicide, starvation, metabolic catastrophe, infection, and cardiac insufficiency. Agents used to induce weight loss may lead to fatal complications.

TREATMENT

Emergency management of patients with eating disorders involves consideration of the complications and effects of the disorder. Nutritional rehabilitation should be the primary goal of treatment in both anorexia and bulimia. Anorexics tend to need a very gradual introduction of macronutrients. Bulimics tend to need fewer calories initially, and it is important to normalize the eating pattern.

Normotensive, hypokalemic, hypochloremic metabolic alkalosis is typical of purging eating-disorder patients. They appear to adapt to these metabolic states, and treatment should consider the whole metabolic state. Automatic replacement of individual deficiencies should be discouraged, since this could be dangerous, with fluid overload and overcorrection as common complications.

Medications have been used in eating disorders. The most helpful in anorexia is cyproheptadine hydrochloride (Periactin). Antidepressants have proved useful in bulimics. Fluoxetine (Prozac), imipramine or desipramine, and phenelzine sulfate (Nardil) have been extensively evaluated and found to be useful. [8]

Emergency management is best accomplished using total parenteral nutrition and slowly correcting the metabolic derangement. Cachectic patients do not need or secrete inducible enzymes, such as lipase or lactase. They have reduced gastric emptying and atrophy of the villi of the small intestines. The use of tube feeding can lead to hypertonic dehydration, hypernatremia, prerenal azotemia, and refeeding pancreatitis. Circulatory volume and caloric requirements should be advanced slowly. The refeeding syndrome, with severe cardiopulmonary and neurologic complications, has been described in anorexics and is associated with rapid electrolyte shifts, hypophosphatemia, hypokalemia, and hypomagnesemia.[9] Anorexics usually present with bradycardia, and monitoring the pulse rate may be the simplest, noninvasive way of monitoring fluid replacement. Serum and urine electrolyte, phosphorous, and magnesium levels should be closely monitored.

A period of 48 h in an inpatient setting is essential to determine the extent and severity of the illness and its complications. Eating disorders units are specifically designed for such evaluations, but they can also be performed in a regular medical unit with involvement of a multidisciplinary psychiatric and internal medicine team.

Hospitalization is suggested for the following:

1. Weight loss greater than 30 percent over 3 months
2. Severe metabolic disturbance
3. Depression severe enough to be at risk for suicide
4. Severe binge eating and purging
5. Failure to maintain outpatient weight contract
6. Psychosis
7. Family crisis
8. Need to confront the patient's and family's denial
9. Need for initiation of therapy (individual, family, and/or pharmacotherapy)
10. Complex differential diagnosis

Treatment algorithms for anorexia nervosa and bulimia nervosa appear in Fig. 283-1 and Fig. 283-2.

FIG. 283-1. Treatment algorithm for anorexia nervosa.

FIG. 283-2. Treatment algorithm for bulimia nervosa.

A trial of outpatient psychological treatment can be attempted if food restriction and weight loss are of less than 3 months' duration and if there is a very positive family support system. Referral to a local health professional who specializes in the treatment of eating disorders or to a self-help group can be obtained by contacting the following national organizations:

284 PANIC DISORDER

Susan L. Siegfreid
Linda Meredith Nicholas

Panic attacks are short-lived episodes of anxiety or intense fear, accompanied by a range of somatic symptoms, which may include tachycardia, tachypnea, dyspnea, chest tightness, weakness, nausea, dizziness, and paresthesias. *Panic disorder* is characterized by recurrent, spontaneous panic attacks. Panic disorder may occur with or without agoraphobia, a condition typified by avoidance of places or situations associated with anxiety. Panic disorder with agoraphobia may be severely disabling, as patients may be incapable of functioning socially or occupationally.

Since many of the symptoms of panic overlap with those of acute medical illness, the first point of contact for patients with panic disorder is often the emergency department. Data from the Epidemiologic Catchment Area study found that, when compared with patients who had either other psychiatric or medical problems, patients with panic disorder had the highest rates of use of emergency room services. [1] A study by Simpson and colleagues reported that this increased utilization preceded the diagnosis of panic disorder by up to 10 years. [2] Therefore, it is important for emergency clinicians to understand panic disorder, its common presentations, and its treatment.

EPIDEMIOLOGY

Panic disorder is relatively common, with a national lifetime and 12-month prevalence of 3.5 and 2.5 percent, [3] respectively, and a cross-national lifetime prevalence of 1.6 to 2.2 percent.[4] The age of onset is usually from late adolescence to mid-30s. The incidence may have a bimodal distribution with the first peak in late adolescence, followed by a second, smaller peak in the mid-30s. [5]

Women are two to three times more likely to develop panic disorder than men. There is some evidence that panic attacks may remit during pregnancy, only to be exacerbated in the postpartum period.[6,7] Cultural factors may play a role in the presentation of panic disorder. A study by Bell and coworkers found that sleep paralysis and hypertension are common symptoms of panic disorder in the African American population. [8] *Ataque de nervios* is an anxiety syndrome in Hispanic cultures that, at times, has a similar presentation to panic disorder. [9]

PATHOPHYSIOLOGY

The etiologic basis of panic disorder is not known. It is most likely multifactorial in origin, with genetic, behavioral, and biologic underpinnings.

Family and twin studies suggest a genetic etiology. First-degree relatives of patients with panic disorder have a four- to sevenfold increased risk of developing the disorder,[10] and monozygotic twins have a higher concordance for panic disorder than dizygotic twins. [11]

Cognitive-behavioral theorists propose that panic disorder is a learned response to interoceptive cues. Heightened awareness of body functions and/or cognitive misinterpretation of these cues are postulated to trigger a conditioned fear response. [12] Anticipatory anxiety and agoraphobia develop as a person begins to associate panic attacks with a particular place or situation.

Neurobiologic research into the etiology of panic disorder utilizes two main approaches: studies that use provocative ("panicogenic") substances and studies that use known pharmacologic treatments. These approaches have implicated multiple neurotransmitters or neuropeptides, including norepinephrine, serotonin (5-hydroxytryptamine or 5-HT), g-aminobutyric acid (GABA), and cholecystokinin (CCK) among others.

Panic disorder patients are generally hypersensitive to carbon dioxide inhalation. [13] One model proposes that carbon dioxide stimulates the locus ceruleus, which contains noradrenergic neurons, and induces panic by stimulating norepinephrine release. [14] In addition, there is also some evidence for impaired receptor sensitivity in panic disorder.[13]

Two agents have been reported to provoke panic attacks by effects on serotonergic receptors. Fenfluramine and *m*-chlorophenylpiperazine (m-CPP) both cause panic in challenge tests.[15] Theories that attempt to explain the results of these tests, as well as to incorporate the known efficacy of serotonergic agents in treating panic disorder, include the following: increased sensitivity of postsynaptic receptors, decreased or increased central nervous system serotonin activity, or interactions between serotonin and norepinephrine, GABA or CCK.[13]

Recently, much attention has been given to the neuropeptide, CCK, as an important mediator in panic disorder. It is present in many of the neuroanatomic areas thought to be involved in panic disorder, including the cerebral cortex, hippocampus, and brainstem. A tetrapeptide form of CCK causes panic when administered to panic disorder patients, and its effects are attenuated by imipramine, a tricyclic antidepressant with efficacy in treating panic. [15] There are also close interactions between CCK and GABA, serotonin and dopamine, as well as endogenous opioids and the excitatory amino acid, glutamate. [15]

The provocative agents sodium lactate, yohimbine, and caffeine, which reproducibly induce panic in patients with panic disorder, have not as yet implicated clear mechanisms by which panic attacks occur.

CLINICAL FEATURES

The cardinal features of panic disorder are recurrent, unexpected panic attacks and persistent worry about having another attack and its potential implications, such as heralding a serious medical illness. Panic attacks are of sudden onset and include feelings of apprehension, fear, and discomfort; they are relatively brief, with a peak in about 10 min and resolution within 1 h. The attacks are accompanied by characteristic somatic and/or cognitive symptoms. [5]

Somatic symptoms are referable to the major organ systems in the body. Cardiovascular complaints include palpitations/tachycardia or chest pain/discomfort. Respiratory symptoms of shortness of breath or the sensation of being smothered are common. A choking sensation and nausea or gastric distress comprise the majority of gastrointestinal complaints. Neurologic symptoms include dizziness, unsteadiness, light-headedness, trembling, shaking, or paresthesias. Sweating, hot flushes, or chills are also common. Cognitive symptoms include feelings of unreality about or being detached from one's environment (derealization) or one's self (depersonalization), as well as the fear of going crazy, losing control, or dying. [5] Some patients alter their behavior to minimize their risk of having more panic attacks, even to the point of becoming fearful of leaving their home and being in places or situations where escape or finding help would be difficult if a panic attack occurred (agoraphobia). [5]

DIAGNOSIS

The panic attacks must not be better accounted for by another psychiatric or medical disorder (Table 284-1). The patient's age, presenting symptoms, time course of symptom development and resolution, and lack of other identifiable medical causes are often helpful in considering the differential diagnosis of a panic attack. [16] For a diagnosis of panic disorder, a patient must have recurrent, unexpected panic attacks followed by at least a month of persistent fear of having additional attacks, worry about the implications or consequence (e.g., going crazy or having a heart attack), or a significant change in behavior. [5]

TABLE 284-1 Medical Differential Diagnosis of Panic

Psychiatric Differential Diagnosis

A panic attack is an episode of intense fear that develops abruptly and reaches a peak within 10 min. During a panic attack, at least four of 13 characteristic symptoms must be present, as listed in Table 284-2. Panic attacks are characterized in the *Diagnostic and Statistical Manual of Mental Disorders,* 4th edition (DSM-IV), as (1) *unexpected* (uncued), (2) *situationally bound* or cued (i.e., always occurring with exposure to a specific trigger), or (3) *situationally predisposed* (i.e., likely to occur in exposure to a given situation). Situationally bound or predisposed panic attacks may occur in association with a wide range of psychiatric disorders, including social phobia, specific phobia, acute or posttraumatic stress disorder, separation anxiety disorder, obsessive-compulsive disorder, and depressive disorders. The occurrence of spontaneous or unexpected panic attacks is necessary for a diagnosis of panic disorder. Patients should always be questioned regarding what situation triggered the attacks. It is often useful to ask if their panic attacks occur "out of the blue" or to inquire if they are ever awakened by panic attacks, in order to determine if the panic attacks are spontaneous versus triggered.

Somatic Symptoms	Cognitive Symptoms
Palpitations, pounding heart, or tachycardia	Fear of losing control
Sweating	Fear of dying
Sensations of shortness of breath or smothering	Derealization (feeling of unreality) or depersonalization (feeling detached from oneself)
Trembling or shaking	
Feeling of choking	
Chest pain or discomfort	
Nausea or abdominal distress	
Feeling dizzy, unsteady, light-headed, or faint	
Paresthesias	
Chills or hot flushes	

TABLE 284-2 Symptoms of a Panic Attack

Medical Differential Diagnosis

Patients presenting with multiple somatic complaints consistent with a panic attack, even if they are known to have panic disorder, should have a thorough medical history documentation, physical examination and, when indicated, other specific tests performed to rule out medical causes. The differential diagnosis is quite extensive, as listed in Table 284-1 , and panic disorder is a diagnosis of exclusion.

The psychosocial history should include questions regarding substance use, situational psychosocial stressors, partner violence, and sexual abuse or assault that may be exacerbating or precipitating panic attacks. The clinician should carefully review the patient's concurrent medical problems, as well as prescribed and over-the-counter medications. Substance intoxication and withdrawal states may also induce panic. A history of caffeine use is important, as panic patients are often exquisitely sensitive to methylxanthines.

Physical exam findings in panic patients most commonly are transient tachycardia and mildly elevated systolic blood pressure. Laboratory findings, when present, are most consistent with hyperventilation with low levels of sodium bicarbonate. The presence of any medical abnormalities suggests a diagnosis other than panic disorder.

ASSOCIATIONS

Panic disorder is closely associated with other psychiatric and medical conditions. Comorbid psychiatric disorders include depression in up to 50 to 65 percent, other mood disorders, substance abuse and dependence, posttraumatic stress disorder, other anxiety disorders, and personality disorders. [5] Certain medical conditions have been associated with panic disorder but are unrelated to its etiology. Panic disorder has well-documented associations with mitral valve prolapse and asthma. [5] Other medical conditions such as idiopathic cardiomyopathy, hypertension, atypical chest pain without evidence of coronary artery disease, irritable bowel syndrome, chronic obstructive pulmonary disease, Parkinson's disease, and migraine headaches have also been associated with panic attacks. [17]

COURSE

The course of panic disorder is variable in frequency and severity. Some patients suffer only intermittent attacks, whereas others have attacks almost continuously. In general, the course of the illness is chronic, with a waxing and waning pattern. Panic disorder patients also can have situationally predisposed attacks when exposed to certain cues or triggers, limited symptom panic attacks in which fewer than four of the 13 recognized diagnostic somatic or cognitive symptoms occur, and nocturnal panic attacks. A 4- to 6-year follow-up study of patients from a tertiary care setting after treatment showed that 30 percent were asymptomatic, 40 to 50 percent were improved, and 20 to 30 percent remained the same or were worse.[18] Lifetime rates of suicide attempts are similar for patients with uncomplicated panic disorder and uncomplicated major depression (7 and 7.9 percent, respectively), whereas rates for patients with comorbid panic disorder and depression are 19.5 percent. [19] Thus, panic disorder should be diagnosed and appropriately treated in order to prevent significant morbidity and mortality.

TREATMENT

Treatment of panic disorder starts with recognition of the illness. Ballenger [20] has proposed that the following screening question be asked of patients for rapid

identification: "Have you experienced brief periods for seconds or minutes of an overwhelming panic or terror which was accompanied by racing heart, shortness of breath or dizziness?"[20] Once panic disorder is diagnosed, the next step is to educate the patient about the disorder, providing reassurance that they are not dying or going crazy, and emphasizing that it is an illness that can be effectively treated. A study by Swinson and colleagues found that, in addition to education and reassurance, instruction on exposure to the situation that triggered the panic attack was potentially helpful in reducing the long-term sequelae of panic disorder. [21]

Both cognitive-behavioral therapy (CBT) and pharmacotherapy are effective treatment modalities for panic disorder. [22] Choice of treatment is based on an individual assessment of risks, benefits, efficacy, availability, acuity, and patient preference. Both CBT and pharmacologic treatment, with the exception of benzodiazepines, take at least 4 weeks for most patients to notice significant benefit. If there is no improvement within 6 to 8 weeks of a particular treatment, often a different treatment is required or combined CBT and medication is used.

Cognitive Behavioral Treatment

CBT involves education about the disorder, symptom and thought records, learning anxiety management skills (e.g., breathing retraining), changing cognitions associated with panic attacks (cognitive restructuring), and exposure to feared situations, usually utilizing a hierarchy created by the patient and therapist. [22]

Medications

Four classes of drugs have been found to be effective in treating panic disorder: selective serotonin reuptake inhibitors (SSRIs), tricyclic antidepressants (TCAs), monoamine oxidase inhibitors (MAOIs), and benzodiazepines. Table 284-3, Table 284-4, Table 284-5 and Table 284-6 list some of the advantages and disadvantages of each class.

Advantages	Concerns
Single daily dose	Delayed onset
Treats comorbid depression	Initial stimulation
Safety	Sexual side effects
Well tolerated	Requires dose titration
No abuse potential	
Demonstrated efficacy	

TABLE 284-3   Selective Serotonin Reuptake Inhibitors

Advantages	Concerns
Single daily dose	Delayed onset
Treats comorbid depression	Anticholinergic effects
Demonstrated efficacy	Postural hypotension
Generics available	Sexual side effects
No abuse potential	Weight gain
	Initial stimulation
	Dangerous in overdose

TABLE 284-4   Tricyclic Antidepressants

Advantages	Concerns
Single daily dose	Delayed onset
Treats comorbid depression	Drug interactions
Effective	Dietary restrictions
No abuse potential	Sexual side effects
	Weight gain
	Dangerous in overdose

TABLE 284-5   Monoamine Oxidase Inhibitors

Advantages	Concerns
Rapid onset	Discontinuation reactions
Demonstrated efficacy	Sedation
Well tolerated	Multiple daily dosing
General antianxiety effects	Abuse potential
Relatively safe in overdose	Dependence
Generics available	Inter-dose rebound
Tolerance rare for antipanic effects	

TABLE 284-6   Benodiazepines

ANTIDEPRESSANTS   Treatment with antidepressants is considered by many clinicians to be the mainstay of treatment for panic disorder, since the potential complications of abuse, dependence, and withdrawal are not associated with their use. Additionally, antidepressants may be beneficial in treating comorbid depression disorders. Due to safety considerations and side-effect profiles, SSRIs are considered the drugs of choice. Although sexual side effects may be problematic with all three antidepressant classes, SSRIs lack the anticholinergic side effects, cardiovascular effects, and toxicity in overdose associated with TCAs or

MAOIs. However, SSRIs are likely to be more expensive than generic TCAs or benzodiazepines.

When initiating treatment with SSRIs and TCAs, the starting dose should be lower than that used to treat depression, because panic disorder patients often are extremely sensitive to side effects. It is helpful to advise patients that they may temporarily notice some increased anxiety or activation when initiating treatment or increasing the dose. Patients should also be told that it might take several weeks before there are noticeable benefits.

MAOIs are usually reserved as second-line treatment due to the dietary restrictions and risk of hypertensive crisis. Interestingly, controlled studies with MAOIs were done prior to the introduction of the panic disorder diagnosis in the 1980 DSM-III and examined the use of phenelzine for treatment of "phobic neurosis." [22] Studies of the use of reversible monoamine oxidase inhibitors (RIMAs), which do not require adherence to a tyramine-free diet, have showed effectiveness in treating panic and phobic symptoms.[23,24] Currently, RIMAs are not approved for use in the United States.

BENZODIAZEPINES   For patients in whom more rapid control of panic symptoms is necessary, such as those who are unable to fulfill expected major psychosocial obligations (work, school, etc.), benzodiazepines may be the drug of choice. Alprazolam has been the most extensively studied benzodiazepine and is currently the only one approved by the Food and Drug Administration for treatment of panic disorder. It may be initiated at a dose of 0.5 mg four times daily. In double-blind studies, alprazolam, in the 5- to 6-mg/day dosage range, reduces panic attack frequency, anticipatory anxiety, phobic avoidance, and disability. [22] Studies suggest that diazepam, lorazepam, and clonazepam in equivalent doses may also be effective in treating panic disorder.

Benzodiazepines may also be administered acutely for a patient who is having a panic attack, regardless of the etiology of the panic. They should be used with caution in patients with a respiratory disorder or in those who have a history of substance abuse or dependence.

It may be beneficial to initiate treatment with both an antidepressant and a benzodiazepine, with the goal to later taper or minimize the benzodiazepine dose as the antidepressant begins to control symptoms. A controlled trial of alprazolam as an adjunct to imipramine during the first 4 to 6 weeks of treatment demonstrated that patients receiving both drugs had a more rapid therapeutic response. [25] However, 10 of 17 patients were unable to discontinue the alprazolam in 2 weeks following the treatment period. Thus, the benefits of a rapid response must be weighed with the risk of difficulty in discontinuing the benzodiazepine.

Both CBT and pharmacologic treatment, with the exception of benzodiazepines, take at least 4 weeks for most patients to notice significant benefit. If there is no improvement within 6 to 8 weeks of a particular treatment, often a different treatment is required or combined CBT and medication are used. Acute treatment usually lasts at least 12 weeks. If medication is being used, often a taper and discontinuation are attempted after 1 year of maintenance treatment. It is unclear whether further CBT sessions ("booster sessions") are beneficial in prevention of relapse. Relapse is treated with CBT and/or medication.

DISPOSITION

Usually, treatment for panic disorder can be initiated in an outpatient setting. If a patient is already being treated for panic disorder, consult with the treating physician before initiating or changing medication. Psychiatric consultation in the emergency department is an option, if consultation is available. The patient should be referred to his or her primary care physician or a psychiatrist for follow-up care.

Patients who are suicidal or who are so incapacitated that they are unable to care for themselves require psychiatric hospitalization. In such cases, a psychiatric evaluation is necessary to determine the extent of dangerousness and need for inpatient treatment.

285 CONVERSION DISORDER

Gregory P. Moore
Kenneth C. Jackimczyk

For a diagnosis of conversion disorder to be made, the following five criteria must be met: [1]

1. A symptom is expressed in which there is a change or loss of physical function suggesting a physical disorder.
2. The patient has experienced a recent psychological stressor or conflict.
3. The patient unconsciously produces the symptom.
4. The symptom cannot be explained by a known organic etiology or culturally sanctioned response pattern.
5. The symptom is not limited to pain or sexual dysfunction.

PATHOPHYSIOLOGY

An illustrative example involves the case of a young wife who is scheduled to visit her debilitated father in the hospital. His recent diagnosis of cancer has left her distraught, and the sight of him depresses her greatly. On the morning of her visit, she suddenly becomes blind.

This example typifies a conversion disorder in which conflict is caused by the patient's intense, but psychically unacceptable, urge to avoid a required action (in this case, visiting her father). The physical symptom (blindness) allows expression of the urge (how can she drive there if she is blind?) without consciously confronting the feelings that led to the wish. At the same time, the symptom imposes morbidity as a punishment for the wish. Often, the presenting symptom will have a symbolic relationship to the conflict, but this is not always the case. In this case, the sight of her father is distressing and therefore loss of sight is the chief complaint. Conversion disorders are often thought of as nonverbal exertion of control on the environment. Two mechanisms are responsible for the symptoms. The first is *primary gain,* in which the symptom allows patients to avoid confronting their uncomfortable feelings. The second is *secondary gain,* in which uncomfortable situations are avoided and support is given that might not normally be available. In the aforementioned case, secondary gain would occur if the patient's husband then stayed home from work to tend to his "blind" wife.

Conversion disorders are described as rare, with an annual incidence in outpatient psychiatric settings of 0.01 to 0.02 percent. An incidence of 5 to 16 percent among inpatients with psychiatric consultations has been noted. Most agree that the incidence is declining. Cases predominantly involve neurologic and orthopedic manifestations, and are seen in the military during times of war, in victims of industrial accidents, and in victims of violence. Conversion disorders are much more frequent in women than men, accounting in the former for up to 80 percent of cases in some series. The most common ages of presentation are adolescence or early childhood, although other age groups are also affected. Conversion disorders are more prevalent in rural, lower socioeconomic, and less educated populations. Other predisposing factors include medical illness, depression, anxiety, schizophrenia, somatization disorder, dependent personality disorder (5 to 21 percent of patients), borderline personality disorder, and passive aggressive personality disorder. [2,3]

CLINICAL FEATURES

Conversion disorders usually present as a single symptom with a sudden onset related to a severe stress. Precise history taking is imperative for making the diagnosis, focusing both on how the problem affects the patient and the surrounding events at time of onset. It may be necessary to interview the patient and family separately to confirm diagnostic suspicions. The most reliable diagnostic criterion for conversion disorder is either a previous history of it or a somatization disorder (each found in one-third of cases). Symptoms may vary in cases of recurrence. [2,3 and 4]

Motor complaints, usually involving voluntary muscles, are more common than sensory complaints. [2,3 and 4]

Rarely, the autonomic and endocrine systems are involved. Vomiting can be a psychogenic manifestation of disgust, and pseudocyesis (false pregnancy) can represent either a wish for or fear of pregnancy.

Classic symptoms of conversion disorders include paralysis, aphonia, seizures, coordination disturbances, akinesia, dyskinesia, blindness, tunnel vision, anosmia, anesthesia, and paresthesia. Pseudoseizures represent 10 to 40 percent of conversion disorders referred to psychiatrists. Patients may describe their condition with surprising lack of concern, considering the severity of the symptom (*la belle indiffeérence*). This was previously thought to be a hallmark of the disorder, but it is absent in about half of the cases and is found just as often in patients with organic disease. It is no longer considered diagnostic. [2,5]

Diagnosis is made first and foremost by ruling out organic pathology. Absence of a medical condition does not solely support the diagnosis of conversion disorder because the appropriate psychological criteria must also be met. Suspicion for the disorder should arise when no physical findings related to the symptom are found or the examination is not consistent with known anatomic or pathophysiologic states. Several techniques that can be used in the physical examination are helpful in testing for true neurologic deficits (Table 285-1). Appropriate laboratory and ancillary studies should be ordered to confirm suspected organic disease. It is important to remember, however, that organic disease may be present concurrently with conversion disorder. [6]

TABLE 285-1 Physical Examination Techniques Used to Distinguish True Neurologic Deficits and Conversion Disorder

DIFFERENTIAL DIAGNOSIS

Careful history taking and physical examination should be used to rule out neurologic disease. A high index of suspicion should be maintained for physical disorders that have a vague onset, such as systemic lupus erythematosus, multiple sclerosis, polymyositis, Lyme disease, and drug toxicity or poisoning. Schizophrenia and depression may have associated conversion disorders. In somatization disorders, the symptoms are more chronic and involve multiple organ systems. With hypochondriasis, patients are usually without loss of function and display the conviction that some terrible undiscovered illness is present. Hypochondriacal patients will be overly concerned with symptoms. In cases of factitious symptoms, usually associated with malingering, patients will consciously complain about symptoms to

get out of undesirable duty or to receive sympathy or undeserved compensation. These patients rarely have neurologic complaints. [7] Amobarbital interviews have been used to diagnose both conversion disorder and/or coexisting diagnoses. They may be therapeutic as well. [8]

TREATMENT AND PROGNOSIS

The patient does not have the insight that the symptoms have no organic cause. Confronting the patient and insisting that nothing "real" is wrong is not helpful in alleviating symptoms and may worsen the patient's condition. The symptoms should be neither trivialized nor reinforced. If the precipitating factor is identified, correction of the situation should be attempted. Meanwhile, the patient should receive reassurance that no serious medical problem has been identified. If both the results of initial testing and exam are negative, it should be suggested to the patient that the symptoms will resolve. Nonspecific supportive therapy should be prescribed. For instance, in the example cited at the beginning of this chapter, it could be suggested that the patient visit her father less often, call daily instead, and have her husband accompany her to the hospital. She should expect the blindness to resolve if she follows this course. [2,9]

Referral is mandatory. Patients with conversion disorders may need repetitive reassurance and suggestion that symptoms will resolve before returning to full function. Periodic follow-up is also important to monitor for subtle organic disease. Between 25 and 50 percent of patients diagnosed with conversion disorders later develop serious organic conditions. [2,10]

Most conversion disorders are brief and quickly resolve. Favorable prognostic factors are (1) lack of other psychiatric disorders, (2) sudden severe stress as a precipitating cause, and (3) absence of medical problems. Some cases are resistant and require hypnosis or amobarbital interview for resolution. This should be coordinated by the primary care provider. Lorazepam has also been found helpful in management of this condition. Approximately 25 percent of patients will have another episode over the ensuing 1 to 6 years, which may involve the same or a new symptom complex. [2,10]

Some patients develop a chronic form of the disorder with complications including contractures and atrophy of muscle groups. In addition, unnecessary diagnostic tests may lead to iatrogenic complications.

INTRODUCTION

Of the 90+ million emergency department (ED) visits in 1995, 339,000 (0.4 percent) deaths occurred in the department. [1] The timing and nature of death is often unexpected and traumatic to the survivors. In one study, 65 percent of ED deaths were considered unexpected versus 7 percent of inpatient deaths. [2] Compounding this difficult, acute situation the ED staff generally have no prior relationship with the patient or the family. [3]

Death notification training is deficient throughout medical education. Medical students question how well they are prepared to tell a family about death. [4] One-half of emergency physicians report training in death notification during medical school, and only one-third during residency. Seventy percent of ED physicians find death notification to be emotionally draining. Without proper training, this role is even more difficult. [5] Educational programs involving videotaping of death notifications and role playing can assist physicians in developing the necessary skills. [6,7 and 8] The ED staff can become desensitized, or preoccupied with moving on to the living patients who are waiting. One-quarter of families describe the ED staff as cold, unsympathetic, and not reassuring. [9]

PREPARING FOR NOTIFICATION

An organized approach is essential (Table 286-1). A secluded area close to the ED is available for the family and friends. This area includes a telephone to allow the contact of relatives, friends, and other supporters. Ideally, a member of the clergy or a social worker is present during the discussions. If the family arrives while resuscitation efforts are continuing, a physician or trained member of the hospital staff informs them of the resuscitation and its progress. Updates are given frequently (every 5 to 10 min) until the effort concludes. [10] Sharing information and empathy during this time allows family members to become knowledgeably prepared for the potential outcome.

Preparation—Private area/room set aside. Family gathered. Family advised of ongoing efforts if any. Social services/chaplain contacted. Physician mentally and physically prepares.

Notification—Introduce yourself and identify family members. Sit down. Give brief synopsis of events to date. Express sympathy and tell the family that the patient has died.

Grief Response—Give physical comfort if able. Do not move away. After initial response, ask one of group a question about the patient. Reassure family that no suffering was involved, if appropriate. Support other physicians/EMS where possible. Stand up. Advise family that you will contact family physician and coroner. Leave the room.

Viewing the body—Allow the family to view the deceased. Don't force a viewing. Body is prepared prior to viewing. Member of staff accompanies family.

Concluding process—Express condolences. Ask if family has further questions. Inquire about autopsy/organ donation. Sign papers. Identify those at risk for pathological grief. Avoid prescribing sedatives. Arrange follow-up as appropriate. Tell the family when to leave.

Source: Modified from Hamilton[10] and Walters.[1]

TABLE 286-1   Sequence of Events

The emergency physician must prepare prior to speaking with the family. After leaving the resuscitation room, the physician must mentally "change gears" over 15 to 30 s. Knowing what to do and what to anticipate can be reassuring. A calm demeanor is essential for effective communication with the family. It is important to collect one's thoughts and organize the presentation. If clothing is soiled, it is changed before the notification. An appropriate amount of time is allotted. Other tasks in the department are delegated to others, or families are informed of the reason for delay. Advance information about which family members are present and their preparation is obtained when possible. This information can be gathered from the clergy, nurse, or physician who has served as intermediary. It is best not to go alone. If clergy or social services support is not yet present, or will not be available in a timely fashion, nursing staff can be enlisted.

TELLING THE SURVIVORS

It is the physician's responsibility to inform family members of the death. [11] As soon as the physician enters the room, the physician should introduce the team to the patient's family. The leading family member is identified and all parties, including the physician, are seated, if possible. Sitting minimizes the chance of trauma occurring from fainting or falling, and signals the family that the physician will remain as long as is needed. The deceased should be addressed by name. The family is then given a very brief summary of the patient's response to treatment, if any. This should be done in plain language, avoiding medical jargon. After these few brief phrases, the family is told that the patient has died and sympathy is expressed. To avoid confusion, terms such as "passed on" or "no longer with us" should not be used. Providing unnecessary detail before announcing the death can rouse false hopes, and can cause extreme anxiety in family members.

Once the initial statement is made, allow a brief period for the initial grief response (30 to 60 s). The physician may give physical comfort to the family if the physician is comfortable doing so. After the initial delay, asking the most stable survivor for their perception of the event allows the initial presentation of information to conclude. Families may receive some comfort from statements that the patient suffered no pain (if appropriate) and that everything possible was done. They are told that the coroner/medical examiner and their private physician will be contacted. They are also told that the physician will return to answer any questions they may have.[12]

GRIEF REACTION

Individual responses to the death of a loved one vary greatly. The initial response has been described as a "psychic pain spike." Although it lasts only a brief amount of time, usually 5 to 15 min, it occurs. During this period, the family can make no decisions. Once this period of acute grief has ended, the family members will progress through other reactions: denial, anger, and/or guilt. [13]

Denial is one of the more frequent reactions to the news of death. The bereaved family may express disbelief, or insist that the information provided cannot be true. The family may insist upon viewing the deceased, and this should be done when possible. [13] Denial may be a protective mechanism, giving the mind time to absorb the situation. It is accepted and tolerated patiently, allowing the bereaved some time to adjust. [3]

Family who find difficulty accepting death may find an outlet in anger. This may be directed at the physician or staff. Accusations of negligence or statements about

what should have been done may be often made. Although difficult to accept, the physician must see these as expressions of grief. This anger is often misplaced guilt at causing or failing to prevent the death. Unconscious frustration with the deceased for abandoning the bereaved can find its outlet in anger directed at others. A defensive posture on the part of the physician is counterproductive. Reflecting the family members' feelings back to them, and not accepting them personally, is the best response. Eventually the anger will dissipate, allowing the family to move on with the grieving process. The physician's handling of this immediate response is an important step in facilitating grief.

Guilt is a nearly universal emotion in the grieving process. There may be issues between the deceased and the bereaved that can no longer be resolved. It is important to intercept survivor's self-accusations and to address the components of survivor's guilt where possible. Exoneration by the physician can be very comforting.[3]

The emotional response to the news of death is dependent upon the cultural background of the bereaved. Responses vary from hysterical crying to cold distraction. Regardless of the initial response, the bereaved must be allowed to express their feelings. The physician's response to these expressions is one of calm and silence. If possible, gently touching the bereaved can be more important than any words. Clichés such as "It's God's will" or "Life must go on," should be avoided. [13]

Normal grieving lasts six to eight months. Physical symptoms include headache, irritability, fatigue, insomnia, restlessness, dyspnea, or anorexia. Emotional symptoms include guilt, denial, anger, depression, difficulty concentrating, lack of organization, and preoccupation with the deceased. These symptoms become pathological grief if persistent over a prolonged period of time or with heightened intensity. Other manifestations of pathological grief may include an exacerbating or remitting pattern of grief or signs of physical disability. Pathological grief can be seen with multiple symptoms including apathy, panic attacks, overactivity, hostility with paranoia, suppression of hostility with resultant flat affect, depression, or symptoms resembling those of the deceased. [3]

Recognition of survivors at risk for or manifesting pathological grief allows for early intervention. Risk factors for pathological grief include sudden or unexpected death, death of an infant or child, death involving suicide or homicide, or death where guilt may be appropriate (i.e., survivor contributed to the death). The death of a spouse is a particularly significant risk factor for pathological grief. A surviving spouse with children may not have time to mourn appropriately. Those spouses with a high-conflict relationship, long duration of marriage, or a dependent relationship upon the deceased are particularly at risk. In the 2 years after losing a spouse over 50, the risk of the survivor dying is increased over fourfold. [3,14]

Physicians may be asked to provide sedatives, tranquilizers, or sleeping medications for the bereaved. The grieving process requires active work on the part of the bereaved. The survivors must learn to adjust to the absence of the deceased, form new relationships, and learn to live in their environment without their loved one. This process is delayed by tranquilizing medications. Their use is to be avoided except in cases of pathological grief and then only as part of a comprehensive psychotherapy plan. Requests for medication should be met with empathy and reassurance.

VIEWING THE BODY

After the family has undergone the initial grief reaction, they should be offered an opportunity to view the body of the deceased, without pressuring them to do so. Failure to view the body may prolong the process by not permitting the survivors to believe the person is really dead. [3,9,15,16] While most find viewing the body to be a helpful experience, those who do not view the body express no regret about their decision. [17]

The body is prepared prior to viewing. Blood and body secretions are cleaned off. The eyes are closed and the body is covered except for the hands and face. If permitted by the circumstances and local protocol, tubes and catheters are removed. If disfigurement has occurred, these areas are bandaged. The family is warned about the temperature and color changes of the deceased. The body is placed in a smaller room away from the treatment area to give the mourners more privacy. The physician, clergy, or nursing staff accompanies the family to provide support or answer questions. The family is encouraged to speak to and touch the deceased if they wish. A family member may wish to be alone with the deceased. This is permitted in appropriate circumstances; a staff member should remain close by for support. The deceased should be referred to by name or "him" or "her" and never by "it" or "the body." [3,11,13]

CONCLUDING PROCESS

Even after the family has an opportunity to view the body, there are several important processes left. Now is the time to make requests for autopsy and organ donation. Any signing of papers is done at this time and copies are given to the family. Any further questions are addressed at this time. Arrangements for funeral home and release of the body are made. The family is told that the patient's private physician will be contacted. [11] The physician and staff should be sympathetic but not apologetic. Families may misinterpret such expressions as an admission of guilt. Expressions such as, "You have my sympathy," or "I know this is very hard for you," are superior to, "I'm sorry."[3,11]

As in any other emergency encounter, follow-up arrangements conclude the visit. The survivors are educated about common grief symptoms. They are told to expect these as a normal part of grieving. At the minimum, the family should have the name and number of a staff member who can provide further information or answer questions that may arise.[11] Most authors recommend a follow-up phone call or letter within one week and again in two months.[3] One facility has established a program in which the staff sends a sympathy card, phone calls are made periodically during the year following the death, and the attending physician sends a letter explaining the autopsy findings.[5]

Finally, the family is told that it is time to leave. Survivors are frequently so overwhelmed with events that they do not know when to leave. They are escorted to the door and given reassurance again. Suggestions are made about contacting other friends or family for notification and funeral preparations.

SPECIAL CONSIDERATIONS

Long Distance Notification

If the survivors have not been notified of their family member's arrival in the ED, then initiate telephone contact. The caller should identify him- or herself and establish the identity of the survivor. Ideally, death notification is not made over the phone. The survivor is told that their relative or friend is severely injured or ill and that they need to come to the hospital immediately. Instruct them to drive carefully. [18]

There are times when distance, environmental, or other factors make physical notification inadvisable. One study showed that many survivors preferred to be notified by telephone if the driving time exceeded one hour. [19] Notification should not be rushed but should proceed in the same fashion as if done in person. The notification should not be forced; if the family member seems unprepared, offer to speak with another family member in the home or another relative. After the notification is made, if the survivor is alone, offer to contact some supporting person. If pathological grief is present, ensure the safety of the survivor by contacting other supporters to attend them. If the survivor appears suicidal, local police may need to be contacted. If no adult is present, ask the oldest child how to contact an adult relative. Assure the child that an adult will be contacting them shortly. Depending on the circumstances (distance, time of day, weather), the survivor should be instructed to come to the hospital driven by some supporter. [18,19]

Coroner's Cases

In most states, the coroner and/or medical examiner has the responsibility to investigate the cause of death within their jurisdictions. Cases the medical examiner may choose for further investigation include those of a sudden, mysterious, unusual, or unnatural nature. Deaths with a possible public health danger, deaths in police custody or in prison, or violent death (including those resulting from motor vehicle crashes) are also medical examiner cases. Autopsy is usually performed in these cases and the family is informed. Organ donation may still be possible, in consultation with the medical examiner. [11] Prior to viewing of the body by the family, resuscitative lines and tubes must be left in place. Except in very unusual circumstances, such as homicide, the viewing of the deceased is still able to take place.

Autopsy

Despite the clinical advantages of the information gained, autopsy rates have continued to decline in the United States. This decline is primarily the responsibility of physicians. Physicians may believe they already know everything about the case, and not want to stress the family further. Medical students are not taught the

importance of the autopsy. Finally, the Joint Commission on Accreditation of Hospitals eliminated its minimum autopsy rate of 20 percent in 1971. [20]

Advantages of the autopsy include improvement in medical care nearly half the time, frequently by clarifying the diagnosis. [21] Diagnosis of new diseases is aided by the autopsy. Autopsies can assist in the grieving process by demonstrating to the family that they did not contribute to the death. Despite physicians' fear that the autopsy will lead to increased liability exposure, postmortem examinations are more often used as a defense. [22]

Public misperceptions concerning autopsy abound. Some of the misperceptions are that diagnostic tests are infallible; autopsy disturbs the patient's "peace"; bodily mutilation occurs; funeral arrangements will be delayed; it's too late to accomplish anything positive; religious prohibitions are present; the family never gets the results; and if an autopsy is necessary, one will be requested. [23]

The most senior physician involved with the case should approach the family with the request for autopsy. Specific points to be discussed include that the autopsy is done by specialists in pathology (an analogy to surgery may be helpful); specific determination of cause of death may help to dispel any doubt the family has; funeral arrangements will not be disturbed; and no mutilation occurs. [11] If the family is concerned about religious prohibitions, they can be reassured that autopsy is not prohibited by most of the major religions, [24] and can be encouraged to consult with the chaplain. The physician requesting the autopsy must be aware of local and institutional policies regarding billing and payment for autopsies. Many teaching institutions consider the autopsy as part of comprehensive care and do not submit a charge. However, there is great variation on policies in community, state, and municipal hospitals, and the patient's family should be so informed when they make their decision about an autopsy.

Organ Donation

Despite a growing need for transplantable organs, health care professionals are uncomfortable approaching families for organ donation. [25] While actually harvesting organs in the ED would be a rare event, many organs can be harvested up to 24 h after death if the body is refrigerated within 4 h of death. These harvestable organs include such tissues as cornea, bone, skin, tendon, fascia, cartilage, saphenous vein, and heart valves. [26] Contraindications to donation include age greater than 80, death from infectious disease, cancer (although corneas may still be donated), or toxic exposure. [26,27] Patients with fatal exposures to cocaine, ethanol, carbon monoxide, lead, and barbiturates have donated successfully. Consultation with a toxicologist is recommended in these circumstances. [28]

There are several barriers to tissue procurement in the ED. One study showed that only 43 percent of families were approached, with a successful donation rate of 12 percent. Reasons given for not approaching families included coroner's case (35 percent), family not available (20 percent), family too upset (18 percent), deceased medically unsuitable (14 percent), and no patient identification (12 percent). Time constraints are an additional barrier to successfully obtaining donation. Limited time to both develop rapport with families and to allow them to come to terms with the death, along with a busy staff, have been cited as reasons for unsuccessful donation efforts.[26]

The appropriate time to make a request for organ donation is after the family has viewed the body. At this point an interval has occurred from the actual notification and the bereaved have had time to come to accept the death as real. A premature request for organ donation may leave the family with doubts about the resuscitative efforts. The family is informed that they are not charged for any procedures related to the donation and that no alteration in appearance of the deceased occurs. [19]

Pediatric Concerns

Regardless of the etiology of the child's death, survivors are at increased risk of pathological grief. [3] Divorce is common after the death of a child.[29] Parents of deceased children display a wide range of emotional responses, but anger and guilt with associated despair predominate. [30] These emotions may be related to a sense of failure of the parent's protective role. [31] Both parents are equally devastated and unable to support each other adequately. [15] The need to care for surviving children may not allow time for proper grieving to occur. In particular, a perinatal death with either a surviving twin or subsequent pregnancy within five months places families at higher risk for pathological grief responses. [32]

Surviving children are also deeply affected by the death of a sibling. Feelings of abandonment, fear of death, and guilt predominate. If the child wished their sibling dead at a time near the death, they may believe that their "magical" thinking was causative. [15] Parents, unable to deal with their own grief, may explain the death in misleading or vague terms.[3]

The autopsy is particularly helpful in cases of pediatric death. It gives an organic, identifiable cause of death, helping to alleviate guilt. It can offer a source of comfort to the family that the knowledge gained may be useful in helping other children. Organ donation is also useful in this fashion. [3,15,33]

287 PATIENTS WHO ABUSE ALCOHOL AND OTHER DRUGS: EMERGENCY DEPARTMENT IDENTIFICATION, INTERVENTION, AND REFERRAL

Edward Bernstein
Judith A. Bernstein
Gail D'Onofrio

BACKGROUND AND RATIONALE

Epidemiology

Alcohol is implicated in more than 100,000 deaths annually in the United States, including 30,000 from unintentional injury and 17,700 from intentional injury. [1] Illicit drug use is associated with over 20,000 deaths, [1] more than 500,000 emergency department (ED) visits, [2] and one-third of the newly diagnosed cases of AIDS each year. [3] The economic cost of alcohol and other drug abuse in the United States was estimated at $276 billion for 1995. Alcohol abuse and alcoholism accounted for 60 percent of this figure, while illicit drug abuse and dependence (controlled substances used for nonmedical purposes) accounted for the remaining 40 percent. [4]

Substance abuse not only affects the individual user but has far-reaching implications for families, communities, the workplace, and the health care system. One out of four Americans experiences family problems related to alcohol, and an estimated 28 million children of alcoholics are at risk because of family dysfunction associated with alcoholism. [5] At the end of 1996, 1.4 million incarcerated adults were seriously involved with alcohol and drugs, and these individuals were parents to 2.4 million children. [6] Substance abuse is also a serious problem in American industry, with daily alcohol use by 8 percent of the work force and illicit drug use in the past year by 15 percent. Approximately 70 percent of the illicit drug users are employed. [5] Despite the proven effectiveness of treatment in breaking the cycle of addiction and reducing recidivism, clinical medicine has until recently lacked the social mandate, resources, will, and training necessary to treat alcohol and drug addiction adequately, and has deferred to the criminal justice system. [7]

Emergency Department Recognition of Substance Abuse

The percentage of ED patients who test positive for blood alcohol at the time of the visit ranges from 6 to 34 percent for injured patients and 1 to 19 percent for the noninjured. [8] At the time of an urban ED visit, 17 percent of patients were found to meet stringent criteria for alcohol abuse and 19 percent for alcohol dependency, while only 9 percent of the study group were breath alcohol positive, and only 14 percent reported a drinking problem. Among a 1-year sample of more than 7100 patients presenting to another urban ED, 41 percent ($n = 2931$) screened positive for alcohol or drug abuse on a health-needs history. [9] Rates of substance abuse as high as 50 percent have been reported among trauma patients, [10] and alcohol is a major risk factor for virtually all categories of injury. [11]

Although emergency physicians are experts in the stabilization, diagnosis, and treatment of acute alcohol and drug emergencies and their secondary complications, they often fail to detect and refer patients for treatment of addiction. In one study, for example, while ED physicians documented past or current alcohol use on the ED chart for 69 percent of patients with an elevated saliva alcohol level (reflecting acute intoxication), they documented alcohol use in only 46 percent of those with positive results on a screening test for at-risk behavior or dependence. [12] Referral rates as low as 13 [11] and 23 percent [12] have been reported among ED patients with documented substance abuse problems. As a result, many ED patients who could be assisted in breaking the cycle of addiction continue to visit the ED with trauma and medical problems.

Time constraints, insufficient education, lack of role models in training programs, inadequate treatment resources, and the misperception that the patient's substance abuse is not an appropriate concern for a health-care provider all act as barriers to systematic detection and referral. [11] Provider attitudes of disinterest, avoidance, disdain, and pessimism are also common, especially when physicians are confronted with hostile, manipulative, or combative patients. Negative stereotypes of patients with substance abuse problems may reflect a physician's prior personal or family issues with substance abuse.

Patients with alcohol and drug problems are primarily encountered in the medical, rather than the treatment, system. According to the Institute of Medicine, more than 5 million Americans currently need treatment for drug abuse. [7] In a recent study, only 3 percent of weekly drug users were in contact with the drug treatment system, but 43 percent had encounters with primary health agencies, 39 percent with the criminal justice system, and 10 percent with the welfare system. [13] In addition, the ED is the usual source of extraprison care for many detainees and prisoners, and most of the 5.5 million individuals currently in the criminal justice system either are or will be returned to their communities to become ED patients again.

Emergency physicians have both an opportunity and an imperative to link patients presenting to the ED with the substance abuse treatment system. The ED, with its high prevalence rate, is an excellent site for taking advantage of a teachable moment in order to increase detection and referral rates and reduce harm associated with substance abuse.

Effectiveness of Brief Intervention

The effectiveness of screening, detection, and brief intervention was established four decades ago in an urban hospital ED study by Chavetz and associates. [14] A randomized, controlled trial among a population consisting primarily of homeless men demonstrated that it was possible to enhance the system of care even in such a hard-to-reach group by "establishing emotionally meaningful communication with these patients." As a result of this intervention, 65 percent completed a referral to an alcohol clinic, compared to 1 percent of the control group. Forty percent completed five or more voluntary visits, compared to 0 percent of the control subjects, who were managed by the ED staff in the routine manner.

That ED intervention represented a paradigm shift from the legacy of prohibition, the Harrison narcotics laws, and their underlying perspective of substance abuse as a moral weakness requiring criminal sanctions for individuals with substance abuse problems and penalties for physicians who tried to intervene. Shortly before the Chafetz study was published, the American Medical Association recognized alcoholism as a disease for the first time and encouraged physicians to care for patients with this problem as they would other sick individuals.

Many models for brief intervention have now been tested. A review of 32 controlled trials of brief counseling, primarily in the alcohol field, found that not only was brief counseling more effective than no treatment, but it compared favorably with more traditional treatments in 11 of 13 randomized trials. [15] The elements common to these trials were feedback, responsibility, advice, menu or choice, empathy, and self-efficacy (FRAMES). A World Health Organization study evaluating heavy problem drinkers across 12 nations with very different cultural orientations and social circumstances confirmed these results. [16] A randomized, controlled trial of brief intervention in 17 community-based primary care practices involving 64 physicians and 723 subjects in 10 Wisconsin counties demonstrated significant reductions in alcohol consumption. [17]

Treatment successes have also been associated with significant cost savings. The California Drug and Alcohol Treatment Assessment Study, for example, demonstrated a gain of $7 for every dollar invested in treatment; overall, the $200 million spent on treatment resulted in a $1.5 billion savings for California

taxpayers.[18]

Changing Role of Emergency Department Physicians

In light of the enormous impact of alcohol and other drug abuse on society and individuals, it is no longer sufficient to treat only the emergency condition and the medical complications of substance abuse without providing proper screening, brief counseling, and referral to further treatment when appropriate. Connecticut State Law 472 mandates universal screening in the health care setting and requires documentation of training in intervention for all personnel working in health care institutions and clinical settings licensed by that state.

In the current managed-care environment where hospitals and physicians are competing intensely for market share and beginning to share economic risks with payers of health care, the desire to contain costs has given impetus to efforts to provide a more consistent approach to the needs of the patient with substance abuse. There is a growing recognition of the importance of a public health approach and the need for early identification, intervention, and access to treatment.

Research is currently under way at a number of EDs to discover best practices. A growing number of emergency physicians and nurses are engaged in helping patients with alcohol and drug problems to change negative behaviors. In some EDs, social workers, addiction specialists, volunteers from Alcoholics Anonymous or Narcotics Anonymous, or health promotion advocates (peer educators) are part of a team approach to providing identification, counseling, referrals to the treatment system, and access to primary health care and other needed services (e.g., housing, food, clothing, and jobs). Alcohol and injury studies in Rhode Island, Connecticut, and Georgia use an intervention conducted by social workers. Project Neighborhood in Missouri employs certified substance abuse counselors in an urban ED. A New York State hospital–based intervention program employs nurses who screen patients at the bedside and perform an interview. At Kaiser in Oregon, a health maintenance organization that has a broad series of prevention and intervention programs, patients are screened with a standardized instrument and referred to a health counselor for interview. Harborview Trauma Center employs social workers to intervene at the trauma center.

One of the first of these models to report ED data is Project ASSERT at Boston Medical Center,[9] in which trained community outreach workers from cultural backgrounds similar to those of the patients use a health-needs history to screen for substance abuse and other preventable conditions, and implement a brief negotiated interview (BNI) when substance abuse is identified. Patients are approached in the ED examining rooms in order to evaluate their overall health and safety needs and provide health education and referral. Among 7118 adult ED patients screened for alcohol and drug problems during the first study year, 2931 problem situations were detected and 1096 ED patients enrolled. Among 245 enrollees who participated in a 90-day follow-up, there was a significant reduction in harm at posttest in self-reported behavior, including a 45 percent decrease in drug-abuse severity scores, a 67 percent reduction in the number of enrollees using cocaine or crack, 62 percent reduction in the number using marijuana, a 56 percent reduction in alcohol use, and a 64 percent reduction in binge drinking. Over 50 percent reported following up with a treatment referral. Patients were also linked to primary care and other preventive services. Treatment options were negotiated with patients, and potential treatment slots were explored. Once placement was secured, taxicab vouchers were provided as needed for transportation to the selected facility.

TECHNIQUES FOR IDENTIFICATION AND BRIEF INTERVENTION

Early Identification and Screening in the Emergency Department

CRITERIA   It is important for emergency physicians to distinguish between *at-risk* alcohol and drug abuse and *dependent* use. Any illicit drug use poses potential risk to the user, such as a criminal arrest, cocaine chest pain, seizures, heroin overdose, asthma exacerbation as a result of smoking drugs, and intentional or unintentional injury under the influence of drugs.

For alcohol risk, the National Institute on Alcohol Abuse and Alcoholism (NIAAA) has developed the following definitions for at-risk drinking among individuals between the ages of 21 and 65: for men, 14 drinks per week or 4 drinks per occasion; and for women, 7 drinks per week and 3 drinks per occasion.[19]

According to the American Psychiatric Association criteria,[20] the diagnosis of alcohol or substance *dependence* requires that at least three of the following criteria be present during a 12-month period:

1. Tolerance manifested by the need for markedly increased amounts of substance over time to achieve intoxication or the desired effect or by a markedly diminished effect with continued use of the same amount of the substance
2. Withdrawal manifested by a characteristic withdrawal syndrome or substance (or closely related substitute) taken to relieve or avoid withdrawal symptoms
3. Consuming larger amounts of substance over a longer period of time than intended
4. Persistent desire or unsuccessful attempts to cut down on or control use
5. A great deal of time spent in substance-related activities, such as obtaining the substance, consuming the substance, or recovering from the its effects
6. Important social, occupational, or recreational activities given up or reduced because of substance use
7. Continued substance use despite knowledge of a recurrent psychological or physical problem that is likely to have been caused by or exacerbated by use

HISTORY   Universal screening in the ED would require that the past medical history include such questions as, Has your partner or any one you live with harmed you? Do you smoke? Do you drink beer, wine, liquor, or distilled spirits? Do you use drugs now and then?

An initial history should include questions about smoking first, then use of alcohol, and finally use of illegal substances in order to normalize the questions; create a nonjudgmental, matter-of-fact atmosphere; and thus enhance the likelihood of obtaining accurate information. If the initial response to drinking is positive, NIAAA guidelines recommend using the CAGE instrument, described below, and following up with quantity and frequency questions, such as, How many drinks containing alcohol do you consume in a typical week? and What is the maximum number of drinks you have had on any given occasion during the last month?

Similar questions can be asked for use of illegal substances. Questions about drugs should elicit the type of substance used, the frequency, the quantity (hits for crack and bags for heroin), the route, and whether drugs are used in combination with each other or with alcohol. It is also important to include an inquiry about nonmedical use of prescription drugs, since this is a common source of problems among women. If concerns about drugs and alcohol arise based on these data, it is recommended that brief intervention and referral be delayed to attend to acute medical issues before negotiating behavior change with the patient. Addressing the secondary diagnosis of alcohol and drug abuse dependency should be an integral part of an appropriate and safe discharge and follow-up plan.

SCREENING TESTS   Although the initial history is important, the limitations of making a clinical diagnosis of an alcohol problem based only on blood, saliva, or breath alcohol testing; smell on breath; self-report; or presenting complaint have been described. A brief screening instrument, such as the CAGE test, is easy to administer, assists in identifying dependent drinkers who would benefit from entry into treatment, and may facilitate the process of matching an individual to the most appropriate treatment resource. In one study, 31 percent of patients presenting to an urban ED had positive results on the screening test, while only 13 percent were biochemically positive for alcohol using a saliva alcohol test.[12]

The CAGE, a mnemonic for the following questions, has been studied extensively, is easy to remember, and is easy to use:

C: Have you ever felt that you should *c*ut down on your drinking?
A: Have people ever *a*nnoyed you by criticizing your drinking?
G: Have you ever felt bad or *g*uilty about your drinking?
E: Have you ever had a drink first thing in the morning to steady your nerves or get rid of a hangover (*e*ye-opener)?

A score of 1 or more is positive for females, and a score of 2 or more is positive for males. Although the CAGE test is designed for assessing lifetime dependency, it should be prefaced with the phrase "in the last 12 months" in order to detect current problems. Patients tend to reveal less when the test is preceded by direct, closed-ended questions about quantity and frequency of drinking. Under such circumstances, the ability of the instrument to detect alcoholism is reduced by a third compared to when the test is preceded by an open-ended question, such as, "Do you drink beer, wine, or liquor now and then?"[21] Because of these findings, the CAGE test and other screening instruments should be employed as part of the history of present illness or past medical history, and not be used later in the physician-patient interaction as part of an intervention to change behavior.

The CAGE test has been specifically studied for its applicability to the ED. [8] The *sensitivity* (the proportion of individuals with a condition who have a positive test) was reported as 75 percent for at-risk drinkers, and 76 percent for dependent drinkers. The *specificity* (the proportion of individuals without the condition who have a negative test) was 88 percent for at-risk drinkers and 90 percent for dependent drinkers.

Intervention

VALUE OF BRIEF INTERVENTION IN THE EMERGENCY DEPARTMENT   The best site for intervention is wherever the individuals who need help can be found. The first principle of intervention is that it comes *to* people, instead of people having to seek it out. The second is that it be timely, and the best time for early intervention is the crisis that brings the person with an alcohol or drug problem into the system for a medical, social, or criminal justice problem. An ED visit, for example, appears to be a teachable moment. Brief interventions have been shown to be effective for the at-risk user to negotiate behavior change, and for the dependent drinker and drug user to negotiate referral to treatment. The entire interaction can be accomplished in less than 10 min, and the dialogue can take place either at discharge or while suturing or casting.

INTERVENTION METHODS   The BNI is a dialogue format developed in a busy urban ED for negotiating change in substance-related behaviors. In this method, the practitioner is the facilitator rather than the agent of change. The BNI may result in behavior change for the individual who is at risk and facilitates contact with the treatment system for the individual who is dependent. Through negotiation, patients' needs are tailored to solutions, and patients are matched with treatment modalities they are able to accept.

The BNI is based on the principles of brief motivational interviewing developed by Miller and Rollnick, [22] which are encapsulated in the FRAMES acronym (feedback, responsibility, advice, menu or choice, empathy, and self-efficacy). Brief cognitive motivational intervention also incorporates elements of a stages-of-change model, [23] in which five stages of change with highly predictable patterns are identified: precontemplation, contemplation, preparation, action, and maintenance, with the possibility of setbacks along the spiral pathway. Substance abusers are thought to cycle through these five stages in the course of changing their addiction behavior. Intervention techniques have been developed to suit each of these stages and explore with individuals the pros and cons of their behavior. In this process, the interventionist assists the addicted person to (1) define the problem, (2) identify his or her present stage, and (3) move through the stages of change toward recovery.

The BNI is used to assist patients to recognize and change behaviors that pose significant health risks. The goal of the interaction is to facilitate resolution of ambivalence through exploration of conflicting motivations (the pros and cons of drug use) and negotiate possible strategies for change, depending on the patient's readiness to change. The patient is seen to possess a unique store of knowledge—his or her own life history—that is essential for behavioral change to occur and just as important for achieving the goal as the interviewer's expertise. The BNI is used to increase intrinsic motivation so that change arises from within, rather than being imposed from without. The patient identifies both the problem and the solutions in order to own them. The general principles for successfully negotiating behavior change include (1) respect for the autonomy of patients and their choices; (2) negotiation based on readiness to change, and tailoring of interventions to level of readiness; (3) appreciation that ambivalence is expected, and exploitation of ambivalence is an important tool for facilitating change; (4) selection of targets for change by the patient, not the expert; (5) definition of the expert as a provider of information and support; and (6) reliance on the patient as the active decision maker.[24] "A patient's motivation to change can be enhanced by using a negotiation method in which the patient, not the practitioner, articulates the benefits and costs involved."[25] This theoretical understanding is the basis of the assertion that the BNI is more productive than simple advice.

The BNI protocol is based on mnemonics familiar to all emergency medical specialists, ABC and CPR:

A: Assessment
B: Brief intervention
C: Call back

C: Cultural competence
P: Patient choice
R: Readiness

The BNI consists of the following steps:

1. *Establish rapport with the patient* throughout the clinical encounter. Establish an atmosphere of positive regard in which the patient is not a problem but a person who has a problem.
2. *Ask the patient's permission to discuss the pros and cons of drug use.* Use open-ended questions and empathic and reflective listening. Explore the importance to the patient of the issues that emerge, and establish which of the pros and cons has the greatest salience in order to concentrate on those with the highest priority.
3. *Summarize what the patient says* to indicate that you understand what has been said (and to be sure you are correct in your interpretation). This summary technique can also elicit more information as trust develops.
4. *Ask the patient to describe his or her readiness to change.* A drawing of a ruler with a scale of 1 to 10 is used to elicit readiness to change use of drugs and or alcohol, as well as readiness to enter treatment. The patient points to the location on the scale that describes the current state of readiness for each score.
5. *Negotiate with the patient based on his or her perception of readiness* (not ready, unsure, or ready). Find out where the patient finds him or herself on the readiness ruler on a scale of 1 to 10 (a score of 1 is least ready and a score of 10 is most ready). If the patient is (a) *ready (a score of 8 to 10),* then the interviewer will solicit previous experience in attempting to quit, and brainstorm alternatives; (b) *unsure (a score of 5 to 7),* then the pros and cons of drugs or alcohol use and the pros and cons of change or treatment need to be explored, further assessment may be proposed, and the question posed, What will it take to help you take a few steps toward being more ready, say, going from 6 to 8?; (c) *not ready (a score of 1 to 4),* then the interviewer expresses concern, offers information about the affects of drugs and alcohol, provides a list of resources for further reference, and suggests the possibility of further contact (Table 287-1).

TABLE 287-1   Sample Brief Negotiated Interview Dialogue

THE REFERRAL PROCESS

If a patient is ready to accept referral, a staff member who is familiar with treatment resources can assist the patient in making an appointment or plans to enter a treatment program. Each ED should provide a resource list for staff and a printed handout or brochure for patients with names, addresses, and phone numbers of treatment programs. The following resources should be available: inpatient detoxification; outpatient detoxification; acupuncture; methadone maintenance; outpatient individual and group counseling; residential communities; self-help groups, such as Alcoholics Anonymous, Narcotics Anonymous, or Alanon; programs focused on the needs of women; and programs that are culture specific.

If, for example, a patient who is injecting drugs is not ready to accept an ED referral, it may be possible to negotiate contact with a harm-reduction program, such as a community-based needle-exchange program that provides sterile needles in exchange for potentially contaminated needles. Such programs have documented

effectiveness in reducing the spread of HIV[24,25,26,27 and 28] and hepatitis B and C[29] among injection drug users and are effective in facilitating entry into the drug treatment system.[3]

MEDICAL CLEARANCE FOR DETOXIFICATION

Medical clearance for transfer to a detoxification or other treatment facility should include the following components:

1. *Past history.* Inquire about past history of hospitalization for delirium tremens, alcohol-related seizures, hepatitis, and pancreatitis; screen for severity of alcohol withdrawal signs and symptoms; review past medical illness and medications; and rule out underlying medical conditions related to substance abuse.
2. *Recent history.* Inquire about and document recent falls, assaults, pedestrian or motor vehicle injuries, head injuries, tuberculosis status, and productive cough; and review notes made by the registered nurse, emergency medical technician, or referring facility.
3. *Examination.* Undress the patient completely; perform a careful evaluation for trauma, hypovolemia, and gastrointestinal bleeding, including a rectal examination for stool guaiac if orthostatic vital signs are abnormal or gastrointestinal bleeding is reported; assess and document a set of orthostatic vital signs, including temperature and O_2 saturation by pulse oximetric analysis for patients with history of lung disease or respiratory symptoms; and evaluate the level of withdrawal (e.g., gait, tremulousness, and change in mental status).
4. *Laboratory testing.* Determine the serum glucose level for diabetics and for patients with altered sensoriu; obtain serum levels of lithium and anticonvulsants as appropriate; and obtain serum potassium levels for patients on diuretics.
5. *Mental health status.* Assess for psychiatric issues and obtain a consultation if the patient is dangerous to him- or herself or others.
6. *Specific risk factors.* Assess routinely; for example, think twice about transferring older people with comorbid conditions.
7. *Specific conditions.* Screen and treat for seizure disorder or alcohol-related seizure.
8. *Medications.* Assure that a reasonable supply of medications is sent with the patient until prescriptions can be filled.
9. *Discharge.* Clear only when the patient is ambulatory, alert, oriented, and able to take fluids orally; if pulse is less than 100 beats per minute and body temperature is less than 38.3°C (101°F); and if there is no significant change in mental status.
10. *Document.* Chart a clear plan for safe discharge, including the method of patient transfer to the detoxification facility.

Sanford H. Koltonow

Physician well-being is an important personal and professional issue. Career satisfaction correlates with the following issues: (1) control over working conditions, (2) hospital administrative support, (3) having time for family and personal life, and (4) departmental security. The practice of emergency medicine requires a large knowledge base and advanced cognitive and interpersonal skills. Not quite as obvious is the need for excellent *intrapersonal* skills. Situations arise that conflict with one's personal values and produce intense feelings of uneasiness. To remain effective, coping methods need to be used that are adaptive and resolve conflict. The thought that one can meet *all* of a patient's needs ignores one's own needs for supports and limits.

Stress is necessary as a force that motivates. When excess stress becomes detrimental, it is more appropriately called distress. Much like Starling's law, each individual has his or her own curve with a point beyond which further stress causes less, rather than more, output.

Burnout is a state of physical, emotional, and mental exhaustion that occurs as a result of intense involvement with people over long periods in emotionally demanding situations. Burnout symptoms are characterized, in their extreme form, by physical depletion and chronic fatigue, feelings of helplessness and hopelessness, and the development of negative attitudes toward self, work, life. and others. Among physicians, symptoms of burnout are thought to be potential precursors of more severe manifestations of impairment, including alcoholism, drug abuse, and suicidal ideation.

Emergency physicians practice in an environment that can foster burnout. Critical decisions must be made with incomplete information. Noises, smells, crowding, children, families, terminal illnesses, substance abusers, psychiatric patients, police, and criminals are part of every day. It is easy to become overwhelmed.

The American Medical Association defines an impaired physician as "one who is unable to practice medicine with reasonable skill and safety because of physical or mental illness, including deterioration though the aging process, loss of motor skill, or excessive use ... of drugs, including alcohol." Various estimates of impairment range from 7 to 13 percent. Well before attrition occurs, there are warning signs that, with awareness, can be identified and remedied before a patient's care and a physician's status are threatened.

Suicide, the ultimate manifestation of impairment, accounts for one-third of the premature deaths among physicians. The percentage is higher for women, particularly young women. Annually, over 100 physicians complete suicide.

BURNOUT

This is a condition born of good intentions. Doctors who fall prey to it are, for the most part, individuals who have striven for perfection in their careers. It grows from unrealistic goal setting. Burnout is fostered by common personality characteristics of those that choose and succeed in emergency medicine. Near-compulsive overachievement, denial of one's limits, a low level of trust, distant interpersonal relationships, and independent self-sufficiency are common. An effect is that the processing of deep feelings is repressed. Instead of addressing their own symptoms of personal stress, *physicians tend to project feelings* of irritability, anger, and frustration on others: patients, nurses, and their families.

The ability to dissociate feelings from one's work is an adaptive coping mechanism for working with contagious disease and dangerous situations, but it can also help physicians ignore their own vulnerabilities. They may not recognize the toll that a lifestyle of little sleep, poor diet, and little time for recreation or reflection may be having on themselves and their families. Dissociation becomes deadly when the "it can't happen to me" philosophy is used to justify increasing alcohol and drug consumption or other self-destructive behaviors.

Fear of incompetence is nearly universal among physicians and is the source of many of the stressors related to medical decision making. When dealing with other people's lives, mistakes can have life-threatening ramifications. If one cannot accept his or her limits and the possibility of making a mistake, one must (at least hope to) be perfect and all-knowing, a situation that promotes arrogance and a strong need to defend against perceived criticism. Even symbolic challenges, perhaps by someone asking a question about care or interjecting a different opinion, can strike deep at defense mechanisms, frequently resulting in inappropriate physician behavior.

PROFESSIONAL ENVIRONMENT STRESSORS

Stressors arising from nonmedical issues within the professional environment as well as from a physician's personal environment can also compound the difficulties in providing quality emergency care.

In urban areas, anywhere from 30 to 50 percent of patients receive *all* of their medical care from the emergency department. Their needs can be immense, including such basic needs as food, shelter, heat, and transportation, which makes assisting these patients much more difficult. Additionally, a physician may be drawn into a patient's dependency needs, creating interpersonal conflict.

Emergency departments and physicians are commonly required to become agents of the police and courts. Laws exist that compel emergency physicians' involvement with intoxicated, violent, and psychotic patients. This also may include victims of personal crimes, such as sexual assault and abuse, where physicians must collect evidence for legal proceedings.

Victims of major trauma are frequently victims of crime, and physicians are frequently subpoenaed to provided testimony in legal proceedings, which are inconvenient. In addition, in such settings, it is not unusual to be cross-examined with hostility.

Death and Dying

Death and dying involve physicians in sharing one of a family's most personal and powerful times. Emergency physicians need to become comfortable exploring patient's wishes and informing families of unexpected death and morbidity, for they will be called on to do so often. Empathy requires emotional energy. Speaking with

a grieving family forces a physician to face both system and personal conflicts.

The need of the patient and family for compassion is a difficult process to rush. Their wishes and belief systems deserve exploration. There are questions from loved ones about the events leading up to a death that must be dealt with empathically to facilitate the grieving process. Offering understanding, comfort, compassion, and solace can be important source of satisfaction for physicians. Often, deaths resurrect powerful feelings in physicians, based on prior personal experiences.

Some difficulties of physicians may stem from the belief that a physician's career represents the battle against death and disease. Facing a surviving family or counseling a dying patient may symbolize "failure" in that battle. In addition, a physician can become a target for misplaced anger and denial.

Malpractice Litigation

Universally, physicians feel the need to expend significant resources to prevent malpractice litigation (as opposed to the resources used to prevent malpractice). For those unfamiliar with the process, a medical malpractice lawsuit can be frightening. It seems to strike at one's very being and self-worth. Many physicians will respond with disbelief, then anger, and finally depression. The process of meetings, testimony, and eventually the trial can be dehumanizing. Physicians who succumb to the emotional trauma of a lawsuit respond in such a consistent manner that it has become known as malpractice stress syndrome (MSS).

The single factor most predictive of a dysfunctional response is the experience of isolation. Embarrassment and self-doubt can cause avoidance of one's very sources of support. Colleagues' responses may reinforce a physician's feeling of shame. Knowing the physician is busy preparing a defense, colleagues may change their referral and social patterns, which can be interpreted as judgment about the facts of the case.

Self-doubt frequently carries over to personal life. Either for reasons of not wanting to bring home the pain or from feelings of shame for getting named in a lawsuit, many physicians withdraw from their spouses and families, furthering their isolation.

PERSONAL ENVIRONMENTAL STRESSORS

Sleep Deprivation

Shift work and scheduling difficulties are the most common sources of stress, career dissatisfaction, and attrition in emergency medicine. People who work swing shifts have a shortened life expectancy. Circadian principles acknowledge the body's natural rhythms and can help in integrating one's work schedule with one's personal life and promote quality sleep and, thus, health.

SLEEP PHYSIOLOGY   Sleep occurs in discrete stages. The bulk of delta sleep or *slow wave sleep* (SWS) occurs early in the sleep period. There is an increase in SWS in subjects who perform challenging intellectual tasks. SWS is thought to be vital for *physical* recuperation. Those deprived of SWS often complain of fatigue and muscle aches.

Rapid eye movement (REM) *sleep* is characterized by rapid conjugate eye movements, a change in electroencephalogram to a pattern similar to wakefulness, the occurrence of dreams, increase in oxygen consumption, and increased cerebral blood flow. Those with shorter sleep periods will likely have REM deprivation, which is difficult to make up. REM sleep is thought to be vital for *psychological* well-being. Those deprived of it complain of irritability and moodiness. They also score higher on testing of aggressive behavior. REM sleep may also be important in the consolidation of complex learning. Experimental subjects deprived only of REM sleep but allowed the other phases begin displaying a thought disorder reminiscent of psychosis within 3 to 4 days.

Humans have a 25 h circadian clock. Many physiologic functions follow circadian patterns and can be transposed by keeping experimental subjects awake at night and sleeping during the day. This process is known as *entrainment* of the circadian rhythm. Many circadian patterns have been demonstrated to be sensitive to entrainment, including alertness and basal body temperature. The *primary* stimulus for spontaneous awakening is a rise in body temperature; thus, the duration of the sleep period depends more on the phase of the circadian rhythm than on the prior period of wakefulness. This partly explains why those working short stretches of nights sleep fewer hours during the daytime than those working night shifts regularly, leading to REM sleep deprivation.

Many physicians attempt to use pharmaceuticals to assist them in falling asleep. Essentially all decrease the proportion of REM sleep. Stimulants, including nicotine and caffeine, impede onset of sleep and normal sleep stage progression.

Studies on sleep deprivation show that the ability to perform challenging intellectual tasks is slowed but otherwise relatively unchanged; however, motivation to perform routine tasks is diminished. Because the quality of emergency medical practice often depends on properly performing routine tasks that may follow prolonged periods of intellectual exertion, it is imperative for physicians who work different shifts to schedule themselves in ways that minimize risk to patients.

SUPPORTIVE STRATEGIES   When planning shift rotations, it is healthier to rotate forward (days to afternoons to midnights), since the human circadian rhythm is 25 h long. Many physicians favor 12 h shifts to increase the number of days off. When rotating shifts, however, it takes longer to reset the biologic clock across a 12 h change than it does for an 8 h change (see Table 288-1).

Given the right set of circumstances, the best strategy is to work the same shift all of the time and keep the same sleep pattern.

For those unable to maintain consistent sleep patterns, use compromise strategies such as anchor sleep and napping to mitigate circadian disruptions.

Rotate all shifts in a clockwise direction, with at least 1-month minimum time per rotation.

One or two night shifts in a row causes minimal circadian disruption.

Sleep in a quiet, darkened room, minimizing disruptions. When working nights, give the work schedule to likely daytime callers.

Start the awake period with a high-protein meal and switch to complex carbohydrates toward bedtime. Avoid caffeine and high-caloric, high-fat snack food before sleep. Eat meals regularly.

Use bright light (more than 10,000 lux) for 2 h after rising, as an adjunct for entraining to new shifts.

Get regular exercise. Vigorous aerobic exercise after rising may diminish the time needed to adjust to new shifts. Avoid heavy exertion before attempting to sleep.

Work with family and friends to plan regular quality time together.

Do not try to live a day-shift lifestyle while working night shifts. Hold administrative meetings early in the morning or late in the afternoon when working night shifts. Respect the circadian rights of those working nights by excusing them from meetings held during the day.

Source: Adapted from Whitehead et al, with permission.

TABLE 288-1   Strategies and Recommendations to Assist in the Health of Shift Workers

The circadian "gold standard" is not to change shifts at all, but those working only night shifts must maintain a daytime sleep pattern, even during days off, to avoid reentrainment to a daytime pattern. Working nights for long periods is difficult due to pressures to participate in daytime family and social activities or to be involved regularly in administrative activities.

There is a compromise known as *anchor sleep*, which minimizes circadian disruption. By sleeping a block of at least 4 h at the same time every day, one tends to anchor the circadian rhythm. It can be useful for permanent night-shift workers during their days off or during short periods of irregular shift work, making it easier to return to "normal" sleep patterns.

Social life is important for shift workers. Maintaining close ties with family and friends helps to relieve stress and mitigates the sense of temporal isolation that shift workers face. Planning for quality social time is as vital as planning for work.

Family

The personality characteristics chosen by and supported in medicine often conflict with family and self-care priorities. With the increasing complexity of a physician's clinical and administrative schedule, social and community obligations, as well as the spouse's and children's interests. are most likely to suffer. A family deserves

planned blocks of time that are sacrosanct.

Specific hardships are associated with being in a relationship with a physician. Two-physician families are becoming more common, with their own specific pressures. Living with the persistent demands of medicine, most physician couples live for the future, convinced that eventually there will be time for each other. The couple unconsciously assumes that the delay will not endanger the quality of the relationship, and it will remain as fresh and intense as the day it was postponed.

Complex defense mechanisms, learned in the milieu of the emotional and physical fatigue of training and practice, frequently lead to a blunting of one's ability to respond to deep personal feelings. The most common complaint from physician families entering counseling is that the physician member is emotionally unreachable, if not physically absent.

Physicians become professionally comfortable being decisive and responsible. Rarely are the feelings or opinions of others welcomed—physicians merely give "orders." As experts, they know what is best for the patients. It becomes a common scenario to translate this to the home, expecting that problems will be solved by directive. The physician is tired, communication falters, and compromise is one sided as the family member decides to "let it go; at least he's [or she's] finally home." Arrogance is enabled. Conflict is postponed until crisis develops.

Spouses can benefit from a support organization. The aim is to assist in understanding medical stress, share coping mechanisms, reduce isolation, and understand their own role in the patterns that shape their intimate relationships. Serious consideration should be given to using a trained communication facilitator and formal group structure for spouses' groups.

Finally, if a physician provides medical treatment to his or her family, the care given can be unsuitable—either excessive or inadequate. A physician can not remain objective in assessing loved ones, and it is most often inappropriate to try. Both the physician and his or her family deserve as complete and thorough an evaluation as would be provided to patients arriving at their emergency department.

Aging

Aging sometimes makes it physically difficult to do all that is required. Changes in the shift rotations are harder. Visual and hearing acuity may suffer. It may be difficult to accommodate medical problems; for example, at what time do you take your morning and evening doses of medications when you are working midnights? What if your diuretic takes effect during trauma resuscitation? How does a professional group deal with the inevitable increase in sick time needed by an aging group of physicians? When does the slowing of reflexes exceed acceptable tolerances?

Career transitions are available in many specialties, but, as a new specialty, emergency medicine does not have as much experience in tailoring the practice to accommodate older physicians, and options other than leaving the field need to be developed.

STRATEGIES FOR WELL-BEING

Table 288-2 lists the author's principles for promoting personal well-being. The overriding tenets are self-awareness and self-responsibility. No individual or institution created your conflicts or can resolve them. One can, however, mold the environment until it best suits one's needs. Choices and alternatives always exist.

TABLE 288-2   Principles for Promotion of Physician Well-Being

Self-Assessment

During a particularly difficult period, most people know they feel stressed and may not be functioning as efficiently as they usually do. Frequently, this is attributed to a difficult patient, a busy shift, or a particular personal stressor outside of one's control. Self-awareness enables individuals to begin to appreciate their patterns of response from a wider perspective. Paradoxically, some physicians, when faced with the disillusionment of a lifestyle not realized, cling harder to their original motives—in denial. This process feeds upon itself, resulting in frustration.

Table 288-3 lists some questions to be used as a starting point to assess one's own emotional fatigue. If several of the answers are affirmative, perhaps this is evidence of divergence between personal values and career activities. This may motivate you to seek feedback from a trusted source.

TABLE 288-3   Questions for Self-Assessment

Principles of Management

Common methods for overcoming professional fatigue use time management, support systems, debriefing/relaxation, administrative training, and physical self-care. Regardless of the validity of the need, one can not say yes to one commitment without saying no to something else. A process of *value clarification* helps identify those concepts one is willing to commit to and provides a starting point for determining personal priorities. One then should set life's major goals in all areas—physical, mental, financial, spiritual, social—according to the individual's most meaningful objectives.

Develop relationships with peers that go beyond the immediate clinical issues. Listen, and provide emotional support and challenge. Be the one to take the risk of

talking about the things that are felt but ignored. Share the social reality of what living and practicing in current society is like, sharing thoughts, feelings, and strategies. The fear that someone may discover one's vulnerabilities needs to be resisted. This encourages low levels of trust in peers and tends to isolate one from the social supports needed in times of crisis.

Concern for the well-being of medical trainees must be constantly modeled in training. Many trainees do not have the advantage of *mentors* who share with them their mistakes, let down their guard, and demonstrate that a lack of perfection does not mean incompetence. Such mentors demonstrate that a mistake is compatible with excellence and compassionate care. Errors in problem solving can be used to improve learned behavior. A faculty that can mentor on personal/professional humility is the best prevention against medical arrogance.

Well-being committees within hospital or medical societies can provide education along with referral to other resources. Lines of communication are opened as physicians learn coping techniques that others have found effective. Topics to present to the medical staff include value clarification, goal setting, time management, grieving, and reframing. A well-being committee is different from professional assistance programs for impaired, disabled, or "troubled" physicians, though their work should complement one another.

The *critical incident stress debriefing* (CISD) team is an approach that attempts to reduce the severity of poststress disorders at the time of occurrence. Personnel who have experienced a critical or anxiety-provoking situation are debriefed as a group. The group is facilitated by experienced group leaders of similar professional background in conjunction with mental health professionals. This occurs within 72 h following the event. The goal is to intercede before unhealthy reactions have time to be fully incorporated. Each individual is asked to describe what he or she saw, heard, and felt. The incident becomes the setting to share feelings. Participants are given the message that the discomfort they are encountering is a normal reaction to an abnormal experience. It also allows the opportunity to identify those individuals who may need further assistance.

Rapport

In emergency situations, one often does not have the benefit of an ongoing doctor-patient relationship. There are some easy things that emergency physicians can do to build rapport and trust. Most revolve around communicating the perception of listening and caring. Physicians should greet patients by name and introduce themselves, shaking hands when appropriate. Physicians should sit down whenever possible—regardless of how long physicians actually remain in the room, patients perceive it as much longer. When touching patients, do so gently with an air of caring. Respect a patient's privacy by closing curtains and exposing only that which is necessary. When clinically appropriate, listen to a patient's overall agenda—it may save time. Do not use complex language. If a patient is lying down, sit or bend down and put your eyes at the patient's level. Set expectations for a patient with the first encounter, i.e., "results will be back in 2 h, and I'll be back to discuss them then," or "I have a critical patient to care for but you'll be next." Finding a small need that you can fulfill (e.g., a glass of water, a pillow, a phone call) will help establish rapport.

Conflict Resolution

Conflict resolution skills are important in emergency medicine for interactions with patients, peers, physicians in other specialties, and other hospital staff. The issues of conflict differ; the dynamics, however, are similar.

Some people believe intrinsically that their concerns, no matter how minor, are more important than anyone else's. Demanding patients or families are best handled by acknowledging their expectations and attempting compromise. Sometimes, it is effective to acknowledge that the patient has been heard and his or her perspective considered, yet the physician has a different perspective and position. Although firmness may be necessary, rarely will anything be gained by hostility or by confrontation.

Administrators, nurses, and consultants may be other sources of conflict; often, ongoing personality conflicts exist, provoked by the intensity of the work environment. One needs to focus on finding the "common ground," which is the patient's needs.

Not every conflict is a battle that must be won. Healthy conflict resolution requires physicians to know when to stand up and when to negotiate or retreat.

Malpractice Litigation Support

Those concerned with physician well-being are beginning to explore malpractice litigation stress support groups. Several common attributes exist in the various models that have been proposed.

The group is educational. Risk management personnel describe what to expect at each step and clarify the meaning of legal terms. Physicians who have contended with lawsuits provide support by sharing their experiences. Hearing that others have felt similarly can be the initial crack in the wall of isolation built by the physician-defendant. Family members can provide insight into the process their family is experiencing and their emotional responses. This will often improve communication at home.

Information is available on how to establish litigation stress support groups, and many state medical societies already have such groups in place.

Physical Health

Most physicians do not get regular preventive health care. This may be due both to the tremendous time constraints of practice and to denial of one's vulnerability to illness. Either way, a physician can wind up caring less for self than for the patients.

Exercise helps maintain physical health and relieves emotional tension. In addition, setting aside the time for one's own health, within one's busy schedule and conflicting priorities, confirms with action the belief that caring for oneself is an important use of time.

The diets of many emergency physicians contribute to both poor health and fatigue: high in fat, sugar and caffeine, usually eaten quickly, without time to sit. Anticipating an urgent interruption also prevents one from relaxing.

Relaxation Techniques

Relaxation is different from leisure. Leisure activity is an important way to achieve balance. Physicians will find the stressors of leisure enjoyable in part because they are so different from the common stressors of professional life. Leisure activity will also usually involve family and friends. However, leisure activity frequently contains stressors of its own that tend to arouse and fatigue, rather then renew.

Relaxation is different from doing nothing. Relaxation actually increases awareness and focuses the mind while resting the body. It is a time to be present, to reflect, and to process experiences and feelings. Systematic relaxation requires concentration and deliberate mental activity. It will lead to lower arousal and release of strain. It can be particularly helpful if the relaxation does not require physically leaving the home, e.g., pleasure reading, gardening, hobbies, and crafts.

For those finding it difficult to achieve this level of relaxation, many techniques are available. Physicians will frequently respond to meditation, progressive muscle relaxation, selective awareness, self-hypnosis, somatics, yoga, breath control, and biofeedback. Many techniques have audiotapes available to help guide one conveniently through the learning process. For some, religious beliefs and activities may fulfill the need for relaxation. The important common denominator is quiet time that allows for personal reflection, integration, and planning.

IDENTIFICATION OF IMPAIRMENT

Emergency physicians frequently feel emotionally overwhelmed temporarily. When does this become maladaptive? Table 288-4 lists behaviors and thoughts, which when seen as a change in established behavior, are suggestive of problems.

Using home time only as time to rest, with withdrawal from family activities.

"Acting out" behavior on spouse, family members, nurses, and staff.

Chronic complaining, cynicism, blaming others

Demaling to see patients.

Writing short, ambiguous charts, Quality Assurance or Utilization Review notice of inappropriate or unintelligible comments.

Requesting frequent consultations.

Inappropriate anger toward medicine, patients, staff, authority.

Over prescribing to a patient's symptoms.

Sharing personal problems with patients, blurring of boundaries.

Degrading of peers, backbiting, questioning motives of others.

Frequent illness, unexplained absence, and patterns of late arrival or early departures.

Frequent job changes.

Excessive "toys" that become time-consuming obsessions, such as computers, boats, and planes.

Spending nonwork time at the practice without apparent reason.

Unusual number of patient complaints.

Passive-aggressive response to change.

TABLE 288-4   Possible Signs and Symptoms of Burnout

Detecting impairment in others is much more difficult. Psychologically and chemically impaired professionals are often able to delay notice by protecting their job performance at the expense of every other dimension of their lives. The common signs of uncharacteristic behavior are frequently ignored. The phenomenon of family, neighbors, friends, and coworkers becoming involved in an exhaustive conspiracy *enabling* an impaired physician to appear to be functioning at his or her job is both common and tragic. Training in pharmaceutical use, functional psychiatric problems, and in the medical problems of addicted and abusing patients, helps physicians feel that they are experts capable of treating their own problems.

Intervention is almost always required with impaired physicians, because of the massive denial and other defense mechanisms they employ. Shame, embarrassment, fear, and guilt keep many health care workers from consciously accepting that they are not in control until confronted by either trusted colleagues or, more commonly, authorities. Intervention is a delicate task, requiring sensitivity, clear motives, and *specialized training*. Members of the physician's support system are consulted, and some are asked to be present at the intervention to deconstruct this "conspiracy of enabling." This will be the critical moment where a firm attitude of concern, without hostility or punitive overtones, has the opportunity to break through the defenses and enable the individual, for maybe the first time, to acknowledge the problem. At this point, the individual is very vulnerable and must be offered options.

The seriousness of the emotional impact of confrontation on the sick physician must be appreciated; it is critical to anticipate and prevent the possibility of a suicide or bodily harm by accident or trauma. These possibilities are not uncommon, particularly among impaired health professionals.

RESOURCES

1. The Society and Center for Professional Well-Being of Durham, North Carolina, is a professional educational and consultative organization that produces programs on behalf of state and county medical societies, hospitals, and group practices. It offers unique programs in value clarification, practice assessment, mediation, and conflict resolution and is a source of manuals on developing litigation, spousal, and other support groups, as well as a speakers' bureau. Several active emergency physicians participate as speakers and contributors. (Contact: Dr. John-Henry Pfifferling, telephone 919-489-9167.)
2. The Talbot-Marsh recovery program for substance abuse and psychiatric disabilities in Atlanta, Georgia, specializes in treating health care professionals and is nationally recognized as a model for extended outpatient treatment of substance-abusing physicians. (Telephone 800-445-4232.)
3. The Menninger Clinic of Topeka, Kansas, provides individual, marital, and family therapy, and is a major psychoanalytic training program, as well. It also sponsors educational workshops in a retreat setting in Estes Park, Colorado, for a week each July. Designed specifically for physician couples, it focuses on the problem of balancing the demands of medical practice with the needs of self and family. (Contact: PO Box 829, Topeka, KS, 66601; telephone 800-288-7377.)
4. The Institute for the Study of Health and Illness is a nonprofit educational and research foundation focused on, among other things, the professional development of physicians who serve people who have life-threatening illnesses. Directed by Rachel Remen, MD, it offers books, tapes, and category I CME credit at small retreats that focus on topics such as loss, grief, personal limitation, impotence, isolation, and the examination of goals, values, and meanings. (Contact: ISHI, PO Box 316, Bolinas, CA 94924.)
5. ACEP, SAEM, and other medical societies provide state-of-the-art educational resources. Most of the topics in this chapter have been included in their presentations. ACEP has a membership section on well-being, which you may join for the informational newsletters of articles by other members, as well as to become active in supporting such issues with the college. (Contact: Well-Being Section, ACEP, PO Box 619911, Dallas, TX 75261-9911.)
6. The American Medical Association's Department of Mental Health has established the Physician's Health Foundation. Its purpose is to provide financial assistance for physicians disabled from any cause, including psychological or chemical impairment and HIV. Identification is through the state medical societies' physician's assistance programs. The foundation also supports research, focused education and retraining programs, job placement, and the International Conference on Physician Health. (Contact: Elaine Tejeck, telephone 312-464-5073.)

SPECTRUM OF CHILD ABUSE AND NEGLECT

The concept of child maltreatment, defined as harm to a child because of abnormal child-rearing practices, is a broadening of the initial description of the battered child syndrome. Child maltreatment is an all-inclusive term covering physical abuse; sexual abuse; emotional abuse; parental substance abuse; physical, nutritional, and emotional neglect; supervisional neglect; and Munchausen syndrome by proxy.[1]

The ease with which physicians are able to recognize these disorders in part depends on their knowledge of normal children and normal development. The physical stigmata of maltreatment are characteristic, although the findings of neglect and sexual abuse are more subtle than those of gross physical trauma.

CHILD NEGLECT

Child neglect includes both physical and emotional neglect. Nearly 1 million cases of neglect occur annually in the United States. Neglect results from failure of the child's caregiver to provide adequate clothing, shelter, food, health care, and/or schooling. Children who are the victims of neglect may appear in the emergency department dirty, improperly clothed, and unimmunized. Their medical problems may not have been attended to in a timely manner. They may have suffered from burns or fractures because of inadequate supervision. Child neglect from early infancy can also result in the syndrome of failure to thrive (FTT). This syndrome usually affects children younger than age 3, although older children who remain in a nonnurturing environment show similar manifestations.

The FTT patient is often brought to the emergency department because of other medical problems, such as intercurrent infections; skin rashes, particularly severe monilial diaper dermatitis; or acute gastroenteritis.

The history of the acute illness may not alert the physician to the chronic nature of the underlying problem. The physical examination provides the clue to the diagnosis of long-standing malnutrition. Overall physical care and hygiene are frequently poor. Infants have very little subcutaneous tissue. The ribs protrude prominently through the skin, and the skin of the buttocks hangs in loose folds. There may be alopecia over a flattened occiput, reflecting that the baby has been allowed to lie on his or her back all day. Muscle tone is usually increased (although sometimes these babies are hypotonic). This increased tone is most notable in the lower extremities, and infants may manifest scissoring, similar to infants with cerebral palsy.[2]

FTT infants also show distinct behavioral characteristics.[3] They are wide-eyed and wary. If brought in close proximity to the examiner's face, they may purposely turn away to avoid eye contact. They become irritable if interpersonal interaction is pursued. They are difficult to console and are not cuddly. They prefer inanimate over animate objects and spend much time with their hands in their mouths. When left alone, they assume a "straphanger's position," with their arms flexed at the elbows and extended over their shoulders.

Weights and lengths should be plotted on the appropriate growth curves. In general, weight is more adversely affected than length, although this depends on the duration of the neglect. This may be reflected in a body mass index [$BMI = weight (kg)/height (m^2)$] below the fifth percentile.[4] Likewise, long-standing neglect results in a diminution in the rate of growth of the head.

In addition to observing for these physical signs, physicians should obtain certain historical information, including the birth weight (to assess the rate of growth); any maternal use of cigarettes, alcohol, and/or drugs during pregnancy; previous hospitalizations; and the parental stature. A full social service assessment should also be obtained, although this is usually done by a medical social worker.

Infants suspected of suffering from significant environmental FTT should be admitted to the hospital. Weight gain in the hospital is felt to be the sine qua non of environmental FTT. Most infants gain weight within 1 to 2 weeks following admission; in addition, the hospitalization enables a more extensive social service assessment while the infant is in a protected environment. A skeletal survey of the long bones should be carried out to detect any evidence of physical abuse.[5]

Children over the age of 2 to 3 years with environmental neglect are termed psychosocial dwarfs. Their short stature is a more prominent finding than their low weight. These children manifest a classic triad of short stature, bizarre voracious appetite (eating from trash cans), and a disturbed home situation. They are frequently hyperactive and have delayed or unintelligible speech.[6] Psychosocial dwarfs have been studied endocrinologically and have been found to have a low to normal level of growth hormone that fails to increase with stimulation of insulin or arginine.[7] These children should also be admitted for evaluation and initiation of appropriate social intervention. The endocrinologic disturbances rapidly reverse following hospitalization or placement in a foster home.

MUNCHAUSEN SYNDROME BY PROXY

Munchausen syndrome by proxy (MSBP) is a relatively uncommon form of child abuse in which a parent either induces or fabricates an illness in a child in order to secure for himself or herself prolonged contact with health care providers.[8] Children with MSBP may arrive at the emergency department with reported symptoms such as bleeding, seizures, altered mental status, apnea, diarrhea, vomiting, fever, rash, or multiple organ system involvement. These symptoms may result from administration of agents such as warfarin or ipecac.[9] Often the cases are medically perplexing, and families frequently move from hospital to hospital, seemingly in search of diagnosis. Children with MSBP are often subject to multiple unnecessary tests as physicians seek to uncover the etiology of the disorder. The parent (biologic mother in 98 percent of cases) encourages the staff to do more diagnostic procedures and often seems uncharacteristically happy if a test is positive.

Social service and psychologic evaluation is mandatory in the evaluation and management of these children, who should be admitted to the hospital both to assure their safety and to institute needed therapy. Covert video surveillance has been used in some centers to document a parent's invasive actions.[10]

SEXUAL ABUSE

Victims of prior child sexual abuse are frequently difficult for inexperienced physicians to assess because of an unfamiliarity with the normal prepubertal genital examination.[11] Children who have been sexually abused are brought to the emergency department because of a disclosure about the abuse or because of other symptoms such as those referrable to the genitourinary tract, including vaginal discharge, vaginal bleeding, dysuria, urinary tract infections, or urethral discharge; behavior disturbances, including excessive masturbation, genital fondling, or other sexually oriented or provocative behavior; encopresis; regression; nightmares; and unrelated complaints.[12] Approximately 15 percent of children diagnosed in an emergency department as victims of sexual abuse in one report had unrelated complaints such as abdominal pain, asthma, and sore throat.

Children who are sexually abused rarely disclose their abuse until time has elapsed from the acute episode. Children who are seen immediately after an assault should be evaluated for evidence of acute injuries and for the presence of forensic material, such as semen.[13]

More often, several years have elapsed since the abuse was initiated, although it may be ongoing. Children 8 to 11 years of age frequently disclose that they have been victims of sexual abuse for a significant period of time. The assailant is known to the child in over 90 percent of cases.

A medical hsitory should be obtained from all children being evaluated for sexual abuse. Because evidence of the abuse may not be apparent until the child is examined, the physician may have to obtain additional medical history information after the physical assessment. The record of the medical history should include pertinent statements about whether the child has any underlying condition or has undergone any previous procedures that might cause changes in the anogenital area. Genitourinary surgery or trauma would be particularly important to note.

The child should be questioned directly about what happened. The child's name for genitalia and other body parts should be recorded, and all statements that the child makes concerning the abuse should be recorded verbatim. The demands of a busy emergency department may make it difficult for physicians to conduct a detailed and sensitive interview. In such cases, a hospital social worker should be consulted. [14]

Examining physicians must maintain a high index of suspicion of sexual abuse when evaluating children who have anogenital or behavioral complaints. The physical assessment should include an evaluation of the child's overall well-being and a general physical examination. The skin should be examined for bruises. Nongenital physical injuries are unusual, even following acute abuse. Rarely, there may be grip marks on the forearms or puncture wounds on the inner aspects of the lips caused by a slap to the face. The age of the child and the degree of sexual development should be noted. [15]

The genital examination should be confined to a careful inspection of the genitalia and perianal area. Generally, there is no need for a speculum examination unless the victim is an older adolescent or unless perforating vaginal trauma is suspected. Likewise, sedation is rarely needed, and most children can be reassured verbally if they are at all apprehensive. Careful inspection of the external genitalia is sufficient to establish physical evidence of genital injury. The examination is sometimes augmented by the use of a colposcope, to enable detection of subtle changes in the hymen. [16] The colposcope also facilitates photographing the external genital area. However, most emergency departments are not equipped with a colposcope, and this instrument is, in fact, not critical to an adequate assessment of the anogenital area. Magnification can easily be achieved with the use of hand-held lenses. Toluidine blue dye applied to the genital area may also detect subtle acute injuries. [17]

A number of different positions have been used to facilitate the examination. Infants may be seated on their parents' laps. Children are easily examined supine on the examining table with their legs in a frog-leg position. Some physicians also place all children in a prone knee-chest position to help fully assess the contour and homogeneity of the hymen. Placing a child in "stirrups" is usually unnecessary unless she is obese or has achieved adult stature. [18]

The normal prepubescent girl has full labia majora and small thin labia minora. The vaginal opening is covered by the hymen, a fine reddish-orange, thin-edged membrane. The thickness and color of the hymen varies as a function of age.[19],[20] It is normally thick during infancy and again with the onset of puberty. In between, it is thinner, most often annular or crescentic, and smooth edged. The hymenal orifice can be measured, although there is a range of variation depending on the child's age, size, position, and degree of relaxation. Trauma may result in changes such as hymenal notches, also referred to as *concavities* or *clefts*.[21] Concavities at the 6:00 position are associated with prior penetrating trauma. Attenuation or reduction in the amount of hymenal tissue may lead to a gaping opening. Irregularities in the contour, particularly deep notches, are also associated with prior injury. Scarring, as evidenced by marked alteration in the vascular pattern (white areas or swirling vascularity), is an additional sign of healed injury. Erythema, on the other hand, may be secondary to irritation, inflammation, and/or chronic manipulation and is not specific for abuse.[22]

Physical findings indicative of a sexually transmitted disease should also be noted, including a vaginal discharge, warts consistent with condylomata acuminata or condylomata lata, and vesicles or ulcers consistent with herpes genitalia.

It is critically important for emergency physicians to be aware that the absence of physical findings does not preclude abuse. There are many sexually abusive activities (such as orogenital contact) that would not be expected to produce scarring trauma. In addition, as is true elsewhere in the body, injuries can heal without residual scarring.[23]

The genital examination in the sexually victimized young boy is less revealing. Rarely, there may be bite marks on the penis or scrotum. There may be a urethral discharge; the penis may become erect without tactile stimulation and remain erect.

The perianal examination is often more revealing, although it too may be completely normal in the case of either acute or chronic sodomy. [24] Acute penetration may produce no changes or may be associated with fissures; abrasions; hematomas; and changes in tone, including both dilatation and anal spasm. In the young female patient, anal penetration is easier than vaginal penetration, and changes in this area may be seen. Anal fissures or tags may be noted. The perianal folds, or rugae, may be thickened in some areas, thinned out in others, and distorted. The perianal skin may be lichenified and thickened secondary to frictional rubbing. Anal tone may be reduced when there has been repeated prior anal penetration. However, stool in the rectal ampulla may lead to similar dilatation, and one should be careful to note the presence or absence of stool.[25]

The laboratory evaluation of sexually abused children should include cultures of the throat, vagina (or urethra), and rectum for gonorrhea; and a culture from the vagina (or urethra) for *Chlamydia*. Rapid antigen assays are not considered reliable in prepubescent children. [26] A serologic test for syphilis is indicated if there is clinical evidence of syphilis, a history of syphilis in the assailant, or the presence of another sexually transmitted disease. HIV testing should only be done after appropriate counseling and if there is reason to suspect infection. [27]

A suspicion of child sexual abuse mandates that a report be filed with child protective services or law enforcement agencies. These agencies will pursue an investigation and attempt to ensure that the child is placed in a protected environment.

Although there is the likelihood that the child may be removed from the home, a return appointment for follow-up of cultures for sexually transmitted diseases and a referral for psychologic counseling should be given.

PHYSICAL ABUSE

The spectrum of injuries in children who have been intentionally traumatized is wide. Familiarity with this spectrum enables physicians in the emergency department to arrive at the correct diagnosis in a timely manner. Two-thirds of the victims of physical abuse are under the age of 3 years, and one-third are under 6 months. The physical vulnerability of such small children is easy to understand.

Historical data may raise suspicions of inflicted trauma. A history that is inconsistent with the nature or the extent of the injuries (e.g., a fractured femur in an infant from a fall off a bed), a history that keeps changing as to the circumstances surrounding the injury, a discrepancy between the story the child gives and the story the caretaker gives, a history of previous trauma in the patient or siblings, or a delay in seeking medical attention should raise one's index of suspicion of physical abuse.[28] Knowledge of normal motor development assists physicians in determining the likelihood that an injury happened in the stated manner. Children under the age of 6 months are incapable of inducing accidents or accidentally ingesting any drugs or poisons. The evaluating physician should record the developmental milestones the child has achieved, e.g., the age of sitting unsupported, walking, etc. A recent study showed that developmental milestones were recorded in none of the emergency department visits in which physical abuse was suspected.[29] Parental behavior in the emergency department should be observed, and it should be noted if the parents appear intoxicated or under the influence of drugs. The level of parental concern about the injury should also be noted.

Toddlers and older children should be questioned about the circumstances of the injury, and the comments should be recorded verbatim on the record. These statements are frequently admissible in court under exceptions to the hearsay rule and may help establish the diagnosis of child abuse.

The physical examination should note the child's overall hygiene and well-being. Normal children, especially toddlers who are just learning how to walk, may have multiple ecchymoses over the anterior shins, the forehead, and other bony prominences. Most falls result in bruises on only one body surface. Bruises over multiple areas, especially the low back, buttocks, thighs, cheeks, ear pinnae, neck, ankles, wrists, corners of the mouth, and lips suggest physical abuse. Handprints may be observed, or there may be uniform but bizarre bruises caused by belts, buckles, cords, or blunt instruments. [30] Bites produce bruising in a characteristic oval pattern, with teeth indentations along the periphery. Lacerations of the frenulum or oral mucosa may be present, especially in infants who have been force fed. Lacerations and abrasions in the genital area are seen in toddlers who are "punished" because of toilet-training accidents.

The duration of a bruise can be estimated by the color of the lesion. No discoloration is noted initially, although the bruised area may be swollen and tender. Within a

day or two, the lesion becomes reddish-blue, and this lasts for about 5 days. This changes to green (days 5 to 7), then to yellow (days 7 to 10), and finally to brown (days 10 to 14) before resolving.[31] For instance, reddish-blue lesions are inconsistent with a 2-week-old injury. However, variability does exist and depends on the size and depth of the hematoma.[32]

Children with multiple bruises should be evaluated with a complete blood cell count, a differential blood count, and coagulation studies including a platelet count, a prothrombin time, and a partial thromboplastin time. Occasionally, a child with leukemia, aplastic anemia, or thrombocytopenia is brought for evaluation because of multiple bruises.

Burns constitute another form of inflicted injuries.[33] These may be scald burns caused by immersion in hot water. Such burns do not conform to a splash configuration; rather, an entire hand or foot ("glove-and-stocking" pattern) may be involved. There is sharp demarcation of the burn margin. The buttocks may be burned during toilet-training "punishment" by immersion in a bathtub filled with hot water. Knees, anterior thighs, feet, and portions of the abdomen are spared, and the buttocks and genitalia are scalded. Cigarette burns leave small (approximately 5 mm) circumferential scab-covered injuries. These lesions may resemble impetigo, as do scald injuries, which may resemble bullous impetigo. A culture of material from these lesions differentiates the burn from the infection. Other inflicted burns can result from forced contact with metal objects, such as an iron, curling iron, or heater grid.

Skeletal injuries may be detected when a child presents with unexplained swelling of an extremity or refusal to walk or to use an extremity. These fractures may take any form, but spiral fractures caused by torsion (twisting) of a long bone, and metaphyseal chip fractures, suggest inflicted injury, especially when present in infants under 6 months of age. Skeletal surveys referred to as a trauma series (or trauma x) should be obtained. These include films of all long bones, the ribs, the clavicles, the fingers, the toes, the pelvis, and the skull. They may reveal periosteal elevation secondary to new bone formation at sites of previous microfractures or periosteal injury; multiple fractures at different stages of healing; fractures at unusual sites such as the ribs, the lateral clavicle, the sternum, or the scapula; or repeated fractures to the same site. Such x-ray findings support the diagnosis of child abuse. Sometimes, bone scans will reveal fractures not readily apparent on x-rays.[34]

Head injuries are a serious and potentially lethal form of child abuse.[35] Infants with significant intracranial hemorrhage may have no apparent external injuries. Intracranial hemorrhages may result from vigorous shaking of the infant or from thrusting the infant down onto a surface, such as a mattress. This is referred to as shaken baby or shaken impact syndrome.[36] Older children may have been beaten about the head or face. Changes in mental status should therefore be evaluated by head computed tomography if there is any suspicion of abuse. Bruises around the ears, eyes, and cheeks, as well as swelling of the scalp secondary to subgaleal hematomas or underlying skull fractures, may be noted. Funduscopic examination may reveal retinal hemorrhages, which are usually associated with subdural hematomas. Such hemorrhages may result from direct trauma to the skull or severe shaking of the child.[37] These children should be evaluated with computed tomography, and coagulation studies should be performed to rule out underlying coagulopathies. Magnetic resonance imaging studies are also being used to help differentiate recent from older intracranial bleeding episodes. Additional eye injuries caused by trauma may include hyphema, lens dislocation, and retinal detachment.

Injuries to the abdomen are equally serious and are a common cause of death from child abuse.[38] Symptoms include recurrent vomiting, abdominal pain and tenderness, diminished bowel sounds, and/or abdominal distention. A history of injury as well as bruising of the overlying skin may be absent. Abdominal x-ray films may reveal a distended stomach with a "double-bubble sign" secondary to a duodenal hematoma. Diffuse distention may also be noted. Laboratory studies may reveal anemia, an elevated amylase level from traumatic pancreatitis, or hematuria from kidney trauma. Other abdominal injuries caused by trauma may include hepatic or splenic rupture, intestinal perforation, or rupture of intraabdominal blood vessels.

Any serious injury in a child under the age of 5 years should be viewed with suspicion. Other injuries that may be viewed as suggestive of child abuse include those which the child states were inflicted by another, were self-inflicted, or were inflicted by an unknown assailant.

The behavioral interaction between the child, the parent, and the physician may provide supportive evidence of the diagnosis of abuse. These children are often very compliant and submissive. They do not resist the medical examiner and readily submit to painful procedures such as blood drawing. They are overly affectionate to the medical staff, frequently preferring the nurse or the physician over the parent. Sometimes they are protective of the abusing parent, try to foster to his or her needs, and lie to cover up the true nature of the injury.

Parental behavior is less uniform, but certain distinct characteristics may be noted. The parents may not interact with the child in a comforting or supportive manner during the examination. They may become angry at the physician early in the course of the evaluation and may refuse diagnostic studies. They may appear to be intoxicated or under the influence of drugs. They may have brought the child in for seemingly minor complaints and ignored the major injuries or lesions. They may insist on hospital admission of the child for these minor problems and may readily confess they can no longer cope with the child. They may express fears of losing control.

The social service assessment may reveal an unstable home situation with frequent moves, poor parental support systems, low parental self-esteem (often caused by battering during their own childhood), parental substance abuse, and/or domestic violence. This adds further supportive evidence of a high-risk situation.

MANAGEMENT

Once the medical assessment has been completed, the physician must initiate the appropriate treatment. The medical management should be guided by the physical findings. Frequently, these children require hospitalization.

Although the specifics of the laws surrounding child abuse and neglect vary from state to state, every state does require that suspected cases be reported.[39] A verbal report is made initially to the police department and/or the child protection agency of the locality in which the abuse occurred. Law enforcement officers often appear in the emergency department, especially if the child does not require hospitalization. The child may be removed from the home and placed in protective custody, taken to a juvenile facility, placed temporarily with other relatives, or placed in a foster shelter home. The final disposition is dependent on a court hearing. The physician is also required to complete an official report detailing the specifics of the evaluation and giving his or her diagnostic opinion as to why the injuries or neglect are nonaccidental. The report should use nontechnical terms, e.g., *bruise* instead of *ecchymosis*, so the law enforcement and social service workers can understand the extent of the injuries.

Physicians are sometimes hesitant to report suspected cases. They are not "100 percent" certain. They are fearful of the parental response to the report. They are concerned about removing a child from the natural home. It is important to remember that physicians are required by law to report all suspected cases of abuse and neglect. Failure to report suspected cases can result in misdemeaner charges and lead to a fine or imprisonment. Additionally, physicians are protected by the law from legal retaliation by the parents.

Parental anger is a natural response to the filing of a report of suspected child abuse. The physician should refrain from being accusatory. Instead, the physician should note his or her concern about the child's well-being and advise the family that a physician is required by law to report any suspicions. The physician should verbally acknowledge the anger but persist in the role of child advocate. This job is facilitated in hospitals that have child abuse teams available to assist physicians in the emergency department.

290 FEMALE AND MALE SEXUAL ASSAULT

Kim M. Feldhaus

EPIDEMIOLOGY

Sexual assault accounts for 5 percent of all violent crimes reported in the 1995 U.S. Uniform Crimes Report. An estimated one in five women will be raped during their lifetimes.[1] Prevalence studies suggest that at least 20 percent of all adult women and 12 percent of adolescent women have experienced some form of sexual abuse or assault during their lifetimes.[2] Most rape victims feel there is a stigma attached to being a victim of sexual assault. As a result, sexual assault is the most underreported violent crime. Authorities believe that as few as one in three cases are reported;[3] some estimates are as low as 10 percent.[4] The vast majority of information and statistics relate to female rape victims. Only recently has male sexual assault been recognized and reported. The estimated incidence is 2 to 4 percent of reported rapes.[5,6]

Many misconceptions are perpetuated about sexual assault. The most common is the assumption that rape is motivated by sexual desire. Rape is a violent crime, motivated by the need for power and control or by anger.[5] Recent literature detailing the injuries sustained by rape victims supports rape as a violent crime. Tintinalli and Hoelzer's study of 372 rape victims reported that facial or extremity injuries were most common, and gynecologic injuries accounted for only 7 percent of all injuries.[7] Genital injuries are not an inevitable consequence of rape, and lack of genital injuries does not imply consensual intercourse. Many victims are threatened with a weapon, the majority of victims suffer minor injuries, and only 1 to 2 percent require hospitalization.[5]

The physician's responsibility is to provide for the patient's physical and psychological well-being first; then, if the patient wishes to prosecute, to provide police with corroborative medical evidence. Victims should be encouraged to undergo an evidentiary examination; critical evidence may be lost if this exam is delayed. The victim may later choose not to proceed through the criminal justice system, as collection of forensic evidence does not commit her to seek prosecution.

CLINICAL FEATURES

The Female Rape Examination

HISTORY   The purpose of the history is to obtain data tactfully about the assault, along with pertinent past medical history, in order to provide proper medical care. The victims should not have to relive every minute detail of the assault and, in fact, an extensively detailed history may hinder subsequent prosecution.[8,9] A professional, caring manner should be conveyed, and the history should be obtained in private; law enforcement personnel should not be present. Beginning with a general past medical history establishes the victim's trust in the physician.[4,8,10,11]

ASSAULT HISTORY[4,8,10,11]

1. *Who?* Did the victim know the assailant? Was it a single assailant or multiple? How many? Ask about their identity and race.
2. *What happened?* Was the victim physically assaulted? With what (e.g., gun, bat, or fist) and where? Determine the type and location of physical injuries and appropriately evaluate these injuries. Delineate actual or attempted vaginal, anal, or oral penetration. Did ejaculation occur? If so, where? Was a foreign object used? Was a condom used? This information will direct the physical examination to areas of potential injury.
3. *When?* When did the assault occur? This will determine the probability of detecting sperm (within 72 h) or acid phosphatase.
4. *Where?* Where did the assault occur? Corroborating evidence may be found based on the location of the assault.
5. *Douche, shower, or change of clothing?* Any of these activities performed prior to seeking medical attention may decrease the probability of sperm or acid phosphatase recovery.

MEDICAL HISTORY[4,8,10,11]

1. *Last menstrual period?* This will help to determine pregnancy risk.
2. *Birth control method?* This will also help to determine pregnancy risk.
3. *Last consensual intercourse?* If the patient has had recent intercourse (less than 3 days) prior to the attack, it may confuse laboratory analysis of sperm, acid phosphatase, and genetic typing.
4. *Allergies and prior medical history?* This information is necessary before prescribing antibiotics or pregnancy prophylaxis.
5. *Prior sexual assault?* Has this ever happened to the victim before?

PHYSICAL EXAMINATION[4,8,10,11]   The physical exam should be performed thoroughly and compassionately. A female chaperone should be present if the examining physician is a man. Document a general medical examination, including vital signs and level of consciousness. Bruises, lacerations, or other signs of trauma should be described in detail; a body map may be useful. As many as 290 percent of rape survivors will have nongenital injuries.[2,5,12,13] The examiner should carefully inspect the victim's face, oral cavity, neck, breasts, wrist, thighs, and buttocks. Areas of tenderness should also be recorded. A pelvic examination should be performed, noting any vaginal discharge or genital lacerations or abrasions. Toluidine blue can be used to detect small vulvar lacerations.[4] Lacerations expose the deeper dermis, containing nuclei that absorb this stain. Prior to inserting the speculum, the dye is applied to the posterior fourchette with gauze and wiped away with lubricating jelly. A linear blue stain will highlight the vulvar lacerations. This simple procedure has doubled the reporting of genital lacerations. Colposcopic photographs may reveal other genital injuries, especially to the posterior fourchette.[14]

EVIDENTIARY EXAMINATION[4,10,11]   Informed consent is required prior to evidence collection, and a system to maintain "chain of evidence" should be established. Most hospitals have a prepackaged rape kit with equipment and directions. The least invasive procedures should be performed first, and unnecessary duplication of procedures should be avoided. Any particulate matter should be collected. Examination with a Wood's lamp will reveal semen stains on a patient's body; these areas should be swabbed with a moistened cotton-tipped applicator. Saliva is obtained for secretor status during the oral cavity examination. Fingernail scrapings and hair samples are collected. During the pelvic examination, vaginal swabbings should be collected, along with gonorrhea and chlamydia cultures. Some physicians prefer to treat prophylactically and consider cultures irrelevant. If indicated by history, rectal or buccal swabs for sperm are collected. A rectal examination is performed if anal assault occurred. Emergency physicians should not examine wet mounts for the presence of sperm; this determination should be left to forensic scientists.[9,10] If blood is present, anoscopy or sigmoidoscopy should be performed. Blood samples are drawn for DNA testing, blood typing, and pregnancy testing. If photographs are used,

they should be carefully labeled and given to the police.

The Male Rape Examination

History taking is similar to that in the female rape examination. The physical examination must be tailored to the particulars of the assault. For example, because the anus is penetrated and the victim is lying prone in the majority of cases, one should search for abrasions on the thorax or abdomen.

Victims of oral penetration require a careful examination of the oral cavity; pharyngeal edema or mucosal lacerations may be found. Swabs should be taken of buccal and gingival areas if indicated by history, and gonorrhea and chlamydia cultures of the pharynx can be taken. [6] In cases of anal assault, inspect the anus externally for signs of trauma. Up to half of victims will have minor genital injuries such as perineal contusions, anal fissures, or rectal mucosal tears. [5] Swabs from the victim's penis should be collected and may be examined for saliva if there is a history of oral copulation. If there is evidence of bleeding on rectal exam, the source should be sought via anoscopy or sigmoidoscopy. Obtain a rectal swabbing or a rectal aspirate in cases of anal assault for evidentiary purposes. [6] Sterile saline can be injected into the rectum, allowed to equilibrate, and then aspirated.

DIAGNOSIS

Rape is not a medical diagnosis but rather a legal determination. The definition of rape is based on legal, not medical, facts and contains three elements: (1) any degree of carnal knowledge; (2) nonconsent—unless the victim is a minor, intoxicated, or mentally incompetent; and (3) compulsion or fear of great harm. [4,58,10,11]

FORENSIC LABORATORY EVALUATION

Sperm Survivability

Historically, the courts and legal professions have placed a high significance on sperm detection as confirmatory evidence for rape. [9] The presence of sperm or seminal constituents in the vagina is evidence of recent sexual intercourse. The detection of sperm depends on several factors, including time lapse between the rape and the physical examination, whether the assailant is azoospermic, whether the victim douched prior to examination, and whether the assailant ejaculated. [4,10,11] Previous studies suggest that one-third to one-half of sexual assault victims will have sperm detected as part of the evidentiary examination. [7,12]

There is general agreement in the literature that 2 to 3 h is the average time for loss of sperm motility in a majority of patients. [4,11] Nonmotile sperm may persist for up to 24 h in the vagina and rectum and for up to several days in the cervical mucus. [8,11] In the mouth, seminal fluid is usually destroyed within hours by salivary enzymes. Semen stains found on the patient's body, clothing, or at the site of the assault (e.g., on bedding) often are useful in obtaining biologic specimens for forensic analysis.

Acid Phosphatase

Acid phosphatase detection in vaginal washings is helpful in cases of azoospermic ejaculations. Acid phosphatase is derived from cytoplasmic sources (erythrocytes, leukocytes, and thrombocytes) or tissue sources (bone, kidney, and liver). Various chemical means are used to differentiate the source of the acid phosphatase. However, a qualitative distinction between seminal and vaginal acid phosphatase cannot be made, because they are identical biochemically and immunologically. The only reliable distinction may be made quantitatively based on the high levels of acid phosphatase in seminal fluid. [11] The acid phosphatase determinations are most helpful when no sperm are found and acid phosphatase levels are markedly elevated, consistent with the presence of semen. [4,11]

Glycoprotein p30

The plasma glycoprotein p30 is unique to males and is produced in large quantities by the prostate. It is found in semen and follows a predictable pattern of degradation after intercourse. A positive glycoprotein p30 test indicates that coitus occurred within the past 48 h. [11]

Genetic Typing

Genetic typing helps to narrow the field of suspects but cannot specify an individual. Forensic analysis of evidence is used to determine genetic markers for the victim, the evidence, and the possible assailants. Four genetic markers are available in semen, blood, and vaginal fluid: ABO blood group antigens, peptidase A, phosphoglucomutase (PGM) and deoxyribonucleic acid (DNA). [4,11]

Of the general population, 80 percent secretes ABO antigens into other body fluids such as saliva. Secretor status is determined by testing for ABO blood type and then testing saliva for the presence of these antigens. Foreign antigens found on a victim may be from the assailant. Peptidase A and PGM are present in semen regardless of secretor status. [11] Peptidase A subtypes are common in black populations; typing of peptidase A is done when the assailant may have been black. [4] Peptidase A activity decreases rapidly after intercourse and can rarely be detected after 3 h. PGM has a number of subtypes. By combining ABO type and PGM subtypes, two individuals can be differentiated from each other 90 percent of the time. [11] PGM is rarely detected beyond 6 h. Semen stains found on a victim can be analyzed for these enzymes as well.

Deoxyribonucleic acid typing can be used to characterize an individual's unique genetic material and distinguish two individuals statistically. There is a 1 in 30 billion chance that two unrelated individuals will have the same DNA fingerprint. [9] This typing can be performed on very small samples of evidence, as well as on old or decomposing samples.

All evidence collected from a victim should be carefully labeled with the victim's name, the type and source of the evidence, the date and time of collection, and the name of the person who collected the evidence. Following instructions for proper collection and storage of evidence is critical to producing optimal laboratory results.[4,11]

TREATMENT

Treatment of the rape victim includes, first and foremost, management of any physical injuries according to standards of care, while attending to the psychological needs of the patient. Tetanus prophylaxis should be given if needed, lacerations sutured, and fractures casted. A pregnancy test should be obtained in order to identify any preexisting pregnancy; a negative pregnancy test should be documented before providing postcoital contraception. Routine drug screens or determination of alcohol levels are not recommended; they may be obtained if medically indicated and if the results will influence treatment.

Pregnancy Prophylaxis

When treating postmenarcheal female rape victims, physicians must consider pregnancy prophylaxis. Although the risk of pregnancy after an isolated sexual encounter during nonfertile periods of the menstrual cycle is thought to be less than 1 percent, it may rise to as high as 25 percent at midcycle. [15] Although the Food and Drug Administration has no approved medication for postcoital contraception, various regimens of high-dose estrogens are often used. Pregnancy prophylaxis must be initiated within 72 h of the sexual assault in order to be most effective. [16] Currently accepted therapy is the birth control pill Ovral (norgestrel plus ethinyl estradiol) 2 tablets orally initially and 2 tablets 12 h later. [17] Many women will experience nausea as a side effect of this regimen; prescribing an antiemetic is advised.[16] This regimen replaces the older 5-day diethylstilbestrol regimen, which had more side effects, lower compliance, and an increased risk of carcinogenesis.

Sexually Transmitted Disease Prophylaxis

Most of the literature demonstrates poor compliance of sexual assault patients with follow-up. [7,12,18] Therefore, prophylaxis for sexually transmitted diseases (STDs) should be given to all sexual assault victims. At a minimum, treatment for gonorrhea and chlamydia should be offered. The current guidelines from the Centers for

Disease Control and Prevention (CDC) also recommend prophylaxis against *Trichomonas* and bacterial vaginosis.[19] Table 290-1 presents the current CDC guidelines for antibiotic choices. A negative pregnancy test should be documented on the chart prior to administering antibiotics; a positive pregnancy test will alter the choice of antibiotics. See Chapter 137 for further information on treatment of STDs. Hepatitis B prophylaxis should be considered if the assailant is felt to belong to high-risk group for the disease. The CDC recommends postexposure vaccination with the first dose administered at the time of the initial exam.[19] Administration of hepatitis B immune globin (HBIG) may also be considered. For those who have been vaccinated, a booster and HBIG should be given only if antibody titers are inadequate.

TABLE 290-1   Treatment of Sexually Transmitted Diseases Following Sexual Assault

Counseling and Testing for Human Immunodeficiency Virus

The true risk of contracting human immunodeficiency virus (HIV) from a single sexual encounter is unknown but believed to be rare. Estimated rates are felt to be highest with receptive, unprotected anal intercourse (0.008 to 0.032 infections per episode with an HIV positive partner). The risk with receptive vaginal intercourse is 0.005–0.0015, and with insertive vaginal intercourse is 0.0003–0.0009 per episode. Local inflammation, bleeding, or trauma can affect the risk of transmission also. [20] Victims should be counseled regarding HIV testing and the need for repeat testing. Besides the uncertainty of risk of exposure after sexual assault, other factors complicating decision making about PEP for HIV include potential inability to identify or test the assailant for HIV; expense of PEP (about $700); side effects of medication (nausea, vomiting, anorexia in up to 50 percent of patients); the need for laboratory testing; and the need to provide follow-up with physicians informed about PEP for HIV. No specific guidelines for PEP in cases of sexual assault are available as of this writing. Physicians who consider offering postexposure therapy with antiretroviral agents should consider the likelihood of exposure to HIV, the risks and benefits of such therapy, the interval between exposure and therapy, the local epidemiology of HIV/AIDS, the nature of the assault, and any high HIV-risk behaviors exhibited by the assailant. Victims should be informed of the risks and benefits of antiretroviral therapy. If a patient decides to take postexposure therapy, the guidelines for occupational mucous membrane exposure would be followed with treatment begun within 72 h.[19] See Chap. 148 regarding occupational exposure guidelines.

ADMISSION INDICATIONS

The indication for admission is based on the nature of injuries sustained from the attack. Only 1 to 2 percent of victims sustain severe-enough injuries to require hospitalization.[5] The majority of injuries can be handled with outpatient follow-up.

FOLLOW-UP CARE

Ideally, counseling for sexual assault patients should be available 24 h a day in the emergency department. Often, a rape counselor will precede the physician in assessing a victim, preparing her for the examination, and providing moral support. Multidisciplinary *sexual assault response teams* are common in some areas of the country and work to provide coordinated, sensitive care of the sexual assault victim, including medical, legal, and psychological needs. [21] If no social worker or rape counselor is available when a sexual assault victim arrives, the physician should provide information on local rape counseling centers where the patient may seek further care.

Follow-up medical care is needed to ensure that any injuries have healed properly. In addition, follow-up at 7 to 14 days is necessary to ensure the effectiveness of the pregnancy prophylaxis and STD treatment. A male rape victim should be referred to an urologist or a proctologist. Young children should be referred to a pediatrician for evaluation. These follow-up instructions should be clearly explained in a written aftercare information sheet, as victims often recall very little of their emergency department encounter.[10]

291 DOMESTIC VIOLENCE

Patricia R. Salber
Ellen H. Taliaferro

It has only been in the last 15 to 20 years that domestic violence has been acknowledged as a social problem with disastrous health consequences. In 1985, at a workshop, the Surgeon General of the United States identified domestic violence as one of the nation's most important health problems. In January 1992, the Joint Commission on the Accreditation of Healthcare Organizations mandated that all emergency departments and ambulatory care facilities establish written guidelines for the identification, evaluation, management, and referral of adult victims of domestic violence. In June 1992, the American Medical Association published guidelines for identification and intervention of domestic violence victims. [1]

In September 1994, the American College of Emergency Physicians approved a policy on emergency medicine and domestic violence that states:

- The identification and assessment for domestic violence is an important, specialized part of the evaluation of the emergency patient;
- Emergency medical services, medical school, and emergency medicine residency training programs incorporate training for identification, assessment, and intervention in domestic violence in their curricula;
- A collaborative, interdisciplinary approach with emergency physician leadership should be used to

  Collect data on the incidence and extent of domestic violence
  Develop clinical and academic research on domestic violence, and
  Use this information to detect, diagnose, and intervene with these patients;
- Hospitals develop multidisciplinary approaches including policies and protocols for emergency department identification, treatment, and referral of domestic violence patients;
- The special nature of and the necessary resources for the domestic violence screening evaluation and examination should be recognized. [2]

Domestic violence is defined as the use of a pattern of assaultive and coercive behaviors, including physical, sexual, and psychological attacks, as well as economic coercion, which adults or adolescents use against their intimate partners. The behaviors used include emotional abuse, psychological abuse, intimidation, deprivation, isolation, economic abuse, stalking, and physical and sexual assault. There are multiple, sometimes daily events. Some are criminal acts and some are not; some are physically injurious and some are not; but all are psychologically and emotionally damaging. Domestic violence, then, is about the use of power by one partner to control the other.

EPIDEMIOLOGY

It is estimated that between 2 and 4 million women are battered each year in the United States. [3,4 and 5] Data from anonymous telephone surveys suggest that 20 to 25 percent of all adult women in the United States have been physically assaulted by an intimate partner at least once over their lifetime. [6] Furthermore, 32 percent of women who have been assaulted once will be battered again within 6 months of the initial incident, [7] and 34 percent of adults in the United States reported having witnessed a man beating his wife or girlfriend. [8]

Approximately 2000 battered women die as a result of partner abuse (homicide and suicide) each year, and 31 percent of female homicide victims were killed by an intimate (spouse, ex-spouse, boy/girlfriend) compared with only 4 percent of male victims. [9] Men and women seem to kill their partners for very different reasons. Men often kill in response to the woman's attempt to leave the abusive relationship, whereas women kill in self-defense or in retribution for prior acts of violence. [10,11 and 12]

Statistics from the Bureau of Justice show that, in greater than 90 percent of reported intimate assaults, victims are women. [4] Although some studies show that female-to-male aggression and male-to-female aggression occur at close to equal rates, the chance of the aggression ending in moderate to severe injury or injuries requiring medical treatment is much higher for female victims. [13] Controlling-type behaviors that are a key component of male-on-female domestic violence are rarely described in the context of female-on-male aggression.

Domestic violence is common among women who present to emergency departments for treatment, including in community hospital as well as urban teaching hospitals. Of all women seen in emergency departments, 2 to 3 percent are there because of acute trauma from physical abuse. [14,15 and 16] In one study, the incidence of acute domestic violence among women with a current male partner was 12 percent; however, only 23 percent of these women subjected to acute domestic violence presented for care because of trauma. [14] Of women seeking care in EDs, 14 percent have a history of having been physically or sexually abused within the past year, and 30 to 54 percent have a history of intimate partner abuse at sometime in their life. [14,16] Of women with a history of suicide attempts, 81 percent had experienced domestic violence at some time in their lives, compared with 19 percent of those with no history of suicide attempts. [17]

EMERGENCY DEPARTMENT PRESENTATIONS

In addition to being a direct cause of traumatic injury, domestic violence also contributes to other conditions frequently seen in emergency departments, such as depression, anxiety, hyperventilation, substance abuse, suicide attempts, sexually transmitted diseases (including HIV), complications of pregnancy, and headaches and other chronic pain syndromes. [18] Both batterers and their victims may abuse alcohol and drugs. Abused individuals with chronic medical conditions may present with exacerbations of their illnesses because the batterer withholds their medications or because they are not allowed to keep appointments with their office-based physician. A history of exposure to violence in the home during childhood has recently been associated with an increase in health risks and health-risk behaviors in adults (such as depression, substance abuse, and high-risk sexual behaviors). [19] It should be considered, therefore, a contributing factor to many conditions commonly treated in emergency departments.

BARRIERS TO DIAGNOSIS

Even though emergency physicians provide care for large numbers of battered women, a recent study documented that only domestic violence is documented in only

a small percentage of cases.[14]

Physicians fail to make the diagnosis for many reasons. Until recently, it was distinctly unusual for medical students or residents to receive training about domestic violence. Instruction on how to recognize domestic violence is now part of the core curriculum for emergency medicine residencies. Physicians aware of domestic violence often have misconceptions that contribute to underdiagnosis. Some of these misconceptions are listed in Table 291-1.

Patient withholds information
Fear of opening "Pandora's box"
Lack of physician training
Fear of offending patient
Time constraints
Does not know what to do about it
Believe intervention will not work

TABLE 291-1   Common Reasons Why Physicians May Not Diagnose Domestic Violence in the Emergency Department

Other barriers to diagnosing domestic violence were revealed in a 1993 study of California emergency department physician directors and nurse managers.[20] Respondents were asked to rank a list of possible obstacles to the identification of adult patients who had been abused as a "major problem," a "minor problem," or "not a problem." Almost half of the respondents listed patient factors such as fear of repercussion, denial, and failure to mention battering as the most significant obstacles to diagnosis. Conversely, staff factors, such as lack of training or awareness or staff busyness, were most frequently listed as "not a problem."

Another important reason for failure to diagnose is the failure to consider domestic violence in cases with nontrauma chief complaints. Battered women seek care in emergency departments for a wide variety of medical complaints, including anxiety, hyperventilation, depression, drug and alcohol intoxication, chronic pain syndromes, and symptoms suggestive of posttraumatic stress disorder (PTSD).

ROUTINE SCREENING FOR DOMESTIC VIOLENCE

Perhaps the most significant reason for missing the diagnosis of domestic violence is the failure to ask. Asking patients directly whether domestic violence is affecting their lives has the potential of overcoming many of these barriers to diagnosis as well as establishing the expectation that the physician believes that domestic violence is not acceptable. Research shows that patients will respond to direct questioning.[21] It has been reported that approximately 45 percent of battered women will speak to an emergency physician about the violence in their lives if direct inquiry is made, although fewer (24 percent) were willing to disclose if asked during a triage encounter.[21]

CONSEQUENCES OF FAILURE TO DIAGNOSE DOMESTIC VIOLENCE

Consequences of failure to diagnose may result in multiple visits to the ED and other provider settings. One study documented that 23 percent of battered women presented to clinicians between 6 and 10 times, and another 20 percent at least 11 times before the abuse was diagnosed.[22] In addition, misdiagnosis of battering-related symptoms such as mental illness can lead to misleading at best and inappropriate use of psychoactive medications or psychiatric hospitalization at worst. It has been estimated that many women hospitalized in psychiatric institutions are, in fact, battered women.[23]

Other consequences of failure to diagnose include an increase in the patient's feelings of hopelessness, despair, isolation, and entrapment. Battered women may resort to substance abuse or develop depression with and without suicide attempts. Continuing or escalating domestic violence can lead to permanent disability or death. Domestic violence has adverse consequences for the children of victims as well. Perpetrators of domestic violence abuse the children in the home in approximately 30 percent of cases.[24] Even if the children are not physically or sexually assaulted, experiencing or witnessing violence in the home as children has both short-term and long-term health consequences, including an increased incidence of adverse health-risk behaviors as adults.[19,25] Finally, failure to interrupt the cycle of violence can lead to repetition of violence in the next generation.[26]

THE BATTERED WOMAN

Who Is She?

Any woman can become a victim of domestic violence. Although it is more commonly reported by women of color and poor women, domestic violence occurs in all socioeconomic classes, races, and cultural groups. It can occur regardless of age, educational background, or profession.

Why Does She Stay?

Many women stay in violent relationships because they are afraid of the consequences of escalating the violence. The highest number of fatalities from domestic violence occur when a woman leaves or tries to leave the relationship.[27] In addition to fearing for their own lives, battered women may fear for the safety of their children, pets, or others whom the batterer has threatened to harm if she leaves.

Some women stay because they have been systematically cut off from family and friends; they believe they have nowhere else to go. The batterer's control of information and giving of "disinformation" may make them think that no one will believe their story. They may also stay because of cultural or religious beliefs about the sanctity of the family.

For many battered women, especially women with small children, the lack of money or skills to obtain gainful employment can be a serious impediment to leaving the relationship. Their concern for their children's well-being may hold them in the relationship.

Finally, battered women may stay because they still love their partner; they don't want to end the relationship, they just want the violence to stop.

Why Doesn't She Tell?

A significant obstacle to identification is the battered women's reluctance to talk about, or outright denial of, battering. Many women do not tell physicians about the violence because the women fear that the information may not be confidential. They fear retribution if the batterer learns of the "betrayal." Some women do not tell because they are embarrassed or ashamed; they believe that their situation is unique and somehow related to their own failures in the relationship. Finally, they may not talk about it because they believe the physician does not care, cannot or will not help, or is too busy for this type of problem.

MEN WHO BATTER

Men who batter are of all ages and come from all socioeconomic, educational, racial, cultural, and religious backgrounds. One study that compared violent with nonviolent men found no statistically significant difference in demographic characteristics. Batterers were heterogeneous, failing to conform to a "batterer profile." Although batterers show higher levels of personality dysfunction than do nonviolent men, no particular personality disorder diagnosis has been identified that consistently discriminates between batterers and nonbatterers. The one thing batterers do have in common is the use of power to control the behavior of their partners

and their children. Other common themes are the use of denial and minimalization as well as blaming others as justifications for their actions.

About 60 percent of men who batter grew up in violent homes where they either witnessed the battering of their mothers or they themselves were emotionally or physically abused. However, 40 percent of men who grow up in similarly violent homes do not go on to batter, and not all men who do batter experienced violence while growing up.

Both batterers and victims of battering may abuse alcohol and other drugs. Although use of alcohol is associated with the intensity of violent behaviors, there is no established link between the use of these substances and the *cause* of violence.

THE EFFECT OF DOMESTIC VIOLENCE ON CHILDREN

As many as 70 percent of children from violent homes witness their fathers beating their mothers. In addition, about 30 to 54 percent of reported cases of spousal abuse also report child abuse. One-quarter to one-half of children in violent homes are hurt incidentally during the violence or are injured when they try to intervene in the struggle. Several studies have documented that children exposed to violence in their homes have significant behavioral difficulties, including depression or PTSD, during childhood and later life. Several studies have documented a link between growing up in a violent home and later high-risk behaviors such as drug use, promiscuity, and criminal behaviors.

MAKING THE DIAGNOSIS OF DOMESTIC VIOLENCE

History and Physical Examination

The following findings are clues to battering that can be gleaned from the clinical history and physical examination:

Pregnancy. Pregnant women are high risk for battering; 40 percent of battering begins during the first pregnancy. Among all pregnant women, 17 percent have a history of domestic abuse, and 8 to 9 percent are battered during the index pregnancy; for pregnant teens, the figure is even higher. Any evidence of injury during pregnancy should prompt direct questioning about domestic violence.

Central pattern of injury. Battered patients are more likely to experience injuries to the head, neck, face, thorax, and abdomen than patients injured by other mechanisms.

Injuries suggesting a defensive posture. Forearm bruises or fractures may be sustained when women try to fend off blows to the face or chest.

Certain characteristic injuries. Fingernail scratches, bite marks, cigarette burns, and rope burns strongly suggest domestic violence.

An extent or type of injury inconsistent with the patient's explanation. Multiple abrasions and contusions to different anatomic sites, which are inconsistent with the history, should raise the possibility of abuse. An example of such an inconsistency would be a woman with a blowout fracture who says she injured herself falling off a bar stool.

Multiple injuries in various stages of healing. Just as x-rays that reveal old fractures help support a diagnosis of child abuse, evidence of new and old injuries help diagnose partner abuse.

Substantial delay between the time of injury and the presentation for treatment. Battered women may wait several days before seeking medical care. They may see their physician at inappropriate times for seemingly minor or resolving injuries. This may occur because they were prevented from leaving the house, or it might reflect their ambivalence about revealing the nature of their home life.

Frequent visits for vague complaints without evidence of physiologic abnormality. A woman who presents frequently with a variety of psychosomatic complaints previously ascribed to depression might actually be a victim of domestic violence.

Suicide attempts. Up to 25 percent of suicide attempts by women may be related to spousal abuse; 20 percent of pregnant battered women will attempt suicide. When asked what precipitated a suicide attempt, a battered woman may respond "I had a fight with my husband." The emergency physician can make the diagnosis by asking specifically if the fight was a physical fight and exploring whether there is a history of physical and psychological abuse suggestive of domestic violence.

Multiple prior visits. Review of the medical record may reveal frequent emergency department visits for a variety of complaints, including both trauma and nontrauma presentations. Extensive workups for chronic pelvic pain or other chronic pain syndromes may also suggest a history of domestic violence.

Partner's behavior. Partners accompanying victims of domestic violence may provide clues to the diagnosis by exhibiting controlling or abusive behavior. Furthermore, the victim may appear frightened of her partner or refuse to answer questions, instead deferring all responses to him.

Routine Screening for Domestic Violence

Although there are certain clues to abuse, the presentations of battered women in the emergency department are so varied that the diagnosis may be missed if the physician fails to ask directly about the presence of violence in the patient's life. As discussed earlier, many battered women will respond truthfully if questioned, in private (not at the triage desk) and in a sensitive, nonjudgmental way. Screening may be verbal or by a written questionnaire. The American Medical Association [1] suggests asking the following questions:

- Are you in a relationship in which you have been physically hurt or threatened by your partner? Have you ever been in such a relationship?
- Are you (have you ever been) in a relationship in which you felt you were treated badly? In what ways?
- Has your partner ever destroyed things that you cared about?
- Has your partner ever threatened or abused your children?
- Has your partner ever forced you to have sex when you did not want to? Does he ever force you to engage in sex that makes you feel uncomfortable?
- We all fight at home. What happens when you and your partner fight or disagree?

It is sometimes helpful to use framing clauses when verbally inquiring about domestic violence. Examples of this type of questioning are as follows:

- Violence in the home is very common and can be very serious. Therefore, I routinely ask all of my patients whether they are experiencing domestic violence, because no one should have to live in fear and because there is help available.
- Whenever I see injuries of this type, it is often because someone hit them with a fist. Is that what happened to you?
- Many women experience some type of physical abuse in their lives. Has this ever happened to you?

TREATMENT GOALS

If physicians have "getting her to a shelter" or "having him arrested" as the goal of the patient encounter, they are bound to become frustrated when dealing with cases of domestic violence. Leaving the relationship may not be the immediate goal of the patient, and she may be loathe to have her husband and the father of their children arrested. The safety of the woman and her children should be the first and foremost goal of every patient encounter. It is the woman, however, who must make the ultimate determination of whether it is safe to return home. By providing women with information about battering, risks, and options, the physician will help the woman to decide what is best for her and her family.

Assess Potential for Suicide or Homicide

The patient should be asked if she is contemplating suicide. Does she have a plan? Does she have a weapon or has she stockpiled medications in anticipation of a suicide attempt? Is she considering homicide as a means to ensure the safety of herself and her children? Does she have a plan or weapon? Psychiatric consultation should be obtained if suicidal or homicidal ideation are present; hospitalization may be indicated.

Safety Assessment

If considering discharge from the emergency department, it is imperative to assess the safety of the woman and her dependents. Although the safety assessment may be delegated to a domestic violence expert, such as a hospital-based social worker or a community-based advocate, the physician is responsible for assuring this assessment has been completed prior to discharge from the emergency department. Safety assessments include the following:

- Ask in detail about the nature of the abuse.
- Is there a pattern of escalating violence?
- Were the police called? Was the batterer arrested? If not, does she know where he is now?
- Does the batterer have a weapon, especially firearms, which can easily turn an abuse situation into a lethal situation?
- Is the woman afraid to go home? If so, does she have somewhere safe to go? Can she stay with friends or relatives? Is she afraid that the batterer would find her if she went to the home of someone he knows?
- Would she feel safer in a battered women's shelter? Emphasize that the location of these shelters is kept secret—the batterer would not be able to find her in a shelter.
- If she feels it is safe and she wants to go home, this choice should be respected. It is appropriate, however, to discuss with her the need to have a safety plan in case violence erupts again.

ESSENTIAL INFORMATION FOR BATTERED WOMEN

Although a battered woman may choose to return to the battering relationship at the end of the physician-patient encounter, important therapeutic interventions can help her begin the process of extricating herself and her children from the violence:

- She needs to know that she is not alone,
- She needs to know that there is help available for her and,
- She does not deserve to be beaten.

All battered women should be referred to hospital-based or community-based domestic violence experts, such as social workers or domestic violence advocates, for further evaluation and continuing intervention.

PREPARING THE EMERGENCY DEPARTMENT FOR OPTIMAL RESPONSE

The optimal response to battered women will require services beyond the confines of the emergency department or hospital. Battered women's shelters, police, and the legal community all provide necessary services. To be maximally effective, there must be coordination between the medical and legal communities.

Every emergency department should develop and maintain close relationships with hospital and community domestic violence experts who can assist in the management of cases of domestic violence. Emergency physicians should ensure that their hospital has a domestic violence committee that meets regularly and includes broad representation from the various hospital departments as well as community-based domestic violence experts. This committee can assume the responsibility for developing a uniform, institution-wide response to domestic violence as well continuing education of hospital staff and, if confidentiality can be assured, complex case review and management.

The emergency department must have current lists of resources available in the community to assist battered women. Battered women's shelters, legal aid, and other legal assistance, and appropriate social service agencies should be included on the list. Community coordinating councils on family violence can be an effective way of improving a community's response to domestic violence.

Protocols

The Family Violence Prevention Fund has analyzed protocols from emergency departments across the country. Sample protocols that can be used to help guide development of an institution's protocol can be obtained by calling the fund's special interest resource center at 415-252-8900. More important than written protocols, however, is the institutionalization of an optimal response to domestic violence victims as described in this chapter.

MEDICOLEGAL CONSIDERATIONS

Careful documentation in the medical record is crucial in domestic violence cases. Such documentation can assist the victim who seeks legal remedies such at temporary or permanent restraining orders, child custody, separation, or divorce. It is recommended that photographs of visible injuries be included. Be sure to obtain consent and to document the date and time of the photographs. A hand-drawn body map detailing areas of tenderness or hematomas should be included to document nonvisible injuries. *Physicians for a Violence-free Society,* which has developed materials to help physicians incorporate forensic documentation into their practices, can be contacted at 415-821-8209. Emergency physicians must be aware of their state's reporting requirements. Some states have mandatory reporting of known or suspected domestic violence; others have mandatory arrest, in addition to mandatory reporting. If the police are called, either at the woman's request or because of a reporting requirement, it is important to discuss a safety plan with the woman. Violence may escalate when the batterer discovers he has been reported, especially if he is not arrested, or if he is arrested but held for only a short period. Physicians must warn potential victims if serious homicidal intent is expressed. Failure to report domestic violence and reporting suspected domestic violence that is not substantiated are both potential sources of physician liability. States in which mandatory reporting exist should have liability protections similar to those for reporting suspected child abuse.

Patricia R. Salber

Although not a new problem, elder abuse continues to be an underrecognized and underreported cause of morbidity and mortality in the elderly for many reasons. Historical information often remains undetected during the medical evaluation process. Social stigmata surround the problem and, like all forms of domestic violence, it is the "disease that is lied about." Finally, detection of elder abuse and neglect is contingent upon physicians' awareness of the problem as well as their ability to recognize and understand the risk factors that often appear before a crisis occurs.

INCIDENCE AND PREVALENCE

General estimates of elder abuse in the United States indicate that it may affect nearly 10 percent of the elderly population. Research suggests that between 3 and 4 percent of the elderly population is affected.[1]

DEFINITIONS

Violence is any harm resulting from intentional action by oneself or others. A very narrow and concise definition of family violence was included in the Family Violence Prevention and Services Act of 1984 of the US Congress: "The term 'family violence' means any act or threatened act of violence, including any forceful detention of an individual, which (a) results or threatens to result in physical injury; and (b) is committed by a person against another individual (including an elderly person) to whom such person is or was related by blood or marriage, or otherwise legally related, or with whom such person is or was lawfully residing." Included in the broadest sense of this definition is psychological battery (e.g., humiliating, rejecting, corrupting acts, and psychosocial injury).

Practical working definitions that permit measurement of elder abuse employ three forms of maltreatment: physical abuse, neglect, and chronic verbal aggression. These definitions do not include material abuse (theft or misuse of an elder's money or other assets) or self-inflicted abuse or neglect (which is sometimes included in definitions of elder maltreatment).

SOCIAL AND ENVIRONMENTAL ETIOLOGIC FACTORS

While in general elderly victims are socially isolated from family and friends, many of them live with their abuser. When abuse occurs, it has been found that the abuser is often dependent upon the victim for housing, and financial and emotional support. Caretakers usually attempt to provide acceptable and appropriate care. However, when the caregiver is overwhelmed, frustrated, or resentful of the responsibilities involved in the task of caring for a less than fully independent elder, abuse and/or neglect may occur.

Certain conditions tend to set the stage for abuse or neglect. A 9-year prospective study of community-dwelling elders recently elucidated risk factors of elders likely to be abused.[2] Functional disability and worsening cognitive impairment, especially an acute decline, was significantly associated with elder mistreatment. Although poverty and minority status were also identified as risk factors, reporting bias was believed to have significantly overestimated their influence.

Risk factors for abuse also reside in the characteristics of the abuser. In one study,[3] elderly abuse victims and a nonabused control group were compared to explore the relationship of caretaker stress to caretaker psychopathology. The authors found that abuse is associated more with personality problems of the caretaker than with stress. Earlier studies substantiated financial dependency of the caretaker as a major risk factor. A more recent study concluded that in general abusers are heavily dependent individuals. That study included family caretakers who were disabled, cognitively impaired, or mentally ill. Other studies have uncovered substantial psychological impairment on the part of the abusers, as well as higher rates of alcoholism, arrest, and other deviant behavior. These deviant characteristics and behaviors appear to be related to the abusers' dependence on elderly relatives for financial assistance, housing, social support, and other help.

Because elder abuse is such a widespread public health problem in the United States and because physicians are in an ideal position to serve as professional advocates of the elderly who are abused, many medical specialty societies are addressing elder abuse through organizational policy statements. The American College of Emergency Physicians adopted a policy statement on the Management of Elder Abuse and Neglect in October 1997.[4] This statement contains the following recommendations:

1. Emergency departments should have written protocols on recognition and treatment of elder abuse.
2. Hospitals should have appropriate ancillary staff and other resources readily available to help in the assessment and disposition of those individuals who may be abused or neglected. The hospital staff should be educated in local laws governing the reporting of such incidents and in defusing potentially hostile situations.
3. Hospitals and emergency departments should establish relationships with agencies that oversee the management and investigation of elder abuse. In jurisdictions that have mandatory reporting requirements, persons reporting in good faith should be immune from liability for compliance.
4. Further research should be conducted in epidemiology, detection, prevention, and management of elder abuse and neglect; standardized definitions of elder abuse developed by the National Center on Elder Abuse should facilitate research in this area.

CLINICAL FEATURES

Mistreatment and/or neglect of elderly patients may be difficult to recognize. The problem is complicated by the fact that when abuse is suspected, it may be difficult to secure confirmation from the patient. The patient may welcome and be relieved by the physician's concern and identification. However, embarrassment, fear of abandonment, fear of retaliation, and fear of nursing home placement can prompt the patient to deny the physician's concerns.

Historical information should focus on the following: (1) detecting the presence of caretaker mental illness, mental retardation, dementia, or drug or alcohol abuse: (2) family history of violence; (3) caretaker dependence on the elder patient for housing, finances, or emotional support; (4) patient isolation, as reflected by the fact that the patient does not have the opportunity to relate with people or to pursue activities and interests in a manner that the patient chooses; (5) whether the patient and suspected abuser are living together; and (6) recent occurrence of stressful life events, such as loss of job, moving, or death of a loved one for the caretaker.[5]

Important historical information concerning the patient should include dependency needs. Problems such as mental confusion, immobility, and need for assistance with hygiene are most often associated with neglect, a common form of maltreatment of the elderly. Eliciting a history of cognitive impairment is essential, since abused victims have been found to have significantly greater cognitive impairment than nonabused elderly patients. Abused patients also have a greater history of problematic behavior such as incontinence, nocturnal shouting, wandering, or paranoia.[1]

An important direct question to put to the patient is, "Are you happy at home, or have you experienced any recent changes in mood or sleeping or eating patterns?" Look also for the sudden onset of behavioral signs and symptoms that suggest victimization: depression, fear, withdrawal, confusion, anxiety, low self-esteem, or helplessness.

Other historical indicators of abuse or neglect include a pattern of "physician hopping," unexplained delay in seeking treatment, lack of medical care, a series of missed medical appointments, previous unexplained injuries, explanation of past injuries inconsistent with medical findings, and previous reports of similar injuries.

The physical examination begins with an observation of the interaction between the patient and accompanying caretakers. The following are findings suggestive of abuse:

1. The patient appears fearful of his or her companion.
2. There are conflicting accounts of the injury or illness between the patient and caretaker.
3. There is an absence of assistance from the caretaker.
4. The caretaker displays an attitude of indifference or anger toward the patient.
5. The caretaker is overly concerned with the costs of treatment needed by the patient.
6. The caretaker denies the patient the chance to interact privately with the physician.

The mental status examination should try to elicit signs and symptoms of confusion or disorientation. These signs and symptoms are risk factors for elder abuse or neglect. If they are present, it is important to seek an underlying cause, especially if they are new, since they may represent underlying medical disorders or may be reflective of intentional or unintentional medication abuse or misuse resulting from abuse or neglect.

The general physical examination should focus on detecting signs and symptoms of poor personal hygiene, inappropriate or soiled clothing, dehydration, malnutrition, and worsening decubiti. Specific injuries suggestive of abuse are unexplained fractures or dislocations, unexplained lacerations or abrasions, burns in unusual locations or of unusual shapes, unexplained injuries to the head or face, the presence of sexually transmitted diseases, and unexplained bruises.

For example, bilateral bruises on the upper arms may indicate holding or shaking. Bruises may be similar to the shape of an object or be clustered on the trunk, indicating striking injuries. The presence of bruises in various stages of healing is suggestive of repeated abuse. Bruises around the wrists or ankles may occur secondary to being tied down. Bruises on the inside part of the thighs or arms are highly suggestive of intentional injury, since bruises obtained from falling are usually located on the outside surfaces of the extremities.

DIAGNOSIS

Detection and diagnosis of elder abuse is dependent on being open to what is reported by the patient or others. Without such openness, reported abuse may be dismissed as paranoia, dementia, or patient noncompliance. A high index of suspicion is necessary. When it is lacking, signs of abuse and neglect may be erroneously ascribed to frequent falls, accidental medication errors, failure to thrive, or the normal decline with aging.

There is no substitute for direct questioning when inquiring about abuse. In one report, [6] 33 percent of abused victims stated on initial presentation to the emergency department that they were involved in an abusive relationship. Another 6 percent of abuse cases were detected by eliciting information from other informants. The remaining cases were elicited by physical examination (43 percent) or by social service evaluation during hospitalization (19 percent).

TREATMENT

Elder abuse treatment is twofold. First, emergency department treatment of the injuries and illnesses resulting from abuse or neglect must be specific for the injuries and illnesses detected. Second, detection of elder abuse or neglect must be aimed at intervention. Therefore, all treatment, whether delivered in the emergency department or the hospital, for both victim and the victim's caregiver, should be on the basis of multidisciplinary assessment and may result in admission of the elderly patient to an extended-care facility.

Intervention includes the resolution of disposition problems brought about through caregiver exhaustion, the inability of patients to care for themselves in the community, and abandonment by individuals and institutions. Intervention requires a complex array of skills. For example, the serious problem of drug and alcohol abuse among the elderly must be recognized and addressed by emergency department staff. Physical problems often disguise the existence of a problem of substance abuse.

In cases of proven or strongly suspected elder abuse or neglect, intervention must include the involvement or adult protective services. [7] All 50 states have passed legislation aimed at protecting elderly victims of domestic abuse and neglect and establishing adult protective services programs. In 1997, it was reported that 42 states had mandatory reporting laws directed toward health care and social-service professionals. These laws require disclosure of suspected elder mistreatment despite the adult victims' wishes.

ADMISSION INDICATIONS

Elderly patients with problems requiring hospital admission should be admitted to the appropriate medical service, and the department of social services should be consulted for evaluation. Patients who do not medically require admission may need to be admitted for protective placement if they cannot be safely discharged to their caretakers or returned to their institutional setting.

DISPOSITION

Safety is a key issue. Patients must not be returned to their living situations if there is any doubt about their safety. A formal safety assessment may dictate consultation with domestic violence experts, such as a hospital-based social worker or an on-call community-based elder abuse professional. It is important to remember that abuse or neglect may occur when a caregiver is overwhelmed, frustrated, or resentful of the responsibilities involved in taking care of the patient. If indicated, caregivers should be provided with intervention options, such as arranging for home care, respite, or counseling, or should be given advice as to the appropriate care for their family member.

The serious problem of drug and alcohol abuse among the elderly must be recognized by emergency department staff and addressed through appropriate referrals. Communities with geriatric treatment centers provide a valuable resource for patients identified through emergency department visits. Identification of such centers and the referral opportunities they represent should be readily available to emergency department staff.

When discharge is safe and appropriate, aftercare instructions should include appropriate treatment and referral for identified injuries and illness. Referrals should include specific available services, such as "Meals on Wheels," home health aides, visiting nurses, transportation, emergency shelter, legal aid, and medical and mental health services.

293 VIOLENCE IN THE EMERGENCY DEPARTMENT

Marshall C. McCoy

Violence once threatened only law enforcement personnel among those dealing with the public. Now it has spread into the health care arena. Violence has become a more frequent resolution of conflict and often with more devastating brutality. No health care providers are more at risk for violence than those involved with the first-line care of patients. Prehospital care providers have shown an increasing fear of violent calls and admit that violent encounters contribute to high levels of burnout.[1] Mock and coworkers found that violence occurs in 5 percent of emergency medical services runs, and an additional 14 percent of calls are precipitated by violence.[2] Recent surveys of emergency department residents have shown that one of their primary concerns is for their safety while working in the emergency department.[3] Although comprehensive data addressing the problem are still being collected from emergency department personnel, urban and rural hospitals are reporting a higher incidence of potential and actual violent episodes in their emergency departments.

By its nature, the emergency department has an atmosphere of controlled chaos. Emergency departments are open 24 h a day, provide generally unlimited and unrestricted access, and have readily available drugs. They are frequented by those who are fatigued or hungry, and they accommodate family and friends of critically ill patients and those for whom daily life stresses have heightened frustration and anxiety. Furthermore, emergency departments are frequented by substance abusers who are often violent. Other factors that may predispose the emergency department to violence are increasing waiting times, staff shortages, overcrowding, patients' financial problems, and the high expectations of the patients. These are just some of the predisposing factors that have escalated violent events in the emergency department.

It has been estimated that 50 percent of all health services providers will be involved in a violent episode in their career. In a 1988 survey of 127 teaching hospitals, 32 percent of the respondents had at least one verbal threat daily, 25 percent reported using restraints at least once daily, and 18 percent had at least one threat from a weapon monthly. Unfortunately, 7 percent reported a death related to emergency department violence in the past 5 years. Of the institutions responding, 35 percent lacked 24-h emergency department security, and of the nine respondents who reported a death, 55 percent lacked 24-h security. [4]

The prevalence of weapons has also led to more violence with increasing severity. It has been reported that close to 5 percent of all psychiatric patients who present to the emergency department for acute care have weapons. One study using metal detectors to screen all emergency department patients over a 6-month period found 33 hand guns, 1324 knives, 97 mace-type canisters, and various other items considered dangerous to the patient and staff. [5] Unfortunately, the escalating problem of violence in the emergency department is often not approached until after a violent event.

RECOGNIZING THE VIOLENT PATIENT

The only agreed upon predictors of violence are gender and alcohol abuse. Most perpetrators of violence are males with a history of substance abuse. The amount of education, ethnic background, marital status, or diagnosis are not reliable predictors, but they may be barriers to patient-staff interaction, which in itself may lead to frustration and anxiety for both the staff and patient. In turn, this subconscious conflict may precipitate a violent encounter.

The most obvious predictor of potential violence is the patient's history. Any patient with a history of being violent in the past must be taken seriously and handled cautiously. Trivializing a patient's threat, no matter how subtle, may be the cause of unrecognized violence escalation in its early stages.

Every patient exhibiting violent or threatening behavior should have a thorough physical and mental-status examination. This may require some form of control (restraints or sedation) before an examination can be completed. Using family members, friends, therapists, and/or medical records as a source of history may be valuable. It is the duty of the examining physician to differentiate between an organic and a functional cause of the behavior (Table 293-1). The treatment of an underlying disorder may completely remove any threat, such as the administration of intravenous glucose to a disoriented, aggressive hypoglycemic patient. The organic diseases most likely involved in a violent episode are those related to drugs and withdrawal syndrome(s), especially delirium tremors. According to the American Psychiatric Association, the presence of any one of the following indicators should prompt a search for an organic etiology: a patient older than 40 years of age with no previous psychiatric history; disorientation, lethargy or stupor; abnormal vital signs; visual hallucinations; or illusions. [6] A thorough evaluation should include laboratory work, toxicology screening, electrocardiograms, and, in some cases, computed tomography scans and lumbar puncture.

TABLE 293-1   Problems Associated with Violence

The most common functional disorder related to violent behavior is schizophrenia, especially in patients in paranoid subgroups or with personality disorders. The most dangerous functional disorder is manic behavior.

PRODROMES OF VIOLENCE

In most cases, violent behavior is not one of the presenting signs of the patient. Therefore, recognition of the prodromes of violence is necessary. The phases of escalation are generally agreed upon. The first is the anxiety phase, followed by defensiveness, and then physical aggression. [7] Each phase evokes a response that is proportionate to the patient's behavior. In general, verbal abuse is best handled by verbal response. Physical aggression is best handled by physical means. It is important to remember that, although these levels may be discrete, they also may overlap.

Phase 1: Anxiety

The first level of behavior seen in a potentially violent patient is anxiety. This may not only occur with the patient. Family and visitors waiting long periods in the emergency department waiting room may also exhibit anxiety and should be dealt with before visiting the patient so as not to intensify the patient's behavior. In

general, the signs of increasing anxiety are indicated by body language. Movements that seem to have no purpose other than to expend energy may be the first clue. These may include pacing, wringing of hands, clenching of fists, unwillingness to stay in the treatment area, or a disheveled appearance. Speech may be pressured and loud. Questions such as "Why am I here?" or "How long is this going to take?" may be asked. It is not necessarily what is said, but the manner of speech that gives a clue to the presence of anxiety. One of the most common reasons that a patient's condition may evolve beyond anxiety is that the staff ignores these signals, rather than acknowledging the potential for violence. Underestimating these gestures as a signal of potential violence is inviting a potential threat.

The appropriate response to the anxiety phase should be developing some type of rapport with the potentially violent patient. Time (a precious commodity to emergency staff and physicians) is usually all that is needed to establish this rapport. Listening to the patient's concerns and addressing him or her appropriately may be all that is required to diffuse the situation. To take an attitude of "I can't be bothered with such a matter" will only cause more anxiety in a person who may be feeling a loss of control. Most patients are fearful of this loss of control and usually welcome the opportunity to politely vent their feelings. This requires sympathy and empathy regarding their concerns. The patient must be treated honestly and with respect. This courtesy will go a long way in gaining rapport and ultimately avoiding future problems. Be supportive with responses that acknowledge the patient's feelings, such as "I understand why you are angry." A peace offering of food or drink may also help. Do not be judgmental. Concentrate on what the patient is saying and do not feign attention. Restating what the patient has just said may help clarify the patient's complaints and allow the patient to continue venting. Remain on the topic and, above all, remain calm. This will help the patient feel more in control.

Phase 2: Defensiveness

The next level in the continuum of violent behavior is characterized by defensiveness. At this point, the patient's behavior is volatile and becomes verbally abusive and profane. These verbal attacks may be directed to staff members or others in the department and may include statements about age, gender, weight, or heritage. The patient's behaviors are irrational and often have nothing to do with why the patient presented to the emergency department. The patient is losing control and may feel helpless. A patient may present to the emergency department in this stage, having passed the anxiety stage outside the hospital. If the patient is restrained, such as a patient in police custody, feelings of helplessness may be further magnified.

Such patients will challenge emergency department personnel and their authority and will respond to staff with body posturing and movements. Emergency department personnel must remain professional and avoid power struggles and loss of patience. Appropriate responses to this phase are preventing total loss of control by the patient and thus deflecting physical aggression. One must be firm in tone and action. The patient must have reasonable limits set and be made aware of the consequences of such continued behavior. Limits must be simple, clear, enforceable, and consistent among all emergency department personnel. Giving the patient reasonable choices may help diffuse the situation and make him or her feel rewarded for good behavior. Emergency staff must not overreact or make counterthreats or false promises. If others are present, the patient and the situation must be isolated. A show of force by uniformed security personnel may be in order, keeping in mind that such a presence may cause further escalation; however, this is the exception, not the rule. It is important that no consequence be stated that is not readily enforceable. Let the patient make the choice.

Phase 3: Physical Aggression

The third level of behavior that may be encountered is that of true physical aggression and assertive behavior. The patient is totally out of control, and no amount of verbal intervention is effective. The physically aggressive patient must be confronted and controlled physically, not only for the safety of the emergency department personnel, but for the safety of the violent patient, other patients, and visitors in the department. Only when all other interventions have failed and once the decision has been made to restrain, no further negotiation is warranted. Physical control of a patient may require personnel skilled in overcoming a person without injury to self or others. Physical control should never be attempted single-handedly and should preferably be deferred to a trained individual. It is important to remember that a health care provider has a *duty* to evaluate a patient's needs. Restraint, in some situations, is only fulfilling that duty. Using appropriate and nonharmful restraint enables the physician to provide necessary care for a violent patient. Physical control is implemented, not for punitive reasons, but in the interest of patient care and safety for others.

PHYSICAL RESTRAINTS

Restraints are used not only to control a patient when verbal interventions have failed but also to facilitate the appropriate evaluations of patients with underlying organic disorders who are too agitated or lack the mental capacity to be reasoned with and control themselves. When used properly and appropriately, restraints are more humane than allowing patients to injure themselves or others. Restraints should be used to prevent harm, to allow for further evaluation of a violent patient, or in response to a patient's request for them. Restraints should never be used with orthopedic problems or certain medical problems, such as myocardial infarction, when a worsening of symptoms may result from using the restraints and sensory deprivations may be more harmful than helpful (Table 293-2).

TABLE 293-2 Guidelines for Using Restraints

Once the decision to restrain a patient is made, appropriate personnel must be assembled. At least four to five people with a single team leader should be present. On the command of this leader, the procedure is carried out without undue force or harm to the patient or staff. Soft restraints should never be used on a truly violent patient, and once the patient is restrained the devices should not be removed except under the order of the treating physician, with the assent of the other health care providers, and with security personnel present. It is important that one explain the reason for restraint to the patient. Once restrained, the patient should not be abandoned.

Strict protocols for the use of restraints should be available in every emergency department. They should incorporate input not only from emergency department staff but from security, law enforcement, hospital legal departments, and, if possible, psychiatric services in order to present a consistent, lawful approach to the use of restraints. Once the protocol is developed, in-service meetings should be arranged to familiarize and train all emergency department personnel in the use of restraints.

Medicolegal issues are part of any restraining procedure. It is law that the minimal use of force be used to hold a violent patient. [8] The presence of security may be the only restraint needed. Anytime a person is placed in restraints, the medical chart should reflect the reason the patient was restrained. The chart should state clearly that a direct physician order is required to remove a restraint. No patient for whom restraints are needed should be allowed to leave the emergency department against medical advice. If necessary, contacting hospital legal authorities may be helpful. In general, restraining a patient against his or her will is preferable to facing the legal issues that arise when patients harm themselves or someone else in the emergency department and the threat of violence was clearly evident.

Restraining also allows the patient to be searched for weapons or drugs, although that is never the primary motivation. Searching can often be accomplished by simply asking the patient to allow such a search or by deferring to security personnel. The best search is done by undressing the patient. Emergency department staff should not attempt to take weapons from a patient without assistance; if weapons are obtained, they should never be returned, despite the patient's insistence.

Those who come to the emergency department in restraints should be left in restraints. Yet law enforcement officials often bring patients in handcuffs to the emergency department only to give them a summons and release them once treatment has begun. No person should be released from law enforcement personnel in

the emergency department. If initial plans were to release the patients (the perpetrators), they should not have been brought to the emergency department, especially those refusing any type of care. Law enforcement officers should not be allowed to leave a patient unattended in the emergency department if physical restraint was needed earlier. Furthermore, prisoners in the emergency department should never be released from restraints; many an escape has taken place from a hospital setting.

CHEMICAL RESTRAINTS

At times a patient may be too violent, even while physically restrained, for an adequate evaluation to be performed. The use of pharmacologic agents can be a safe and effective means of controlling such patients, provided the drugs are used appropriately and that physicians are aware of their adverse affects (Table 293-3). The term *rapid tranquilization* has been used to describe delivery of medications in a titrated fashion to gain control of patients with psychiatric illness, substance abuse, dementia, or withdrawal symptoms.[9] Standard doses of neuroleptic agents or benzodiazepines are given at 30- to 60-min intervals until the desired effect is reached. In general, doses for elderly patients should be half of those used on younger patients.

TABLE 293-3 Rapid Tranquilization of Violent Patients

Physicians who use any of these medications should become familiar with their adverse effects and the treatment of these effects, which include anticholinergic effects, hypotension, and extrapyramidal symptoms. Haloperidol is generally considered the neuroleptic of choice, since the adverse effects are usually less common. Short-acting benzodiazepines, such as lorazepam, are also recommended for intoxicated states and withdrawal syndromes. With the advent of flumazenil, a benzodiazepine antagonist, respiratory depression or oversedation with these agents can be reversed.

PREVENTION

The single best way to handle a violent patient or curtail the potential for violence in the emergency department is by prevention. Careful planning of the work area, cooperation with security, and training of all emergency department personnel to recognize violent patients are critical.

The physical plan of an emergency department should be one of controlled access. Visitation policies should be reasonable yet enforced. Some hospitals use visitor identification badges to monitor visitors in the department. A busy emergency department, packed full of visitors, only increases anxiety and tension. It is also the perfect place for a weapons-carrying violent patient to take hostages. Although a history from family and friends can be important in the evaluation of any potentially violent patient, interviews should be conducted in a safe, calm environment.

Seclusion rooms for interviewing patients should be safe for both the patient and the interviewer. Solid walls with sturdy, heavy furniture that would be awkward to lift should be used. Lighting should be able to be dimmed or brightened, depending on the circumstance. No free-standing objects, such as ashtrays, pictures, or pencils, should be allowed, since they all could become potential weapons. Exits should be clear of obstruction and readily available to the interviewer. Panic buttons may be installed or signals developed to be used in the event of threatening behavior on the part of the patient. If violent aggression does develop, the room should be large enough for a team of security personnel to safely overcome the patient without undue harm.

Deterrence is also a preventive technique. Signs outside the emergency department should clearly state that weapons of any type are not permitted, and trained hospital security personnel should be visible to everyone entering the emergency department. Not only does this set a tone of behavior, but security measures can be invaluable in preventing as well as curtailing any violence. The use of metal detectors and x-ray machines for personal articles, such as handbags, may allow for easy screening of those entering the treatment area. Once believed a luxury, metal detectors are now reasonably priced. Carefully placed monitors and alarm buttons may also be warranted. However, metal detectors, monitors, and alarms are only a part of an overall security system and complement personnel training in the management of potential and actual violent situations.[10,11]

Seclusion rooms and deterrent measures are needed, yet the education of the emergency department personnel is the most important factor in curbing violence in the emergency department. Several national programs, such as that offered by the National Crisis Prevention Institute, are invaluable in teaching a basic understanding of violent behavior, its recognition and management, and basic self-defense against violent patients. In-services by security personnel and law enforcement officials may also be of benefit. Physicians should learn how to examine a patient while still protecting their personal space in order to prevent injury should the patient lash out.

Common sense and a heightened awareness of the potential for violence is the first step in this education. Being aware of the position of one's body, clothing, and equipment in relation to the patient can save one from assault. The physician should never let a violent patient get between him or her and the exit. Physicians should defer to trained security personnel if a patient needs to be searched or disarmed. Incidents and reasons for restraint must always be properly documented.

Violence in emergency departments is not uncommon. Both rural and urban hospitals are plagued by increasing episodes of violence. Careful preparation and a heightened awareness of the potential for violence are basic. Education is important in understanding the dynamics of violent behavior and will help to detect and manage the violent patient. Training should be reviewed periodically. Management strategies should involve a team of emergency department staff and security, law enforcement, and hospital legal departments. Strict policies should be established for visitation. Making the work environment safe will make all involved more comfortable. Health care providers should feel as safe at work as they do at home. Physicians should trust their intuition. If the physician is afraid, then the potential for violence probably exists.

John Eng

Iodinated intravascular contrast agents significantly improve the visualization of structures in many radiologic examinations, and millions of doses are administered each year in the United States for this purpose. As with any pharmaceutical product, appropriate use of intravascular contrast agents requires knowledge of the risks and benefits of their use. Unlike most drugs, however, contrast agents provide the potential benefit, not of a therapeutic effect, but of an improvement in diagnostic information.

This chapter begins with an introduction to the pharmaceutical properties of iodinated intravascular contrast agents, followed by clinical points to consider prior to their administration. While it is always advisable to discuss the need for iodinated contrast with a radiologist on a case-by-case basis, some general indications are offered. Iodinated contrast for visualization of the gastrointestinal tract is also briefly discussed. Finally, the diagnosis and treatment of contrast reactions are outlined. Throughout this chapter, *contrast agent* refers to iodinated intravascular contrast material unless otherwise indicated.

IODINATED INTRAVASCULAR CONTRAST AGENTS

Mechanism of Action

Iodinated intravascular contrast agents are water-soluble molecules that contain several radiodense iodine atoms per molecule. Following injection, contrast agents remain in the vascular space for only a short time and are rapidly distributed into the extracellular space. Contrast agents do not enter the intracellular space or cross an intact blood-brain barrier. They are rapidly excreted by the kidney via glomerular filtration without tubular resorption.

Since the radiodense iodine atoms absorb more x-rays than do biological tissues, contrast agents appear white (like the bones) if they are present in high enough concentration during examinations made with x-rays (radiographs). Contrast agents are visible on arteriography during the short time they are in high concentration in the vascular space. They are visible in the urinary tract during intravenous urography (IVU), after excretion by the kidney. Because of its ability to discriminate subtle differences in radiodensity, computed tomography (CT) shows the presence of contrast agents in all tissue compartments even though they may be present in relatively low concentration (compared to arteriography or radiography).

Types of Agents

Contrast agents are classified according to osmolality (Table 294-1). High-osmolality agents have been in clinical use since the 1950s, and they are often called ionic contrast agents because they are all organic salts (Fig. 294-1). Low-osmolality agents have been in use since 1986, and they are commonly called nonionic agents because all but one are organic molecules without electronic charge (Fig. 294-2). A number of studies have demonstrated that low-osmolality contrast agents are associated with at least a 50 percent reduction in the incidence of both minor and severe reactions (Table 294-1). Anecdotally, injection of low-osmolality agents is associated with less subjective effects, such as flushing, heat, chemical taste, and osmotic diuresis. Currently in the United States, low-osmolality contrast agents cost on average 8 to 10 times more than an equivalent dose of a high-osmolality agent. The use of low-osmolality contrast agents is surrounded by some controversy due to the significant cost differential for a relatively modest difference in the incidence of severe reactions, which are rare.

Characteristic	High-Osmolality Agent (Ionic)	Low-Osmolality Agent (Nonionic)
Approximate osmolality relative to serum	5	2
Overall incidence of adverse reaction	5–8%	1–2%
Incidence of severe reaction	1–2 per 1000	1–2 per 10,000
Incidence of fatal reaction	1/40,000–1/170,000	1/200,000–1/300,000
Relative cost	1	8–10

TABLE 294-1   Comparison of High- and Low-Osmolality Contrast Agents
FIG. 294-1. The general chemical structure of the anion of a high-osmolality contrast agent. The R groups are either diatrizoate or iothalamate, depending on the manufacturer. The corresponding cation is either sodium or meglumine.
FIG. 294-2. The general chemical structure of a nonionic, low-osmo-lality contrast agent. There are four such agents currently on the market, each with a different R group: iohexol (Omnipaque), iopamidol (Isovue), iopromide (Ultravist), and ioversol (Optiray). All of the R groups contain multiple hydroxyl groups for solubility. A fifth low-osmolality agent, ioxaglate (Hexabrix), has a different chemical structure (not shown) that is unique because it is both ionic and low osmolality.

Types of Contrast Reactions

Contrast reactions can be divided into three categories: anaphylactoid, chemotoxic, and vasovagal (Table 294-2). Anaphylactoid reactions occur idiosyncratically, and they mimic allergic or anaphylactic reactions and shock. Anaphylactoid contrast reactions are not true anaphylactic reactions because they have no known consistent pathophysiologic mechanism. They may involve one or more of the following mechanisms: histamine release, complement activation, hapten formation, contact sensitivity, endovascular reactions, and central nervous system factors. However, unlike true immunoallergic or anaphylactic reactions, they do not involve IgE mediation. An increased risk of anaphylactoid contrast reaction is associated with a history of asthma, food or drug allergy, or a previous contrast reaction. Low-osmolality agents are associated with a lower risk of anaphylactoid contrast reaction.

TABLE 294-2   Classification of Contrast Reactions

Chemotoxic reactions are related to osmotoxic and other chemical effects of contrast agents. The pathophysiologic mechanisms for chemotoxicity are not well understood, but its occurrence is less idiosyncratic. Since many of the chemotoxic cardiovascular reactions, such as dysrhythmia and pulmonary edema, occur primarily with coronary artery injections, their occurrence in the emergency department setting is probably of less concern than in the cardiac catheterization suite.

Contrast agents can also cause vasovagal reactions, a result of increased vagal tone of the heart and blood vessels of unknown etiology but thought to be related to the central nervous system. In addition to being caused by contrast agents, vasovagal reactions may also be caused by the circumstances surrounding their administration, such as fear, anxiety, or discomfort from needle puncture.

RISK ASSESSMENT AND PATIENT PREPARATION

There are no absolute contraindications for receiving intravascular contrast agents. Certain clinical conditions either increase the risk of developing a contrast reaction or increase the severity of the reaction should one develop. Risk assessment and, in some cases, preventive measures should be performed prior to contrast administration. Considerations for patient preparation are summarized in Table 294-3, and additional comments are offered below.

TABLE 294-3   Summary of Patient Preparation Prior to Intravascular Administration of Iodinated Contrast Agents

History of Allergy

A history of asthma or severe allergy (e.g., anaphylaxis) to one or more allergens is associated with an increased risk of a contrast reaction. Patients with a history of asthma may have a fivefold greater risk of an adverse reaction than in the general population, and a history of allergy may double the risk. [1] A history of reaction during a previous contrast administration is associated with a three- to eightfold greater risk of a subsequent adverse reaction than in the general population. [1]

Renal Disease

Classically, the risk factors for developing renal insufficiency from contrast agents are preexisting renal insufficiency (creatinine level > 1.5 mg/mL), diabetes mellitus, volume depletion, use of diuretics in cardiovascular disease, advanced age (>70 years), multiple myeloma, hypertension, and hyperuricemia. [2,3] More recent studies have shown that the most important risk is associated with the coexistence of diabetes *and* renal insufficiency. [4]

As a preventive measure, patients with preexisting renal insufficiency, diabetes, or volume depletion should receive hydration in the form of 0.45% sodium chloride at 100 mL/h beginning 12 h before and continuing 12 h after contrast administration. In patients with end-stage renal failure receiving chronic dialysis, contrast agent and extra fluid must be removed by dialysis, but the dialysis does not need to be performed emergently [5] unless there is significant underlying cardiac dysfunction (and thus increased risk of direct cardiac chemotoxicity).

Cardiac Disease

Patients with significant cardiac disease appear to be at increased risk for contrast reactions. Significant cardiac disease includes severe angina pectoris, congestive heart failure, severe valvular disease, primary pulmonary hypertension, or cardiomyopathy.

Metformin Therapy

Metformin (Glucophage) is an oral antihyperglycemic agent used to treat non-insulin-dependent diabetes mellitus. Development of potentially fatal lactic acidosis is a rare adverse effect of metformin and may occur if contrast-induced renal insufficiency (itself a rare event) develops. Therefore, metformin should be discontinued 48 h prior to contrast administration and withheld for 48 h afterward. The drug may be restarted after the patient's renal function is rechecked and found to be normal.

Anxiety

There is some evidence that severe contrast reactions may be partially mediated by anxiety. Therefore, an anxious patient should be reassured and calmed prior to contrast injection.

Other Diseases

In patients with pheochromocytoma, pretreatment with phentolamine, an a-adrenergic antagonist, is recommended prior to contrast administration. In a nonstabilized patient with recent seizures, pretreatment with diazepam may be advisable. [1] Convulsions or seizures following contrast administration may be due to a lowering of the seizure threshold, or they may be a final result of a severe hypotensive or vasovagal reaction. [4]

As mentioned above, hyperuricemia and dysproteinemias, such as multiple myeloma, are associated with an increased risk of contrast-induced renal insufficiency, but there is conflicting evidence regarding the strength of this relationship. Similarly, some studies suggest that sickle cell trait and disease are also associated with an increased risk of contrast reaction, but the significance of the relationship is unclear.

Premedication

Premedication with a steroid regimen has been shown in some studies to reduce the overall incidence of contrast reactions to both high- and low-osmolality agents. However, no controlled studies have been performed to determine whether premedication reduces the incidence of *severe* reactions. Most institutions prescribe premedication if there is a history of a significant (more than nausea, vomiting, or a few hives) reaction to a previous contrast injection. [6] Some institutions also premedicate if there is a history of severe allergy to any substance. There are no standard indications or protocols for premedication. Two commonly prescribed premedication regimens are listed in Table 294-4. [7,8]

Regimen	Dosage
1	Methylprednisolone (Medrol) 32 mg PO 12 h and 2 h before contrast injection
2	Prednisone 50 mg PO 13 h, 7 h, and 1 h before contrast injection, *and* Diphenhydramine (Benadryl) 50 mg PO 1 h before contrast injection

Abbreviation: PO, oral.
Source: Regimen 1 from Lasser et al[7] and regimen 2 from Greenberger and Patterson,[8] with permission.

TABLE 294-4   Commonly Prescribed Regimens for Premedication Prior to Contrast Administration

Serum Creatinine

A baseline serum creatinine level should be determined prior to contrast injection for patients with suspected renal dysfunction or considered at increased risk for contrast-induced nephrotoxicity (Table 294-5). [4] Determination of the serum creatinine level is *not* necessary in patients without suspected renal dysfunction. Furthermore, in cases of suspected renal dysfunction, clinical judgment may determine that an urgently needed contrast-enhanced examination should not be delayed by determination of the serum creatinine level.

History of "kidney disease" as an adult, including tumor and transplant

Family history of kidney failure

Insulin-dependent diabetes mellitus of 2 years' duration or greater

Non-insulin-dependent diabetes mellitus of over 5 years' duration (if on diabetic medication for that period)

Paraproteinemia syndromes or diseases (e.g., myeloma)

Collagen vascular disease

Patients taking certain medications: metformin (Glucophage), nonsteroidal anti-inflammatory drugs, or nephrotoxic antibiotics (e.g., aminoglycosides)

Source: American College of Radiology,[6] with permission.

TABLE 294-5   Recommendations for Obtaining Serum Creatinine Level Prior to Administration of Intravascular Iodinated Contrast Agents

Selective Use of Low-Osmolality Agents

Because of their lower incidence of reactions, low-osmolality agents are used by many institutions with selected patients at higher risk for developing a contrast reaction. The American College of Radiology has suggested guidelines for the selective use of low-osmolality agents (Table 294-6). [4] These guidelines are the result

of a consensus and are not evidence-based because it is difficult to study severe contrast reactions due to their rarity. Some practices have elected to use low-osmolality agents exclusively, especially since they are generally better tolerated by patients (e.g., less nausea, vomiting, flushing, and heat sensation).

Patients with a history of any previous adverse reaction to intravascular iodinated contrast material, with the exception of a sensation of heat, flushing, or a single episode of nausea or vomiting

Patients with asthma

Patients with a previous serious allergic reaction to materials other than contrast agents

Patients with known cardiac dysfunction, including recent or potentially imminent cardiac decompensation, severe dysrhythmias, unstable angina pectoris, recent myocardial infarction, and pulmonary hypertension

Patients with renal insufficiency (particularly those with diabetes)

Patients with generalized severe debilitation, as determined by a physician

Patients at high risk for contrast extravasation

Any other circumstances where, after due consideration, the radiologist believes there is a specific indication for the use of low-osmolality contrast material, examples of which include but are not restricted to (1) sickle cell disease, (2) patients at increased risk for aspiration, (3) patients who are very anxious about the contrast procedure or who request or demand the use of low-osmolality contrast material, and (4) patients in whom the risk factors cannot be satisfactorily established

TABLE 294-6   American College of Radiology Suggested Guidelines for the Selective Use of Iodinated Intravascular Low-Osmolality Contrast Agents

INDICATIONS FOR INTRAVASCULAR CONTRAST AGENTS

An intravascular contrast agent is required to visualize vascular structures in arteriography, venography, and vascular CT (e.g., aorta and pulmonary arteries). Intravascular contrast agent is also required to visualize the urinary tract in an IVU. In such situations, decisions regarding the use of intravascular contrast agents are concerned with whether to perform the examination. Aside from these indications, decisions regarding the use of contrast usually arise in the context of nonvascular CT. Although highly desirable in many situations, contrast enhancement is not *absolutely* required for nonvascular CT, and may not add much to the ED evaluation in many situations. While the potential imaging benefits versus the risks of contrast-enhanced CT should always be discussed with a radiologist on a case-by-case basis, some general guidelines are offered below (Table 294-7).

Required
    Arteriography
    Venography
    Intravenous urography
    Vascular CT (CT aortography for injury, dissection, aneurysm; CT pulmonary arteriography for embolism)

Highly desirable but *not absolutely required*
    CT for trauma to abdominal or pelvic organs
    CT for abdominal or pelvic abscess
    CT for appendicitis or diverticulitis
    CT for bowel obstruction
    CT for orbital infection

Not indicated
    Musculoskeletal CT for trauma (e.g., face, spine, pelvis)
    Cranial CT for trauma or acute neurologic symptoms
    Abdominal CT for urolithiasis

TABLE 294-7   Indications for Iodinated Intravascular Contrast Agents

Vascular Computed Tomography

As with conventional angiography, intravascular contrast is required for CT evaluation of vascular structures. In the emergency department, such an examination is most commonly done to evaluate the aorta for trauma, dissection, or aneurysm. If the clinical suspicion is high, initial evaluation with conventional aortography should be considered instead of CT because, in such cases, aortography (requiring additional doses of contrast) would probably be performed whether or not the CT findings are positive.

Helical CT (a form of high-speed CT) has been used in conjunction with rapid contrast injection to perform CT pulmonary arteriography as an alternative to conventional arteriography for the detection of pulmonary embolism. A scintigraphic ventilation-perfusion scan is usually performed as a screening study prior to either type of pulmonary arteriography. If results of the ventilation-perfusion scan are normal or near normal, pulmonary embolism is ruled out and in most cases further evaluation with a contrast study is unnecessary.

Intravenous Urography and Urolithiasis

The IVU, or intravenous pyelogram, is the classic study for the evaluation of ureteral obstruction due to urolithiasis. During an IVU, contrast excreted by the kidney visibly flows in the urinary tract up to the level of obstruction. If the obstruction is partial, its severity may be estimated. However, the obstructing calculus is not always visualized. More recently, noncontrast helical CT has been applied to detect ureteral calculi directly in the setting of suspected obstruction. [9,10] The size and location of the calculus, which indicate the likelihood of spontaneous passage, can be accurately determined. However, the degree of functional obstruction cannot be evaluated without contrast administration. Therefore, noncontrast CT is not helpful in evaluating a patient with known calculi who presents with new symptoms.

Renal ultrasound is often requested in the evaluation of suspected acute ureteral obstruction. In such a setting, ultrasound is usually *not* helpful because (1) hydronephrosis may be absent in early acute ureteral obstruction, (2) a dilated renal collecting system may be due to causes other than acute ureteral obstruction, and (3) the detection of calculi within the kidney does not necessarily imply obstruction by a more distal calculus.

Abdominal Trauma

Intravenous contrast is indicated in all CT examinations performed to detect intraabdominal injuries from blunt trauma, including liver laceration, splenic laceration, renal trauma, bowel hematoma, pancreatic fracture, ureteral injury, and bladder perforation. Intravenous contrast agents differentiate normal organ parenchyma from hematoma within an area of injury. In patients for whom the risk of administering intravenous contrast is thought to be too great, noncontrast CT is probably still of benefit, but small-to-moderate intraabdominal injuries may be missed, especially if there is no associated intraperitoneal fluid from hemorrhage. Because of the importance of intravenous contrast, some institutions proceed with contrast injection (using a low-osmo-lality agent) in all patients undergoing emergent abdominal CT, regardless of past medical history. With such a policy, it is felt that the imaging benefits of contrast enhancement combined with an emergency situation outweigh any possible risk of adverse reaction.

In the setting of penetrating trauma to the back or flank, intravenous contrast material is administered as part of the "triple-contrast" CT, the other two types of contrast being orally and rectally administered. Triple-contrast CT should be reserved for patients who have a wound that penetrates the muscular fascia, are clinically stable, and have no obvious signs of intraperitoneal or other internal injury. [11] In such patients, intravascular contrast imaging is required to detect renal and vascular injuries, and rectal administration of contrast material is particularly important for detecting subtle colonic injury.

Acute Abdomen

Intravenous contrast enhancement is indicated for all CT examinations performed for the evaluation of acute abdomen. Acute abdominal conditions for which CT is commonly performed include appendicitis, diverticulitis, intraabdominal abscess, and bowel obstruction. While intravenous contrast material enhances the visualization of all of these conditions, its role is not as great as in CT for abdominal trauma. For example, mesenteric inflammation is detectable in the absence of

intravenous contrast enhancement in the case of appendicitis or diverticulitis. Furthermore, intravenous contrast enhancement is not involved in the detection of the complications of acute gastrointestinal inflammation, such as bowel obstruction, abscess formation, and bowel perforation. One cause of an acute abdomen, bowel ischemia, is an exception, in that intravenous contrast enhancement plays a major role in its detection, especially when strangulation is present.

The role of intravenous contrast enhancement in the detection of intraabdominal abscess is somewhat controversial, and good opacification of bowel loops by an oral contrast agent is arguably more important than the use of intravenous contrast agents in optimal CT evaluation for the diagnosis of intraabdominal abscess. As in other pathologic processes in the female pelvis, radiologic evaluation of intrapelvic abscess in a female should usually begin with transabdominal and endovaginal ultrasound rather than CT. The uterus and ovaries are almost always better visualized by endovaginal ultrasound.

For the diagnosis of appendicitis, ultrasound with graded compression is an accurate alternative to contrast-enhanced CT. [12] The technique is rapid and requires no intravascular contrast material. Its main disadvantage is the requirement of a sonographer skilled in the specific technique of examining the appendix.

Focused helical CT of the appendix without intravenous contrast enhancement has been shown to be a cost-effective method of evaluating patients with clinically suspected appendicitis. [13] This examination is performed with both oral and rectal contrast material but without intravenous contrast agents, and images of only the axial levels surrounding the appendix are obtained. [14] A focused CT examination of the appendix should be considered only if the primary clinical question is the presence or absence of appendicitis. Evaluation for other intraabdominal pathologic conditions may be limited in this type of focused CT examination.

Cranial Computed Tomography

Contrast-enhanced cranial CT is rarely indicated in the emergency setting. Abnormalities detected only on contrast-enhanced cranial CT, such as meningitis, some subacute infarcts, and small metastases, rarely change the immediate diagnostic workup and treatment and are more appropriately evaluated with magnetic resonance imaging (MRI). In the case of infarction, administration of a contrast agent may exacerbate the patient's clinical condition. Furthermore, intravenous contrast material may obscure intracranial hemorrhage, especially in the subarachnoid space.

Skeletal Trauma

Since bone appears much denser on CT than does even intravascular contrast, imaging of the skeletal system does not require contrast injection. Emergent skeletal CT is most often performed to evaluate fracture of the axial skeleton. Intravenous contrast enhancement may be necessary to detect concomitant injury of the abdominal or pelvic organs.

CT of the spine, particularly of the lumbar spine, following administration of *intrathecal* contrast material is occasionally performed for the evaluation of back pain. This procedure, CT myelography, has been essentially replaced by MRI, which provides significantly better visualization of the spinal cord, nerve roots, and intervertebral disks. CT myelography should only be performed in special cases, such as preoperative evaluation and planning.

IODINATED GASTROINTESTINAL CONTRAST AGENTS

In most nonemergent fluoroscopic studies of the gastrointestinal tract, oral or rectal barium sulfate contrast material is preferred over iodinated contrast material (e.g., Gastrografin, Gastroview, Hypaque) because barium demonstrates the mucosa in greater detail and is less susceptible to dilution. However, iodinated contrast agents are indicated in many emergent situations in which barium contrast is contraindicated: (1) suspected or potential bowel perforation (including trauma or abscess), (2) administration before gastrointestinal surgery or endoscopy, and (3) evaluation of the position of percutaneously placed bowel catheters. Iodinated contrast agents are appropriate in these situations because they are rapidly reabsorbed from the peritoneal and interstitial spaces. [4] If a fluoroscopic study with iodinated contrast material does not demonstrate a suspected perforation, many radiologists repeat the study using barium to look for small leaks, which are often more apparent with barium than with iodinated contrast agents.

For gastrointestinal studies involving iodinated contrast material, low-osmolality agents are indicated in the following situations: (1) oral administration in patients who are at risk for aspiration, because contrast-induced pulmonary edema is less with low-osmolality agents; and (2) patients with fluid or electrolyte imbalances, because low-osmolality agents cause less dilution and fluid shifts into the bowel lumen. [4]

Following oral or rectal administration, a small amount of iodinated contrast agent (approximately 1 to 2 percent) is absorbed by the bowel and excreted into the urine.[4] Therefore, the risk of developing an anaphylactoid contrast reaction is theoretically the same as it is for intravascular administration, and the same preprocedural evaluation and precautions apply. However, moderate or severe contrast reactions are only very rarely reported following oral or rectal administration of iodinated contrast agents. Therefore, the actual risk may be lower than that for intravascular administration. These comments are also applicable to administration of iodinated contrast material into the bladder or male urethra for the evaluation of trauma. In such examinations, it is likely that absorption of the contrast agent is even less than in the gastrointestinal tract.

The administration of oral or rectal contrast material is important in a number of indications for abdominal CT. Unlike fluoroscopic studies, gastrointestinal CT studies entail no significant difference in diagnostic quality between barium and iodinated contrast agents because only very dilute gastrointestinal contrast material is required. Therefore, high-osmolality iodinated contrast agents may be routinely used for emergent CT evaluation of the gastrointestinal tract.

DIAGNOSIS AND TREATMENT OF CONTRAST REACTIONS

The great majority of adverse effects from contrast agents are mild or moderate events that are not life-threatening and require only observation, reassurance, and general supportive measures. However, vigilance must be maintained because most severe contrast reactions begin with mild-to-moderate symptoms and signs. The vigilance need not be prolonged because essentially all life-threatening contrast reactions occur immediately or within 15 min of injection. [15]

From a clinical perspective, acute reactions to contrast agents can be classified in the following types: (1) nausea and/or vomiting, (2) urticaria (hives) without respiratory symptoms, (3) bronchospasm (wheezing) without cutaneous or cardiovascular manifestations, (4) isolated hypotension, (5) vagal reaction, (6) isolated laryngeal edema, and (7) generalized anaphylactoid reaction. [1,4] Clinically, an anaphylactoid reaction is characterized by a severe or rapidly accelerating combination of one or more of the following: bronchospasm, generalized urticaria, angioedema, laryngeal spasm or edema, and hypotension with tachycardia (shock). Table 294-8 presents one approach to the treatment of acute contrast reactions. Contrast reactions may also have nonspecific manifestations, such as pulmonary edema, angina, seizure, or hypertensive urgency. Such reactions should be treated with standard therapies and protocols (see Chap. 30).

Emergency ultrasound examinations should usually be restricted to those areas that are amenable to the type of limited, goal-directed examinations described in this chapter and textbooks on emergency ultrasonography. Any abnormality noted on a bedside examination that the examiner cannot explain should be evaluated with further testing with formal ultrasound or another imaging modality. Many potential applications have been proposed, but only a half-dozen emergency department (ED) applications are firmly established as a major contribution to daily ED practice (Table 295-1). The first four of these are life-threatening, time-sensitive conditions for which the bedside ultrasound examination provides rapid, easily interpreted information that is often unavailable in a timely manner by any other means. The other two applications, for suspected obstructive renal disease and acute gallbladder pathology, are ordinarily not acutely life-threatening but are so common and so amenable to ultrasound studies that they have gained widespread acceptance as primary indications. Other potential applications, which are not reviewed in detail in this chapter, include determination of urinary bladder postvoid residual volume, soft-tissue foreign-body of deep venous thrombosis (DVT) evaluation, detection, soft-tissue abscess evaluation, and vascular access.

Indication	Key Sonographic Finding
Abdominal aortic aneurysms	Aortic diameter >3 cm
Trauma evaluation	Hemoperitoneum
First-trimester pregnancy	Intrauterine pregnancy
Cardiac evaluation	Cardiac activity, pericardial fluid
Obstructive uropathy	Hydronephrosis
Gallbladder disease	Gallstones, sonographic Murphy sign*

*See the text for full details of sonographic findings.

TABLE 295-1   Primary Indications for Emergency Department Ultrasound

FUNDAMENTALS

The basic principles and terminology employed in emergency ultrasonography are straightforward but differ in important respects from that of other imaging techniques. The ultrasound image is created electronically from high-frequency sound waves generated by the transducer (or probe), which also receives the reflected waves. The time required for the reflection of each structure determines its depth on the image, and the intensity of the reflection determines its shade on a black-to-white scale. A perfect reflector of ultrasound waves appears white and is referred to as *hyperechoic.* A perfect transmitter of ultrasound waves has no reflection and appears black, or *anechoic.* A great advantage of ultrasound is that most structures, particularly those not well visualized by standard x-ray, have intermediate echogenicity that is quite characteristic and allows for identification of normal and abnormal organs and tissues.

An important factor in determining the quality of the image is the frequency of the transducer employed: the lower the frequency, the greater the depth of penetration but the lower the resolution. For all the primary ED indications (except endovaginal ultrasound), a general-purpose probe of approximately 3.5 MHz is appropriate and will allow visualization even in obese patients. A 5 MHz probe can be used in thin adults or pediatric patients, providing better resolution. Some of the specialized applications, including many vascular and procedural uses (Table 295-2), require higher-frequency probes for adequate sonographic examination.

Appendicitis

Ascites evaluation

Cardiac wall motion abnormalities
Deep venous thrombosis

Pelvic masses

Pleural fluid visualization

Procedural applications
 Abscess drainage
 Foreign-body removal
 Suprapubic aspiration
 Vascular access

TABLE 295-2   Examples of Specialized Applications for Emergency Department Ultrasound

Color Doppler technology provides information on blood-flow characteristics of vascular structures by superimposing colors over the normal gray-scale image. The displayed colors, which range from red to blue, indicate the direction of blood flow relative to the transducer. While this technology is helpful in identifying vascular structures, it is not necessary for any of the primary ED applications of ultrasound.

An important limitation of ultrasound is that even small amounts of air (e.g., in bowel loops and pneumoperitoneum) preclude effective visualization distal to the gas. Bone, too, is poorly imaged by ultrasound (compared to plain x-ray), and finding appropriate acoustic windows that avoid these problems is one of the skills required of the emergency sonologist.

Orientation

Certain arbitrary but generally accepted conventions are utilized for creating and displaying ultrasound images. The skin-transducer interface is placed at the top of the image. Each transducer has a mark of some sort, which is used for left-right orientation. The *marker always points to the left side of the screen, as viewed from in front.* When scanning in the transverse plane, the physician points the marker groove to the patient's right side, and the image is displayed as a cross section from the patient's feet (Fig. 295-1). For longitudinal or sagittal views, the *marker points to the patient's head.* The image then appears with the most cephalad portion on the left (Fig. 295-2).
FIG. 295-1. Transverse ultrasound image. This is obtained by directing the marker dot on the probe toward the patient's right side. (From Heller M, Jehle D, eds: *Ultrasound in Emergency Medicine.* Philadelphia, Saunders, 1995, with permission.)
FIG. 295-2. Longitudinal ultrasound image. The marker dot on the probe is directed toward the patient's head. (From Heller M, Jehle D, eds: *Ultrasound in Emergency Medicine.* Philadelphia, Saunders, 1995, with permission.)

The transmission of ultrasound waves is blocked by highly echogenic structures (e.g., gallstones), resulting in a relatively anechoic area distal to the echogenic structure. This effect is known as *acoustic shadowing. Acoustic enhancement* occurs distal to an anechoic, fluid-filled structure, such as the gallbladder. The area distal to the anechoic structure has increased echogenicity due to the greater number of ultrasound waves reaching this area through the anechoic structure. Examples of these phenomena are present in almost every ultrasound image. However, the many other technical factors that influence the creation of ultrasound images and artifacts are beyond the scope of this discussion. Two of the most common and useful are illustrated in Fig. 295-3.

FIG. 295-3. Acoustic shadow created by solitary gallstone. Note increased echogenicity distal to gallstone (acoustic enhancement).

Characteristics of the Emergency Department Ultrasound Examination

The ED ultrasound examination is significantly different from the formal sonography that is performed in the radiology suite. The most important distinction is that the ED examination is very focused. Five of the six examinations seek only one primary finding: a yes-or-no answer (Table 295-1). This generally allows the examination to be performed in a single position (supine) and within only a few minutes. Also, the ED examination can be more interactive. The physician can use the patient's response and clinical findings together with the ultrasound image to aid in interpretation.

The ED applications described are usually performed with relatively modest, very portable, non-Doppler units. The addition of Doppler technology, which allows for evaluation of function (flow) as well as form (anatomy), can be expected to significantly expand the utility of bedside emergency ultrasound during the next decade.

PRIMARY INDICATIONS

Primary applications are those examinations that are critically time-dependent and/or of such nature that the information gained is likely to be of major benefit to the patient and physician (Table 295-1). These examinations each involve looking for only a few easily recognized findings. The straightforward, limited nature of these examinations allows emergency physicians to perform them with less formal training than the imaging specialist, occasionally under severe time constraints.

Abdominal Aortic Aneurysm

Ultrasound is as accurate as computed tomography (CT) and more accurate than angiography in measuring aneurysmal diameter. Specific indications for ultrasound evaluation of the aorta include abdominal pain in hypotensive patients and elderly patients with unexplained back, flank, or abdominal pain.

SONOGRAPHIC CONSIDERATIONS   The aorta is located in the midline of the abdomen, to the left of the inferior vena cava (IVC), just anterior to the spine and posterior to all other abdominal contents (Fig. 295-4). The aorta normally tapers as it progresses distally, and any diameter greater than 3 cm is abnormal. An

ultrasound examination that images the aorta from the diaphragm to its distal bifurcation is extremely accurate at confirming or refuting the diagnosis of abdominal aortic aneurysm (AAA). Although pressure on the transducer usually displaces intervening bowel gas, complete visualization is sometimes impossible. Such examinations are considered indeterminate.
FIG. 295-4. Transverse view of a normal abdominal aorta and inferior vena cava (IVC). Note vertebral body is represented by the large hypoechoic area in the far field.

With experience, it is generally not difficult to differentiate the aorta from the IVC/Fog. The IVC, usually to the right of the aorta, has thinner walls and changes remarkably in size with probe pressure and the Valsalva maneuver. Both the aorta and the IVC are pulsatile, although the gentle, undulating pulsation of the IVC can, with experience, be differentiated from the forceful, centripetal aortic pulsation.

The primary sonographic finding of AAA is an aortic diameter greater than 3 cm. When AAA is suspected, the aorta should be imaged in the transverse and sagittal planes from the diaphragm to its bifurcation at the level of the umbilicus. Transverse images measured horizontally from outside wall to outside wall are the most reliable in accurately determining true aortic size. Echogenic thrombus within the outer margins of AAAs is very common, and care must be taken to identify the outer limits of the aortic wall (Fig. 295-5). While ultrasound is very accurate in measuring AAA size, it is often impossible to determine sonographically whether the AAA has ruptured, since rupture most often occurs into the retroperitoneal space. A hypoechoic retroperitoneal hematoma may be seen but is often very difficult to identify. AAA rupture into the peritoneal space is usually fatal.

FIG. 295-5. Abdominal aortic aneurysm with intraluminal thrombus.

Renal Colic

Intravenous pyelogram (IVP), spiral CT, and ultrasound are all used in evaluating patients thought to have renal colic. Bedside ultrasound often allows a much more rapid diagnosis and disposition of ED patients than either IVP or spiral CT, and there are situations where the use of contrast material or iodizing radiation is unwise (e.g., pregnancy, renal insufficiency, and volume depletion). False-negative ultrasound results occur, but the sonographic appearance of hydronephrosis in the appropriate clinical setting aids in diagnosis, and negative findings on examination should lead to an alternative diagnosis.

SONOGRAPHIC CONSIDERATIONS   A standard 3.5-MHz probe is generally used for renal scanning, but a 5-MHz transducer can be used with better resolution in thin adults and children. The right kidney is best visualized in the anterior to midaxially line over the lower ribs, but a subcostal approach can at times be successful in imaging the kidneys, avoiding the distraction of rib shadows. The left kidney is more difficult to see due to overlying bowel and stomach and the absence of the liver, which acts as an acoustic window, but is perfectly amenable to ED visualization as well. The best initial approach to the left kidney is somewhat more dorsally, in the posterior axillary line over the lower ribs. Occasionally, a posterior thoracic approach is necessary to adequately visualize the kidneys. Deep inspiration lowers the diaphragm and may move the kidneys caudally into a more easily visualized location. To fully evaluate the kidneys for hydronephrosis, both longitudinal and transverse images should be obtained, and both kidneys should be scanned with each examination.

The kidneys are retroperitoneal organs measuring approximately 12 cm in length and 5 cm in width and are divided into two sonographically distinct areas: the renal cortex and the renal sinus. The renal cortex occupies the periphery of the kidney and has an echogenicity similar to that of the liver or spleen. The renal sinus appears as a central echogenic stripe within the kidney and includes the collecting system as well as major vessels of the hilum (Fig. 295-6). Renal medullary pyramids appear hypoechoic relative to the cortex and are triangular in shape, occurring at the junction of the cortex and the more echogenic renal sinus. When the urine produced in a kidney flows freely into the bladder, there is no appreciable urine within the renal sinus and therefore no significant anechoic space within the hilum. Obstruction of urine outflow from a calculus results in the development of hydronephrosis, which appears as an anechoic fluid collection within the echogenic renal sinus (Fig. 295-7). Hydronephrosis can be graded from mild, with minimal separation of the sinus echoes, to severe, manifested by extensive separation of the central echoes, with renal parerchymal thinning.

FIG. 295-6. Normal appearance of the right kidney.

FIG. 295-7. Hydronephrosis of the right kidney with distended renal collecting system (*).

Renal cysts occur commonly and can be confused with hydronephrosis. Renal cysts are thin-walled, round, anechoic structures with distal acoustic enhancement that typically occur in the periphery of the kidney and lack the more echogenic border typical of the collecting system, as seen with hydronephrosis.

The urolith (calculus) causing the obstruction most often lodges at the ureterovesicular junction, the ureteropelvic junction, or the pelvic brim. While stones at the ureterovesicular junction can occasionally be seen sonographically through the bladder window, calculi are usually not identified on ultrasound examinations. One study found that the ureteral calculi were identified on ultrasound in only 19 percent of patients with documented stones, whereas spiral CT and IVP were able to identify 94 and 52 percent, respectively. Hydronephrosis was identified sonographically in 73 percent of the patients with ureteral calculi. [2] In another study, emergency physicians performed bedside renal ultrasound after a 500-mL bolus of normal saline solution in 108 patients suspected of having renal colic. When used in conjunction with the history and a kidney-ureter-bladder film, the emergency physicians were able to diagnose renal colic with a sensitivity of 97 percent. The specificity and accuracy were 59 and 83 percent, respectively. [3] It is possible that the fluid loading the patients received prior to the ultrasound studies resulted in a number of the false-positive results that contributed to the low specificity.

Hydronephrosis occurs in over 65 percent of pregnant women, peaking between 24 and 28 weeks of gestation. This is believed to be due to mechanical pressure of the enlarged uterus on the ureters and is usually more pronounced in the right kidney. This condition resolves within several weeks of delivery. False-positive scan results are also seen with overly vigorous hydration or a very full bladder. Peripelvic cysts and extrarenal pelvis are two fairly common conditions that may also cause confusion.

Gallbladder Disease

Ultrasound is generally accepted to be the modality of choice in the evaluation of biliary disease. [4] Greater than 90 percent of biliary disease is calculous in origin, and, regardless of composition, even the smallest of gallstones are visible sonographically. Conversely, only 15 percent of gallstones are visible with standard radiographs.

SONOGRAPHIC CONSIDERATIONS   The gallbladder is an ideal organ for sonographic evaluation. This cystic structure is typically filled with anechoic bile and can be imaged through the liver, an excellent acoustic window. The gallbladder can be imaged in the right upper quadrant over the lower ribs or just below the costal margin. Deep inspiration moves the gallbladder caudally, often facilitating its visualization. The gallbladder varies in size, being smallest after fatty meals and largest after fasting, but it is typically 7 to 10 cm in length and 2 to 3 cm in width. The absence of reflective surfaces within the gallbladder results in distal acoustic enhancement. With experience and high-quality equipment, it is possible to visualize the common bile duct, especially when dilated, and this finding may be of considerable clinical import.

The primary sonographic finding in biliary disease is gallstones. Gallstones appear as bright, echogenic foci within the gallbladder and move with changes in position unless impacted (Fig. 295-8). A minority of gallstones float within the bile. Symptomatic gallstones may be very small in relation to the volume of the gallbladder, and a thorough search of the organ is mandatory. In order to ensure this, the patient should be instructed to halt inspiration when the gallbladder is well visualized. During this breath holding, the entire gallbladder should be visualized in one axis, sweeping from one side of the gallbladder to the other. This should be repeated with scanning done 90° to the axis of the first scanning plane, thus obtaining both sagittal and transverse images.   *Acoustic shadows* appear as anechoic lines distal to the echogenic stones. These shadows are due to the blockage of ultrasound wave transmission distal to the stone and are helpful in identifying stones, often being more readily identified than the gallstone itself. Gallbladder polyps can mimic the appearance of gallstones but do not change position upon moving the patient and do not create acoustic shadows.

FIG. 295-8. Multiple dependent gallstones with acoustic shadowing.

A second extremely important sonographic finding of biliary disease is a positive sonographic Murphy sign. The sonographic Murphy sign is considered positive when the point of maximal tenderness to transducer pressure is directly over the sonographically located gallbladder. A positive sonographic Murphy's sign in the presence of cholelithiasis is reported to have a 92 percent positive predictive value for symptomatic gallbladder disease. Gallbladder wall thickening, defined as proximal gallbladder wall thickness greater than 3 mm, occurs in 50 to 75 percent of patients with acute cholecystitis, but this finding is not specific for cholecystitis. Edematous states, as well as such conditions as liver disease, AIDS, ascites, renal disease, and the postprandial state, can also result in gallbladder wall thickening. Gallbladder sludge is nearly always abnormal in the ambulatory patient, suggesting biliary disease. Sludge is composed of calcium bilirubinate and cholesterol granules, and generally form a bile-sludge layer within the gallbladder and does not create acoustic shadows (Fig. 295-9). Finally, a fluid collection around the gallbladder, or pericholecystitic fluid, is evidence of marked inflammation and often of perforation. This is usually seen in patients with other clinical and sonographic evidence of cholecystitis.

FIG. 295-9. Gallbladder sludge. The sludge is seen to layer out in the gallbladder. Multiple gallstones are also present. (From Heller M, Jehle D, eds: *Ultrasound in Emergency Medicine.* Philadelphia, Saunders, 1995, with permission.)

In summary, the sonographic signs of biliary disease are gallstones, sonographic Murphy sign, gallbladder wall thickening, gallbladder sludge, and pericholecystic fluid. The combination of a positive sonographic Murphy sign and any of the other sonographic findings described is highly reliable in diagnosing acute gallbladder disease. In fact, the presence of any two of the sonographic signs in the appropriate clinical setting is highly suggestive of the disease. Completely normal examination findings, including a negative sonographic Murphy sign, are reliable in excluding symptomatic gallbladder disease.

Focused Abdominal Sonography for Trauma

Abdominal CT scanning remains an important tool in evaluating trauma, with an accuracy of more than 90 percent in detecting intraabdominal injuries. However, CT is expensive and requires a hemodynamically stable, cooperative patient. It also involves contrast-medium administration and ionizing radiation. Diagnostic peritoneal lavage (DPL) has sensitivities greater than 90 percent for hemoperitoneum. However, up to one-third of laparotomies performed on the basis of positive DPL findings are unnecessary. As little as 20 mL of blood mixed with the standard liter of peritoneal lavage fluid will result in a positive DPL (100,000 red blood cells per cubic millimeter). In addition, this invasive procedure requires significant time and causes complications in up to 5 percent of patients.

Focused abdominal sonography for trauma (FAST) has proven to be a valuable tool in the evaluation of trauma victims. More than two dozen studies in European and North American centers have demonstrated that ED sonography has an accuracy similar to that of DPL for the detection of hemoperitoneum but has several advantages: it is more rapid (generally completed in under 5 min), requires no preparations (e.g., nasogastric tube and Foley catheter), has no contraindications, and is noninvasive. While ultrasound cannot reliably identify intraabdominal organ injuries (as can CT), it is accurate in predicting the need for laparotomy in trauma patients. Large studies have found the sensitivity of ultrasound to be 85 percent or higher with specificities of 96 percent or higher, [5] depending on the gold standards employed. Some studies have used the need for a therapeutic laparotomy as the gold standard, whereas others have used the presence of any intraabdominal injury or blood on CT as the gold standard, regardless of need for laparotomy (see Chap. 252 for further discussion.) Subcutaneous emphysema and marked obesity can impair the ability of ultrasound to image the abdomen, but it is uncommon that they prevent an adequate FAST examination. Training for as little as 2 to 8 has been sufficient for emergency physicians and surgeons to learn the FAST examination [6] and in many centers it has completely replaced DPL.

SONOGRAPHIC CONSIDERATIONS   The primary finding in the FAST examination is anechoic fluid collections (blood) within the peritoneal cavity. The four standard views of the trauma ultrasound examination are depicted in Fig. 295-10. The right upper quadrant view, the easiest of the FAST examination views to visualize, is obtained by imaging over the lower rib cage in the area of the anterior to midaxillary line with the marker dot pointed cephalad. The liver, kidney, and Morison pouch are examined (Fig. 295-11). The Morison pouch is a potential space between the Gerota fascia of the kidney and the Glisson capsule of the liver and is usually devoid of fluid. Because the Morison pouch is one of the most posterior compartments of the supine abdomen, blood tends to accumulate in this space, creating an easily identified anechoic stripe (Fig. 295-12). Organ lesions, while not reliably identified on ultrasound, may appear as anechoic areas within the organ or as echogenic foci. The left upper quadrant view examines the potential space between the spleen and the kidney, the splenorenal space (Fig. 295-13). This view is obtained by placing the transducer in the mid to posterior axillary line over the lower left costal margin. Here again, blood will appear as an anechoic stripe between the spleen and kidney. While not routine, placing the patient into a Trendelenburg position may increase the amount of blood in the upper abdomen, facilitating sonographic identification of blood in both the right and left upper quadrant. Both upper abdominal views are also capable of identifying hemothorax, where the anechoic fluid collection appears above the diaphragm. Studies have found ultrasound to be at least as accurate as chest x-ray in identifying hemothorax. [7,8] The pelvis is the most dependent location within the intraperitoneal cavity in a supine patient, explaining why hemoperitoneum commonly collects in this location. The pelvic view seeks to identify intraperitoneal blood in the potential space between the rectum and uterus (pouch of Douglas) or its homologue in the male, the rectovesicular space. As with the other views, blood here appears as a fluid collection between two adjacent soft-tissue structures (Fig. 295-14). Unclotted intraperitoneal blood is anechoic, with sharp borders against the peritoneal confines. The pelvic view is facilitated by a full bladder, which can be produced by instilling 250 mL of normal saline solution via a Foley catheter. The full bladder acts as an acoustic window, optimizing the view of the pelvic structures. As little as 250 mL of intraperitoneal blood should be routinely noted with ultrasound; even smaller collections can often be identified.
FIG. 295-10. Standard four views of the FAST examination. (From Sisley AC et al,[7] with permission.)

FIG. 295-11. Normal ultrasound image of the right upper quadrant demonstrating an absence of fluid in Morison's pouch (mp).

FIG. 295-12. Positive right upper quadrant FAST examination findings. Note "stripe" of fluid in Morison's pouch.

FIG. 295-13. Normal findings on left upper quadrant ultrasound. The potential space between the kidney and spleen is devoid of anechoic fluid.

FIG. 295-14. Positive pelvic FAST examination findings. An anechoic fluid collection is seen distal to the large fluid-filled bladder.

The last view, that of the subcostal area, examines the heart for evidence of pericardial fluid collections, which would suggest cardiac injury (Fig. 295-15). Rapid ultrasound evaluation of the heart has resulted in faster times to diagnosis and to surgical intervention, as well as improved survival rates and neurologic outcomes in patients with penetrating cardiac injuries. [9] It is occasionally necessary to differentiate pleural from pericardial fluid. Any fluid collection that follows the contours of the heart and is surrounded by the echogenic pericardium is pericardial fluid. There is no pleural reflection between the liver and heart; the subcostal view will therefore demonstrate pericardial, but not pleural, fluid. Blood within the pericardial space can appear anechoic but may be partially echogenic, depending on the degree of clotting and defibrination that occurs.

FIG. 295-15. Subcostal echocardiogram demonstrating pericardial hemorrhage (PH). Hep, hepatic parenchyma; RV, right ventricle; LV, left ventricle. (From Heller M, Jehle D, eds: *Ultrasound in Emergency Medicine.* Philadelphia, Saunders, 1995, with permission.)

The great majority of research in the use of trauma sonography has focused on blunt abdominal trauma. The studies that have utilized ultrasound in penetrating abdominal trauma have found that sonography has a sensitivity and specificity for predicting need for laparotomy similar to those found for blunt trauma. Several studies have examined trauma sonography in blunt pediatric trauma and have demonstrated it to be as accurate in detecting hemoperitoneum in this setting as in the adult population.

A number of centers routinely repeat the ultrasound examination in all patients not taken immediately to surgery. The fact that ultrasound is inexpensive, rapid, and noninvasive makes this a practical approach to minimizing the chance of missing intraabdominal injuries that develop more slowly. Repeat scans are performed within 30 min to 6 h, depending on the stability of the patient.

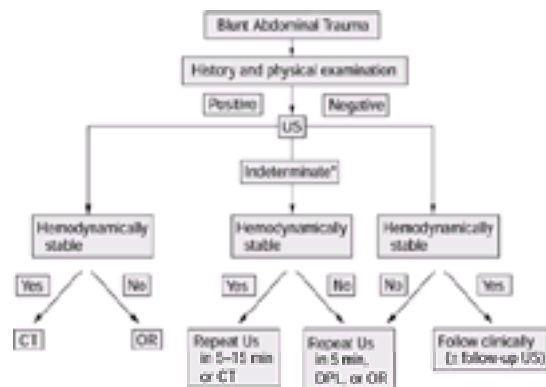
Ultrasound can be easily incorporated into routine trauma care. Sonography is often performed at the completion of the primary survey, allowing rapid identification of hemoperitoneum. Figure 295-16 illustrates an algorithm depicting how ultrasound can be used in a clinical setting. A hemodynamically unstable patient with positive trauma ultrasound findings should be taken immediately to laparotomy. A stable patient with positive sonogram findings can be evaluated with CT to identify the specific organ lesion and to determine the feasibility of nonoperative intervention.


FIG. 295-16. Ultrasound utilization in a blunt abdominal trauma patient.

First-Trimester Pregnancy Evaluation

No set of historical factors, signs, or symptoms can accurately identify patients with ectopic pregnancy, and no laboratory tests are diagnostic of this condition. Sonographically identifying an intrauterine pregnancy can markedly reduce the possibility of ectopic pregnancy, since heterotopic pregnancies (concurrent intrauterine and ectopic pregnancies) occur with an incidence of less than 1:30,000 pregnancies, except for infertility or in vitro fertilization patients, who must be managed in concert with their obstetrician.

The incidence of ectopic pregnancy has been increasing for several decades. Stovall et al found that 7.5 percent of all ED patients with a positive pregnancy test, regardless of history, symptoms, or physical examination had an ectopic pregnancy. [10] Studies that evaluate ED patients with any abdominal pain, vaginal bleeding, risk factors for ectopic pregnancy, adnexal masses, or tenderness have found the incidence of ectopic pregnancy to be more than 10 percent. When ultrasound is used only in selected first-trimester ED patients (rather than all patients), 40 to 50 percent of the ectopic pregnancies are not identified. Approximately one-half of these ectopic pregnancies are ruptured at the time of diagnosis, which increases the risk of morbidity and mortality while decreasing the likelihood of subsequent normal pregnancy. Ultrasound evaluation of *all* first-trimester pregnant patients presenting to the ED with any abdominal or pelvic pain, vaginal bleeding, or risk factors for ectopic pregnancy has been recommended. Such an approach has been found to markedly decrease the frequency of delayed diagnoses and ectopic rupture at the time of diagnosis. [11] Emergency physicians have been proven capable of performing pelvic sonography in the evaluation of women at risk for ectopic pregnancy with an accuracy similar to that of obstetrics-gynecology consultants. Further, when an emergency physician performed the sonography, the patients were dispositioned much more quickly than when the ultrasound was performed by an obstetrics-gynecology consultant (60 versus 180 min). [12]

SONOGRAPHIC CONSIDERATIONS   The pelvic organs can be imaged transabdominally or endovaginally. The transabdominal approach is best accomplished with a full bladder. The patient can avoid emptying the bladder, or 250 mL of normal saline solution can be instilled via a Foley catheter. The full bladder displaces bowel gas from the pelvis and functions as an acoustic window for the pelvic structures. The 3.5-MHz probe, or 5-MHz probe in thin patients, is used for this examination. Endovaginal scanning is performed with a 5- to 7.5-MHz probe designed for this purpose and is best performed with an empty bladder. A condom or sheath is placed over the transducer, which is then introduced several centimeters into the vagina. The endovaginal approach is not uncomfortable, and most patients prefer it to transabdominal probe pressure on a distended bladder. With the transducer tip in close proximity to the structures of interest, high-frequency, high-resolution probes can be utilized, resulting in much greater sonographic detail and allowing for earlier identification of an intrauterine pregnancy. While endovaginal scanning can identify a gestational sac as early as 4.5 weeks after the last menstrual period (LMP), transabdominal scanning is often not able to visualize it until 5.5 to 6 weeks after the LMP. In fact, all the landmarks of pregnancy are visualized approximately 1 week earlier with the endovaginal approach (Table 295-3). Transabdominal scanning provides a view of the entire pelvic contents, but with less resolution than the endovaginal approach. Endovaginal scanning can miss masses in the upper pelvis and lower abdomen due to the shallow depth of acoustic penetration of the higher-frequency transducer. These two approaches should, therefore, be thought of as complementary; one may yield the diagnosis if the first does not.

Structure	Transabdominal, Weeks	Endovaginal, Weeks
Gestational sac	6	4.5
Yolk sac	6–6.5	5–5.5
Fetal pole	6.5–7	5.5–6
Cardiac activity	7	6

TABLE 295-3   Earliest Sonographic Visualization of Embryonic Structures

The primary ultrasound finding to be evaluated in first-trimester patients is evidence of an intrauterine pregnancy. The earliest sonographic finding of pregnancy is the gestational sac. This appears as a round or oval anechoic area within the uterus (Fig. 295-17). Care should be exercised in identifying gestational sacs, since up to 20 percent of ectopic pregnancies have a "pseudogestational sac," which looks sonographically similar to a true gestational sac but is caused by intracavitary blood surrounded by a decidual reaction. True gestational sacs have two concentric echogenic rings surrounding the gestational sac (*double decidual sign*), representing the decidua parietalis and the decidua capsularis, and tend to appear to be adjacent to, not within, the echogenic endometrial complex (*intradecidual sign*). The first true embryonic structure that can be seen sonographically is the yolk sac (Fig. 295-9). This echogenic ringlike structure can be seen with endovaginal scanning at approximately 5 weeks after the LMP. As the pregnancy progresses, the fetus is seen at 5.5 to 6 weeks, with fetal parts being visible at 8 weeks endovaginally. Fetal cardiac activity can generally be seen from the time the fetal pole is identified but should always be present when the embryo is greater than 10 mm if the fetus is viable. The presence of fetal cardiac activity is very helpful prognostically. The rate of spontaneous abortion is less than 5 percent when normal cardiac activity is seen at 8 to 12 weeks of gestation.
FIG. 295-17. Normal intrauterine pregnancy. The fetal pole (within calipers) and the round, echogenic yolk sac are seen within the anechoic gestational sac.

Although the primary goal of bedside US is to identify an intrauterine pregnancy, ectopic pregnancies can result in a number of sonographic findings. First, a living extrauterine pregnancy may be seen, obviously securing the diagnosis of ectopic pregnancy. This occurs in approximately 20 percent of ectopic pregnancies. The sonogram may also demonstrate abnormal structures suggestive of an ectopic pregnancy, such as an echogenic ringlike mass in the adnexae. The most common finding seen with ectopic pregnancies is that of an empty uterus with either no other findings or nonspecific findings (e.g., fluid in the cul-de-sac).

The quantitative b human chorionic gonadotropin (b-HCG) level is extremely helpful in evaluating pregnant patients with an empty uterus on ultrasound. A number of authors have suggested "discriminatory zones," b-HCG levels above which an intrauterine pregnancy should be visualized if present. The value utilized in clinical practice depends on the skill of the sonographer, the quality of the ultrasound machine, and individual patient factors. Based on the work of several authors, it is expected that intrauterine pregnancy is detectable on endovaginal scanning if the b-HCG level is greater than 2000 MIU/mL. [11] In some institutions, the discriminatory zone could be as low as 1000 MIU/mL. Patients with b-HCG levels greater than this (the discriminatory zone) who do not have evidence of an intrauterine pregnancy on ultrasound are at very high risk for an ectopic pregnancy, and obstetrical consultation is needed. Such patients may undergo observation with repeat b-HCG level determinations, and ultrasound, laparoscopy, or surgical intervention, depending on the individual patient and the preferences of the obstetrician. For hemodynamically stable patient's with a b-HCG level less than 2000 MIU/mL and no intrauterine pregnancy on ultrasound, disposition is usually arranged in concert with the obstetrician. If the patient is discharged, obstetric follow-up is needed in 48 to 72 h, whereupon repeat b-HCG and ultrasound examinations are performed. Mateer and colleagues followed such a protocol and were able to decrease the number of delayed diagnoses of ectopic pregnancy from 43 to 28 percent, and the incidence of ectopic rupture at diagnosis decreased from 50 to 9 percent. [11]

Cardiac Ultrasonography

Two-dimensional echocardiography has become an invaluable tool in the evaluation of cardiac anatomy and function. Echocardiography is capable of evaluating myocardial wall motion, valve function, the great vessels, and pericardial fluid collections. The examination of these structures can be technically demanding, requiring specialized transducers and specialized training. Applications of bedside ultrasound by emergency physicians is therefore limited to critically time-dependent diagnoses that can be recognized by emergency physicians with a modicum of training and the standard ultrasound equipment available in the ED. The evaluation of cardiac trauma, pulseless electrical activity (PEA), and pericardial tamponade are such applications. The sonographic findings of interest in such settings are pericardial fluid collections and myocardial wall activity.

The use of ultrasound in the evaluation of potential cardiac trauma is discussed earlier, in the section on the FAST examination. Both blunt and penetrating trauma can result in hemopericardium, which can be rapidly diagnosed with ultrasound (Fig. 295-7). Electromechanical dissociation is a cause of PEA that has an extremely poor prognosis. An echocardiogram demonstrating a flaccid, inactive heart in a patient with PEA suggests very little chance of survival. In contrast, a hyperdynamic heart with small right-heart dimensions suggests hypovolemia, a readily treatable condition. Cardiac tamponade can be very difficult to diagnose at the bedside without the assistance of ultrasound. Echocardiography provides a means of rapidly determining whether a pericardial fluid collection is present, without which there can be no tamponade.

A number of windows used to sonographically evaluate the cardiac structures have been described. The *subcostal view* is the most useful to emergency physicians. This view can be obtained while other procedures are being performed with a 3.5-MHz transducer. Other views are best obtained using specialized transducer heads with small footprints (the surface area of the portion of the transducer that comes into contact with the patient) in order to image between the ribs. The subcostal view, obtained by placing the transducer in the area of the xiphoid process aiming toward the left shoulder, provides visualization of all four cardiac chambers. As always, structures that are closest to the transducer appear at the top of the image monitor; the liver, therefore, appears uppermost on the monitor, with the right atrium adjacent to it. The left atrium and ventricle appear closest to the bottom of the screen.

Other views used to evaluate cardiac structure include the left parasternal short-axis (LPSA), the left parasternal long-axis (LPLA), and the apical views. The *parasternal window* is obtained by placing the transducer between the second and fourth intercostal spaces adjacent to the sternum. In the LPLA, the ultrasound beam is directed in a plane parallel to a line drawn from the right shoulder to the left hip. This view images the aortic valve, proximal ascending aorta, and left ventricle well. The short-axis view (LPSA) is obtained by rotating the transducer 90°, so that the beam is parallel to a line drawn from the left shoulder to the right hip. Here the left ventricle appears as a round, thick-walled chamber, and the right ventricle appears more anteriorly in a crescent shape. The LPSA view is best used to image the mitral valve, papillary muscles, and aortic valve. The *apical view* is obtained by placing the transducer over the point of maximal cardiac impulse on the precordium (the apex) with the beam directed to the right shoulder. This view allows for the assessment of chamber size and the identification of aneurysms and intracardiac masses. The emergency physician can generally obtain the information necessary for the bedside indications mentioned above using only the subcostal view. The other views described may provide added information if the examiner has the appropriate equipment and training.

SONOGRAPHIC CONSIDERATIONS   The echocardiographic evaluation of cardiac tamponade requires little training and can be rapidly performed at the bedside. The subcostal view should visualize any pericardial fluid collection large enough to result in tamponade. The pericardium is a dense, fibrous, echogenic sac that surrounds the heart. The pericardial space contains less than 50 mL of pericardial fluid under normal circumstances. Pericardial effusions appear as echo-free areas within the pericardial space. Small pericardial effusions (<100 mL) usually occupy a dependent position in the pericardial sac, while large effusions (>300 mL) are present both anteriorly and posteriorly. Whether a pericardial fluid collection affects cardiac function depends on such variables as the amount of fluid present, the rate of formation, and the underlying condition of the pericardium (diseased or not). Intrapericardial pressure rises abruptly after 80 to 200 mL of fluid has collected rapidly in the previously normal pericardial space. Early sonographic signs of increased intrapericardial pressure include right atrial and right ventricular collapse in diastole, but these findings are not always appreciable during the ED sonographic examination.

The interpretation of an echocardiographic finding of pericardial fluid collection must incorporate the clinical status of the patient. While the absence of a pericardial fluid collection excludes the diagnosis of cardiac tamponade, the mere presence of a pericardial fluid collection in an unstable patient is not diagnostic of pericardial tamponade. When pericardiocentesis is deemed necessary, sonographic localization of the heart will assist in determining the best approach for the procedure.

The patient with PEA (i.e., electrical cardiac activity without a palpable pulse) can be suffering from a wide variety of conditions, some fatal, some easily treated. Ultrasound greatly assists in the rapid diagnosis and treatment of such patients. The sonographic examination is straightforward. Cardiopulmonary resuscitation should be stopped briefly during the ultrasound examination. Any of the standard cardiac windows can be utilized, but the subcostal view has the advantages of easy imaging with standard ultrasound transducers and lack of interference with other procedures. Once visualized, the ventricles and valves are examined for evidence of activity. A patient in true electromechanical dissociation has no demonstrable cardiac activity. Several treatable causes of PEA can be diagnosed with a sonogram and appropriate treatment instituted. The ventricles of a hypovolemic patient contract vigorously, while the right-heart dimensions are diminished. Cardiac tamponade, another treatable cause of PEA, can also be easily diagnosed with echocardiography, as discussed above.

MISCELLANEOUS EMERGENCY DEPARTMENT APPLICATIONS

Formal radiology department ultrasound studies have been helpful in a great number of conditions beyond those already discussed. Emergency physicians, given the appropriate time, training, and equipment could technically perform any of these examinations at the bedside. This section discusses some applications that have been used by emergency physicians but are not now considered primary indications.

Deep Venous Thrombosis

Compression ultrasound has been performed by emergency physicians to evaluate ED patients suspected of having lower-extremity DVT. [13] Such studies detect venous thrombosis based on the fact that a vein filled with thrombus is not compressible whereas normal veins can be easily compressed. An examination of the lower extremity for DVTs, therefore, consists of sonographically identifying the common femoral vein and artery and proceeding distally to the trifurcation of the popliteal vein, imaging the veins at 3- to 5-cm intervals. The inability to compress a vein by transducer pressure is diagnostic of DVT in the portion of the vein being imaged. Echogenic thrombus is occasionally visualized within the vein, but slow-flowing blood may have a similar appearance, making this finding nonspecific. Compression ultrasound has been found to have both a sensitivity and a specificity of approximately 95 percent in venographically proven proximal leg DVTs, but the test is not accurate in identifying calf DVTs. Since approximately 20 percent of calf DVTs propagate to the proximal leg, repeat studies of the lower extremity are recommended in patients suspected of having a DVT found to have negative findings on compression ultrasound study. (See Chap. 55 for a detailed discussion.)

Visualization of Bladder and Fluid Collections

Ultrasound excels at identifying fluid collections, and a number of possible ED applications utilize this property. Unless devoid of urine, the bladder is very easy to identify on ultrasound, and most ultrasound machines have the ability to estimate bladder volume based on easily performed measurements. The invasive and painful procedure of catheterizing the bladder to determine postvoid residual volume can often be obviated by ultrasound. Furthermore, suprapubic bladder catheterizations and aspirations are easier and more likely to be successful when guided by ultrasound. Identifying abscesses is another area where ultrasound can be of assistance. With the use of high-frequency transducers (7.5 to 10 MHz), the presence or absence of fluid collections within subcutaneous masses can be determined. If an abscess is present, the depth of the abscess and surrounding structures (e.g., vessels) can be identified. The fluid within the abscess appears anechoic or has scattered echoes within a hypoechoic collection, representing necrotic debris. Just as ultrasound can identify hemothoraces, it can identify even small pleural effusions and guide aspiration attempts.

Procedural Uses

In addition to the bladder aspiration, mentioned above, there are several other procedural applications for ultrasound in the ED. While plain-film radiography or fluoroscopy is very accurate at identifying radiopaque foreign bodies, other objects, such as wood, can be very difficult to identify in a wound. Ultrasound is capable of identifying wooden objects as small as 2.5 by 1.0 mm in soft tissue and is also capable of identifying metal, plastic, glass, and vegetable matter. [14] With high-frequency probes (7.5 to 10 MHz), foreign bodies appear echogenic, often with acoustic shadowing. [15] With a small wound that is not amenable to exploration, it is acceptable to image directly over the potential entry site with the transducer and gel.

Sonography may also be used to assist in the percutaneous placement of central venous catheters. [16] Studies have found that the use of ultrasound to guide this procedure results in a decreased failure rate and lowers the overall incidence of complications. [17] Here, a 7.5- to 10-MHz probe identifies the location of the vein to be cannulated (e.g., internal jugular vein), and then the percutaneous puncture can be performed with accurate knowledge of the location of the vein. The vein is seen to compress considerably before puncture occurs.

Appendicitis

The sonographic evaluation of patients suspected of harboring acute appendicitis is mentioned here primarily as a cautionary note. The finding of a noncompressible appendix greater than 6 mm in diameter has been found to be helpful in making the diagnosis of appendicitis in the appropriate clinical setting. [18] However, several aspects of this examination make it particularly unsuited for performance by emergency physicians. This examination is generally quite time consuming, requires specialized training and experience, and can be very difficult technically. The diagnosis of appendicitis is also not as critically time dependent, as are such entities as ruptured AAA or hemoperitoneum in a trauma patient, and generally is best left in the hands of sonologists trained in this technique. Other potential uses for bedside ultrasound in the ED can be found in standard emergency ultrasound texts.

BASIC PHYSICS AND TERMINOLOGY

Computed tomography (CT) is a technique that creates cross-sectional images with the use of x-rays and computerized image reconstruction. The patient passes through a gantry that contains an x-ray tube on one side and a set of detectors on the other. The gantry rotates around the patient, obtaining information from the detectors that is then analyzed by computer and displayed as an image. The image information can be manipulated by the computer to display a greater spectrum of densities than can be displayed on conventional x-ray film.

Image Formation and CT Numbers

The various shades of gray that make up a CT image are determined by the density of a structure and the amount of x-ray energy that passes through it. This phenomenon is referred to as the attenuation of the x-ray. The degree of beam attenuation on a CT image is quantified and expressed in Hounsfield units (HU), which are also referred to as CT numbers. Attenuation values span a range of 4000 CT numbers, from air at −1000 HU, to cortical bone at +3000 HU, and water is assigned the density of approximately 0 HU.

In conventional CT, each cross-sectional slice through a patient's body has a thickness, referred to as its z axis. The data are then further divided into tiny cubes of equal volume called *voxels* (volume elements). Each voxel is assigned a CT number that is determined by the degree to which the material in that voxel absorbed the x-ray beam. The two-dimensional CT image is formed by displaying the front face of each voxel, termed a *pixel* (picture element), in a composite matrix. The most common matrix size of CT scanners is 512 rows of pixels by 512 columns, or a total of 262,144 pixels[1] (Fig. 296-1).
FIG. 296-1. The gray disc represents a cross-sectional slice corresponding to the patient. To create an image, the patient's data are segmented. A pixel is a two-dimensional square. A voxel incorporates the thickness of the slice and is a three-dimensional cube.

Volume Averaging

Certain factors affect the accuracy of the Hounsfield units and the accuracy of the image. The degree of linear attenuation and the resultant CT number are determined by the average density of the material within that voxel. Therefore, when a voxel is filled with several structures (or the structure of interest is smaller than the voxel), the voxel will be assigned a CT number or HU that is subject to *volume averaging* artifact. If the resolution of a very small structure is important, decreasing the scan thickness will improve accuracy. However, the benefits of thinner sections must be considered along with the risk of a higher radiation dose to the patient with the increased number of slices. Scanning protocols are designed to balance image resolution with acceptable radiation dose.

Image Noise

Although thinner sections increase image resolution, some of the advantages are lost due to increased image *noise,* also known as *quantum mottle.* Image noise is due to an insufficient number of x-ray photons reaching the detectors, resulting in a grainy image. Image noise can be reduced by increasing the radiation dose, but, again, a compromise between radiation exposure and image noise determines the quantitative x-ray dose.

Window and Level

Window width and *window level* are display settings that can be manipulated to optimize the appearance of the image. Selecting a window width determines the range of CT numbers that will be represented on a specific image. The computer assigns different shades of gray to CT numbers that fall within the selected range. CT numbers that are above the chosen range will appear white, while numbers below the chosen range will appear black. By increasing the window width, a greater range of CT numbers are each assigned to a shade of gray. This technique is used when it is desirable to view a variety of tissues that vary greatly in density (e.g., lung). The disadvantage to wider windows (400 to 2000 HU) is that subtle differences in density will not be visualized.

When the goal is to visualize a section of anatomy with minor discrepancies in tissue density, narrow window width is chosen (50 to 400 HU). A good example of the use of narrow window width is in the brain, where there is little difference in tissue densities; yet, with the higher contrast achieved with a narrow window, white and gray matter can be differentiated.

Window level determines the CT number that will be the center of the gray scale. The window level is generally set at the same value as the average attenuation number of the tissue of interest.

The image from a single data set can be displayed at different window widths and levels to highlight various tissues of interest. For example, in chest CT, settings that optimize the image of the soft tissue mediastinal structures use a moderate window width (e.g., 350) centered at a level just above water (e.g., +30). However, this setting does not allow visualization of the details of the lungs (Fig. 296-2A). On the other hand, lung settings use a wide window (e.g., 1400) and a low level (e.g., −600) to center the gray scale so it includes air densities (Fig. 296-2B). To optimize the image of a bony structure, a wide window (e.g., 1500) and a higher level (e.g.,

+305) would be used to center the gray scale toward higher-density tissues (Fig. 296-3).
FIG. 296-2. CT windows. **A.** Mediastinal window. Note that the mediastinal anatomy is well shown; no lung detail can be seen. Note also the following structures: A, aorta; S, superior vena cava; and P, pulmonary artery. **B.** Lung window. Note that the vascular anatomy of the lungs is now well seen.
FIG. 296-3. A and B. The same CT scan at different window and level settings. A posterior wall fracture of the left acetabulum is shown at settings for bone **(A)** and at settings for soft tissue **(B)**. The wider window and higher level of the bone settings enable better visualization of bone detail but make all soft tissue structures nearly the same shade of gray. Soft tissue settings allow examination for hemarthrosis and adjacent soft tissue hematoma.

SCANNER GENERATION

The terms *first-generation through fourth-generation scanners* are used to represent the developments in technology that relate the configuration of the x-ray tube to the detectors. The first-generation scanners, which are no longer in use, had a thin x-ray beam pass linearly over the patient in a 180° arc, followed by a single detector on the opposite side.[2] Scanning time was very lengthy. Second-generation scanners used multiple detectors and a fan-shaped x-ray beam that continued to pass linearly across the patient before rotating. Scan times improved but were still very long.

Third-generation scanners represented a significant advance in technology, and scan times were greatly reduced. This design incorporates a fan-shaped beam and a detector array, and both move in a circle within the gantry. With the use of a rotating detector, all of the readings that make up a view can be recorded at the same time.[1] Third-generation scanners are the most common conventional models in use today.

Fourth-generation scanners have a detector array that is fixed and positioned in a complete circle within the gantry. The x-ray tube produces a fan-shaped beam that rotates around the patient. Scan times are theoretically shorter than with third-generation scanners, but few fourth-generation scanners have been installed. [2]

SPIRAL COMPUTED TOMOGRAPHY

The biggest technological advance came with the advent of spiral or helical scanning. Rather than scanning with the traditional axial method where the slices lie parallel to one another, spiral scanning obtains data continually in a spiral fashion. There is a continually rotating x-ray gantry and continuous table movement. This was achieved by a critical advance in hardware technology with the introduction of slip-ring interfaces in gantry construction, allowing for continuous rotation of the source detector assembly.[3] With conventional CT, a patient is required to hold his or her breath for each additional slice. When a patient breathes to varying depths with each slice, lesions as large as 1 cm can be missed as a result of slice *misregistration*. (Fig. 296-4). In a typical spiral scanner, 60 images can be acquired in 1 min, therefore there is less breath holding, which decreases slice misregistration.
FIG. 296-4. Slice misregistration caused by a patient's breathing. Each consecutive slice was 10 mm or more inferior, yet the second image appears the most superior. Lesions as large as 1 cm can be missed as a result of slice misregistration.

Because spiral scans are acquired at a slight slant, computer software must adjust for the angle by averaging the data. This statistical method of processing the data is referred to as *interpolation* (linear and nonlinear). The evolution of mathematical software processes enabling missing data to be estimated in helical data sets has also been critical to the advancement and success of spiral CT. [3] There is, however, a small decrease in resolution inherent to interpolation (Fig. 296-5).
FIG. 296-5. Spiral scans are acquired at a slight slant because of the continuous motion of the x-ray tube and table. By interpolating the data, the computer then creates an image that is not slanted. This process increases the effective slice thickness and causes some loss of image resolution. The more pronounced the slant, the more interpolation is required. The slant is affected by selected slice thickness and pitch.

The term *pitch* refers to the relation of table speed to slice thickness. If pitch is set at 1:1, the table will move at a speed that allows the gantry to rotate once for every slice thickness chosen. For example, with slice thickness at 5 mm, the table moves at a speed that allows the gantry to rotate once every 5 mm of table travel. If the pitch is adjusted to 2:1 and the slice thickness is maintained at 5 mm, the tube rotates only once for every 10 mm of table motion. Pitch is sometimes adjusted toward 2:1, which, in essence, "stretches the spring" and less data are acquired.[1] Pitch is usually set at close to 1:1 but may be increased when it is important to cover a long anatomic area in a very short time, as with CT angiography.

Spiral CT scanning has optimized the delivery of intravenous (IV) contrast. The rapid speed of the scanning technique allows for much finer control over which phase of IV contrast enhancement is imaged and allows for the possibility of obtaining more information from a single bolus of contrast. For example, in the abdomen, images can be obtained during the hepatic arterial, portal venous, and equilibrium phases. Delayed images are also easily and rapidly obtained when enhancement characteristics of certain lesions need to be visualized or when the urinary excretory phase must be imaged. This capability is widely utilized in trauma where major organ lacerations and active bleeding sites are best visualized during early phases of contrast enhancement, while bladder perforation may be better imaged on delayed contrast imaging.

The major advantages of helical scanning over conventional scanning are

1. Volumetric data acquisition is acquired rapidly.
2. Less contrast material is needed because of increased scanning speed.
3. Images can be retrospectively reconstructed at any desired interval or thickness or may be overlapping without rescanning the patient.
4. Respiratory, cardiac, and other motion artifacts are reduced.
5. The continuous nature of the data allows high-quality three-dimensional and multiplanar reconstruction.

Although the advantages of spiral CT predominate, there are some disadvantages:

1. If pitch (relation of table speed to slice thickness) is increased from 1:1 toward 2:1, image resolution can be lost.
2. When scanning very large patients, there will be increased image noise if the milliampere setting cannot be maintained. Scanners vary regarding weight limitations, although the average maximum patient weight is approximately 350 lb.
3. Some image resolution may be lost due to the interpolation required to process spiral data.
4. Contrast material injection must be timed precisely, although this problem has been minimized with the use of established contrast protocols and power injectors.
5. Children and uncooperative adults need sedation and thus, close monitoring.

Spiral CT scanners continue to have the capability of acquiring axial images. For example, at some institutions, CT protocols for cervical spine trauma use a spiral CT scanner to obtain axial images because of the potential improvement in image resolution in this anatomic area.

An important issue raised by the advent of spiral CT is what constitutes an appropriate examination archive. At this point, because of the enormous space required to store all the information, most CT scanners delete the raw data soon after the scan is acquired. Thus, it is important to select the reconstruction interval quickly and appropriately so that the opportunity is not lost to request additional reformatted images before the raw data is deleted.

GENERAL USES AND LIMITATIONS

As CT technology has advanced, the role of CT in the emergency department (ED) has also increased enormously. A CT scanner is in, or adjacent to, many EDs today in the United States, in recognition of its fundamental utility and to minimize necessity for patient transport. The only real disadvantages of CT are its relatively high cost and the use of ionizing radiation. Standard charges for conventional and spiral CT are the same. Head CT continues to be the primary imaging study for screening ED patients acutely, particularly for detection of acute hemorrhage, trauma, and cerebrovascular accident. Magnetic resonance imaging (MRI), however, may have an additional role when posterior fossa pathology or subtle parenchymal abnormalities are suspected. In general, CT is the imaging study of choice for the examination of the retroperitoneum and for many disorders of the abdomen and pelvis. At many institutions, spiral CT has become the primary imaging modality for detection of acute appendicitis[4] and ureteral calculi. It is also the modality of choice for many disorders of the mediastinum and lungs. Fractures and other bone pathology are often best visualized with CT, and it is excellent for detecting cervical spine, pelvic, and facial bone fractures.

Only a few areas of the body are poorly imaged with CT. The pituitary fossa and the posterior intracranial fossa are difficult to visualize because the adjacent bony structures cause significant streak artifact. MRI is the preferred study in these anatomic areas. CT is not sensitive in differentiating spinal cord or nerve roots from cerebrospinal fluid (CSF) unless contrast has been injected into the CSF space. MRI is the imaging study of choice to evaluate the spinal cord.

Although spiral scanning data can be reformatted into high-quality sagittal and coronal plane images, conventional CT is usually limited to the axial (transverse) plane. There are anatomic areas (such as the head and ankles) that can be positioned in the gantry of conventional CT scanners to obtain direct coronal images.

The role of CT in the evaluation of all potential ED presentations is beyond the scope of this chapter. The reader is referred to specific chapters of chief complaints or diagnoses for a discussion of the potential value of CT for each topic.

THE USE OF CONTRAST

Contrast materials for CT examinations can be administered via oral, rectal, intravenous, intraarterial, intraarticular, or intrathecal routes, and usage varies according to the examination desired. In general, contrast usage in the ED is limited to the oral and/or IV routes.

Oral Contrast

Oral contrast agents are used for most CT examinations of the abdomen and pelvis to ensure adequate contrast opacification and distention of the bowel. This is necessary to enhance the appearance of the bowel wall to detect hematoma, edema, mass, or laceration. This is usually achieved with *positive* contrast agents, such as iodine-based and barium-based agents. At times, however, *negative* contrast is optimal in the upper gastrointestinal tract and is achieved by using an oral water preparation. This is helpful, for example, when the indication for the abdominal CT is to evaluate the pancreas in a patient with jaundice. Occasionally, distention of the upper gastrointestinal tract can also be achieved by the additional administration of effervescent granules that cause gas formation within the bowel lumen. It is important that the radiologist and/or technologist know the purpose of the study so that the correct oral preparation is ordered. It is much more common to administer

water-soluble iodinated oral agents to ED and trauma patients to avoid complications from extravasation of barium agents.

The iodine-based oral contrast used for CT is very dilute compared with the full-strength iodine-based contrast used for conventional radiography (upper gastrointestinal and barium enema series). Full-strength solutions may cause artifacts on CT because of their high density. Whereas full-strength iodine-based contrast aspiration may cause life-threatening pneumonitis, the dilute contrast used for CT poses much less risk. Nonetheless, use of this agent should either be avoided, or it should be used with caution in patients at risk for aspiration. If oral contrast is necessary in a patient with a known iodine allergy and a known gastrointestinal tract disorder, a dilute barium sulfate suspension should be administered instead.

Administering oral contrast takes approximately 2 h in a patient with a normal transit time if the entire bowel needs to be opacified. For example, intraluminal contrast must be present in the right colon to evaluate a patient adequately for possible appendicitis. For evaluating certain upper abdominal conditions, an additional 200 mL of oral contrast should be given just before scanning, to opacify the stomach and proximal small bowel. Not infrequently, an ED patient has nausea and vomiting, and a nasogastric tube and antiemetics are required in order to facilitate the oral contrast administration. Some contrast protocols use rectally administered contrast. The terms *double contrast* and *triple contrast* usually refer to the possible combined routes (oral, rectal, or vascular), but in some situations may refer to the concentration.

Intravenous Contrast

IV contrast is frequently utilized for emergency CT studies, because it creates a more detailed image of many structures, particularly abdominal, pelvic, and retroperitoneal organs. The contrast material causes beam attenuation that is directly related to the iodine concentration achieved by the vascular supply to that tissue. Abnormal tissue, whether due to a malignant, inflammatory, or infectious etiology, has different contrast enhancement patterns than normal tissue and may appear avascular, hypovascular, isodense, or hypervascular. Images can be obtained at various phases following contrast administration. Depending on the diagnosis in question, the study should be tailored to acquire data at the appropriate time (Fig. 296-6).
FIG. 296-6. Scans of a 16-year-old boy after a skiing accident. **A.** Scan before intravenous (IV) contrast bolus enhancement is displayed at standard abdominal soft tissue settings; the intrahepatic clot and laceration are difficult to see. **B.** After bolus IV contrast administration during dynamic scanning, a scan at the same level as in **(A)** shows the hepatic laceration well. The laceration extends immediately behind but does not apparently involve the right hepatic vein. Note that the clot appeared hyperdense relative to the liver before IV contrast administration and appears hypodense relative to the enhanced liver after bolus contrast. The clot did not change density. The liver increased in density because of the circulating metal in the IV contrast. **C.** The upper abdominal component of this patient's relatively small hemoparitoneum is seen as blood in the Morison pouch (the right posterior subhepatic space between the liver and kidney).

In certain circumstances, it may be necessary to perform both a noncontrast CT scan and a contrast CT scan. CT scans to evaluate patients with potential urinary tract calculi must initially be performed without IV contrast, because the presence of contrast can easily obscure any renal stones present. In addition, an obstructing ureteral calculus may often be detected on an unenhanced CT study. However, IV contrast can be useful to determine the exact level of ureteral obstruction or to determine whether a pelvic calcification lies within the ureter. It may also provide information on the function of the kidneys. In general, the best way to optimize any study is to discuss the purpose of the CT adequately with the radiologist and/or technologist performing the study.

Irwin D. Weisman

The significant advances in imaging technology of recent years have dramatically expedited diagnosis and improved outcomes in emergency department patients. Magnetic resonance imaging (MRI) has been at the forefront. In just a short time, it has become a major adjunct for neurologic and musculoskeletal evaluation. This chapter briefly describes MRI and elucidates its role in emergency medicine:

Magnetic resonance imaging has the following major advantages:

1. Like ultrasound, it does not use ionizing radiation and no short-term or long-term side effects have been demonstrated. This is in contrast to the high-energy ionizing radiation of computed tomography (CT) and other x-ray methods, which produce small but finite biologic damage that may have long-term carcinogenesis implications. Because of this consideration, where applicable, MRI should be preferred over CT and tomography in the pediatric and childlbearing female populations.
2. It produces variable-thickness, two-dimensional slices in any orientation through the body part of interest, thus optimizing visualization of tissues and their interfaces. With few exceptions, CT is restricted to a scan plane that is transverse to the long axis of the body.
3. Because of the different physical principles underlying magnetic resonance (as opposed to x-rays), it provides better contrast resolution and tissue discrimination in many areas compared with x-rays or ultrasound. For example, spinal cord, bone marrow, muscles, and tendons are better visualized with MRI than with CT. As a result, MRI is replacing invasive methods such as myelography, arthrography and, in limited situations, angiography.

MRI is a specific application of nuclear magnetic resonance to medical imaging. [1,2] Nuclear magnetic resonance was discovered simultaneously in 1946 by Bloch and colleagues at Stanford University[3] and by Purcell and colleagues at Harvard University.[4] Bloch and Purcell shared the Nobel Prize in 1952 for their outstanding contribution to the physical sciences.

PHYSICAL BASIS

The nuclei of hydrogen in water and fat molecules behave like small spinning bar magnets. When placed in a strong uniform magnetic field (greater than 0.01 tesla or 100 gauss), they execute a circular motion, or precession, weakly aligning to form a net nuclear polarization nearly parallel to the external magnet field. If a short pulse of radio frequency (rf) energy (radio wave), precisely tuned to the precession frequency of the water and fat proton nuclear magnets, is applied, the nuclei absorb a small amount of energy, change their alignment, and then gradually return to their previous equilibrium positions. In responding to the radio wave, the net nuclear magnetization generates a small voltage: the nuclear magnetic resonance signal. This can be detected and recorded electronically.

Two parameters T1 and T2, also known as respectively longitudinal and transverse relaxation times, govern the behavior of the electronic signal detected. The relaxation times are a function of the immediate environment of the resonating protons and vary in the different biologic tissues. For example, free water exhibits long T1 and T2 values and fat exhibits short T1 and relatively short T2 values. Image generation requires a large number of repetitions of the sequence that produces the nuclear resonance signal. The time between repetitions is called TR. For technical reasons, a two-pulse sequence is used to generate a particular type of signal called a spin echo. The spacing between pulses is labeled TE/2, and an echo occurs at a time TE. There are important relationships between the intensity of the nuclear magnetic resonance echo and TR, T1, TE, and T2. Based on the effects of the different relaxation times (T1 and T2), two types of imaging are carried out. Short repetition times (TR) between successive cycles of rf excitation pulses and short echo times (TE) produce stronger signals from tissues with relatively short T1 times, such as fat, especially bone marrow. Hence, weighting favoring short T1 results from pulse sequences using short TR and short TE. On the other hand, longer TRs eliminate much of the T1 signal difference between fat and water so that further manipulation of the rf pulse spacing (longer TE) will enhance signals from tissues with long T2 times, such as edema fluid. Long TR, TE pulse sequences preferentially weight long T2 tissues. Thus, the two basic methods of MRI scanning are labeled T1-weighted and T2-weighted imaging.

To construct an image from the tissue-specific signals of an object (for example, a patient), it is necessary to apply small, spatially inhomogeneous, three-dimensional magnetic fields called gradients. They modify the signal decay of the nuclear magnetization and spatially tag the hydrogen nuclear magnets in the object for mapping the image. The actual reconstruction of an image is complex, just as in CT scanning, and requires a relatively fast computer with a large memory. The ultimate result is a two-dimensional, medically diagnostic, cross-sectional body image that is displayed on a video monitor and recorded on film or digitally stored on a hard disk or magnetic tape as a permanent record. In most gray-scale imaging formats, the strongest signal corresponds to maximum brightness on the black-and-white monitor. Therefore, in heavily T2-weighted images, water appears bright, whereas fat appears intermediate gray. On the other hand, on T1-weighted images, fat appears bright and water appears dark (Fig. 297-1). Table 297-1 lists the expected signal intensities for several biologic tissues in these two cases. Many newer and more sophisticated imaging pulse sequences have evolved from this imaging framework, such as chemical fat suppression, inversion recovery, short T1 inversion recovery (STIR), fluid attentuation inversion recovery (FLAIR), gradient echo recall, magnetization transfer, rapid acquisition with relaxation enhancement (RARE), echo planar, and diffusion gradient. For a more complete discussion of the technical aspects and clinical applications of MRI, readers are referred to more specialized texts. [5,6]
FIG. 297-1. Examples of T1-weighted and T2-weighted magnetic resonance images. **A.** T1-weighted coronal image: note that the urine in the bladder (*arrow*), which is essentially water with a long T1, appears dark, whereas the femoral bone marrow, subcutaneous, and perivesical fat (short T1) appear bright. **B.** T2-weighted axial image of the same patient as in **A:** note that the urine, which has a long T2, now appears bright, whereas the surrounding fat with its shorter T2 is intermediate in brightness.

Tissue	T1 Image	T2 Image
Fat	Bright	Intermediate
Water	Dark	Bright
Muscle	Intermediate	Intermediate
Ligaments	Dark	Dark
Bone cortex	Dark	Dark

TABLE 297-1 Tissue Appearance in Magnetic Resonance Imaging

The physical basis of image formation using MRI is quite different from CT, which is based on differential x-ray absorption coefficients. Even though both are tomographic imaging techniques, the meaning of bright and dark signals in MRI is relative to the pulse sequence eliciting them and has very little resemblance to the contrast in CT.

The core of an MRI system is the large magnet needed to generate the strong, constant, and uniform magnetic field, as well as the magnetic gradients. The magnet is composed of coils of a special superconducting wire that loses all resistance to electrical current when submerged in liquid helium. At this temperature, −450°F (−269°C), the coils can handle the relatively large currents of electricity required to produce the magnetic field. A specially designed, thermally insulated container encloses the magnet coils and the liquid helium. The liquid slowly boils away and must be replaced at regular intervals. The magnet is housed in a special room containing steel sheets and copper screen, which shield the system against interference by steel and radio waves on the outside and vice versa. The other components of the system, consisting of a radio transmitter, a sophisticated rf receiver, and a high-speed large-memory computer, are located near the operator's console just outside the room.

SAFETY

In a few cases, the large magnetic field could be a health hazard to the patient,[7,8] necessitating the use of alternative diagnostic methods such as ultrasound or CT. Internal cardiac pacemakers may be converted to an abnormal asynchronous mode by the magnetic field. Certain types of steel cerebral aneurysm clips (ferromagnetic as opposed to nonmagnetic stainless steel) may experience strong forces, with the potential of harming the brain. Small steel slivers imbedded in the eye (occasionally seen in asymptomatic sheet metal workers or welders) could injure the retina and cause blindness. Life-support equipment containing magnetic steel will be strongly attracted into the magnetic field, threatening both the patient and the system. Cochlear implants may be damaged or cause unacceptable injury due to eddy current heating effects. Patients in any of the aforementioned categories cannot be scanned with MRI. There are other devices, such as implantable cardiac defibrillators, neurostimulators, and bone growth stimulators, that may malfunction in the presence of high magnetic fields. Certain prosthetic heart valves contain nearly magnetic stainless-steel components that are subject to strong forces when placed in powerful magnetic fields. However, it has been pointed out that the forces on the valve from the heart exceed those generated by even high-field magnets, and hence this is a relative contraindication for MRI scanning.

The pulsed radio waves are a source of heat energy deposited within the body. Software programs built into the computers restrict the frequency of pulsing so that the maximum allowable power deposition averaged over the whole patient is never exceeded. Occasionally, skin burns have been reported when a patient's skin has come into direct contact with uninsulated rf leads, but proper precautions prevent this from happening.

The complete examination takes from 30 to 60 min, is painless, and is well tolerated by most patients. It does require suspension of all motion, except for breathing, for periods ranging from a few seconds to 15 min at a time, depending on the particular pulse sequence. Some patients are claustrophobic and have difficulty with the examination. Most problems of this nature are satisfactorily treated with minor tranquilizers administered orally. Infants, younger pediatric patients, and agitated adults need to be sedated, as in CT, because any motion degrades the MRI scan.

Some minor precautions are necessary. Magnetically encoded plastic cards, such as credit, cash, and parking cards, may be damaged when they come within a certain range of the magnetic field. Some watches with steel parts and hearing aids (and their batteries) are vulnerable to damage. Any ferromagnetic steel objects are potentially lethal missiles if carried into the magnet room. Patients need to leave such objects outside the scanning room.

APPLICATIONS

MRI has been widely applied to the brain and spinal cord,[9] where it provides images that are superior in diagnostic quality to those obtained with CT. Furthermore, this information can be obtained with less risk to patients because CT myelography requires intrathecal contrast agents for a specific diagnosis. Although special intravenous contrast agents are frequently required to improve the sensitivity of MRI, they have been associated with much less toxicity and reactions as compared with the intravenous CT contrast agents.[10] Except in the cases of acute intracerebral hemorrhage, skull fracture, and some calcified brain lesions, MRI may completely replace CT of the head. The exact role of MRI versus CT in trauma and degenerative disease of the spine is still evolving. CT visualizes fracture fragment relationships and bone detail more optimally, but MRI visualizes the soft tissues with better resolution. Some spine surgeons still prefer CT myelography to MRI.

MRI has been useful in examining the chest and abdomen (especially the chest wall, mediastinum, liver, spleen, adrenals, and aorta), but has played a lesser role compared with CT, because of respiratory motion and heart pulsation artifacts that degrade anatomic delineation of critical structures. They can be compensated for, to some degree, with electrocardiograph and respiratory gating and associated electronic manipulation, but the methods are cumbersome and difficult to implement with an acutely ill patient. A recent innovation is the introduction of breath-hold MR cholangiography for the noninvasive evaluation of the biliary and pancreatic ducts.[11] It has had limited application to cooperative patients with biliary or pancreatic disease not amenable to ultrasound, CT, or other conventional methods. There has also been progress in cardiac MRI,[5,12] but introduction of these methods into the emergency practice are currently limited due to cost and availability.

MRI has a major role in other areas of the musculoskeletal system[6] especially the knee, shoulder, hip, and temporomandibular joints. Although MRI is not indicated for most acute fractures, it may be preferred in the diagnosis of rotator cuff tear of the shoulder, internal derangement of the knee (meniscus, tendon, and ligament tears), tendon or soft tissue injury to any of the small joints, soft tissue injury in the spine, and posttraumatic avascular necrosis of any bone. In addition, carpal tunnel syndrome has been evaluated using MRI. Figure 297-2 demonstrates a meniscus tear in the knee. Before MRI, arthrography, which involves injection of contrast agents into the joint, was used to detect cartilage injuries. This type of examination is not only painful but carries a small but measurable risk of infection and contrast reaction. MRI of these joints is painless and only requires that the patient be able to hold still for a moderate length of time. The information obtained in the knee and hips exceeds what can be obtained using other methods. In the hips, MRI has proven to be the most reliable method for detecting avascular necrosis.
FIG. 297-2. Meniscal tear: **A.** Normal medial and lateral menisci as demonstrated on a magnetic resonance proton-density coronal image (partial T2 weighting). The

menisci are the dark triangular structures marked with *arrowheads*. **B.** Proton-density coronal scan showing a large complex tear involving the posterior horn of the medial meniscus (*arrowheads*)

In problematic cases, MRI has detected stress fractures and occult fractures in the small bones of the hand. Even though it does not visualize cortex, any break in the medullary cancellous bone can be readily detected.

The sequelae of soft tissue musculoskeletal trauma, such as complete muscular or tendon tears, hemorrhage, and edema, are very easily diagnosed with MRI. Even injuries to the medium-sized nerves and brachial plexus can be demonstrated.[13,14]

MRI has also been used to study infection in bone and soft tissues, where in many cases it has been superior to modalities such as nuclear medicine and CT.[15,16,17] However, if the patient has a metallic prostheses in the region of abnormality, rf currents or magnetic field inhomogeneities due to the metal induce artifacts in the MRI scan that reduce the sensitivity (Fig. 297-3). This is even more of a problem in CT, where x-ray scattering from the prosthesis may completely obliterate the scan. Then, only nuclear medicine studies may be useful, in particular indium 111 tagged to white blood cells.

FIG. 297-3. Magnetic artifacts: **A.** Lateral radiograph of a foot of a patient with a talar fracture reduced with two cold-worked stainless-steel screws. **B.** Proton-density-weighted coronal magnetic resonance imaging: ferromagnetic artifacts almost completely obliterate the talar marrow signal, rendering it diagnostically useless. **C.** Ultra-high-resolution coronal computed tomographic (CT) scan on the same foot yields useful information on the condition of the talar fragments (nonunion and avascular necrosis). This is unusual in that the ferromagnetic properties of the screws are responsible for a disproportionate deleterious effect on the MRI compared with the CT. Note that both show a lateral calcaneal dislocation.

MRI is extremely sensitive and specific in detecting metastatic disease in bone when questions arise after a positive bone scan. MRI is neither practical nor cost effective to use for whole body surveys, but when applied to specific lesions the anatomic information expedites diagnosis.

CT continues to be the modality of choice for suspected head, spine, and abdominal injuries, because it is quick, more widely available, and more compatible with life-support equipment. Although MRI-compatible respirators and pulsed oxymeters are now available, most standard life-support equipment either contains magnetic steel components or sensitive electronics that will not operate properly in the presence of rf or large static or dynamic magnetic fields. MRI is used in an elective setting after a patient has been stabilized and there is time to address the less acute problems.

MRI IN THE EMERGENT SETTING

At present, there are two areas where MRI is the procedure of choice in the acute setting: (1) evaluation of suspected spinal cord compression from any cause and (2) radiographically occult femoral intertrochanteric and neck fractures. In both cases, the unique ability to form images in axial, coronal, or sagittal planes gives MRI a distinct advantage. Another major factor is the superb contrast resolution of MRI that facilitates detection of spinal cord injury or fracture through cancellous bone of the hip. Figure 297-4 demonstrates an example of cervical cord compression resulting from a traumatically herniated disc. Figure 297-5 is an example of an occult femoral intertrochanteric fracture best demonstrated on MRI. Small studies[18,19] have confirmed higher sensitivity and specificity for MRI as compared with radionuclide bone scanning, tomography, and CT in the detection of occult fractures, especially in femoral head and neck fractures.

FIG. 297-4. Cervical spinal cord compression: T1-weighted sagittal magnetic resonance imaging demonstrates moderate spinal cord compression by an acute traumatically herniated disc at the C2–3 level (*arrow*). The patient was in a motor vehicle accident and also suffered associated bilateral C2 pedicle fractures.

FIG. 297-5. Occult hip fracture: **A.** Anteroposterior radiograph of a 55-year-old patient on steroids who had right hip pain after a fall. No fracture is evident. **B.** T1-weighted coronal magnetic resonance scan of the same hip clearly demonstrates a non-displaced intertrochanteric femoral shaft fracture (*arrows*).

Another potential area for MRI evaluation in the acute setting is aortic dissection. MRI is superior to contrast-enhanced CT and possibly transesophageal ultrasound in delineating the intimal aortic flap. Unfortunately, many of these patients are unstable hemodynamically and are agitated, requiring life support and sedation. Thus, few, if any, good candidates for MRI. As more MRI-compatible life-support and monitoring equipment becomes available, this situation will change.

Finally, a second potential application is in pediatric fractures [20] when there may be significant injury to unossified cartilage around open growth plates. Fractures through cartilage are not seen on plane films but are easily identified on MRI.

One innovation—the development of low and very low magnetic field imaging systems—may have some impact on emergency departments. Most of the hazards previously delineated apply to high-field systems. In low-field systems where the magnetic flux density is less in magnitude and more restricted in spatial extent, it is easier to accommodate life-support equipment. The design of these units allows more access to the patient and reduces the chances of interference with the proper operation of the life-support electronics. Thus, installation of a low-field MRI scanner in the emergency department becomes more feasible. However, because of theoretical considerations, signal to noise is much less (i.e., less signal) at low field. Therefore, there may be trade-off in diagnostic quality of the scans. Some signal can be recovered with optimal design of the software and hardware, but this remains a controversial area. There may be a place for low-field MRI in the emergent setting in the evaluation of subacute intracerebral hemorrhage and brain edema.

MR angiography, which (except for innocuous intravenous contrast) is noninvasive, has been evolving slowly and improving steadily. [5,21,22] It may eventually be the method of choice in the emergent evaluation of suspected subarachnoid hemorrhage or in leaking aortic aneurysms. An example of a normal noncontrast MR angiogram is shown in Fig. 297-6.
FIG. 297-6. Normal magnetic resonance angiogram of the circle of Willis in the brain. Summation image of maximum-intensity projection data from computer reconstructions after a three-dimensional time-of-flight acquisition in the axial plane. The examination required about 9 min, and no intravenous contrast was necessary.

Recent developments in echo planar and diffusion imaging make it possible to diagnose cytotoxic cerebral edema almost immediately after an acute ischemic event, even earlier than with CT or conventional MRI. [23] This has obvious implications with the advent of more aggressive lytic therapy aimed at early salvage of brain tissue after strokes.

MRI continues to evolve with more potential applications to emergency medicine in addition to its role in spinal cord compression, radiographically occult fractures, and acute aortic dissection. The new areas are diffusion imaging (to detect early strokes), noninvasive cerebral and body MRI angiography, and in the future cardiac and pulmonary MRI angiography. Taking advantage of its compatibility with life support equipment, further development of a low magnetic field system with improved signal to noise might accelerate introduction of the above applications into emergency medicine practice.

298 INTRAVENOUS DRUG USERS

Sarah A. Stahmer
Suzanne M. Shepherd

The practice of intravenous injection and the lifestyle of the intravenous drug user (IVDU), place the individual at risk for a wide variety of infectious and noninfectious complications.[1,2 and 3] In addition to those entities typically associated with IV drug use, such as endocarditis and hepatitis, IV drug use remains one of the greatest risk factors for acquiring the human immunodeficiency virus (HIV). The lifestyle associated with IV drug use increases the risk of trauma and sexually transmitted diseases. This population is also is placed at risk by a high incidence of homelessness, nutritional deficiencies, smoking and alcohol use, and mental illness.

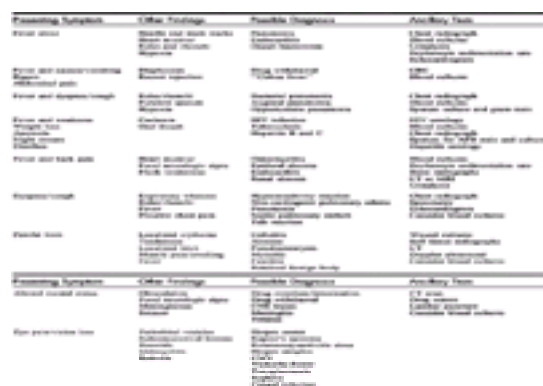
Complications of the IVDU may be obvious from the start, such as a painful swelling due to a skin abscess. However, constitutional symptoms such as weakness, anorexia, body pains, weight loss, and fever are common and may be the only subtle sign(s) of serious underlying disease (Table 298-1).


TABLE 298-1   Evaluation of IVDUs in the ED

It is estimated that over 2.5 million individuals have used IV drugs in the United States alone, [4] and the emergency department (ED) is a common point of entry to health care.[5] Health care providers should be aware of drugs used in their catchment area and the street names and preparation and use rituals for those drugs. IVDUs should be asked about drug type(s) and amount, preparation of materials for injection (e.g., spitting on needles or use of saliva for drug reconstitution, reuse of needles), needle sharing, use of antibiotics, and coincident illness. Socioeconomic issues such as the IVDU's ability to purchase medications and return for follow-up also must be addressed when making dispositions. The IVDU patient should receive nonjudgmental instruction in measures to reduce their risk of complications and infections.

PATHOPHYSIOLOGY

A number of markers of immune dysfunction have been described in IVDUs separate from those produced by coincident HIV infection, other viral infections, or liver disease:

1. Exaggerated lymphocytosis and atypical lymphocytosis
2. Diminished lymphocyte responsiveness to mitogenic stimulation
3. Immunoglobulin G (IgG) and IgM hypergammaglobulinemia and increased opsonin production
4. A higher incidence of false-positive complement fixation tests for syphilis and febrile agglutinins

The use of IV drugs continues to play a major role in the acquisition and spread of HIV. In the United States, the proportion of AIDS cases directly attributable to IV drug use is estimated to exceed 30 percent, and HIV seroprevalence rates in IVDUs are as high as 10 to 50 percent. [6] In addition to transmission among IVDUs, HIV also can be spread to their sex partners and offspring. Transmission of HIV infection in IVDUs accelerated dramatically in the 1980s, largely due to the widespread use of injectable cocaine. Cocaine, by virtue of its highly addictive properties and short duration of effect, encourages frequent injections and widespread sharing of injection paraphernalia.

The prevalence of HIV in IVDUs has expanded the spectrum of diseases associated with IV drug use to include those typically associated with HIV infection. [7] HIV infection dramatically increases the probability of activation of latent *Mycobacterium tuberculosis* infection in IV drug users.[8] In addition, new tuberculosis infection is more likely to progress to active disease in HIV-infected drug users. AIDS-defining illnesses that present in IV drug users are similar in spectrum to those in non-IV drug users, but the distribution of such diseases appears to be different. IVDUs have proportionally more cryptococcal disease, *Pneumocystis carini* pneumonia, tuberculosis, and wasting syndrome, and significantly less cytomegalovirus (CMV) infection, non-Hodgkin's lymphoma and Kaposi's sarcoma. [9] HIV-positive IVDUs also appear to be at increased risk of acquiring bacterial infections, such as skin abscesses, pneumonia, and endocarditis. [10,11 and 12] It has been hypothesized that HIV infection, even in the early stages, leads to early loss of regulation of immunoglobulin production, resulting in an ineffective response to bacterial infections. Greater immunosuppression, as defined by lower CD4 counts, is associated with both an increased risk of developing and dying from endocarditis. In those studies specifically comparing endocarditis in HIV- and non-HIV-infected IV drug users, there was no detectable differences in types of infecting organisms, frequency of right- and left-sided valve involvement, and duration of fever.

CLINICAL FEATURES

Fever

Fever is part of the presenting complaint in the majority of ED visits by IVDUs. [5,13,14,15 and 16] Fever is associated with infection in over two-thirds of patients. Prospective studies of febrile IVDUs have found bacteremia in up to 42 percent, pneumonia in 26 to 38 percent, and endocarditis in 6 to 13 percent. [13,14,15 and 16] These studies found that neither clinical judgment nor derived predictive rules were reliable in identifying those with serious underlying causes of fever. [13,14,15 and 16] While an elevated erythrocyte sedimentation rate (ESR) of greater that 100 mm/h is associated with serious infections in febrile IVDUs, a normal ESR does not reliably exclude serious

disease.[17]

Noninfectious causes of fever in the IVDU include acute toxic reactions to substances of abuse, reactions to injected adulterants, and withdrawal syndromes. Cocaine and amphetamines can cause fevers acutely, occasionally in excess of 40°C (104°F). Adulterants used to dilute active substances can cause dramatic febrile reactions accompanied by alteration in mental status and leukocytosis.[18] One syndrome, associated with the use of cotton balls as filters for drug suspensions, is called *cotton fever*.[19] Patients with cotton fever develop high fever, chills, headache, dyspnea, myalgias, arthralgias, nausea, and vomiting within hours after injection. Physical findings may include tachypnea, tachycardia, abdominal pain, and inflammatory retinal nodules. Chest radiography may reveal inflammatory pulmonary granulomata. This is a self-limited syndrome that resolves completely within 24 h. While the cause of this syndrome remains unclear, it has been proposed that the acute symptoms are due to either endotoxin from gram-negative rods introduced by injection or the pyrogenic effect of injected cotton particulate matter. Patients withdrawing from barbiturates or heroin also may appear acutely ill, with chest and abdominal pain, diaphoresis, tachycardia, and fever.

Since there are no reliable markers excluding serious underlying disease in the febrile IVDU, common practice has been to obtain blood cultures and admit such patients for observation, awaiting culture results. In those patients for whom follow-up can be ensured and who appear clinically well, outpatient evaluation is reasonable as long as an adequate number of cultures are obtained.[14]

Dyspnea

A wide range of both infectious and noninfectious causes may produce dyspnea and cough. The febrile IVDU with dyspnea and/or cough should be assumed to have tuberculosis until an alternative diagnosis is found, particularly those with known or suspected HIV.[20] Other common causes of dyspnea include both community-acquired and opportunistic pneumonia and septic pulmonary emboli from right-sided endocarditis. Opportunistic infections, such as *P. carini* pneumonia, reflect the prevalence of HIV disease in this patient group.

Noninfectious causes of dyspnea include pneumothorax, hemothorax, and toxic reactions to injected substances.[21] Pneumo- and hemothorax are seen most commonly with the practice of "pocket shooting." As drug users run out of easily accessible veins, they will inject into veins in the supraclavicular fossa to access the subclavian, jugular, or brachiocephalic vein. When talc is injected, it can cause a syndrome of progressive respiratory distress and diffuse interstitial infiltrates known as *talc lung*.[22] Hypersensitivity reactions, associated with both heroin and cocaine injection, present with cough and wheezing and usually respond to inhaled beta-agonist therapy. Noncardiogenic pulmonary edema also has been described in association with heroin and cocaine use. Patients complain of dyspnea, and chest radiographs reveal diffuse alveolar infiltrates. Needles breaking off in the peripheral circulation can embolize into the lungs.[23] Pericarditis also has been reported secondary to central migration of a needle fragment.

Altered Mental Status

Causes of altered mental status include drug intoxication or withdrawal, stroke syndromes, hypoxia, delayed leukoencephalopathy, infectious diseases, mycotic aneurysms, and secondary trauma from either loss of consciousness and fall or drug-related violence.[24] CNS infections occur as primary infections, as embolic complications of distant infections (e.g., endocarditis), and as extensions of local vertebral osteomyelitis. Infections commonly seen in this population include epidural abscess, bacterial meningitis, fungal meningitis, and brain abscess. Bacterial meningitis is usually caused by meningococcus, pneumococcus, or *Staphylococcus aureus* spreading from a primary endocarditis. Patients also may develop mycotic aneurysms or meningitis due to coincident brain or epidural abscess or as an inflammatory response to microemboli and bacteremia from endocarditis. In addition, CNS infection may occur from opportunistic organisms in the patient with coincident HIV infection.

Stroke syndromes have been well-reported complications secondary to low-flow states during heroin intoxication, hypertensive hemorrhage from amphetamines, phencyclidine, or cocaine, and embolized vegetations from infectious endocarditis. Delayed leukoencephalopathies, both hypoxia-related and unrelated to hypoxia, have been reported in IVDUs but are rare.[25]

Back Pain

Epidural abscess is characterized by a chronic course of 1 to 15 months in most patients. However, a more acute course with pain, paraplegia, and urinary incontinence developing over several hours to days can occur. The earliest and most prominent symptom is localized pain, which may develop a radicular component. Cerebrospinal fluid (CSF) analysis often demonstrates a mononuclear pleocytosis and increased protein. Myelography, computed tomography (CT), and magnetic resonance imaging (MRI) can help to define the extent of infection. *S. aureus* and *Pseudomonas aeruginosa* are the most commonly reported bacterial isolates. *M. tuberculosis* also has been reported in those concurrently infected with HIV. Emergent neurosurgical evaluation should be obtained for adequate drainage and decompression of these lesions.

SPECIFIC INFECTIONS

Endocarditis

The incidence of endocarditis in the IVDU has been estimated to be 30 times that of the general population, or approximately 1.4 cases per 10,000 patients per year. Patients with IVDU-related endocarditis usually have no evidence of prior valve damage. Several mechanisms have been proposed by which IVDU contributes to endocardial injury. Talc, a common contaminant of injected material, has been recovered from subendothelial granulations during autopsy of IVDUs. In animal studies, valvular inflammation has been seen after repeated injection with horse serum or dead streptococci, suggesting that frequent antigenic exposure may produce valvular damage. Lastly, IV cocaine use has been associated with increased risk of endocarditis compared with other drugs. A likely basis for this increased risk is the fact that cocaine users inject more frequently, exposing the valves to frequent bacteremia and showers of particulate matter. Cocaine users are less likely to sterilize needles because cocaine does not need to be heated to go into solution. Furthermore, cocaine users are more likely to share needles and be injected by communal needles in "shooting galleries." An alternative explanation is that the vasoconstrictive properties of cocaine may cause interstitial or endothelial damage, predisposing to infection.

The cardinal sign of endocarditis in the IVDU is fever. There may be foci of infection, such as dental abscess, cellulitis, or septic pulmonary emboli. A cardiac murmur is present in over one-half of patients with endocarditis.[27] Right-sided murmurs, which vary with respiration, are usually pathologic and more specific for the diagnosis. Cough, pleuritic chest pain, and hemoptysis are common presenting complaints, particularly in patients with right-sided cardiac infection and septic pulmonary emboli. Pulmonary infiltrates on chest radiographs, associated with moderate hypoxia, have been described in over one-third of patients with IVDU-related endocarditis. Pulmonary findings may falsely lead the clinician to identify the lung as the primary source of infection. Pyuria and hematuria are ascribed to glomerulonephritis, embolic renal infarction, and perinephric abscess.

Blood cultures will be positive in over 98 percent of cases of IVDU-related endocarditis if three to five sets are obtained. True culture-negative endocarditis in the setting of high clinical suspicion and careful laboratory procedure is rare. *S. aureus* has been isolated from blood cultures in over half of patients. Up to one-third of *S. aureus* isolates, particularly those reported from large urban areas, are methicillin-resistant. *Streptococcus* is the second most frequently reported isolate, particularly *S. viridens. S. aureus* has a predilection for the tricuspid valve, whereas streptococci are more likely to involve left-sided structures.

Other less commonly isolated organisms include enterococci and gram-negative bacteria, particularly *P. aeruginosa, Serratia marcescens,* and *Klebsiella pneumoniae.* Other organisms, less frequently identified as causative agents, usually reflect local environmental pathogens or drug-injecting habits. For example, licking the needles prior to injection has been implicated in infections that result from oral pathogens such as *Eikinella corrodens, Hemophilus parainfluenzae, Bacteriodes* spp. and *Neisseria* spp. Up to 20 percent of IVDU-related endocarditis is polymicrobial in nature. Although rare, fungal endocarditis has been reported increasingly. Most fungal infections are due to *Candida* spp., in particular *C. parapsilosis,* which accounts for over half of all isolates.

Although right-sided cardiac structures have been associated with IVDU-related endocarditis, any valve potentially can be involved. The tricuspid valve is infected in 40 to 50 percent, the mitral valve in 30 to 40 percent, the aortic valve in 10 to 20 percent, and multiple locations in 10 to 20 percent. Four types of valvular lesions have been described, vegetations, ring abscesses, cuspal tears or perforations, and ruptured chordae tendineae.

Diagnosis generally requires microbial isolation from a blood culture, which typically takes at least 24 h, and/or the ability to demonstrate typical lesions on

echocardiography.[16] The classic findings of embolic phenomena, Janeway lesions and Roth spots, are usually not observed until the infection is advanced.

A complete blood count (CBC), chest x-ray, and urinalysis are useful screens, although no single abnormality is specific for endocarditis. Chest radiographs will be abnormal in over 50 percent of patients, and typical findings include infiltrates consistent with septic emboli, pneumonia, or congestive heart failure.

Transthoracic echocardiography (TTE) will reveal diagnostic cardiac lesions up to 80 percent of the time in patients (both IVDU and non-IVDU) in whom the diagnosis is strongly suspected. Transesophageal echocardiography (TEE) is the most sensitive imaging modality for demonstrating vegetations, myocardial and ring abscesses, and tricuspid valve involvement in IVDU-related endocarditis. The timing of echocardiography is debatable. Some echocardiographers advocate early imaging to confirm the diagnosis of endocarditis. Others have suggested that imaging should be performed only on those patients who have positive blood cultures, to assist in determining disease response to therapy and length of treatment.

Attempts to develop criteria that would prospectively identify endocarditis in the IVDU in the ED. with reasonable certainty have failed. [13,14,15 and 16] Generally, patients with suspected endocarditis should be cultured and admitted to the hospital. The need for empirical antibiotic therapy should be determined by the patient's clinical stability and ability to wait 24 h for the initial results of blood cultures. Treatment should be directed to *S. aureus* and *Streptococcus* spp., with consideration of local sensitivities and pathogens. Vancomycin or nafcillin and gentamicin are often initial therapy. The addition of an aminoglycoside has been shown to shorten the duration of bacteremia and duration of treatment in patients with *S. aureus* infections. Although 4 to 6 weeks of antibiotic therapy is standard, excellent cure rates have been achieved with only 2 weeks of treatment for patients with right-sided endocarditis caused by sensitive *S. aureus.*

Complications of endocarditis range from pump failure secondary to valve insufficiency, dysrhythmias due to myocardial infiltration, and pulmonary and systemic emboli. Mortality is related to the side of the heart involved, vegetation size, response to antibiotics, and compliance with treatment. Left-sided endocarditis is more likely to be complicated by left-sided congestive heart failure, septic cerebral emboli, and the need for surgery. Overall mortality for IVDU-related left-sided endocarditis is 14 to 21 percent, compared with 2 to 7 percent for IVDUs with right-sided endocarditis. Emboli can travel to the extremities, pulmonary bed, spleen, kidney, or brain. With right-sided endocarditis, septic pulmonary emboli occur in 30 to 60 percent of patients. Most complications related to right-sided endocarditis can be managed medically, and the prognosis is excellent. Valve replacement should be considered for those patients with congestive heart failure, failure to respond to antibiotics, myocardial abscess, or recurrent embolization. Early echocardiography can be instrumental in identifying those patients at risk for embolic events by identifying large (>2.0 cm) vegetations on valve leaflets.

Pulmonary Infections

S. pneumoniae and *H. influenzae* are frequent causes, and in those with septic emboli or endocarditis, *S. aureus* should be considered. Aspiration may result in infection with *S. pneumoniae*, polymicrobial oral flora, *S. aureus,* or *Pseudomonas* spp. *P. carinii,* cytomegalovirus, or atypical mycobacteria should be considered in HIV-positive patients. Drug-resistant tuberculosis also should be strongly considered. IVDU patients are also more likely to have extrapulmonary tuberculosis, including infection in cervical lymph nodes, CNS, bone, abdomen, genitourinary system, pericardium, skin, and the eyes. [28]

Because of the risk of atypical infection, coincident bacteremia, and endocarditis, admission to the hospital is recommended in all patients with pneumonia or other pulmonary infection. Patients should be placed on respiratory isolation until tuberculosis has been excluded.

Skin and Soft Tissue Infections

Unique features of skin infections in the IVDU[29,30] are (1) a high rate of skin and pharyngeal colonization with *S. aureus* and streptococcal species, (2) the high frequency with which cutaneous abscesses are due to oral flora,[31] and (3) the fact that infection with HIV also confers an additional risk for the development of skin abscesses.[10] The IVDU will self-inject, often multiple times a day, with unsterile needles, which may be licked prior to injection. Tap or toilet water or saliva often is used to dissolve narcotics, and each has been implicated as harboring the causative agent in both skin and blood-borne infections. Female gender is associated with increased incidence of skin infections, due to a relatively high rate of skin injection (skin popping).

Local infections of the skin and soft tissue include cellulitis, subcutaneous abscesses, septic phlebitis, necrotizing fasciitis, Fournier's gangrene, gas gangrene, and pyomyositis. Cellulitis is typically due to *S. aureus* and *Streptococcus* spp. Cultures from cutaneous abscesses are often polymicrobial, with aerobic gram-negative rods, anaerobic cocci, and bacilli.[31] Quinine, which is often used to "cut" heroin, can increase the risk of abscess formation. The extensive interconnected abscesses produced by skin popping provide ideal growth conditions for *Clostridium botulinum* and *C. tetani.* Broken needles lodged in the skin are foreign bodies that stimulate infection.[32] Groin injection has been associated with local gangrene and also the development of rapidly progressive and fatal Fournier's gangrene. Cutaneous abscesses in the neck may involve the carotid triangle and produce airway obstruction, vocal cord paralysis, and laryngeal edema.

Presenting signs and symptoms of cutaneous infections, including pyomyositis, are fever, pain, localized erythema, and edema. The painful area should be carefully inspected for fluctuance, crepitance, and lymphangitis. Infections over venipuncture sites suggest infected pseudoaneurysms. Pulsatile masses should be imaged with ultrasonography prior to incision and drainage, as attempts to aspirate or incise and drain an infected pseudoaneurysm can result in significant hemorrhage. Angiography may be required to identify vasospasm, thrombosis, emboli, mycotic aneurysms, or septic hematomas. Plain radiographs can demonstrate air in the soft tissues, which may be present even when localized tenderness and erythema are the only findings. CT is useful to clearly delineate the involvement of other structures and the extent of deep abscesses, especially in complex areas such as the neck. Whenever crepitus or subcutaneous air is detected or deep tissue or muscle involvement is suspected clinically, a prompt surgical consultation for possible exploration or debridement is appropriate. Wound botulism and tetanus have been reported in IVDUs.[33,34]

IVDUs with superficial cellulitis and no evidence of systemic involvement can be managed as outpatients. Empirical antibiotic choices should cover streptococci and staphylococci, and tetanus immunization should be updated. Febrile or toxic-appearing patients or those not responding to outpatient treatment should be admitted to the hospital. Blood and wound cultures should be obtained, and broad-spectrum intravenous antibiotics should be initiated pending culture results. For such patients, coverage should include a penicillinase-resistant synthetic penicillin or vancomycin plus an antipseudomonal aminoglycoside, antipseudomonal penicillin, or cephalosporin.Surgical consultation is needed for deep tissue and necrotizing soft tissue infections.

Vascular Infections

Vascular injury associated with IVDU includes inadvertent arterial injection with resultant vasospasm or thrombosis, septic thrombophlebitis, venous and arterial pseudoaneurysms and infected hematomas. Arterial injection rarely results in major vessel occlusion; instead, a commonly observed effect is pain, edema, and patchy mottling of the affected limb due to ischemia.[35] Peripheral pulses are usually preserved. Tissue necrosis and gangrene are the consequence of persistent focal ischemia. The etiology is thought to be a combination of vasospasm of distal vessels, embolization of particulate matter, and endothelial injury leading to thrombosis and vasculitis.[36]

For limb ischemia, the vascular surgeon should be involved early to decide if surgical intervention or intraarterial thrombolysis is indicated. However, the majority of cases involve distal vessels, and treatment is primarily supportive medical management with heparinization. Limb edema can progress to compartment syndrome or rhabdomyolysis. Fasciotomy may be required for compartment syndrome. For patients who develop rhabdomyolysis, careful monitoring of fluid balance and renal function is required.

Infected pseudoaneurysm is one of the most common vascular complications reported in IVDUs.[37,38] Although pseudoaneurysms can form in any artery, they are most often reported in the femoral, followed by the radial and brachial arteries. Venous pseudoaneurysms are relatively rare and are usually secondary to septic phlebitis. The femoral vein is the vessel most often involved. Patients with either infected arterial or venous pseudoaneurysms usually present with fever and a painful mass, typically in the groin. Although similar in gross appearance to an abscess, the presence of pulsations and often a bruit should suggest this diagnosis. Because of the disastrous hemorrhagic consequences of attempted incision and drainage or medical management with a course of antibiotics, all painful masses, particularly in the groin, should be imaged, usually with duplex ultrasonography. Treatment for infected pseudoaneurysm usually involves resection of the infected vessel. Broad-spectrum antibiotics should be initiated in the ED and should cover the most likely organisms. Early revascularization at the time of resection of the pseudoaneurysm may be necessary.[39]

Bone and Joint Infections

Bone and joint infections usually occur from (1) contiguous spread from an overlying skin or soft tissue infection or (2) hematogenous spread from a distant site. Infecting microorganisms tend to be unusual compared with the general population, with *Candida* and gram-negative organisms the most common examples. In IVDUs, osteomyelitic lesions are seen more frequently in the axial skeleton than in the bones of the extremities. [40]

Pyogenic infections are the predominant type seen involving bones and joints. In contrast to the general population, in which approximately two-thirds of bony infections are caused by *S. aureus,* the infecting organisms in an IVDU with osteomyelitis or septic arthritis is more likely to be polymicrobial and involve uncommon organisms, although recent studies have demonstrated an increasing frequency of *S. aureus* and groups A and G streptococcal bone infections in IVDUs. One also must consider gonococcal arthritis and tenosynovitis because of the high incidence of sexually transmitted diseases in this population. *E. corrodens* osteomyelitis also has been reported in IVDUs who lick their needles prior to injection. Nonpyogenic organisms may cause osteomyelitis and septic arthritis in IVDUs. Mycobacterial infections usually involve the ribs and vertebral column (Pott's disease). Symptoms include night sweats, fevers, weight loss, and localized pain. These are often associated with systemic involvement of the lungs, CNS, pelvic organs, and adrenal glands. *Candida* spp. have been reported with incidences as high as 20 percent in osteomyelitis in these patients. [41] Candidal infections are postulated to spread hematogenously. Some patients report an initial syndrome of high fever, headache, and myalgia lasting 3 to 4 days, followed by the appearance of metastatic lesions involving the skin, eye (chorioretinitis and endophthalmitis), and the bones and joints several days to weeks later. Rarely, *Aspergillus* spp. may cause osteomyelitis of the sternum in these patients. [40]

IVDU-related osteomyelitis is more likely to involve the vertebral column, particularly the lumbar segments. [42] Collected series have tabulated that 53 percent of all bony infections involved the vertebral column, 18 percent involved the sternoclavicular joint, and 17 percent involved the extremities, particularly the hip and knee joints.

Vertebral osteomyelitis usually presents with localized pain and tenderness to palpation over the involved bone. A soft tissue mass may be palpable, which in the case of *Candida* may not exhibit evidence of inflammation. Symptoms may be present for days in the case of bacterial infections to weeks in the case of fungal or mycobacterial infections. Many patients will exhibit neither fever nor leukocytosis. An elevated ESR is helpful if present, but its absence does not exclude these infections. If present, drainage from contiguous abscesses should be cultured. Biopsy or needle aspiration may be necessary for joint space and bony infections, especially in the case of unusual or fastidious organisms, such as *Mycobacterium, Candida,* or *Eikenella.* Appropriate imaging for osteomyelitis will vary with institution; however, MRI and CT are both useful. Patients with osteomyelitis warrant admission. Unless the patient appears septic or coincident endocarditis is a concern, antibiotic administration should be based on culture results. Antibiotic treatment will usually continue for 4 to 6 weeks.

Septic arthritis in the IVDU usually involves the knee or hip. Sternoclavicular infectious arthritis is also well described in this population and, if found, should strongly suggest IVDU. Patients often will note a recent history of trauma to the area, but causality has yet to be proven. Patients will note pain, localized tenderness, and swelling at the sites. The ESR is usually elevated, and fever and leukocytosis are usually present. Up to 80 percent will have normal plain radiographs; however, joint space widening, articular surface erosion, and surrounding soft tissue infection may be noted. Bone scans are often positive early in the process, and these infections also may be delineated with CT or MRI. The most sensitive but nonspecific finding on synovial fluid analysis is a white blood cell count greater than 20,000/mL with a predominance of neutrophils. Gram stain of the synovial fluid may aid in antibiotic selection. Immobilization, physical therapy, therapeutic arthrocentesis, and occasionally open drainage of a septic hip may be warranted.

Hepatic Disease

The IVDU may develop liver disease, including cirrhosis, from both parenterally and sexually transmitted hepatitis A, B, C, and G virus as well as the delta virus. [43,44, and 45] It is estimated that over 80 percent of IVDUs have had hepatitis, with the majority of reported cases due to hepatitis B and C. These patients frequently progress to chronic active hepatitis with a high mortality. When an IVDU patient presents with the clinical syndrome of acute hepatitis, appropriate laboratory testing includes serum transaminases, bilirubin levels, alkaline phosphatase, prothrombin time, and serologic testing. If other significant disease can be excluded, most can be managed as outpatients. Admission criteria include inability to tolerate oral intake, toxicity, and prolonged prothrombin time with bleeding. Patients should be counseled on both sexual contact and needle exposure and should be encouraged to inform all sexual and needle partners and household contacts of exposure. Seronegative patients should receive hepatitis B and A immunization. [43,44]

Ophthalmologic Infections

Ophthalmologic infections in the IVDU are usually the result of hematogenous seeding from a primary source of infection, such as endocarditis, or of opportunistic infections associated with coincident HIV disease. Bacterial endophthalmitis often presents acutely, with rapid progression of pain, redness, lid swelling, and decrease in visual acuity. [46] Inflammation is usually present in the anterior and posterior chambers. White-centered, flame-shaped hemorrhages (Roth spots), cotton wool exudates, and macular holes may be present. *S. aureus* is the most commonly isolated organism, followed by *Streptococcus* sp. A rare but rapidly destructive infection has been reported with *Bacillus cereus.* Treatment involves subconjunctival and systemic antibiotic therapy; surgical intervention may be needed. Fungal endophthalmitis, usually due to *Candida,* is more common than bacterial endophthalmitis. The clinical picture is often indolent, progressing over days to weeks. Symptoms include blurred vision, pain, and decreased visual acuity. White cotton-like lesions are seen on the choroid retina, with vitreous haziness. Uveitis, papillitis, and vitritis also have been reported.

Since 1980, a marked increase in *Candida* sp. infections has been reported in those individuals who use brown heroin. *Candida* chorioretinitis or endophthalmitis in these individuals is characterized by the appearance of a high fever, followed in 3 to 4 days by the appearance of ocular symptoms, cutaneous lesions, and costochondral involvement. Aspergillosis is the second most common fungal cause of endophthalmitis in IVDUs. Initial complaints often include decreased visual acuity, pain, and conjunctival injection. The physical examination may reveal iritis, vitritis, vitreal mass, or hyphema. The treatment is similar to that for *Candida.* The prognosis for both infections depends on prompt diagnosis and treatment. Fungal endophthalmitis secondary to *Torulopsis, Helminthosporium,* and *Penicillium* sp. also has been reported. As the incidence of HIV in these patients has increased, an increased frequency of cytomegalovirus, toxoplasmosis retinitis, and choroidal *Cryptococcus* and *Mycobacterium avium intracellulare* infections have been reported.

William A. Berk

Alcoholism is a ubiquitous medical and social problem that crosses social and economic boundaries. Ethanol dependence, defined as regular use resulting in tolerance to the drug and the likelihood of withdrawal symptoms if intake is suspended, is experienced at one time in their lives by 4.4 percent of Americans. [1] Ethanol abuse, affecting another 3 percent of the population, [1] is a separate problem marked by social or medical problems that result from inappropriate use of ethanol but without the presence of dependence.[1] Examples of ethanol abuse include intermittent bouts of drinking resulting in aggressive or antisocial behavior or driving while intoxicated.[1]

Although alcoholism by itself is not a medical emergency, alcohol abuse and dependence are common threads in the presentation of many conditions in the emergency department. Such presentations include trauma, infections, acute alcohol intoxication and withdrawal, hepatitis, and pancreatitis. Alcohol is often used with other drugs, including cocaine, benzodiazepines, and marijuana. Emergency physicians should recognize alcoholism as both a contributor to a patient's presenting problems and as an underlying problem requiring care itself.

Alcoholism is a "primary, chronic disease with genetic, psychosocial, and environmental factors influencing its development and manifestations ...[and] is characterized by impaired control over drinking, preoccupation with the drug ethanol, use of ethanol despite adverse consequences, and distortions in thinking, most notably denial. Each of these symptoms may be continuous or periodic." [2] Male gender, age of 25 to 34 years, poor education, preexistent psychiatric disorder, and homelessness are common associated factors. However, alcoholism is a disorder that crosses all socioeconomic boundaries and involves all age groups. Among the homeless, estimated at 250,000 on any given night and 3 million people per year in the United States, 20 to 45 percent are alcoholics. [1] Secondary psychiatric diagnoses, including antisocial personality, mania, and schizophrenia, are more common in alcoholics than in the general population. Suicide attempts and problems with drugs other than ethanol are also common among alcoholics.

The fact that almost 10 percent of the population experience at some time ethanol-related problems means that alcoholism touches most Americans' lives at some time, whether at home, on the road, or in the workplace.

The pathogenesis of alcoholism is multifactorial, with both genetic and environmental inputs. Studies of isolated twins, adopted children, and families in general have confirmed a heritable component to alcoholism. Similarly, twin research has shown that the risk of alcoholism for an identical twin of an alcoholic is much greater than that of a fraternal twin. Close relatives of alcoholics have a fourfold risk of alcoholism over control subjects, even when they are adopted children raised away from their genetic family from birth.

DIAGNOSIS

The diagnosis of alcoholism can be self-evident or exceedingly difficult (e.g., an executive who develops confusion when hospitalized for an unrelated medical condition and is abstinent for a few days).[3] Researchers utilizing sophisticated, comprehensive, and time-consuming diagnostic instruments have found that specialty physicians, including emergency physicians, miss the diagnosis in over half of all cases. Emergency physicians can maximize their success by consistently taking a social history, by asking repeatedly and pointedly about alcohol intake in patients who present with potentially associated conditions, by consulting medical records when available, and by conferring with patients' family members and associates.

EFFECTS OF ALCOHOL ON HEALTH

Ethanol abuse and its association with trauma represent a major public health issue. Forty percent of Americans will be involved in an ethanol-related motor vehicle collision in their lifetime, and over 40 percent of fatal motor vehicle accidents are associated with use of ethanol. [1] Those who drink are also at increased risk for accidents within the home and for injuries from assault.

Alcoholics have been estimated on average to have a life span 10 to 15 years shorter than that of moderate drinkers or nondrinkers. [4] Increased mortality rates result chiefly from heart and liver disease, cancer, and accidents. Although the occurrence of coronary artery disease is decreased among alcoholics, heavy ethanol use increases the likelihood of hypertension and can cause alcoholic cardiomyopathy. Ethanol is the most common cause of liver failure both in the United States and worldwide. Fatty liver is present in virtually all alcoholics, while 10 to 35 percent develop alcoholic hepatitis. Heavy ethanol use is also associated with increased risk of cancer of the esophagus, stomach, pancreas, liver, and breast.

Chronic toxicity from ethanol abuse may have serious health consequences for nearly every major organ system (Table 299-1).

TABLE 299-1   Some Adverse Health Effects Associated with Ethanol Abuse and Dependence

There is good evidence that moderate ethanol use may actually promote health. A large population-based study found that subjects who consumed between one drink per month and one drink per day had a lower mortality rate than did those who drank either more or less. [5] This is the basis for the "U-shaped" curve of mortality in relation to alcohol consumption, with mortality greatest at the lowest and highest levels of consumption and lowest in the middle, at moderate levels of consumption. Decreased mortality rates may result from diminished coronary risk among users of ethanol, apparently mediated through increased blood high-density lipoprotein levels. While this effect persists at higher levels of ethanol use, the other deleterious effects of excessive chronic use outweigh the benefits. [5]

INJURED ETHANOL-INTOXICATED PATIENTS

Alcohol is an important predisposing factor for trauma of all types, but most important as far as morbidity and mortality rates are concerned is its association with

motor-vehicle collisions. The proportion of fatal collisions involving a driver with a blood alcohol level greater than 10 mg/dL dropped from 51 to 41 percent between 1987 and 1996, when alcohol-related fatalities totaled 17,126 (Fig. 299-1). Nevertheless, alcohol-related motor-vehicle accidents continue to represent a significant public health problem with a large impact on emergency medicine practice.

FIG. 299-1. Traffic fatalities 1977 to 1993: all versus those associated with use of alcohol. (From Campbell KE, Zobeck TS, Bertolucci D: Trends in Alcohol-Related Fatal Traffic Crashes, United States 1977–1993. Rockville, MD, National Institute on Alcohol Abuse and Alcoholism, 1995.)

Injured intoxicated patients present particular challenges for the clinician. In particular, the effect of ethanol on the sensorium complicates efforts at cost-effective diagnosis and treatment, since physical examination findings may be unreliable. Also, obtaining studies that require the patient's cooperation can be problematic, with the physician compelled to administer a second central nervous system depressant in order to satisfactorily evaluate injuries.

Evaluation of intoxicated head-injured patients is particularly difficult. Serious head injuries are easily overlooked in intoxicated patients, some of whom, especially in inner-city locales, may arrive at the emergency department with no definite history and no external signs of head trauma. In fact, the most common serious error made in management of intoxicated patients may be to assume for too long that a depressed or abnormal mental status is secondary to intoxication. Intoxicated patients should undergo computed tomography (CT) evaluation if there is a history of head injury and the rating on the Glasgow coma scale is less than 15; for any worsening of mental status while under observation; or if there is no improvement in mental status by 3 h after admission. Once the decision to perform CT has been made, no delay should be allowed due to lack of cooperation by the patient, which may be the result of ethanol, concomitant drug use, or head injury. Sedation may be required, with careful attention to airway protection and paralysis and intubation if necessary.

The general recognition that ethanol intoxication may also delay diagnosis of operatively remediable abdominal injuries makes it more likely that intoxicated injured patients will undergo such procedures and studies as intubation, diagnostic peritoneal lavage, and abdominal CT. [6] Such procedures and studies may not be necessary in all intoxicated patients. The results of one small study suggested that intoxicated trauma victims with a Glasgow coma scale rating of 15 and no abdominal complaints or physical findings suggestive of abdominal injury are candidates for careful observation. [7]

It is uncertain whether ethanol intoxication itself worsens the prognosis of injured patients. A study of over a million motor-vehicle accidents that attempted to control for safety-belt use, vehicle deformation, vehicle speed, and other factors found that drivers who drank were more likely to suffer a serious injury or death, [8] but other studies have found no difference in outcome for intoxicated injured patients. [9] Recent observations suggest that chronic alcoholism—but not acute alcohol intoxication—adversely affects the prognosis of injured patients. [10] These findings most likely reflect the comorbidity of underlying organ system dysfunction.

HYPOTHERMIA AND ETHANOL INTOXICATION

Most cases of hypothermia during winter months in urban settings are associated with ethanol use. Many homeless persons are heavy users of ethanol and on cold nights may employ ethanol to inure themselves to the effects of low temperature. While the sedative effects of ethanol may result in exposure predisposing to hypothermia, ethanol also directly contributes to body cooling by depressing central thermoregulatory mechanisms, decreasing shivering, and enhancing heat loss through vasodilatation. Management of the hypothermic intoxicated patient is similar to that of hypothermia in other patients. Prognosis is related to severity of hypothermia and the presence of underlying diseases, but does not appear to be adversely affected by ethanol intoxication.

ETHANOL WITHDRAWAL

Some alcoholics exhibit one or more symptoms of withdrawal upon discontinuation of ethanol intake. Symptoms and signs include tremor, anxiety, agitation, and signs of autonomic hyperactivity, including cardiac dysrhythmias, most frequently sinus tachycardia or atrial fibrillation. Seizures may occur, while hallucinations, usually visual, reflect moderate-to-severe withdrawal. Signs and symptoms of withdrawal are most likely to reach peak intensity at 48 h after the patient's last drink. There is wide variation in the timing of onset and peak severity of alcohol withdrawal, which reflects differences in patterns of ethanol intake, individual susceptibility to withdrawal, and concomitant illness. For example, significant withdrawal may occur while alcoholics still have detectable blood ethanol levels or within a short time after the last drink. Such situations probably reflect a recent pattern of decreased but continued intake of ethanol, or alcoholics' common practice of self-treatment with ethanol when symptoms first appear, followed by presentation for medical care if those symptoms fail to resolve.

Since ethanol withdrawal is a syndrome complex, more than one sign is present in most cases. When alcoholic patients present with a single sign typical of ethanol withdrawal, other causes should be considered. Seizures, in particular, can be due to other causes, most notably recent or remote head trauma, whether the patient recounts a history of head injury or not. Hallucinations may be secondary to a psychiatric disorder (although alcohol withdrawal hallucinations are more likely to be auditory, not visual) or concomitant drug use.

After the diagnosis of alcohol withdrawal is established, an examination for complicating medical conditions or injury should be performed. Patients with alcohol withdrawal may be volume depleted and require crystalloid infusion. If possible, patients should be placed in a quiet area with a minimum of stimulation. For patients who have experienced seizures, CT examination is indicated for focal seizures, when a focal neurologic finding is elicited, or when the patient has a persistent postictal defect in consciousness. [11]

Benzodiazepines are indicated for treatment of withdrawal, with most studies suggesting that lorazepam is the drug of choice, particularly in the elderly and those with significant liver disease. [12] The initial dose is 2 mg IV, followed by doses of 2 to 4 mg IV every 15 to 30 min until light sedation is attained. At the same time, 1 L of 5% dextrose in normal saline solution with 100 mg of thiamine and 4 g of magnesium sulfate is given IV over 1 to 2 h. Although magnesium has not been shown to be effective against ethanol withdrawal in general, hypomagnesemia has been closely associated with tremor in alcoholics and may play a role in the genesis of seizures. An alternative primary drug is phenobarbital, starting with a dose of 260 mg administered intravenously over 15 min, followed by doses of 130 mg every 30 to 45 min as needed. Phenobarbital has a relatively long half-life, 24 to 96 h, obviating the need for outpatient prescriptions if the patient is discharged. [13] Clinicians should approach treatment of alcohol withdrawal prepared to administer lorazepam (or phenobarbital) repeatedly and in cumulatively large doses. There is no evidence that prophylactic phenytoin prevents ethanol withdrawal seizures. [14]

Patients with alcohol withdrawal and complicating medical problems, such as infections or congestive heart failure, should be admitted to the hospital. Patients who fail to respond to one or two doses of sedative medications should also be admitted. Administration of more than 8 mg of lorazepam or 500 mg of phenobarbital is in most cases an indication for admission to a nursing unit where the patient can receive close observation by both nursing and physician staff, in many hospitals, an intensive care unit. Patients with mild alcohol withdrawal that respond to treatment may be discharged. If they have been given phenobarbital, no outpatient prescription is necessary. In any case, the benefit of prescribing outpatient benzodiazepines is doubtful if a patient is likely to resume drinking after discharge from the emergency department.

ELDERLY PATIENTS AND ALCOHOL

Fewer older people drink regularly, and intake among older drinkers is less than among younger people. Nevertheless, alcohol is still a significant problem among the elderly, and alcohol-related problems are by far the most common drug-related problem in this age group. Moreover, since many physicians are even less likely to consider the possibility of alcohol abuse or alcoholism in older than in younger patients, the diagnosis is often missed. Even so, the prevalence of alcohol-related hospitalizations during a recent year for people over 65 years of age was 54.7 per 10,000 population for men and 14.8 per 10,000 for women. [1] Alcohol plays a significant role in motor-vehicle collisions and other trauma involving the elderly and has a greater impact on the health of the elderly than on that of younger persons. Mortality and morbidity rates due to all types of trauma are higher for older patients. [15]

WOMEN AND ALCOHOL

Women are less likely than men to abuse alcohol but are more prone to experiencing alcohol-associated health problems, especially cirrhosis. [1] A population-based study found that, among those averaging six or more drinks per day, the relative risk for mortality for women was five times that of men. The reason for this is unclear but may be related to the fact that women have virtually no first-pass metabolism of alcohol by gastric alcohol dehydrogenase and a smaller volume of distribution than men, resulting in considerably higher blood alcohol levels following ingestion of a given dose of alcohol. [16]

Women who drink during pregnancy predispose their children to growth retardation in utero and to the fetal alcohol syndrome, characterized by facial dysmorphology and mental and growth retardation after birth. Even women who report intake of less than one drink a day are at increased risk of having a child in the bottom 10 percent for birth weight.[17] Since emergency physicians frequently diagnose pregnancy and patients with alcohol problems are often seen in emergency departments, emergency physicians are likely to have the opportunity to advise pregnant patients about the risks inherent in using alcohol during pregnancy.

LONG-TERM OUTLOOK FOR ALCOHOLICS

Alcoholic patients should be referred for counseling when possible. A fifth or more may achieve permanent abstinence with the aid of Alcoholics Anonymous or other self-help groups. Unfortunately, the rate of recidivism is related to socioeconomic status and availability of family and social support systems. Thus, while 60 percent of middle-class alcoholics remain ethanol free for at least 1 year after completing a rehabilitation program, the outlook is considerably bleaker for those who are less advantaged.

300 THE ELDER PATIENT

Arthur B. Sanders

Older patients represent a special population for emergency medicine. The approach that focuses on one chief complaint, and develops a differential diagnosis based on life-threatening and common diseases, may miss significant conditions in older persons. Older patients are more time consuming, more difficult to evaluate, and take more resources compared with younger adult patients. The complexity of their presentations and dispositions, as well as communication problems with the patients, their families, and primary care providers, all make the emergency department (ED) evaluation of elderly persons more difficult compared with younger adult patients.[1] The physiology of aging results in altered disease presentations, altered pharmacodynamics, and decreased functional reserve, as well as social problems, which must be dealt with in the setting of a busy ED.

EPIDEMIOLOGY

The demographics of the population in the United States demonstrate the importance of older persons in our society, the rapid growth of the elderly from 1920 projected to 2050, and the potential effects of these demographic changes on our health care system (Fig. 300-1). About 12 percent of the population was 65 years of age or older in 1990, whereas 20 percent of the population (or 55 million persons) will be 65 years of age or older by the year 2030. [2] The oldest elderly, those 85 years and above, are the most rapidly increasing segment of the population. This is also the population with the most health problems and in greatest need for health care. There is great variability in the physiologic age of individual patients. A 55-year-old with multiple chronic diseases and poor physiologic reserve may have a physiologic age much older than a healthy 80-year-old.
FIG. 300-1. Percentage increase of elderly population from 1920 projected to 2050. (From Eliastam M: Elderly patients in the emergency department. *Ann Emerg Med* 18:1222, 1989.)

In 1990, about 15 percent of ED visits were made by patients 65 and older, and over 30 percent of older patients use ambulances to come to the ED. [3] The rate of ambulance use increases with age: more than half of those 85 years of age and older are transported by ambulances. Older patients require comprehensive emergency department services, and more than 40 percent are admitted to the hospital. [3] Older patients spend more time in the ED, require more ancillary tests, and are more likely to be admitted to critical care units. [4] A survey by the National Center for Health Statistics (NCHS) found that persons aged 65 to 74 years had an estimated 3l.4 ED visits per 100 persons per year, and persons aged 75 years and older had 55.8 visits per 100 persons per year, twice the rate for younger persons. [5]

PATHOPHYSIOLOGY

To meet the needs of older persons in the emergency medical care system, principles of geriatric emergency medicine have been defined and are listed in Table 300-1.[6] Patients may present with vague or ambiguous symptoms, such as not feeling right, feeling weak, or not doing usual activities. Vague complaints, such as general weakness or functional decline, may indicate important diseases, such as sepsis, subdural hematoma, or myocardial infarction. Tools such as an assessment of functional status can be used for classifying and evaluating these complaints.

1. The patient's presentation is frequently complex.
2. Common diseases present atypically in this age group.
3. The confounding effects of comorbid diseases must be considered.
4. Polypharmacy is common and may be a factor in presentation, diagnosis, and management.
5. Recognition of the possibility for cognitive impairment is important.
6. Some diagnostic tests may have different normal values.
7. The likelihood of decreased functional reserve must be anticipated.
8. Social support systems may not be adequate, and patients may need to rely on caregivers.
9. A knowledge of baseline functional status is essential for evaluating new complaints.
10. Health problems must be evaluated for associated psychosocial adjustment.
11. The emergency department encounter is an opportunity to assess important conditions in a patient's personal life.

TABLE 300-1   Principles of Geriatric Emergency Medicine

Common diseases often present atypically in older persons, [7] resulting in missed diagnoses unless physicians understand and suspect the atypical presentations in this population. For example, fewer than half of patients 85 years of age and older will present with chest pain as a symptom of acute myocardial infarction. Instead, patients present atypically with dyspnea, syncope, weakness, or dizziness. [8] Acute abdominal catastrophes are often missed in older persons because of the atypical disease presentations. Abdominal guarding or even rigidity may be lacking with significant abdominal pathology. Fever or leukocytosis may not be present. Only about half the older patients with acute appendicitis have that diagnosed upon admission to the hospital. A large percent of patients with appendicitis present more than 48 h after the onset of symptoms, with up to 20 percent presenting after 3 days. The abdominal pain is vague, and the symptoms may be poorly localized. Classic patterns of pain and accompanying symptoms, such as nausea and vomiting, are present in only a minority of older patients with acute appendicitis. [9]

Older patients frequently will have confounding comorbid diseases, and emergency physicians must evaluate whether the presenting complaint reflects an

exacerbation of one of the comorbid diseases or a new disease process. Comorbid diseases, especially those treated with multiple medications, may also affect the management and disposition of patients. Older adults take an average of 4.5 prescription drugs and 2.1 over-the-counter drugs each day. [10] About 30 percent of older persons will develop adverse medication effects, and they are twice as likely as younger adults to have adverse effects. Adverse medication effects account for approximately 5 percent of hospital admissions. [10] The number of medications that a patient takes is directly related to the chance of adverse drug effects. Normal aging results in a loss of cardiac, pulmonary, hepatic, and renal functional reserve. Thus, the margin of error decreases for many medications, such as nonsteroidal anti-inflammatory drugs. The distribution of drugs changes with age, lean body mass decreases, and the larger proportion of adipose tissue increases the volume of distribution of drugs, such as benzodiazepines, phenytoin, barbiturates, and prolongs their duration of action. Drug clearance depends primarily on hepatic and renal function. The decreased renal function with age may effect drugs such as digoxin and the aminoglycoside antibiotics. Drug receptor interactions also play a role in pharmacodynamics. Older persons have an increased sensitivity to warfarin and benzodiazepines. Common complications of medications or drug interactions include delirium, depression, functional decline, worsening dementia, orthostatic hypotension, weakness, dizziness, falls, and incontinence. The impact of new medications prescribed in emergency departments, such as anticholinergics, sedatives, and diuretics, as well as adverse interactions with current medicines, must be anticipated. [10]

Older persons will frequently have cognitive impairment that may not be recognized by health care providers. Cognitive impairment includes both acute confusional states (delirium) and dementia. Abnormal cognitive states in older patients affect the reliability of the history and impact disposition planning. Acute cognitive impairment can be an important symptom of sepsis, congestive heart failure, metabolic abnormality, adverse drug effect, or subdural hematoma. When older emergency department patients are screened for cognitive impairment, 30 to 40 percent of those who have no previous history of impairment will have abnormal cognition based on formal mental status exams. [11],[12] About 10 percent of patients will meet formal criteria for delirium, which should be considered a symptom of a medical emergency. Formal tools for evaluation of cognition are recommended later in this chapter.

Accurate test interpretation requires a knowledge of which "normal" values are altered with aging. Although many laboratories control for age variations in neonates and children, few list control values for older patients. For example, laboratory parameters such as the sedimentation rate, glucose and creatinine levels, and arterial blood oxygen tension change with physiologic aging.

The likelihood of decreased functional reserve must be anticipated in older persons. Most patients are asymptomatic until they are stressed or reach a critical threshold in which symptoms are manifested. Most organ functions decline with age. Resting cardiac output decreases at approximately 1 percent per year after age 30. Pulmonary, renal, neurologic, and immunologic functions also decrease with age. Chronologic and biologic age, however, may vary considerably, depending on genetics, environment, health behaviors, diet, tobacco use, alcohol use, exercise, or stress. When older persons are stressed, for example, by extreme heat or cold, their regulatory mechanisms are not as effective.

Older persons must be viewed in the context of their home environment and social support network. Simply addressing an injury or illness may not be adequate. Over 20 percent reported a change in their ability to care for themselves following their emergency department visit. [13] An independent-living 80-year-old woman who sprains her ankle may become incapacitated. Enlisting the help of a social service network, home health providers, etc., will ensure that such patients are able to carry on the functions of daily living. In addition, many older persons need to rely on caretakers, so an assessment of the caretaker's ability to help the patient is important. Is the caretaker an elderly spouse who will predictably injure himself or herself in trying to lift a patient who is incapacitated by a new injury? Elder abuse and neglect is a significant issue [14] (see Chap. 292, "Abuse in the Elderly and Impaired") that should be assessed by questioning the patient and caretaker separately.

The emergency health care professional can play a key role in screening for such important conditions such as elder abuse, depression, alcoholism, malnutrition and incontinence, falls, and immunizations. In a multicenter study in which patients were screened, almost 80 percent of older patients demonstrated a problem in one or more of these areas. [15]

SPECIFIC ISSUES

This section reviews how the principles of geriatric emergency medicine (Table 300-1) can be applied to the specific medical conditions of altered mental status, functional decline, trauma, falls, and infections.

Altered Mental Status

Of emergency department older patients with no prior history of cognitive problems, 30 to 40 percent will meet the criteria for either delirium or cognitive dysfunction, and this is often unsuspected by the physician. [11],[12] Consequently, older patients should be routinely screened for cognitive dysfunction. The simplest screening tool is evaluation for orientation and three-item recall. If no problem is detected, no further testing needs to be done. If the screen is failed, further testing can be done. The Confusion Assessment Method (CAM) scale (Fig. 300-2)[16] is a useful tool for the emergency physician. Using the CAM scale, the patient is evaluated for (1) acute onset, (2) fluctuating course, (3) inattention, (4) disorganized thinking, and (5) altered level of consciousness. These factors are assessed through the emergency department history and observation, as well as structured questions such as three-item recall, stating the days of the week or months of the year backward. Patients who present with inattention—either acute onset or fluctuating course—and disorganized thinking or altered level of consciousness should be considered to have delirium and evaluated for acute medical problems as the cause. Cognitive function can be further assessed with formal mental status tools such as the Mini-Mental Status Exam (MMSE). [17] These scales are useful because they are widely accepted as indicative of cognitive dysfunction and can be followed by different clinicians over time (Fig. 300-3).

FIG. 300-2. Confusion Assessment Method (CAM) worksheet. The diagnosis of delirium is suggested with the presence of the first two criteria and either the third or fourth criteria. From Inouye et al, [16] with permission.

FIG. 300-3. Mini-Mental State Examination (MMSE). Courtesy of Marshall Folstein. Reprinted from Folstein et al, [17] with permission.

Delirium, dementia, or decreased level of consciousness are usually obvious on history and physical examination. The Glasgow Coma Scale (see Chap. 221) is useful for classifying a decreased level of consciousness. Acute mental status changes in older patients represent a medical emergency of presumed organic cause requiring extensive diagnostic tests to determine the etiology. The differential diagnosis is more difficult because a large number of disorders such as pneumonia, urosepsis, electrolyte imbalance, medication reaction, or congestive heart failure can cause a decrease in mental status.

Functional Decline

Functional decline represents a change in a patient's ability to perform tasks of independent living and is not a part of normal aging. This can be assessed with the use of a standard scale for Activities of Daily Living (ADL), which evaluates a patient's ability for bathing, dressing, toileting, transferring (in or out of a bed or chair), continence, and feeding (Table 300-2).[18] The patient is asked whether he or she can perform each of these functions with no assistance, with partial assistance, or cannot perform these functions. If a patient cannot perform these basic activities of daily living, then a caregiver is necessary. Deterioration in ADL generally follows an orderly progressive pattern of bathing, dressing, toileting (including continence), transferring, and feeding. When this pattern is not seen, such as a deterioration in feeding before the others, organ disease should be suspected. Another scale, the Instrumental Activities of Daily Living (IADL), assesses more sophisticated skills, such as telephone use, walking, shopping, preparing meals, housework, handiwork, laundry, taking medicines, and handling finances (Table 300-3).[19] It is best to use these formal scales in evaluating older patients and assessing changes over time. Acute functional decline represents an acute medical syndrome that needs appropriate workup and treatment. An algorithm for the ED evaluation of functional decline is presented in Fig. 300-4.[20] The differential diagnosis for functional decline includes serious diseases such as myocardial infarction, sepsis, and subdural hematoma, as well as adverse drug reactions. Patients will often present with a vague symptom, such as weakness, that on further questioning and use of the scale is noted to be functional decline.

Trauma

Trauma is a major cause of morbidity and mortality among older persons. Although fewer than 20 percent of trauma patients are 65 years of age or older, older patients represent 28 percent of trauma deaths.[21,22] They are more likely to have significant complications and prolonged hospitalizations because of their decreased functional reserve.[21] Falls are the most common mechanism of injury for older persons, followed by motor vehicle crashes and pedestrian accidents. Regardless of injury severity or mechanism of injury, mortality increases for patients at 50 years of age and continues to increase with increasing age. The major challenge for emergency physicians who treat older patients who have multisystem trauma is that the standard physiologic indices, such as blood pressure and pulse, often remain within normal limits until the patient deteriorates acutely. Occult shock must be strongly suspected in all older patients who experience significant trauma. Early hemodynamic monitoring of older trauma patients can detect occult shock early in the course and improve the chance of survival. [21,22] (See Chap. 245, "Geriatric Trauma.")

Falls

Falls are not a normal part of aging. A fall is a symptom, and emergency physicians need to assess both the cause and the consequences of the fall. The causes of a fall may include acute or chronic diseases, medications, and environmental factors. [22] Consequences of a fall include injury and fear of falling, resulting in a decrease in activities. A fall can represent a sentinel event in an older person's life and result in a downward spiral of decreased activities, leading to death. As many as 50 percent of older patients admitted to the hospital after a fall die within 1 year. An emergency physician obtains the history of what caused the fall and determines whether further emergency department screening tests (electrocardiography, computed tomography, laboratory tests, social service consultation, etc.) will be done to

evaluate the cause.[22] The patient should then be informed about fall assessment programs that decrease the incidence and morbidity from falls.

Infections

Multiple factors as well as changes in the immune system with age are responsible for the increased susceptibility to infection in the elderly. [23] In addition, older persons will have atypical disease presentations of sepsis. Focal symptoms or signs of infection may be lacking. Instead, patients may present with isolated fever or nonspecific symptoms of anorexia, weakness, fatigue, and functional decline as the only evidence of infection. Hypothermia may be evident instead of fever. The most common sites of infection include the lungs, urinary tract, abdomen, and skin.

Bacteremia and occult bacterial infection are common in the febrile elderly. Mellors and coworkers identified the following multivariate predictors of bacteremia and occult bacterial infection in febrile adults without localizing symptoms or signs: (1) age older than 50, (2) diabetes, (3) white blood cell count (WBC) more than 15,000, (4) neutrophil band count more than 1500, and (5) erythrocyte sedimentation rate more than 30 mm/h.[24] Patients with one or two of these factors had a seven- to eightfold relative risk for bacteremia or focal bacterial infection. Other studies in the febrile elderly have also found that leukocytosis and "left shift" on the WBC differential was also associated with a two- to threefold greater likelihood of bacterial infection. [25]

DISPOSITION

For all the foregoing reasons, elderly patients in EDs are more likely to require hospital admission for their illness or injury compared with younger patients. When discharged from an ED, elderly patients may not fully understand the instructions, may not be able to obtain and take prescribed medications, may not be able to access appropriate follow-up, or may not be able to care for their personal needs during the period of illness. An elderly patient's family, friends, and social support system should be informed and involved before the patient leaves the ED.

301 ADULTS WITH PHYSICAL DISABILITIES

Cara B. Siegel
Paul J.W. Tawney

Advances in medicine and surgery have prevented the deaths of many injured and sick patients. Although they survived, many such individuals live with significant impairments and disabilities. Some estimates are that 5 to 10 percent of the total population of the United States has major disabilities. Persons with disabilities seeking medical care in an emergency department (ED) may present with problems that are specific to their impairment or with signs and symptoms different from those that would occur in a nondisabled patient. The individual who is disabled is not unable, and every effort should be made to obtain the history directly from the patient. Do not automatically direct questions to persons with the disabled individual without first finding out whether the patient is capable of giving accurate responses. It is helpful to sit down and speak to a patient in a wheelchair at eye level, and to make an effort to use a dysphasic or dysarthric patient's communication system so that they may tell their story.

SPINAL CORD INJURY

Autonomic Dysreflexia

Patients with spinal cord injuries at or above the T6 level are at risk for developing autonomic dysreflexia (also called autonomic hyperreflexia). [1] This reflex is initiated by a noxious stimulus from below the level of the patient's spinal cord lesion. Intact sensory neurons below the level of the lesion transmit a message up the spinal thalamic tract and posterior columns, where interconnections stimulate the intermediolateral gray matter neurons, producing sympathetic outflow from spinal cord levels between T6 and L2, releasing norepinephrine, b-hydroxylase, and dopamine. This sympathetic reflex is relatively unopposed because the normal inhibitory impulses that would prevent it originate above T6 and are blocked at the level of injury. [1]

The sympathetic response produces a rise in blood pressure, vasoconstriction, skin pallor, and piloerection below the level of the lesion. Intact carotid and aortic arch baroreceptors detect the hypertension, producing increased parasympathetic activity in the vagus nerve and bradycardia. Sympathetic outflow above the lesion is inhibited, which causes profuse sweating, vasodilation, and skin flushing. [1,2]

Common symptoms and signs of autonomic dysreflexia are a pounding headache, profuse sweating and flushing above the level of the lesion with pallor below the level of the lesion, nasal congestion, feeling of apprehension or anxiety, visual changes, and, most significant, a marked increase in systolic and diastolic blood pressure above baseline. [1,2] Patients with spinal cord injury at or above the T6 level often have lower baseline systolic blood pressures, in the 90- to 110-mmHg range. Therefore, blood pressure elevations of 20 to 40 mmHg or systolic pressures of 130 to 150 mmHg are significant. Acute elevation in blood pressure is the most worrisome and potentially life-threatening manifestation of this syndrome.

A variety of stimuli can produce an acute episode of autonomic dysreflexia. The commonest causes usually involve the urinary system: bladder distention, urinary tract infection, and kidney stones. The second commonest reasons involve the colon: fecal impaction or bowel distention. However, any noxious stimulus below the level of injury can lead to autonomic dysreflexia, including other abdominal problems, such as ulcers, appendicitis, and gallstones. Other causes may be fractures, deep venous thrombosis (DVT), pressure ulcers, ingrown toenails, tight-fitting clothing, sunburns, blisters, heterotopic ossification, sexual intercourse, pregnancy, and labor and delivery.

Treatment starts with monitoring and controlling the patient's blood pressure. If possible, the patient should be sat up to lower blood pressure. [2,3 and 4] If the systolic blood pressure is above 150 mmHg, an antihypertensive agent with a rapid onset and short duration should be used to lower the blood pressure. [5] Nifedipine and nitrates are the most commonly used agents. More aggressive treatment should be undertaken if these agents do not adequately correct the elevated blood pressure.

After assessment of the blood pressure, the bladder should be checked for distention and infection. [3,4] If the patient does not already have a urinary catheter, one should be placed immediately. The stimulus of catheterization may add to the autonomic reflex, and lidocaine jelly should be used if it is readily available, but its lack should not delay the placement of the catheter. If the patient already has an indwelling Foley or suprapubic catheter, it should be checked for obstruction and correct placement. The bladder can be gently irrigated through either catheter with body-temperature normal saline solution to check for obstruction and improper placement. [4] Urine should be obtained for urinalysis and culture (see below).

If the problem does not appear to be bladder related, the physician should suspect fecal impaction. [3,4] Prior to the rectal examination, the patient's blood pressure should be managed, and the anal opening should be anesthetized with lidocaine jelly placed into the rectum for 5 min before beginning the examination. [4] The patient's blood pressure should be monitored to ensure that the hypertension is not aggravated during this procedure, since rectal examination can exacerbate autonomic dysreflexia. If the blood pressure increases, stop the examination, instill more anesthetic agent, and wait additional time. If the bladder or bowel does not appear to be the cause of the patient's symptoms, a search for other causes should be undertaken.

Following relief of an acute episode, patients should be monitored for at least 2 h after resolution to make sure that there is no recurrence. Patients with bladder distention do not routinely require discharge with an indwelling urinary catheter. It is best to discuss that option with the patient's physician. If the patient responds poorly or the cause has not been identified, the patient may need to be admitted for more aggressive pharmacologic control of blood pressure and a more thorough investigation of the cause. [2,3,4 and 5]

Urinary Tract Infection

A urinary tract infection should be suspected when a spinal-cord-injured patient presents with fever, discomfort over the kidney or bladder, change in spasticity, development of urinary incontinence, an episode of autonomic dysreflexia, cloudy or foul-smelling urine, a change in energy level, or a feeling of apprehension. [6,7] Unless there are confounding factors, the urinalysis shows pyuria and significant bacteriuria. In a patient with the abovementioned symptoms and signs and pyuria, empiric treatment for urinary tract infection should be started. Absence of pyuria makes the diagnosis less likely but does not completely exclude it. Conversely, pyuria in an asymptomatic patient with spinal cord injury does not warrant treatment. Pyuria without infection can occur from irritation of the bladder wall in patients with indwelling catheters and in those who use intermittent catheterization. [8]

Significant bacteriuria for the spinal-cord-injured population is defined according to the method used for bladder emptying. For women who can spontaneously void, significant bacteriuria is defined as greater than 100,000 colony-forming units (CFUs) of bacteria per milliliter. For men who spontaneously void or use condom catheters, greater than 10,000 CFUs/mL is considered significant. For both women and men who use intermittent catheterization, greater than 100 CFUs/mL indicates significant bacteriuria. For patients with indwelling urethral or suprapubic catheters, any detectable level of bacteriuria is significant. [6]

Urinary tract infections in the spinal-cord-injured population are considered complicated urinary tract infections. [9] Antibiotics with broader-spectrum coverage should be used, since such organisms as *Proteus, Klebsiella, Pseudomonas, Serratia, Providencia,* enterococci, and *Staphylococcus* are more common. Because of the higher risk of upper-tract infection, 7 to 14 days of treatment should be considered. [10,11]

Asymptomatic bacteriuria is very common in patients with a neurogenic bladder that requires periodic or indwelling catheterization. Asymptomatic bacteriuria should not be routinely treated. [6] Because signs and symptoms of urinary tract infections may be less obvious in spinal-cord-injured individuals, the physician should be aware of subtle clues to the presence of infection and have a low threshold for urinalysis as the best method of diagnosis. [9]

Acute Abdomen

Classic signs of acute abdomen are often missing in patients with spinal cord injury. The diagnosis of perforated peptic ulcer, intestinal obstruction, appendicitis, peritonitis, cholecystitis, and renal abscess is often delayed because the classic findings of abdominal muscle rigidity, rebound, abdominal tenderness, fever, and leukocytosis may not be present. [12] In patients with spinal cord injury, other signs and symptoms suggestive of an acute abdomen are autonomic dysreflexia, referred shoulder tip pain, abdominal pain, abdominal distention, change in muscle spasticity, nausea and vomiting, and a sense of apprehension. [12,13 and 14] A high index of suspicion, along with laboratory and imaging tests, is necessary to avoid missing the diagnosis. One confounding factor is that urinary tract infections may present with similar signs and symptoms. Thus, the finding of pyuria or bacteriuria alone should not be used to exclude the diagnosis of an acute abdomen. [13] Unexplained leukocytosis is a helpful, but not diagnostic, clue to the presence of an acute abdomen. While abdominal radiographs are also useful in the diagnosis of intestinal obstruction, many spinal-cord-injury patients have chronic dysmotility problems and have baseline increased bowel gas and air-fluid levels that may mimic a mechanical obstruction. Ultrasound, contrast, and computed tomography (CT) imaging studies are often required for correct diagnosis in such patients. [14]

Syringomyelia

Posttraumatic syringomyelia may present months to years after a spinal cord injury. [15] This process produces a cystic cavitation of the central cord that may extend over several levels. Ascending sensory level (i.e., a decrease or loss of sensation above the preexisting sensory level) and pain are the most common presenting symptoms. Motor weakness, a change in spasticity, and a change in deep-tendon reflexes may also be seen. Magnetic resonance imaging is the imaging study of choice for making the diagnosis of syringomyelia. Surgery is indicated in progressive neurologic deterioration.

Immobilization Hypercalcemia

Most cases of immobilization hypercalcemia are seen in adolescent boys following recent spinal cord injuries. [16] Risk factors include age less than 21 years, complete neurologic injuries, cervical injuries, prolonged immobilization, and dehydration. [16] Presenting symptoms include anorexia, nausea, headache, malaise, and depression in mild cases. In more severe cases, patients may have persistent nausea and vomiting, gastric dilatation, fecal impaction, and abdominal pain. Microscopic calcium deposition in the kidney may impair its ability to concentrate urine, leading to polyuria and polydipsia. Patients may also develop cardiac dysrhythmias and seizures. [16]

The pathophysiology of immobilization hypercalcemia is thought to be due to the combination of increased bone resorption and the inability of the kidneys to excrete the excess calcium. Compared to other age groups, an adolescent has a higher than normal bone turnover rate and more total bone mineral. [16] Immobilization causes a decrease in osteoblastic activity in the weight-bearing bones and an increased rate of bone resorption. Together, these factors lead to a higher-than-normal serum calcium level when subjected to a prolonged period of immobilization. In most cases, the kidneys can usually excrete the calcium, but in some patients this ability breaks down.

Treating immobilization hypercalcemia starts with hydration and diuresis with normal saline solution 2 to 3 L/day with the addition of furosemide. Calcitonin in doses of 1 to 4 IU/kg subcutaneously every 12 h can also effectively reduce the serum calcium level. [16]

Heterotopic Ossification

Heterotopic ossification (HO) is the formation of bone in the soft tissues. [17] The mechanisms of the formation of heterotopic bone are not precisely known. In spinal-cord-injured patients, it is more common among those with spasticity. Symptoms may present as early as 1 month after injury. Pain is prominent in other patients with HO but is often absent in spinal-cord-injured patients. For spinal-cord-injured patients, the commonest symptom of HO is a decreased range of motion. Other findings are a change in spasticity, fever, erythema, joint effusion, and swelling. [17] The differential diagnosis includes DVT, infection, and tumor. Sometimes HO and DVT are seen together.

The incidence of HO in spinal-cord-injured patients has been reported to be 16 to 53 percent. The most common sites are the hip, knee, femur, and shoulder. [18] Plain radiograph findings are often negative in the early stages of HO. The gold standard for diagnosis is the three-phase bone scan. [19,20] Serum alkaline phosphatase (ALP) levels have been used as a screening test for HO, since developing bone produces ALP. [21] However, this is a nonspecific test indicating increased bone metabolic activity, which may occur in fractures or tumors. [19]

Treatment for HO is usually disodium etidronate (20 mg/kg/day for 2 weeks followed by 10 mg/kg/day for 10 weeks) along with gentle physical therapy. [21] Referral to a physiatrist (a physician specializing in the care of patients with disabilities) or other spinal-cord-injury specialist is recommended to institute and monitor treatment.

BRAIN INJURY

Posttraumatic Hydrocephalus

Patients with a history of traumatic brain injury may present to the emergency department with the complaint of changing functional status, including psychomotor slowing, cognitive decline, change in gait, and loss of continence. An evaluation for possible infectious or metabolic causes must be undertaken, but a CT scan of the head is critical to exclude posttraumatic hydrocephalus. [22,23] A CT scan revealing periventricular lucency, diminishing sulci, and dilatation of the ventricles suggests posttraumatic hydrocephalus. [23] Consultation with a neurosurgeon for appropriate treatment options, such as shunting, should be undertaken.

Cerebrovascular Accident

Medical complications occur in up to 40 percent of stroke patients. Common complications include DVT, pulmonary embolism, skin breakdown, shoulder dysfunction, pneumonia, and increased risk of falls and injuries. Patients with strokes often have coexisting atherosclerotic heart disease. Heart disease is the second commonest cause of death during the first month after a stroke and the commonest cause after that. [24]

Leg Pain

In a brain-injured patient who presents with a swollen and painful leg, the differential diagnosis includes trauma (e.g., contusion, sprain, or fracture), DVT, heterotopic ossification, and reflex sympathetic dystrophy. [25] Especially with individuals whose impaired language or cognition hinder the history and physical examination, a high index of suspicion and liberal use of ancillary studies are critical. Plain radiographs are usually adequate for evaluating trauma. Noninvasive venous studies (duplex Doppler) are usually adequate for evaluating DVT. Once fracture and DVT have been ruled out, referral to a physiatrist or other specialist in the care of patients with brain injury should be arranged.

302 THE MENTALLY RETARDED ADULT

Linmarie Sikich
L. Jarrett Barnhill

Evaluating a developmentally disabled adult in the ED poses a number of challenges, including accurately assessing the ability of the individual to communicate his or her complaints, the ability to make an accurate diagnosis in the absence of sufficient historical information, and the recognition of unusual presentations of common disorders. In addition, 25 percent of individuals with developmental disabilities appear to have significantly increased pain thresholds that result in reduced responses to illnesses and to physical examinations.[1] Such pain insensitivity may limit recognition of medical problems (e.g., intestinal obstruction) until late in the disease process with potentially catastrophic consequences.[2] Treatment of developmentally disabled individuals is also complicated by questions about guardianship, decreased ability of the patient to understand the treatment recommendations and, often, inadequate preventative and routine medical care. However, it is essential that health care providers overcome these obstacles to provide care to this special population that has difficulty advocating for itself. This has become a growing issue over the past 20 years as large numbers of developmentally disabled adults have moved from specialized institutional settings where a small number of physicians were familiar with their special needs to individual and group homes in the community.

EPIDEMIOLOGY

The primary developmental disability is mental retardation. Mental retardation is defined as significant cognitive (IQ less than 70) and functional delays with onset before adulthood. Over 40 percent of individuals with mental retardation have associated medical conditions. Typically the lower the patient's IQ, the more likely a specific etiology of the mental retardation can be identified. Etiologic factors implicated in mental retardation may be prenatal, perinatal, postnatal, or traumatic. Genetic factors account for 7 to 15 percent of all mental retardation; there are 500 genetic syndromes known to be associated with mental retardation. Most of these genetic syndromes are multisystem disorders with a large number of associated medical problems. Cardiac, orthopedic, connective tissue, and neurologic disorders are particularly common.[3] Down syndrome (trisomy 21) is the most common genetic cause of mental retardation, accounting for 4 to 12 percent of all mental retardation, with an incidence of 1/1000 live births.[4] Fragile X is the most common single-gene disorder and accounts for 1 to 6 percent of all mental retardation. The incidence of fragile X syndrome in males is 1/1000 with almost all affected individuals having mental retardation. In females the incidence of fragile X syndrome is 1/2000, but less than half of females with fragile X syndrome have mental retardation. Other common genetic etiologies include Prader-Willi syndrome and Williams syndrome, each with a prevalence in live births of 0.1/1000, Lesch-Nyhan syndrome, with an estimated prevalence of 0.02/1000, and phenylketonuria (PKU), with a prevalence of 0.08/1000.[5] Exposures to toxins may cause as much as 15 percent of mental retardation with fetal alcohol syndrome (FAS) responsible for about 10 percent of all mental retardation.[6] Depending on the etiology, some medical problems are associated with specific mental retardation syndromes (Table 302-1).

TABLE 302-1   Medical Problems Associated with Specific Mental Retardation Syndromes

It is estimated that between 1 and 2.5 percent of the population has mental retardation; thus 3 to 6 million individuals in the United States and 61 to 150 million in the world are affected. In recent decades, the reduction in the number of children born with mental retardation, coupled with the markedly improved survival of mentally retarded adults, has shifted the age distribution of persons with mental retardation. The largest age group with mental retardation is the 10- to 20-year-old group. Most studies have demonstrated increased medical problems in mentally retarded adults as compared with developmentally normal adults. These are particularly seizures and cardiovascular disorders.

Other developmental disorders important for health care providers to recognize are the autistic spectrum disorders and developmental language disabilities. Autism is defined by the presence of qualitative differences in social reciprocity, communication, and the ability to purposefully shift attention. About 50 to 70 percent of individuals with autism are also retarded. The remainder, despite normal or superior cognitive abilities, has difficulty communicating their symptoms and understanding, appropriately generalizing, and responding to information about suggested medical treatments. A large number of autistic individuals have tactile defensiveness and become very agitated when they are touched, which complicates physical examination. Autism is estimated to have a prevalence of 1 to 2/1000 individuals, with as many as 5 to 7/1000 affected with milder forms of the disorder. Individuals with language disorders are also likely to have difficulty describing their medical history and understanding treatment recommendations. In both cases, the individuals' limitations may not be immediately obvious.

Over the past 20 to 30 years there has been a movement in the United States to remove mentally retarded individuals from institutional settings and care for them in the community. Consequently more than 60 percent of those institutionalized in the 1970s have been released into the community.[7] The push for deinstitutionalization has come from desires to improve the quality of life of affected individuals and to reduce societal costs. It is estimated that only 11 percent of American working-aged adults with mental retardation currently reside in institutions.[8] However, Strauss and colleagues found that adults with mental retardation who had been moved from an institutional setting to the community had a 51 percent greater mortality rate than those who remained in the state facility.[9] This difference rose to 67 percent when cancer deaths were excluded. The greatest increase in mortality was found in the two months following the move from the institution. Mortality was greater in those individuals who moved in 1995 as compared to 1993. Several hypotheses were proposed to explain the observed increase in mortality, but the most important was that the deinstitutionalized patients had relatively poor access to health care. For example, the caretakers of recent movers may have lacked adequate knowledge of the movers' baseline and thus did not recognize important changes, or the caretakers may not have been able to provide doctors with adequate past medical history. When these patients are evaluated by a physician, the greatest obstacle to patient care may be an inadequate past medical history.[10] Finally, physicians in institutions may be more familiar with the unusual presentations of common illnesses within the mentally retarded population or more experienced with the specialized

evaluations these individuals require. These factors highlight the critical need for physicians, particularly those in emergency settings, to be familiar with the special needs of developmentally disabled patients.

GENERAL APPROACH

Assess the Individual's Developmental Level

Developmentally disabled individuals have a broad range of cognitive abilities. It is essential to approach patients in a manner consistent with their abilities and to be sensitive to and respectful of their thoughts and feelings. About 85 percent of mentally retarded individuals are mildly impaired; they typically function at about a fifth to sixth grade level, although under the stress of illness and the emergency department, this may be reduced. Once their anxiety is alleviated, they can generally provide some relevant history and describe many of their symptoms. They are also likely to understand simple written directions provided jargon is avoided. About 10 percent of mentally retarded adults are moderately affected; they function at the level of a preschool child, are likely to be able to follow commands, and may be able to answer simple questions. The remaining 5 percent are likely to have no expressive language although they sometimes can follow simple commands.

When assessing any verbal developmentally disabled individual, it is important to ask open-ended rather than yes/no questions to verify the patient's understanding of your question. It is also helpful to ask higher functioning individuals to repeat back information to make sure they have sufficient understanding. Many mentally retarded individuals have particular difficulties with time and causality concepts. Nonverbal patients may be able to point in response to simple questions; however, the bulk of information they provide is nonverbal. Painful regions of the body often become targets for self-injurious behaviors. Similarly, the patient may be splinting or mouthing a painful area. Finally, the mentally retarded often have reduced pain sensitivity that may lead to unusual illness presentations.

Collateral Informants

The evaluation of developmentally disabled patient usually requires collateral information from others, including parents or other family members, group home staff, or social service agency staff. The extent and importance of such information increases as the developmentally disabled patient's ability to communicate decreases. Unfortunately, the person with the patient may have relatively little information about the patient's current problems and/or past history. For example, 55 percent of caregivers in a community setting could not supply basic medical information about the patient. It is important to ask the collateral source explicitly how much information they have and whether there are others who can be contacted by phone who can provide additional information. It is also important to ask if they brought any written information with them. Frequently, lower functioning individuals will be living in group settings where a medical chart with a complete medical history, current medications, sleep logs, and longitudinal vital signs are available. Lack of sufficient information is likely to be the primary obstacle to care of the adult developmentally disabled individual.

Essential Information

Because individuals with mental retardation have a broad range of function, it is essential to determine the patient's specific baseline in a number of areas.

1. How the patient normally communicates.
2. How aware they typically are of their environment.
3. What are their usual motor skills and level of activity.
4. What is the patient's elimination pattern? Constipation and urinary tract infections are common in the mentally retarded and often present with increased agitation or self-injurious behavior.
5. What are the patient's usual sleep pattern and appetite? Both may be disrupted with infectious and psychiatric disorders.

Many mentally retarded patients have multiple medical problems that, either directly or as a consequence of medication side effects, contribute to their acute problem. Therefore, it is essential to get a complete past medical history, an accurate list of medications and doses, and history of prior adverse reactions including allergies. Frequently used medications and associated side effects are shown in Table 302-2. Often increasing use of prn medications is associated with changes in mental status. Finally, one should ask about the patient's visual and hearing status and the use of assistive devices such as glasses, hearing aids, dentures, and walkers. Nearly 60 percent of mentally retarded adults have significant visual impairments, and they are twice as likely to have severe hearing impairments as nonmentally retarded individuals. [11,12] It is not unusual for someone with hearing or visual impairments to become agitated or withdrawn if an assistive device is lost or malfunctioning.

Medications	Frequency of Use[13]	Important Side Effects
Psychotropics	44%	
Antipsychotics		Extrapyramidal symptoms, neuroleptic malignant syndrome, dystonia; can affect swallowing and breathing; sedation, orthostatic hypotension, weight gain, constipation
SSRIs		GI distress, agitation, insomnia, sedation
Benzodiazepines		Sedation, disinhibition, agitation, delirium
Anticholinergics		Blurry vision, urinary retention, constipation
Lithium		Hypothyroidism, delirium, cardiac arrhythmias
Anticonvulsants		Sedation, delirium, ataxia
Carbamazepine		Blood dyscrasias, rashes, constipation, Stevens–Johnson drug levels
Lamotrigine		Severe rashes
Cardiovascular	33%	Overdosage may lead to cardiotoxicity
Laxatives	20%	Vitamin deficiencies
Bronchodilators	14%	Agitation, decreased bone mineralization
Medications	Frequency of Use[13]	Important Side Effects
Analgesics	12%	Renal problems, anemia
Histamine blockers	10%	Psychosis
Thyroid supplement	8%	Psychosis, agitation, hot flashes, cold skin sensations

TABLE 302-2   Frequently Used Medications and Side Effects

Next it is important to determine the patient's living situation. Even relatively minor changes in routine or caretakers can have a dramatic impact on the functioning of some developmentally disabled individuals, particularly those with autism. It is also essential to determine the patient's resources for appropriate follow-up care within the community. The provision of routine and preventative care is particularly important in the developmentally disabled population because of the higher incidence of medical problems. Finally, determine whether the patient has a guardian or, if not, whether they are capable of making their own decisions about medical care.

Physical Examination

A careful and thorough physical examination is essential because sufficient history is often not available to focus the examination. Often, developmentally disabled individuals will be very agitated or have extreme tactile defensiveness, making a thorough examination and detection of physical signs difficult. Special attention should be given to all body orifices (ears, nares, mouth, anus, vagina, and urethra) because foreign objects are often inserted into these areas without the caretakers' knowledge. A dental examination is also important because a large number of individuals with mental retardation have significant periodontal disease.

Vital signs should be obtained when the patient is calm, if possible. If not medically contraindicated, it may be helpful to offer the patient food or distractions (toys, magazines) so that they feel less threatened. It also is essential to carefully explain what you are doing and periodically check to see if the patient understands. It is usually very helpful to have a familiar person present during the examination and procedures, particularly if the patient is nonverbal. If none of these approaches decreases the patient's anxiety sufficiently to allow an evaluation, assistance is required to briefly hold the patient.

Ancillary Studies

Given the difficulties with communication and high frequency of medical problems observed in developmentally disabled adults, it is often useful to obtain ancillary studies that would ordinarily not be required in nondisabled adults. Although the results of some laboratory examinations (e.g., thyroid function tests) will not be available while the patient is in the ED, it is often important nonetheless to obtain them, particularly if there are any difficulties with phlebotomy or concerns about the adequacy of outpatient care. Most ancillary studies are chosen based on the complaints elicited or behavior observed. If the presentation does not suggest localizing

symptoms or have helpful physical signs, generalized "screening" studies may be necessary. For most developmentally disabled patients, these screening studies include a complete blood count, electrolytes, liver function tests, urinalysis, and serum drug levels if the patient is on anticonvulsants or lithium [13],[14] (Table 302-3). When obtaining these studies, it is essential that all procedures are carefully explained at the patient's developmental level. It may also be helpful to use topical anesthetic cream for phlebotomy.

Situation	Diagnostic Evaluations
ED Screening	CBC; electrolytes; BUN; creatinine; liver function tests; serum drug levels (anticonvulsants, lithium); UA
If agitated	Add B12; thyroid function (T4 and TSH); pulse oximetry; abdominal radiograph; consider EEG
"Spells"	Add EEG; ECG; pulse oximetry
Delirium	Add thyroid function tests (T4 and TSH); pulse oximetry; carnitine
GI Bleeding	Endoscopy; abdominal radiograph for foreign bodies
Ataxia	CK; cervical spine radiographs to evaluate atlantoaxial instability
Fatigue	Glucose; calcium; lactate; pyruvate; parathyroid hormone; prostate specific antigen; serum protein electrophoresis
Initial outpatient screening	ED screening plus chest radiograph; ECG; thyroid function tests (T4 and TSH); antinuclear antibody; erythrocyte sedimentation rate; B12; folate

TABLE 302-3   Suggested Ancillary Studies in Developmentally Disabled Adults

Some presentations suggest the need for specific studies:

1. If agitation is the primary complaint, vitamin B$_{12}$ levels, thyroid abnormalities, and the level of oxygenation as measured by pulse oximetry should be assessed, and impaction should be excluded with an abdominal radiograph.
2. If the agitation is cyclic, consider the possibility of a psychomotor seizure and the need for an EEG.
3. If "spells" are reported, an EEG, ECG, and pulse oximetry are appropriate.
4. If a change in mental status or delirium has precipitated the evaluation, consider infections, seizures, and drug interactions or toxicities. Check thyroid function, carnitine levels (especially if patient is on valproic acid), and serum drug levels. Anticholinergics, antihistamines, and benzodiazepines are frequently associated with delirium and agitation.
5. If the patient presents with ataxia, consider drug toxicities, neuroleptic malignant syndrome (NMS), and atlantoaxial instability.
6. If fatigue is the primary complaint, consider viral illnesses, diabetes, and metabolic disturbances (including calcium, lactate, pyruvate, carnitine, and parathyroid).
7. If movement disorders are observed, withdrawal dyskinesias caused by reduction in antipsychotics and tardive dyskinesia should be considered.

FREQUENTLY ENCOUNTERED PROBLEMS

The incidence of medical problems is greater in the developmentally delayed population than in the general population. However, these problems often manifest in unusual ways. A recent study of elderly mentally retarded individuals found that 24 percent had arthritis; 23 percent had gastrointestinal problems (including 7.5 percent with ulcer disease); 23 percent had vascular disease; 16 percent had hypertension; 20 percent had respiratory disorders; and 19 percent had epilepsy. [15] Thirty-five percent of emergency department visits were precipitated by infections (usually respiratory); 33 percent by trauma; 15 percent by seizures; and 5 percent by gastrointestinal concerns.[15] In addition, agitation or aggression frequently leads to ED evaluations. In the study of recently deinstitutionalized adults with mental retardation, deaths were caused by respiratory problems (particularly pneumonia) in 24 percent; cardiovascular events in 22 percent; gastrointestinal illnesses in 15 percent; seizures in 15 percent; sudden asphyxiation in 9 percent; nonrespiratory infections in 4 percent; and trauma in 4 percent. [9]

Injuries

Injuries may be self-inflicted, accidental, or sustained by assault from others. Developmentally disabled individuals are quite vulnerable to assault, and it is important that health care providers be aware of the risk of abuse and their duty to report suspicious injuries. However, the majority of injuries that mentally retarded individuals experience are the result of self-injurious behaviors. Although self-injurious behaviors may be self-stimulating or compulsive, it is essential to rule out medical and environmental precipitants. This is particularly true if self-injurious behaviors are of sudden onset. Bosch and colleagues found that in 28 percent of their patients, treatment of previously undiagnosed, painful medical conditions resulted in significant reductions in self-injurious behaviors. [16] Constipation, gastrointestinal reflux, and peptic ulcer disease were the most common disorders. In these cases, there had often been a cyclic pattern to the self-injurious behaviors or a recent exacerbation. Similarly, increased self-injurious behaviors are often observed with anxiety which frequently results from environmental changes. If no medical or environmental precipitants can be identified it may be useful to treat individuals with selective serotonin reuptake inhibitors (SSRI). However, mentally retarded individuals often respond to lower doses of these agents than individuals with obsessive compulsive disorder. Because these agents may take three to six weeks to act, it is essential that behavioral measures be taken to avoid further injury to traumatized tissues, such as covering affected areas (e.g., a helmet to prevent head-banging damage; mittens or splints to limit the ability to scratch or hit; or a helmet with a face mask to prevent biting). Very close supervision can also prevent a great deal of self-injurious behaviors. Other pharmacologic interventions being examined include the use of naltrexone or atypical antipsychotics.

Infections

Infections, which are often quite fulminant at the time of diagnosis, are frequent in the developmentally disabled population. Mentally retarded individuals frequently have oral-motor dyspraxias that result in frequent tracheal aspirations. Aspiration is also more common in individuals with esophageal reflux and with tube feedings. Urinary tract infections are common. An increased incidence of neurogenic bladder, limited mobility, and poor hygiene all contribute to this increase. Because individuals may initially not recognize or describe dysuria, they are at greater risk for pyelonephritis. With a history of repeated urinary tract infections, it is important to exclude congenital malformations of the urinary system. Skin infections are also frequent. In low functioning individuals, these most commonly occur over pressure points or in the skin folds of the genital and anal regions. Poor mobility and hygiene contribute significantly. In higher functioning individuals, skin infections may be a consequence of repeated biting or scratching or the insertion of foreign objects under the skin. Finally, 16 percent of mentally retarded individuals had severe periodontal disease as compared to 3 percent of controls. [17] It is likely that both poor hygiene and anticonvulsant use contribute to this finding.

Neurologic Problems

SEIZURES   Thirty to 50 percent of all developmentally delayed individuals have seizure disorders. Often, an individual experiences several different types of seizures, which may have complicated presentations such as Lennox-Gastaut seizures. Occasionally, patients, particularly those who are verbal, also have pseudoseizures. As with any other patient, the priorities are to insure adequate oxygenation and to stop the seizure. Subsequently, one must determine the precipitants for the seizure, specifically whether the precipitant is medication or infection. Seizures are commonly precipitated by a change in medications. Frequently, in an effort to reduce side effects and potential drug interactions, efforts are made to reduce the number of anticonvulsants or to switch from an older agent such as phenobarbital even though the patient's seizures are under good control. Occasionally, unintentional medication changes occur when the developmentally disabled individual moves to new living situations because a medication has been forgotten or given incorrectly. Addition of new concurrent medications may also have altered the seizure threshold. For example, theophylline decreases seizure threshold. Infections, especially UTI may also precipitate seizures in individuals whose seizures had been previously well controlled.

DELIRIUM   Developmentally disabled individuals appear to be particularly vulnerable to delirium. Typically caretakers will describe a relatively acute change in mental status. However, this change may be relatively subtle if the individual is inactive or nonverbal at baseline. Visual and tactile hallucinations and agitation are not uncommon. Most often the change in mental status is related to infection or to drug toxicity. Drug toxicity may occur at lower medication doses than observed in other populations. Toxicity may also be precipitated by interactions with other medications. For instance, erythromycin and fluoxetine both slow the metabolism of several anticonvulsants and may result in toxic levels. Anticonvulsants and anticholinergics frequently cause delirium. Less often, delirium results from metabolic disturbances including hyperglycemia, hypothyroidism, hypoxia, or vitamin or cofactor deficiencies (e.g., vitamin B$_{12}$ in individuals with limited diets or carnitine in individuals treated

chronically with valproic acid). In addition, changes in mental status are often seen in sleep apneas, which is common in Prader-Willi and Down syndromes.

DEMENTIA   Dementia leads to many of the same symptoms as delirium but does so more gradually. Some subgroups of mentally retarded individuals appear especially likely to develop dementia. For instance, over 80 percent of individuals with Down syndrome who are older than 40 years, have symptoms of dementia. The differential diagnosis of dementia should include depression and chronic overmedication.

SPINAL CORD COMPRESSION DUE TO ATLANTOAXIAL INSTABILITY   Individuals with Down syndrome are particularly vulnerable to spinal cord damage resulting from instability between the atlas and the axis of the cervical spine. This instability is a consequence of two factors. First, there is a general laxity of the connective tissue in Down syndrome. Second, congenital anomalies of the atlas and axis (particularly the odontoid process or hypoplasia of the posterior arch of the atlas) are common with an incidence of 26 percent in Down syndrome.[18] Although atlantoaxial instability is described primarily in Down syndrome, individuals with a number of other mental retardation syndromes associated with prominent hypotonia, connective tissue problems and bony malformation are also likely to develop atlantoaxial instability.

With atlantoaxial instability, the spinal cord is vulnerable to compression between the odontoid process anteriorly and the arch of the atlas posteriorly when the neck is flexed. Spinal cord compression may also occur during neck extension when there is atlantoaxial subluxation and/or dislocation. Intubation, cardiac catheterization, laryngoscopy, bronchoscopy, tracheal suctioning, sedation for neuroimaging, auditory- and visual-evoked potential studies, and dental work all involve positions with extreme neck extension and may be dangerous. The neurologic manifestations of atlantoaxial instability may be relatively subtle and include easy fatigability, difficulties in walking, neck pain, limited neck mobility, torticollis, incoordination and clumsiness, sensory deficits, problems with incontinence, and spasticity. These symptoms may progress to paraplegia, hemiplegia, quadriplegia or even death. Most individuals have had symptoms for more than a month prior to their diagnosis and many will have had symptoms for a year or more. Rarely, sudden subluxation has occurred when there is a sudden change in momentum (e.g., when a motor vehicle crashes and on carnival rides such as bumper cars and roller coasters).

Radiographic screening for atlantoaxial instability consists of measuring the atlantodens interval with intervals of greater than 4.5 mm considered suggestive of atlantoaxial instability. However, there has been a great deal of controversy about the reliability and stability of atlantodens interval measurements. Relatively few individuals with radiographic evidence of atlantoaxial instability are symptomatic and some symptomatic individuals have normal radiographs. Recently, some have argued that screening radiographs for atlantoaxial instability should be abandoned and careful neurologic exams should be substituted. [19]

Treatment of atlantoaxial instability typically involves surgical stabilization. There are frequent medical complications with procedures, but it is not clear that these are any greater in the developmentally disabled population than in the general population.

Psychiatric Disorders

Psychiatric disorders are estimated to afflict up to 50 percent of the developmentally disabled population. Although mood disorders, particularly depression, are most frequent, they are relatively unlikely to precipitate ED evaluations. Instead, emergency visits are usually precipitated by aggression or extreme agitation. In such cases, benzodiazepines or low-dose, low-potency antipsychotics, such as chlorpromazine, may be acutely helpful in controlling the patient's behavior sufficiently to proceed with an evaluation. However, it is essential to try to identify the underlying etiology of these behaviors and changes in their frequency or intensity. Undiagnosed, painful medical problems, including severe constipation, often lead to exacerbation. [16] Sleep apnea can also be manifest as increased irritability. In addition, anxiety may be manifest primarily as agitation. Often environmental factors can be identified that are increasing the patient's anxiety. Such factors may include changes in caretakers or recent onset of sensory deficits that have not yet been corrected. Sometimes the anxiety is the result of posttraumatic stress disorder. At other times, it may occur in the context of "panic attacks," which are manifested atypically due to language limitations. Akathisia, a dose-related side-effect syndrome caused by both typical and atypical antipsychotics, is manifest as agitation and hyperactivity. It should be considered anytime there is a history of worsening agitation with increased antipsychotic medications. Similarly, large doses of some of the newer anticonvulsants (e.g., gabapentin and lamotrigine) have been associated with agitation. Rarely, the agitation may occur in response to psychotic symptoms such as hallucinations or paranoid delusions.

If the patient appears to be psychotic, it is important to distinguish between true responses to internal stimuli, motor and verbal tics, and self-stimulating behaviors characteristic of autism. Catatonic behavior may reflect delirium, depression, or status epilepticus with absence or partial-complex seizures. Psychosis is probably the most common misdiagnosis in this population. Mood disorders typically present with changes in the patient's sleep, appetite, and activity level. Treatment with antidepressants is indicated and effective. Appropriate treatment for any underlying medical or psychiatric disorder should be undertaken. Remember that developmentally disabled individuals often require smaller doses of psychotropic medications and may be more sensitive to adverse effects.

Gastrointestinal Disorders

Mentally retarded individuals frequently present to the ED with gastrointestinal bleeding and it is the most common reason for hospital admission. In 70 percent of cases studied, erosive esophagitis was the diagnosis. [20] A large number of developmentally disabled individuals also have ulcers, usually duodenal. Such conditions respond well to aggressive treatment with proton pump inhibitors and H_2 blockers. In addition, perhaps as many as 40 percent of mentally retarded individuals have a neurogenic bowel with resulting constipation, overflow diarrhea, and infrequent rectal tears. It is important to carefully evaluate for constipation. Treatment must include both acute and long-term measures, including establishment of a regular stool pattern and provision of adequate fluid and fiber intake. It is also important to determine whether the patient has pica and may have developed bezoars. About 10 percent of individuals with pica will develop intestinal obstruction. [21] While surgery is often necessary for obstruction, it is also important to develop a treatment program to deal with the patient's pica. Behavioral measures are the cornerstone of such work, but pharmacologic interventions with SSRI may also be useful. It is also essential to determine whether a nutritional deficiency is related to pica. About 10 percent of mentally retarded individuals have parasitic infections. *Enterobius vermicularis* and *Strongyloides stercoralis* are common. Finally, there is a high prevalence of hepatitis within the mentally retarded population, particularly those individuals in group care.

Orthopedic Problems

As many as 50 percent of severely retarded individuals suffer from orthopedic problems. The problems are often multiple, with congenital abnormalities, limited mobility, obesity, and age-associated changes all contributing. Often these problems are painful and result in increased agitation. Treatment is generally symptomatic. However, efforts to increase mobility and reduce weight are also important.

Malignancies

Overall, the rates of malignancy in the developmentally disabled population do not differ from the general population. [22] However, malignancies are often much more advanced when diagnosed. Difficulties in communicating early, less-specific symptoms, markedly decreased self-monitoring (e.g., monthly breast self-examination), and a relative absence of preventative care, all contribute to this problem. Some mental retardation syndromes have an increased risk of malignancy. Adults with Down syndrome have a 10-fold increased risk for leukemia. Individuals with tuberous sclerosis are prone to brain tumors, particularly subependymal giant cell astrocytomas (SEGAs), rhabdomyomas of the heart, and angiomyolipomas of the kidney. Giant cell astrocytomas often present with an increase in seizure frequency.

303 THE HOMELESS PATIENT

Rama B. Rao
Lewis R. Goldfrank

Homelessness is a social problem of epidemic proportions worldwide.[1] In the United States alone, estimates of the homeless population range between 3 to 13.5 million. As much as 7.4 percent of the general population will experience homelessness in their lifetime.[2] Homelessness affects a diverse population of all ethnic groups and includes both urban and rural families, the elderly, children, veterans, migrant farm workers, mentally ill persons, and persons with substance abuse disorders. Minority groups are overrepresented in this population, most likely due to disparities in economic opportunities. Causes of homelessness are related to divorce or separation, domestic violence, pregnancy, adolescent runaways, substance abuse, eviction, acute or chronic unemployment, and the deinstitutionalization of persons with mental illness. A disparity between the need for low-income housing and its availability has also contributed to the epidemic of homelessness.

Homelessness has been defined in a variety of ways, including living on the "street," in shelters that provide temporary residence, or in single-room occupancy hotels with shared bathrooms. The consequences of homelessness are profound. A study of homeless adults in Philadelphia found that their age-adjusted mortality rate was nearly four times higher than that of the general population.[3] The median age of death of homeless adults in Atlanta was 44.[4] Infant mortality rates are more than twice those for nonpoor, domiciled mothers and 50 percent higher than those for poor domiciled mothers. The effects of homelessness on children may be profound and are discussed below. Other risks important to homeless populations include communicable diseases, environmental exposures to extreme heat or cold, and traumatic injury due to violent encounters, foraging for food, and seeking shelter.[5] These factors contribute greatly to acute medical illness in the homeless. Some of the increased risks are associated with poverty, and others are specific to undomiciled patients. Chronic illnesses, such as hypertension and diabetes, are neglected or poorly managed due to desperate living circumstances. Homeless individuals often delay care of minor medical problems until they become severe or unbearable.

The emergency department is often used as a primary source of medical care for acute and nonacute illnesses of the homeless.[6,7] Outpatient community- and shelter-based clinics provide medical care in a limited fashion and can lead to ED referral for more extensive evaluation and management. In some cities, homeless patients may arrive by police or emergency medical services because of extreme weather emergencies or other health and safety mandates. All of these factors make knowledge of this population important to emergency physicians. The management of the homeless patient is complex, and similarities to the domiciled layperson are limited. Medical evaluation and care, homeless health issues, and special conditions and populations are reviewed in this chapter.

CARE AND EVALUATION

Homeless patients may have both specific and nonspecific medical complaints.[8] Once the primary reason for the visit is addressed, a thorough examination of the entire body, including the skin and particularly the feet, should be considered. This is especially necessary for the homeless patient who presents disheveled, intoxicated, or with a significant psychosis. A valuable medical history may include the last evaluation for tuberculosis exposure, tetanus immunization status, vaccination status in children, psychiatric history, history of chemical dependence, and potential for substance withdrawal while receiving care in the emergency department. A social history may include family support, precipitants of homelessness, and prior contact with a social worker.

SPECIAL MEDICAL CONSIDERATIONS

Lower Extremity Diseases

Homeless patients have a variety of lower extremity disorders.[9] Such patients may spend a disproportionate amount of time with their legs in a dependent position while sleeping upright or ambulating for extended periods. The poverty associated with homelessness may prevent some patients from obtaining adequate or appropriately fitting socks and shoes that are seasonally appropriate. Ulcers and wounds from lack of foot protection, blisters from poorly fitting shoes, or bites from rats or insects may occur.

Some homeless patients may not have an available change of footwear or a place to change and bathe. Socks and shoes may not be removed for days to weeks for reasons such as warmth, fear that footwear may be stolen, embarrassment, or coexisting mental illness. These factors, along with limitations in hygiene, predispose to fungal infections, which can be treated with topical or oral therapy. Also of concern in this population is the condition known as trench foot.[10] Protracted exposure to moisture around the foot (usually from wet or sweaty socks) leads to absorption of water into the stratum corneum. Over 1 to 2 days, such exposure causes inflammatory changes that result in foot pain and skin breakdown. Bacterial superinfection with *Corynebacterium* species and *Pseudomonas* species can ensue. In the absence of superinfection, analgesia, leg elevation, and drying are adequate to treat trench foot. In colder climates, frostbite from formation of ice crystals in the tissues is a serious threat to limbs, ears, and nose. Careful in-hospital management is warranted, since the environmental risks persist as long as the patient remains homeless, and compliance with treatment may be difficult if not impossible.

Patients predisposed to peripheral vascular disease can have exacerbation of their illness due to inadequate nutrition, poor protein stores, alcoholism and substance use, use of tobacco, and inability to elevate the legs while sleeping upright. The resulting edema can lead to chronic venous stasis ulcers. The ulcers can become infected with common skin flora or even maggots (fly larvae). For uninfected ulcers, the use of venous support garments, such as Una boots, is a valuable management tool. Una boots are impregnated with antibiotic ointment and require less frequent changes. Infected ulcers require admission. The erythema associated with cellulitis may be difficult to distinguish from deep venous thrombosis or venous stasis changes. When the diagnosis is unclear, an evaluation of venous flow should be undertaken. For lesions infected with maggots, chloroform is a traditional therapy for deinfestation. Chloroform may not be available due to safety issues of combustibility. Ethyl chloride is an alternative. Ironically, maggots survive by ingesting necrotic tissue, keeping ulcers clean and well débrided. Once deinfestation is completed, close follow-up is mandatory, since natural débridement via fly larvae is terminated. Maggot infestation is a grave sign of serious neglect and suggests the inability to manage a clinical plan outside a supervised setting.

All homeless patients need education to minimize the risk of trench foot and fungal infections. Patients should be told to change or remove all footwear when environmental conditions allow, examine the feet, and attempt to find rest with the legs elevated. Intravenous drug abusers should be warned about the risk of skin infection from drug administration into the extremities. Community resources, which can provide clean, dry socks and well-fitting shoes, should be identified. Such preventive measures are especially important for diabetic patients and those who suffer from peripheral neuropathy.

Infections

Homeless patients develop common community-acquired respiratory infections, but tuberculosis is also a threat. The incidence of tuberculosis increases dramatically when people live under crowded conditions and when patients are immunosupressed from diseases such as AIDS, malnutrition, or alcoholism.[11] Multiple studies of various homeless populations confirm the high incidence and prevalence of tuberculosis in homeless patients. For homeless patients, compliance with a treatment regimen for an exposure to tuberculosis may be limited. Daily, directly observed therapy programs have been very successful by using incentives to organize therapy and decrease the risk of respiratory tuberculosis.

Homeless patients in shelters or other group living arrangement are also at higher risk than are domiciled patients for communicable skin diseases, such as pediculosis (lice), scabies, and impetigo. Dein festation of lice and scabies is problematic for patients, since bathing facilities and the ability to wash and change clothing are limited. Patients may return to the environment where infestation originally occurred, and they are at high risk for reinfestation. A dermatologic disease known as bacillary angiomatosis-peliosis has been identified in homeless patients exposed to lice. [12] The causative organism is *Bartonella quintana,* and the condition can be treated effectively with macrolide antibiotics.

The living conditions of the impoverished can place them at risk for other infections. Diarrheal illness from the ingestion of improperly preserved or discarded food has been poorly studied but has been described by homeless patients and is particularly problematic when access to toilet facilities is limited. Fecal-oral transmission of illness is also increased.

Sexually transmitted diseases are prevalent in homeless individuals who engage in sexual activity voluntarily or by coercion to obtain food, shelter, cash, or other goods. Money for prophylactic condoms or other forms of contraception is limited, unavailable, or a low priority for survival. These problems, in addition to injected drug use, have lead to epidemic rates of HIV among the homeless. Discrimination and disability from HIV disease are also implicated as a cause of homelessness.

The management of HIV disease is complicated for both patients and medical practitioners even under ideal circumstances. Newer drug regimens, which include multiple medications, are expensive and depend on a reliable dosing schedule and follow-up. CD4+ counts and exposure to tuberculosis should be checked, and prophylaxis for *Pneumocystis carini* pneumonia and tuberculosis should be offered accordingly. The use of reverse transcriptase and protease inhibitors may depend on the ability of patients to comply with therapy. [13]

Compliance

Prioritization of other life-sustaining activities, such as finding food or shelter, may interfere with compliance with medical regimens or follow-up despite the intention to do so. [14] Money may be unavailable for prescriptions. Even hospital-dispensed medications may be traded for cash or other items perceived as more essential, depending on the patient's level of despair and how well the patient understands the consequences of forgoing treatment. Some items necessary for treatment, such as insulin syringes or other medications, are valuable for illicit use and are at risk of theft. Agents such as insulin may lose their efficacy and safety when stored improperly. It may be impossible to refrigerate medications. A regular dosing medication schedule is complicated by a lifestyle devoid of daily routines.

Lack of medical insurance may cause patients to be turned away from medical care or follow-up. Negotiating eligibility for various types of state and federal medical coverage is usually complicated but may be of tremendous benefit to patients with chronic illnesses, for which poverty potentially thwarts adequate management. Patients should be referred to social workers familiar with eligibility requirements and processing. Unfortunately, even eligible patients may require several visits to social-services agencies to establish medical coverage, and this process alone may be too complex to complete.

Other barriers to care include lack of transportation or mental illness. The precarious existence of such patients must be considered with compassion, and they should be treated with a medical regimen that accommodates the limitations of their situation. For example, patients dependent on soup kitchens should have follow-up that does not compete with mealtimes. Shelter-based clinic systems may be more realistic than tightly scheduled appointments.

SPECIAL POPULATIONS

Women and Children

Women and children comprise a rapidly increasing proportion of the homeless population. Women may present for routine medical problems or as a result of domestic violence or rape, for which they are at particularly high risk. [15] Some women may resort to prostitution to support themselves or their children. Preventive gynecologic care is often inadequate and extends from inadequate screening for cervical cancer and venereal diseases to insufficient or absent prenatal care. The consequences are devastating. Children born to homeless mothers often have lower birth weights, higher rates of prematurity, and higher rates of infant mortality. Iron-deficiency anemia, malnutrition, elevated blood lead concentrations, and a higher rate of asthma are found in homeless children, as in other impoverished children. [16] Unlike impoverished domiciled children, homeless children are more likely to be inadequately immunized and suffer disproportionately from developmental delay or a lack of progression in school. The long-term psychological, social, and educational consequences of homelessness have yet to be evaluated.

Homeless adolescents, especially runaways, have high rates of alcoholism, illicit substance use, violent encounters, and psychiatric illness. Engaging in sex for survival has resulted in high rates of unplanned pregnancy, sexually transmitted disease, and HIV infection. Patients should be offered a variety of resources, including education regarding safe-sex practices, counseling, and the location and availability of drop-in centers. Social workers, psychiatrists, and adolescent specialists can cooperatively provide support for homeless runaways regardless of their chief medical complaint.

The Elderly

There are few studies of the homeless elderly. [17] Limited, fixed incomes with progressively increasing housing costs account for the displacement of many elderly people from their homes. Another factor may be gradual changes in cognitive and psychosocial performance, which may not be realized on a brief medical examination. For all people at risk, reassessment for organicity, dementia, and depression is essential to ensure an appropriate care plan.

Substance Use

Patients who are dependent on alcohol or illicit substances should be identified in order to facilitate appropriate disposition. For homeless patients who present intoxicated and sedated, close monitoring of body temperature, blood glucose monitoring, and serial evaluations for arousability should be performed in addition to a thorough physical examination. Whenever possible, a specific history of substance use should be obtained. A specific history of withdrawal from any sedative-hypnotic agent or ethanol should alert the clinician to the need for careful observation while primary evaluation of the chief complaint is undertaken. The patient should be asked whether he or she has a past history of participating in detoxification programs and whether that is a current desire. Accordingly, psychiatric evaluation can be undertaken.

Psychiatric Evaluation

Some homeless patients without documented history of chronic psychiatric illness or substance dependence may present to the ED with psychiatric complaints. The stresses of sustaining life without a home are associated with a variety of diagnoses, including adjustment disorders, substance use, and major depression. [18] Alternatively, some homeless patients have a chronic history of psychiatric illness, including schizophrenia or bipolar disorder, that may be partially responsible for precipitating homelessness. [19] The psychiatric assessment of homeless patients is important to providing adequate disposition of medical problems whose management may be compromised by mental illness. In addition, primary pharmacologic therapy can be evaluated or instituted in patients with chronic psychiatric disorders.

EMERGENCY DEPARTMENT TREATMENT

ED management includes the history and physical examination, as reviewed. Adjuncts to care include use of vitamin supplements and food, dispensation of medications, updating of immunizations, and reviewing documentation of past medical care. Pregnancy status and potential for sexually transmitted diseases should be investigated in homeless women of childbearing age. Appropriate gynecologic care, prenatal care, or family planning services can thus be arranged. Once a diagnosis and treatment plan are defined, patients should be assessed for language barriers, literacy, and capacity to comply with routine care instructions, medical regimens, or follow-up. An old chart may indicate immunization status, forgotten or disregarded health problems, and the ability of homeless patients to follow up. A lower threshold for admission should be maintained for patients with an impaired ability to manage their own care. This decision is easily acceptable if one appreciates how the patient arrived at the condition in question and how difficult, if not impossible, outpatient care may be in certain circumstances. A multidisciplinary approach to care, including social workers and nursing, medical, and psychiatric staff, may offer the most supportive environment for homeless patients. Such compassionate care in the ED, using trained and motivated individuals, will ensure that patients receive the care they need, increase patients' satisfaction, and reduce

the rate of return ED visits among frequent users.[20]

304 THE MORBIDLY OBESE PATIENT

Robert J. Vissers
Kathleen A. Raftery

Obesity is the condition of an excessive proportion of adipose tissue to total body weight. It is a common problem in the industrialized world, with approximately one-third of all adults in the United States estimated to be overweight.[1] Since body fat is difficult to measure in the clinical setting, body mass index (BMI) is frequently utilized. BMI is calculated by dividing the weight in kilograms by the square of the height in meters. A BMI greater than 28 kg/m[2] defines obesity in both sexes, and morbid obesity is associated with a BMI of 40 kg/m^2 or greater.

Morbidly obese patients pose a number of challenges for emergency health care providers. Prehospital care may be delayed due to problems in moving and transporting these patients. Appropriate-sized gurneys may not be readily available. Even providing common amenities, such as hospital gowns or bedpans of adequate size, can be difficult. In addition, the emergency department (ED) staff must anticipate and be prepared for challenges in performing technical procedures. Excess tissue makes access to body fluids and body cavities a formidable task, while performing imaging procedures can be difficult or impossible. Morbidly obese patients may also evince changes in cardiopulmonary physiology and patterns of traumatic injury, which add to the complexity of their care.[2] This chapter discusses these problems and suggests strategies and techniques that will facilitate the diagnosis and management of acute illness and injury in this unique group of patients.

PATHOPHYSIOLOGY

Cardiopulmonary Disease

Morbidity and mortality are considerably greater among the obese than in normal-weight patients, and many of the health risks associated with obesity increase progressively and disproportionately with increasing weight.[3] The most significant physiologic disturbances pertain to the cardiopulmonary system.[4]

Coronary artery disease, hypertension, and congestive heart failure are highly correlated with obesity. Both left- and right-sided heart failures are often observed in patients with obesity-hypoventilation syndrome. Obesity has also been linked to depressed left ventricular function even in young, asymptomatic patients.

Obesity is associated with an increased risk of venous thromboembolism, especially after surgery.[5] This is due to several factors found in the obese patient, including decreased levels of circulating antithrombin III, preexisting venous disease, and increased immobility.[6] The obesity-hypoventilation syndrome, also known as the *pickwickian syndrome,* occurs in 5 percent of the morbidly obese. Disturbances in the ventilation-perfusion relationship are prevalent.[7] Pulmonary hypertension is a common finding, resulting from chronic hypoxemia, hypoxic pulmonary vasoconstriction, and the added contribution of compromised cardiac function.[7]

Recognition of the increased risk of cardiorespiratory compromise in the morbidly obese patient is crucial, even when the patient presents to the ED with a problem unrelated to the cardiovascular system. The morbidly obese patient who states that he or she can only sleep in the upright position should be maintained in an upright position as much as possible or in a lateral position with the head up while performing procedures. Pulse oximetry should be used for monitoring, particularly if the patient needs to be supine. Elevate the head of a patient who is on a backboard by placing towels under the board.

Pregnancy

Obesity will also complicate pregnancy. Body weight before pregnancy and weight gain during pregnancy both influence labor, and obese women are more likely to require cesarean sections and to experience abnormal labor.[8] In addition, these infants tend to be heavier than those born to nonobese women, increasing the potential for difficult labor and delivery. Other complications such as hypertension, diabetes, preeclampsia, and eclampsia occur with increased frequency in pregnant obese women.

Trauma

The obese trauma patient is the product of two modern epidemics: the increasing prevalence of obesity and the increasing incidence of trauma.[2] Differences in the mechanisms of injury and associated injury patterns have been described, and obesity has been identified as an independent premorbid risk factor in trauma.[6]

Excessive weight interferes with activities of daily living, therefore increasing the risk of injury. Moreover, the presence of obesity-related diseases such as diabetes, heart disease, and somnolence secondary to sleep apnea may contribute to accidents. Obese patients have also been noted to be less likely to wear seat belts because of poor fit or discomfort.

Obesity appears to protect the blunt trauma victim from head injury but is associated with a significantly higher incidence of injuries to the chest, primarily rib fractures and pulmonary contusions. It is hypothesized that the larger torso serves as a physiologic airbag, and although this offers some protection from head injury, there is an associated increase in thoracic injury. This may explain the dramatically higher mortality rate due to respiratory causes in morbidly obese trauma patients. A study that specifically examined the impact of obesity on mortality in blunt trauma found a 42.1 percent mortality rate in severely overweight patients, compared with 5.0 and 8.0 percent in the average and overweight groups.[9]

Despite the logistical difficulties the obese patient presents, the principles of trauma management must still be adhered to, with necessary spinal precautions maintained and full exposure obtained. The presence of subcutaneous fat obscures physical findings in thoracic and abdominal injuries.[6] The limitations of physical findings are further compounded by poor quality, portable chest radiographs in this population. A more aggressive approach to airway management with early intubation and assisted ventilation may be indicated.

The incidence of pelvic fractures is higher in the obese trauma victim. Portable films are often of a poorer quality in the obese patient, therefore any clinical suspicion of a pelvic fracture should be pursued by repeat views or computed tomography, despite a negative portable pelvic radiograph. A higher incidence of displaced ankle and elbow fractures has been described in obese patients sustaining minimal trauma (stumbling, low-energy falls).[10]

A higher frequency of postoperative morbidity and mortality has been recognized in obese patients undergoing elective surgery and is often attributed to their predisposition for pulmonary compromise and significant hypoxemia noted prior to, during, and after surgery. It is unclear if this is the primary cause of increased

posttraumatic mortality in the obese patient or whether it is related to delayed diagnosis or intervention.

PROCEDURES

Procedures are more difficult to perform on the obese emergency patient (Table 304-1). Landmarks are obscured or nonpalpable, access is often impaired by excessive tissue, and positioning problems are common. Airway management may be difficult, intravenous access delayed, and investigations cumbersome or impossible to obtain in the obese patient. These factors all contribute to inevitable obstructions to rapid assessment and resuscitation. Having alternative approaches readily available is the ideal strategy. The appropriate equipment, such as the right blood pressure cuff, must be easy to access. Extra personnel are often required, and a minimum of six people is usually necessary to transfer the patient, particularly when cervical spine precautions must be maintained.

Procedure	Problem	Solution
Bag-mask ventilation	Reduced pulmonary compliance	Occlude pop-off valve
Oral intubation	Access to airway	Adjustable angle laryngoscope
	Potentially difficult airway	Objective predictors of difficulty
		Esophageal tracheal Combitube
		Surgical airway
Sphygmomanometry	Falsely elevated readings	Use larger cuff size
Pulse oximetry	Poor signal	Earlobe probe
Vascular access	Inability to locate vein/artery	Use 3- to 4-in. catheter
		Patient positioning
		Ultrasound-facilitated cannulation
Lumbar puncture	Difficulty in palpating landmarks	Upright patient positioning
	Difficult to obtain cerebrospinal fluid	Increase needle length to 5 in.
Diagnostic peritoneal lavage	Accessing peritoneal cavity	Modified Seldinger technique

TABLE 304-1   Procedural Problems and Solutions in the Morbidly Obese

Airway Management

Obesity has not been shown to be an independent predictor of a difficult intubation. [11] Although a short thick neck seems to be more common in obese individuals, other objective predictors of a difficult intubation must be recognized and assessed. Use of the Mallampati scale, [12] a test based upon the pharyngeal structure visible when the patient's mouth is wide open, can be helpful. Another method is to measure the distance between the mentum of the chin and the hyoid bone or thyroid prominence. Less than three finger-breadths or less than 6 cm, respectively, when the head is extended, suggests a potentially difficult intubation. Atlantooccipital extension, maxillary overgrowth, temporomandibular joint mobility, nostril patency, and micrognathia are other anatomic features known to influence ease of intubation.

As with nonobese patients, the procedure of choice in the ED setting for the morbidly obese is tracheal intubation using rapid sequence induction (RSI) unless contraindications are present. Patients should be kept sitting upright or semirecumbent as long as possible prior to intubation.

Preoxygenation is critical, since morbidly obese patients will desaturate more quickly than normal adults. [13] If bag-mask ventilation is required, the obese patient often has reduced pulmonary compliance, which necessitates higher ventilatory pressures. The pop-off valve on the ventilation bag may have to be occluded in order to provide adequate ventilation.

Once the process of intubation is begun, access to the airway is enhanced by elevating both the head and shoulders with towels or by placing a rolled blanket between the scapulae and under the occiput. Elevation of the shoulders allows displacement of the breasts away from the midline. The greater elevation of the head places it in the sniffing position, and creates more space, as the chest wall of the morbidly obese patient may actually obstruct the handle of the laryngoscope. A shorter than average handle for the laryngoscope or an adjustable-angle laryngoscope is useful in this situation.

There are several other methods of securing a patent airway, including nasotracheal intubation, oral intubation, transtracheal jet ventilation (TTJV), the laryngeal mask airway (LMA), or the esophageal tracheal Combitube (ETC). Nasotracheal intubation is technically more difficult than orotracheal intubation but may be relatively advantageous if used by an experienced physician to intubate a spontaneously breathing patient with a short thick neck. Oral intubation should be used in the apneic trauma patient. TTJV requires higher ventilatory pressures and therefore may be less useful in the obese patient with decreased pulmonary compliance. The LMA may not provide adequate ventilation and may not protect against aspiration. Thus, it is not a first choice owing to the obese patient's tendency for rapid desaturation and aspiration. The ETC appears to be a reasonable alternative, providing ventilation as well as protection against aspiration, and its utility in the morbidly obese patient has been documented.[14] A fiberoptic bronchoscope can also be used to aid intubation, although visualization may be impaired by circumpharyngeal fat.

Finally, a cricothyrotomy may be indicated if other maneuvers fail. Needle cricothyrotomy is difficult given the anatomy of a morbidly obese patient's neck.

Electrocardiogram Analysis

Host factors such as body mass influence the ease of obtaining and interpreting an electrocardiogram (ECG). Landmarks for lead placement may be difficult to determine, and optimal lead placement and patient positioning may not be possible. Breast size and fat deposits in the chest wall can result in inaccurate lead placement. Variation in fat deposits in the chest wall and fat deposits surrounding the heart can lead to inconsistent voltage changes, although in general obese patients demonstrate loss of voltage.[15] Flattening or inversion of the T wave in the inferior or lateral leads is one consistent change. None of these ECG changes is pathognomonic for obesity, and such abnormalities should not be attributed to obesity alone.

Sphygmomanometry

Inadequate cuff width and circumference will artificially elevate pressure readings. [16] However, many morbidly obese patients are hypertensive, and a high pressure reading cannot always be blamed on inappropriate equipment. In order to minimize errors in blood pressure recording, a correct ratio of cuff width to arm circumference, approximately 2:5, should be chosen. The bladder length should be 80 percent of the arm circumference. The ED should stock a variety of sizes of blood pressure cuffs specifically for use in the obese population.

Pulse Oximetry

Tissue thickness can make the transmission of light waves more difficult in the extremely obese and thus make pulse oximetry readings unreliable. However, pulse oximetry in the moderately obese is generally accurate. In morbidly obese patients, the earlobe should be used instead of the finger for probe placement, as the earlobe is usually thinner than the digit, with higher perfusion, and the probe stays in place more easily. If use of an earlobe probe is not possible, use of the fifth digit of the hand or foot can be tried. Other areas of placement include the nose, lip, or temporal artery. [17]

Venous Access

Morbidly obese patients are notoriously difficult candidates for intravenous catheterization, venipuncture, or arterial puncture. Anatomy is distorted by subcutaneous fat, and landmark vessels are often not visible or palpable. This leads to multiple attempts, delay in access, and an increased incidence of central line placement with delays in changing a line after admission. All these factors contribute to a higher rate of complications, such as wound infection, pneumothorax, phlebitis, and thrombosis. In addition, standard 1.5-in. needles or catheters may not be long enough to penetrate the subcutaneous tissue and reach the target vessel; 3- or 4-in. needles and catheters are preferred. Locating the radial or femoral artery in order to obtain a sample for arterial blood gas analysis can also be extremely difficult. It may be necessary to change needle lengths on the prepackaged arterial blood gas syringes.

Various techniques can be employed to improve access to the vessel. Application of heat, light tapping over the vessel, active or passive pumping of the extremity, and application of topical nitroglycerin are commonly used to encourage vasodilation. Reactive hyperemia can be created by occluding the circulation for 3 to 4 min, then releasing the sphygmomanometer to 10 to 15 mmHg below the diastolic pressure.

The medial cubital and basilic veins are the first choice in the morbidly obese, since they are large, the antecubital crease is visible, and the skin and subcutaneous tissues are thinner in this area. Branches of the median and basilic veins on the volar surface of the forearm may be too deep to the adipose tissue to be easily accessed. The cephalic vein on the radial aspect of the wrist is a good second choice if it is not also obscured by fat. Another option is the vessels of the dorsum of the hand. The veins of the fingers may be accessible, especially those over the dorsal aspect of the thumb and forefinger. The veins of the feet are usually not good candidates, since they tend to be obscured by fat or the ravages of peripheral vascular disease. However, no vein should be excluded if it is accessible.

If peripheral veins are not available, a cutdown at the forearm veins or an attempt at cannulation of the external jugular vein should be the next choice. Cannulation of the femoral vein is another option, and will be facilitated by placing a towel under the ipsilateral buttock and having an assistant retract the panniculus. Venisection at the saphenous vein, a common alternative in patients of normal weight, will be challenging because of excess adipose tissue. Femoral catheterization is preferred over saphenous venisection in the obese patient with a palpable femoral pulse.

Because of the difficulty of peripheral access in the obese patient, a central line is more frequently required. Unfortunately, central line placement is also challenging.[18] Subclavian vein cannulation may be preferable to the internal jugular, since the bony landmarks are more easily palpable and the complication rate is lower than with other central venous access methods. The patient is usually placed in the Trendelenburg position. Change positions gradually while continuing to monitor the ECG and oxygen saturation. In some cases, as when the patient reports the need to sleep upright, the Trendelenburg position may be relatively contraindicated.[19] During subclavian line placement, abduction of the arm (as opposed to the standard recommendation of arm adduction) and retraction of chest tissue away from the clavicle may reduce excessive tissue layers at the site. It is common practice to insert a roll under the shoulders or a pillow lengthwise along the spine to improve access.

Ultrasound can facilitate venous cannulation and arterial puncture, allowing a higher success rate with fewer attempts because it is performed independent of landmarks.[20]

Lumbar Puncture

A lumbar puncture is difficult because landmarks tend to be obscured and depth is difficult to estimate. The procedure is most successfully performed with the patient sitting and bent forward. With the patient upright, the midline is easier to estimate and both iliac crests are usually palpable. Bone encountered after only a few centimeters usually represents spinous process and suggests an adjustment in the vertical plane above or below this point. A deeper bony encounter is likely lamina and requires a medial adjustment. Ultrasonography can be used as an aid to locating the vertebra.[21] Despite the excessive tissue, the standard 3-in. needle is adequate for many obese patients, although this may require pushing the needle hub to the point of dimpling the skin. The 5-in. needle is sometimes needed. It is best to have both sizes readily available. Tight intervertebral disk spaces are common in this population and may not allow passage of a 16- or 18-gauge needle. It may be necessary to use a much smaller gauge (albeit more flexible) needle as a guide for locating the disk, then a larger-gauge needle to puncture the space. The best choice is a 22- or 24-gauge needle, which allows adequate flow and decreases the likelihood of postpuncture headache.

Diagnostic Peritoneal Lavage

Diagnostic peritoneal lavage (DPL) is used for the early recognition of intraabdominal injury requiring celiotomy. In many centers, the use of DPL has been supplanted by imaging techniques because of increased accessibility to improved computed tomography (CT) and ultrasonography. However, size and weight restrictions and transport difficulties may preclude the use of CT scanning in the obese trauma victim. Abdominal ultrasonography is also less reliable in the morbidly obese patient. Therefore DPL may be the preferable diagnostic approach in these patients.

There are three general DPL techniques: the open, semiopen, and closed. In the open technique, a catheter is passed into the abdominal cavity through a large incision that exposes the peritoneum. This technique requires two people and in a normal-weight person may take more than 25 min.[22] Because of the larger incision required, the technical difficulties presented by the panniculus, and a potentially higher rate of wound infection and herniation, morbid obesity has been described as a relative contraindication to this procedure.

The traditional closed technique uses a larger trochar and is associated with an unacceptable rate of complications. A blind Seldinger technique using a smaller 18-gauge needle has been shown to be as efficient as the open technique. We recommend this as the method of choice in the obese patient. In patients whose abdominal wall thickness exceeds the reach of the needle, a modified Seldinger technique has been described in which 2- to 4-cm incision is carried down to the midline fascia and an 18-gauge needle is then inserted at that point. This procedure was used successfully in six morbidly obese patients whose weight exceeded the weight limit of the CT scanner.[22]

Imaging

Radiographs have limited utility in the morbidly obese. Standard film cassettes are too small to accommodate the entire chest or abdomen, and two or more films may be required. Excessive soft tissue can result in extremely underpenetrated films. Since transport is invariably problematic, morbidly obese patients may need to undergo portable radiography, resulting in lower-quality images.

CT and magnetic resonance imaging (MRI) scans are clearly superior to radiographs, offering better resolution and greater penetration. However, many CT scanners have a weight limit of 400 to 450 lb and a girth limit of 30 in. Most standard MRI scanners have a maximum shoulder-to-shoulder width of 52 in. and a weight limit of 350 lb. Thus many morbidly obese patients will be excluded from undergoing these studies. There are, however, private companies, veterinary schools, and zoos that have scanners with a larger capacity.

EQUIPMENT PROBLEMS SPECIFIC TO ED CARE

From the time the obese patient enters the waiting area to the time he or she leaves the ED, issues related to the patient's size challenge both personnel and equipment. Waiting-room chairs may be too small. Most wheelchairs also have weight limits and are not designed to safely accommodate patients weighing over 200 kg. Gurneys are often too small for the patient if the protective side rails are in place, and without the side rails the patient is not safe. In addition, collapsible gurneys are not designed to hold the weight of the morbidly obese patient, leading to instability and concomitant patient and staff danger. We recommend that EDs stock one heavy-duty stretcher (one with additional cross-brace supports) and at least one wheelchair designed to hold patients weighing more than 200 kg.

The comfort and modesty of morbidly obese patients should be thoughtfully considered during his or her ED stay.[23] The ED should stock oversized hospital gowns. Patients should also be allowed to wear their own night clothing as long as it does not obstruct care.

Any care that requires lifting or turning of the obese patient is difficult, as techniques used for average-sized patients cannot be used. In general, more than two providers should always be utilized to move the patient. Provision of an overhead trapeze will greatly facilitate patient-assisted transfers and should be available in the ED.

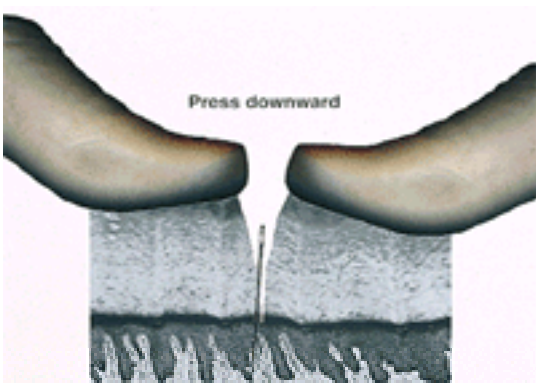
Color Plates
PLATE 1 ([FIG. 42-1A](#)). This patient's leg was punctured by a wooden stake 2 days prior to presentation. Surrounding cellulitis and
PLATE 2 ([FIG. 42-1B](#)) point tenderness lateral to the wound increased the probability of a retained foreign body.
PLATE 3 ([FIG. 42-1C](#)). The entrance to the wound was extended, and 1.5-cm piece of wood was removed from a 3.5-cm-deep wound.
PLATE 4 ([FIG. 42-2A](#)). An incision is made perpendicular to the needle at its midpoint. The needle is grasped through the incision with a hemostat and backed out of the puncture wound. The entrance site is enlarged with a skin incision. If the incision passes to the side of the object, the skin is undermined.


PLATE 5 ([FIG. 42-3C](#)). Pressure on the skin edges displaces the foreign body into the center of the wound.
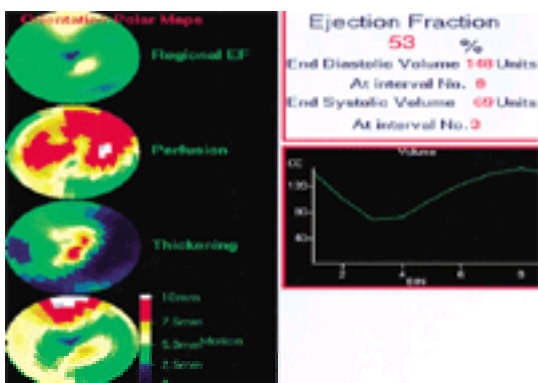
PLATE 6 (FIG. 42-5B). Block excision is effective for foreign bodies that are friable, difficult to find, buried in fatty tissue, or stain surrounding tissue. A small, elliptical incision is made around the original wound. The incision is undercut until contact is made with the foreign body. The block of tissue is grasped with a forceps, the foreign body is clamped with a hemostat, and both are removed.
PLATE 7 (FIG. 57-7). Three-dimensional representation of gated SPECT data at end diastole.


PLATE 8 (FIG. 57-8). Bull's-eye representation of gated SPECT data. Hypoperfusion of the proximal inferolateral wall as well as mild hypokinesis and diminished wall thickening. There is preserved global left ventricular function.
PLATE 9 (FIG. 230-7). Positive Seidel test showing aqueous leaking through a full-thickness corneal wound. Aqueous will turn fluorescein lime-green under a cobalt-blue light as it oozes through the wound while being observed at the slit lamp.
PLATE 10 (FIG. 230-8). Hyphema secondary to blunt trauma. Note the blood filling the lower half of the anterior chamber and hazy appearance of cornea suggesting increased IOP.
PLATE 11 ([FIG. 230-9](#)). Corneal ulcer with hypopyon. The ulcer is seen as a shaggy white corneal infiltrate surrounding the borders of the epithelial defect. The hypopyon represents the accumulation of white cells layering out in the lower one-sixth of the anterior chamber.
**PLATE 12 ([FIG. 230-10](#)).** Herpes simplex corneal dendrite seen with fluorescein staining and cobalt-blue light.

PLATE 13 ([FIG. 230-11](#)). Slit-lamp measuring wheel. The length of the light beam on the cornea can be varied and the reading on the dial represents the length in millimeters. Useful in measuring corneal abrasion dimensions.

PLATE 14 ([FIG. 230-13](#)). Traumatic canalicular laceration repair requires microsurgical stenting to reestablish patency.
PLATE 15 ([FIG. 230-14](#)). Inferior wall blowout fracture of the left eye with entrapment of the inferior rectus muscle. The patient's left eye is unable to look upward, causing diplopia on upgaze.
PLATE 16 (FIG. 230-16). Acute angle-closure glaucoma. Pupil is middilated and nonreactive. The cornea is hazy due to stromal edema.

PLATE 17 (FIG. 230-17). Central retinal artery occlusion. Note macular "cherry-red spot" and retinal pallor between macula and disk. The retinal veins appear normal size, but the arteries are barely visible and attenuated.

PLATE 18 (FIG. 230-18). Central retinal vein occlusion "blood and thunder fundus." Note diffuse retinal hemorrhages in all retina quadrants and blurred disk margins.

PLATE 19 (FIG. 230-20). Horner's syndrome. Note ptosis and miosis of the right eye. This patient sustained an acute right carotid artery dissection after being hit in the neck with a football.
PLATE 20 (FIG. 230-22). Optic nerve head edema. Vascular congestion, elevation of the nerve head, and blurred disk margins are characteristically seen in papilledema, papillitis, and compressive lesions of the optic nerve.

PLATE 21 (FIG. 239-1). Chronic *candida paronychia*. The cuticle is absent. Erythema and edema are prominent at the proximal and lateral nail folds. The dystrophic ridged nail is a sign of chronic disease.

PLATE 22 (FIG. 239-7). Stasis dermatitis. Note the surrounding red-brown pigmentation and the central weepy erythema on the pretibial leg.

PLATE 23 (FIG. 239-8). Erythema nodosum. An erythematous indurated nodule is seen. This patient's disease was initially diagnosed as cellulitis. However, after no response to antibiotics, a biopsy confirmed the diagnosis of erythema nodosum. Most patients with erythema nodosum will have multiple lesions.

PLATE 24 (FIG. 239-9). Norwegian scabies. The thick scale, erythema, and exudate resemble a foot dermatitis. This disorder should not be forgotten when presented with a patient with extremely pruritic scaly eruption. Norwegian scabies is more common in immunocompromised and debilitated patients.

PLATE 25 (FIG. 240-2). Candida intertrigo. Note the bright-red erythema, erosions, and satellite papules and pustules in this striking example of inframammary candida intertrigo. A KOH examination will confirm the diagnosis.

PLATE 26 (FIG. 241-1A). Erythema multiforme: Symmetrical, plaque-like lesions involving the flexor surface of the upper extremities—lesions which may be misdiagnosed as the IgG-mediated urticarial allergic reaction. Also note the erythematous macules on the palms. (Reprinted with permission from Brady W, DeBehnke D, Crosby D: Dermatologic emergencies. *Am J Emerg Med* 12:217, 1994.)

PLATE 27 (FIG. 241-1B). Iris or target lesion, a finding strongly suggestive of EM. This iris lesion is composed of a central bullous lesion with dusky, edematous center and erythematous halo. (Reprinted with permission from Brady W, DeBehnke D, Crosby D: Dermatologic emergencies. *Am J Emerg Med* 12:217, 1994.)

PLATE 28 (FIG. 241-2). Exfoliative dermatitis—generalized, warm erythema accompanied by scaling or flaking.

PLATE 29 (FIG. 241-3). Blanching, nonpruritic erythroderma with a "rough" texture in a patient with toxic shock syndrome. (Reprinted with permission from Brady W, DeBehnke D, Crosby D: Dermatologic emergencies. *Am J Emerg Med* 12:217, 1994.)

PLATE 30 (FIG. 241-4). Large bullous lesions on the lower extremity in a patient with streptococcal toxic shock.

PLATE 31 (FIG. 241-5). A single dermatomal involvement in a patient with herpes zoster infection in a thoracic distribution.

PLATE 32 (FIG. 241-6). Herpes zoster ophthalmic infection: Facial zoster involving the ophthalmic branch of the fifth cranial nerve with nasal lesions strongly suggestive of corneal infection.

PLATE 33 (FIG. 241-7). Disseminated HSV infection in an immunocompromised adult patient; note the widespread distribution of vesicular lesions on an erythematous base.

PLATE 34 (FIG. 241-8). Disseminated gonococcal infection in a sexually active adult female; note maculopapule with a petechial component and an erythematous periphery located on the extensor surface of the wrist.

PLATE 35 (FIG. 241-9). A patient with Rocky Mountain spotted fever revealing petechiae on the ankles.
PLATE 36 (FIG. 241-10). Early findings of meningococcemia with petechiae evolving into purpuric lesions. (Reprinted with permission from Brady W, DeBehnke D, Crosby D: Dermatologic emergencies. *Am J Emerg Med* 12:217, 1994.)

PLATE 37 (FIG. 241-11). Purpura fulminans with hemorrhagic bullae. (Reprinted with permission from Tangoren IA et al: Ecchymoses and epidermal necrosis in a 75-year-old man with bacteremia. *J Crit Illness* 13:108, 1998.)

PLATE 38 (FIG. 241-12). Scattered bullous lesions intermixed with erosions and painful inflammatory plaques.
