ANESTHESIOLOGY

NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

ANESTHESIOLOGY

Edited By:

David E. Longnecker, MD, FRCA
Robert D. Dripps Professor Emeritus
Department of Anesthesiology and Critical Care
University of Pennsylvania
Philadelphia, Pennsylvania

David L. Brown, MD

Dedication

"Life is no brief candle to me; it is a sort of splendid torch which I've got a hold of for the moment and I want to make it burn as brightly as possible before handing it on to future generations."

George Bernard Shaw
Irish playwright (1856–1950)

The editors were fortunate indeed to have outstanding mentors who dedicated their professional lives to the development of our generation in the specialty. Through their guidance, wisdom and actions, they truly handed the torch to us. As their progeny, we are ever grateful for both their professional guidance and their personal friendship. In recognition of their influence on us individually, and the specialty overall, we dedicate this book to:

Robert M. Epstein,
Harold Carron Professor and Chair
Emeritus of Anesthesiology,
University of Virginia,
on behalf of David E. Longnecker

Richard J. Kitz, Henry Isaiah Dorr Distinguished Professor
of Research and Teaching in Anaesthetics and Anaesthesia,
Harvard Medical School and Massachusetts General Hospital,
on behalf of Warren M. Zapol

Edward Lowenstein, Henry Isaiah Dorr Professor of Research
and Teaching in Anaesthetics and Anaesthesia,
Harvard Medical School and Massachusetts General Hospital,
on behalf of Warren M. Zapol

Daniel C. Moore, Chair Emeritus of Anesthesiology,
Virginia Mason Medical Center, Seattle, Washington,
on behalf of David L. Brown

Jerry Reves, Vice-President for Medical Affairs and Dean,
College of Medicine, Medical University of South Carolina,
Professor of Anesthesiology and Pharmacology
(former Chair, Duke University Department of Anesthesiology),
on behalf of Mark F. Newman

Foreword

Fifteen years ago, Dr. Mark C. Rogers, then Chair of Anesthesiology at Johns Hopkins, "conned" the late Benjamin Covino, MD, then Chair at the Brigham and Women's Hospital and Professor at Harvard, and me, then Chair at Iowa, into joining him at a small hotel near Washington, D.C., where he spent the better part of a day "selling" us on his idea to create a more "user friendly" general text of anesthesiology. (The term "user friendly" was quite new and in vogue in those days.) His vision was to approach the subject in a way that would benefit the brand new trainee, while at the same time creating a definitive reference work for the "veteran" anesthesiologist. Up to then, major texts had started with dry history, then jumped into complex theories of anesthesia, then physiology and pharmacology. Rogers' idea was to start with the preoperative evaluation of the patient and delineate anesthesiology in the manner that trainees actually approach patients.

As Dr. Covino and I neared our saturation point with Rogers' "hard sell," the two of us adjourned outside to talk it over. We agreed that Rogers had an exciting concept. That was never the issue. We simply wanted to try to figure out whether or not we had it in us to do that much work, at that stage in our careers! We decided to tackle the task.

Ben Covino's tragic death, before the first edition was completed, was devastating to us. Without the addition of David Longnecker, MD, Chair of Anesthesiology at the University of Pennsylvania, the submitted manuscripts would probably still be causing my office shelves to sag. Longnecker brought an organizational ability, and a "toughness" that spurred us on to finish the job.

A subsequent edition, which came out in 1998, was much improved; cleaner, leaner, and simply all-around better, but it followed the same philosophy. With that effort, I determined to "hang up my spikes" and not participate in another major editing effort, for the work is daunting.

Fortunately for the specialty of anesthesiology, Longnecker was persuaded by an outstanding medical publisher, McGraw-Hill, to carry this concept forward into an entirely new work which you have here. This new text builds on the tradition of former efforts but is expanded considerably to include the increased breadth of the specialty in areas such as regional anesthesia, pain medicine and critical care medicine, yet all with the same philosophy of approaching the specialty as a medical discipline that encompasses the full range of patient care, not simply the technical aspects of anesthesia practice. With his legendary "arm twisting" ability, Longnecker even managed to persuade me to tackle writing a preface.

This is much more than a new cover on an old work. Dr. Longnecker and his colleagues have recognized that anesthesiology has moved dramatically forward. They have made a major effort to capture new concepts and have succeeded in encompassing the full spectrum of state-of-the-art anesthesiology. Section 1 sets the stage by discussing where we came from, where we are, and where we might go. The emphasis is on quality care and safety principles. Just as "user-friendly" was in vogue fifteen years ago, now a key principle is "evidence-based medicine." The chapter authors and editors have worked diligently to apply this modern principle wherever possible throughout the work.

There is a new emphasis on the "operations" aspects of anesthesia care, which has been termed "OR management," but which really emphasizes that we do need to learn how to run our OR suites more efficiently for the benefit of the patients and their surgeons. Notably, the emphasis on preoperative evaluation and preparation of the patient is extensive and rooted in the concept that anesthesiologists must think of themselves as perioperative physicians.

There has clearly been a resurgence of interest in and emphasis on regional anesthesia care, both intraoperatively and for postoperative pain management. Similarly, a separate and thorough section on chronic pain underscores the importance of this area in modern anesthetic practice.

Critical Care Medicine (CCM) has been an important part of anesthesiology training and practice for many years, but recently emphasis on this aspect of our specialty has grown dramatically, and soon will result in a doubling of the required time in CCM in training programs. This new work has recognized this with an expanded ten chapter section dealing with the critically ill patient.

I would like to thank David Longnecker, MD, for several major contributions: first, for stepping in after Ben Covino's untimely death and helping us complete our prior book, next for spearheading a second edition of that work, and now for giving our specialty a wonderfully useful new general text.

From my early primitive attempts to blindly find the internal jugular vein so as to be able to pass a Swan Ganz catheter, to today's transesophageal echocardiography; from my primitive attempts to "find" a paresthesia to today's sophisticated nerve blocks using stimulators; from the monitors I began with in 1969, where the "bouncing ball" EKG signal disappeared, sometimes for minutes, whenever the surgeon fired the "spark gap Bovie;" from early volatile anesthetics which were associated with frightening hypotension and dysrhythmias, not to mention wakeups that had surgeons pacing and muttering, we have made strides in anesthesiology that are truly amazing. If anyone had told me in my training that patients would go home directly after a general or major regional anesthetic, I'd have told them...never mind what I'd have told them!

The famous Baltimore Oriole third baseman Cal Ripken, as he ended his career, said, "it's been a good run." For me, that's just as true. It is just as exciting for me, nearing the end of my "good run," to see the vitality, and feel the excitement, of my colleagues and trainees who are continuing to move forward with our wonderful specialty of anesthesiology. This new text and reference will make us proud.

With respect and admiration,

John H. Tinker, MD
Professor and Chair
Department of Anesthesiology
University of Nebraska Medical Center
Editor Emeritus, *Anesthesiology*

Preface

The specialty of anesthesiology continues to evolve from an earlier era when it was often viewed as a technically oriented procedural discipline, to its present status as a medical discipline whose practitioners focus their expertise in the areas of perioperative and intraoperative care, critical care medicine and pain medicine. Anesthesiologists are now viewed as physicians who use combined medical and interventional approaches to achieve desired endpoints and enhanced outcomes across a broad spectrum of medical practice. Further, the specialty is recognized as the pioneering leader in the growing movement for patient safety. That movement is perhaps the most important new initiative to emerge in health care in the last century. The patient safety movement will likely be viewed in the future as akin to the "sea change" that Abraham Flexner pioneered in medical education some 100 years ago. We believe that positioning our specialty at the continued forefront of this movement is a key strategy for both the current and future success of anesthesiology and its practitioners.

In 2000, the Institute of Medicine published its landmark analysis of American health care, "To Err is Human," a treatise that emphasized the fallibility of humans, even those with the greatest dedication to their profession and their patients, and emphasized that systems of safe care must be constructed to protect patients from potential harm. That report specifically cited anesthesiology as a leader in the patient safety movement and urged others to follow the lead of our discipline, which many throughout health care have done subsequently. A subsequent IOM publication, "Crossing the Quality Chasm; A New Health System for the 21st Century" (2001), went beyond patient safety alone; it described the attributes of a model health care system as one that is safe, timely, efficient, effective, patient centered and equitable to all. We agree with these principles and have worked diligently to adopt them in our own practices and departments, for they are guideposts to the professional and ethical practice of medicine and anesthesiology. In particular, we have designed this text around the concepts of safe, effective and patient-centered care, and we urge others to approach their practice with the same enthusiasm that we share for these principles.

There are multiple sources of information about the clinical practice of anesthesiology, or about the research that forms the basis for that practice. Further, there are numerous subspecialty books that delve into the subdisciplines in great detail—often more detail than the advanced trainee or practitioner desires or needs. In this text, we have focused on what is truly important for the clinical practice of anesthesiology in all its dimensions, while being efficient in the presentation of this essential material. Throughout, we have asked "What is important?" "Why is it important?" "When should it be applied?" and "How should it be applied?" Our overarching goal was to write for the practitioner, not for the small cadre of physician scientists who may be exploring a narrow subdiscipline in great detail—such work is essential for the future scientific basis and direction of the specialty, but it often leads to extensive discussions of minutiae that distract rather than enlighten the clinical practitioner; it simply becomes too difficult to glean the key clinical principles from the blizzard of scientific detail. That said, this is not a users manual of anesthesia care, but rather a text that constantly builds on the concepts of safe, effective (i.e., evidence-based) and patient centered care, hopefully distilled in a manner that facilitates easy access to the key concepts that underpin the rationale for that practice.

We have taken a comprehensive approach to the full range of anesthesiology practice, and to the role of anesthesia care within the overall care process. Thus, we have emphasized the trends in both the specialty and the health care system in general, to assure that the reader is not required to go elsewhere for additional information to support the mainstream of their practice. Those trends in the specialty include the expanded use of regional anesthesia, the remarkable explosion in pain medicine practice and the expanded need for the skills and experience that anesthesiologists bring to the practice of critical care medicine. No careful observer of the specialty could miss these trends, and no text could be considered "comprehensive" if it did not address each of them in a way that embraces them as full components of the modern practice of anesthesiology.

We view the key trends in health care overall as those involving patient safety, quality, patient centered care and a systems approach to care that encompasses the entire care process, rather than individual components that function independently. Here again, we have woven these concepts into the text by emphasizing that anesthesia care is a system of care within a larger system of care that focuses on overall patient outcomes, not isolated events by individual practitioners working in isolated clinical disciplines.

We have approached these and other key "drivers" of contemporary and future anesthesia practice with care, commitment and enthusiasm for the future of the specialty. We trust that you share this enthusiasm and hope our efforts will serve you well as you continue to translate your knowledge and skills into safe, effective, efficient and patient-centered care; our patients want nothing less and our surgical and medical colleagues are looking to anesthesiology to continue to set the example for implementation of these principles. We are honored to serve you through our efforts here.

PART 1

THE SPECIALTY OF ANESTHESIOLOGY

CHAPTER 1

The Evolution of Anesthesiology as a Clinical Discipline: A Lesson in Developing Professionalism

Douglas R. Bacon, MD, MA

The quest for insensibility to the surgeon's knife is a primordial one. Stretching back to antiquity, physicians have sought ways to render a patient pain free while an operation was being performed. Many different regimens were tried, with varying success, until October 16, 1846, when surgical anesthesia was publicly demonstrated at the Massachusetts General Hospital by William Thomas Green Morton. Yet, there remained a long road from that fall day in Boston to the current operating room full of electronic machines whose sole purpose is to measure the anesthetic state, or physiologic parameters of the anesthetized patient. How did anesthesiology evolve from a simple glass globe inhaler to the vast array of machines that makes the modern operating room?

In many ways, the history of anesthesiology is the history of the men and women who have devoted their career to the administration of anesthetics. Without physicians interested in the anesthetic state and the ability to adapt to new conditions demanded of anesthetists by surgeons, there would be neither modern surgery nor the specialty of anesthesiology. Yet each individual was a real human, many displaying professionalism beyond what was required or expected; others seem reprehensible by "modern" standards. Although many of the individuals in this story would not consider themselves specialists in anesthesia, their contributions were critical in moving this area of the practice of medicine forward. The development of anesthesiology can be told as the history of involved physicians who dedicated themselves to providing safer, focused care of the patient, first in the operating room, and later in the critical care unit and pain clinic. The story begins in ancient Egypt, and ends in the sterile environment of the modern operating room.

KEY POINTS

1. The history of anesthesiology is an interesting and complicated story of professionals seeking to understand the anesthetic state and to safely anesthetize patients.
2. Shortly after the first public demonstration of ether anesthesia on October 16, 1846, the news spread across the world. At first anesthetics were given based on written accounts, often in the lay press.
3. John Snow, a London physician, worked out the physics of vaporization of volatile agents using ether and chloroform and used this information to design vaporizers and anesthetic techniques that were safer for the patient.
4. The first professional organization devoted to anesthesia was the London Society of Anaesthetists founded on May 30, 1893. The first similar group in the United States was the Long Island Society organized by Adolph Frederick Erdmann in 1905. The Long Island Society eventually became the American Society of Anesthesiologists.
5. Francis Hoffer McMechan, crippled by rheumatoid arthritis and unable to work clinically after 1911, organized professional anesthesia. He helped create the first national organization, the Associated Anesthetists of America in 1912, and went on to found several national and international organizations, of which the International Anesthesia Research Society (IARS) remains active. He was the founding editor of the first journal in the world devoted to the specialty, *Current Researches in Anesthesia and Analgesia,* which is currently published as *Anesthesia and Analgesia*, giving the specialty a way to communicate the most recent advances in science, technique, and technology.
6. Ralph Water is credited with the first department of anesthesia within an academic setting at the University of Wisconsin in 1927. Much of the current residency structure comes from this seminal department. This helped establish the specialty on an equal footing with other medical specialties—and created a method to train physicians in the art and science of anesthesia.
7. John Lundy, working at the Mayo Clinic, organized the Anaesthetists Travel Club, whose members were the leading young anesthetists of the United States and Canada. These individuals helped create, by 1938, the American Board of Anesthesiology, which defined what it meant to be an anesthesiologist in the United States.
8. The need for physician specialists in World War II exposed a large number of young men to anesthesiology who would not have otherwise considered the specialty. After the hostilities ceased, these physicians returned and helped create the tremendous growth in the 1950s and 1960s that the specialty enjoyed.
9. In the mid-1950s, the World Federation of Societies of Anesthesiologists (WFSA) was formed. It was the culmination of a dream that dated to the late 1930s. The WFSA made it possible for nations with a long tradition of physician specialization in anesthesia to help train and create the specialty in countries that were either recovering from the effects of the war or were beginning their national infrastructure in healthcare.
10. In the 1980s, the Anesthesia Patient Safety Foundation (APSF) and the Foundation for Anesthesia Education and Research (FAER) were created. They are additional examples of the professionalism demonstrated throughout the history of anesthesiology. These two organizations work to create a safe anesthetic environment. In addition, they support educational and research efforts in the specialty.

PREHISTORY: THE QUEST FOR SURGICAL ANESTHESIA

Imagine, for a moment that there is no surgical anesthesia. The Edwin Smith Papyrus describes 48 surgical cases done between 3000 and 2500 B.C. Al-

though there is no specific mentioning of anesthesia, within the papyrus there is evidence of compression anesthesia. In one instance, a surgeon is compressing the antecubital fossa while operating on the hand; in another instance, the patient is compressing his brachial plexus while the surgeon operates on his palm.[1] The ancient Chinese reported the use of an anesthetic for surgery in the 2nd century B.C.[2] The use of hemp smoke as an anesthetic was noted in India[3] long before Western medicine developed crude forms of anesthesia.

During the Middle Ages and early Renaissance, a mixture of herbs purported to induce anesthesia was created. Boiled into a sponge, at the time of surgery the sponge was placed in water and the vapors inhaled. Although the vinca alkaloids were a major component of the drugs used in the *spongia somnifera*, the resultant anesthetic was less than satisfactory. Another Renaissance solution was the use of parallel lines of ice, with the incision placed between them. This was effective for simple operations, and found use in the Russo–Finnish War of 1939–1940. Compression anesthesia, whereby a large clamp-like device was used to put pressure on a nerve, succeeded in short, peripheral operations.[4] Yet, the nerve compression itself caused pain. Alcohol, when drunk in sufficient quantities, was noted to render individuals insensible. Thus, the age-old intoxicant was used as a standard against which all anesthetics could be measured.[3]

In the early 1840s, the effects of nitrous oxide and diethyl ether were well known. Humphry Davy had described the intoxicating effects well in his book, *Researches Chemical and Philosophical: Chiefly Concerning Nitrous Oxide,* published in 1800. Ether, which had been first synthesized in the 1500s, had been observed to lessen the "air hunger" of asthmatics.[5] Both drugs were well known to medical students as intoxicants. In January 1842, in Rochester, New York, a medical student, William E. Clark, anesthetized the sister of a classmate, for the extraction of a molar using ether. Instructed not to pursue this observation, as it most likely was a "hysterical reaction of women," Clarke continued his training and became a respected Chicago, Illinois area physician.[6]

Two months later, in rural Georgia, a country doctor, Crawford Long, who had hosted parties where ether was used as an intoxicant, used the drug to render James Venable insensitive for the removal of tumors from the back of his neck. He charged Venable $2 for the anesthetic, thus delineating anesthesia as part of a professional service. Two years later, in 1844, Horace Wells, a Hartford Connecticut dentist, would gain the insight that, during a nitrous oxide (N_2O) show, when an individual was intoxicated by N_2O, pain was abolished. Wells then tried this idea on himself for the removal of one of his teeth by his partner, and was successful. Soon he was using "painless dentistry" as part of his professional advertisement. Wells even attempted to demonstrate a painless tooth extraction at the Massachusetts General Hospital in 1844, but the patient groaned, and the demonstration was considered a failure.[7]

Clearly, by the middle of the 19th century, there were sufficient observations about chemical agents that could potentially abolish the pain of surgery. On a limited scale in rural Jefferson, Georgia, surgery with ether anesthesia was happening. Yet, Long lacked sufficient cases to study the effects of this new agent because of the rural nature of his practice.[8] Wells' use of nitrous oxide was groundbreaking, yet he lacked the emotional stability to overcome his failed demonstration.[9] Thus, the stage was set for another dentist to demonstrate reproducible surgical anesthesia, and give birth to what would grow and develop into the specialty of anesthesiology.

DISCOVERY

On October 16, 1846, William Thomas Green Morton, a dentist and medical student, provided surgical anesthesia for Gilbert Abbott for the removal of a tumor of the jaw at the Massachusetts General Hospital. The events of that day are well known.[10] Upon completing the operation, the surgeon, John Collins Warren, remarked, "Gentlemen, this is no humbug." The miracle of pain-free surgery so impressed the Boston medical establishment that letters were sent to colleagues across the world. Considerable scholarship has been spent discerning when these letters arrived, and where they arrived, and who provided anesthesia first in the new location. For example, the generally accepted view of the spread of anesthesia to the United Kingdom is a letter from Jacob Bigelow to Francis Boot. However, by careful study of the ships sailing between Boston and Liverpool, another letter, written almost 2 weeks before Bigelow's and only 12 days after the public demonstration of ether, arrived in England on November 1, 1846. Interestingly, this letter was to a patent attorney.[11]

Morton wanted to patent the process by which ether was administered, so writing to the foremost patent attorney in England to secure rights to the administration of ether in the United States and the United Kingdom,[9] and perhaps the world, is not surprising. He also tried to patent ether itself, calling his anesthetizing mixture "Letheon." However, the distinctive odor of ether gave away the true nature of the concoction. The Boston medical establishment had convinced Morton to allow the Massachusetts General Hospital to use Letheon without charge. With ether a well-known and easy-to-synthesize compound, and its effects reproducible without the "Morton's Inhaler," the patent was quickly broken. Morton would spend the rest of his life attempting to be compensated for patent infringement, fighting with the medical establishment and into the halls of Congress.[8] Morton clearly was not the embodiment of medical professionalism as we currently understand it.

Despite the patent, news of Morton's achievement did travel, and quickly, given the nature of communication in the 1840s. On December 16, 1846, the news, in the form of a letter, arrived in London. On December 19, the first ether anesthetic was given in the United Kingdom for the removal of a tooth. On December 21, Robert Liston, the famous surgeon, amputated the leg of a butler and uttered the famous words, "This Yankee dodge beats mesmerism hollow." By early 1847, anesthetics were being given in Europe. By June of that year, the news had spread to Australia.[12] Peter Parker, minister and physician missionary in China, gave the first anesthetics there on October 4, 1847.[13]

How the news traveled, and when it arrived are matters of historical fact. Yet, for the profession of anesthesia, and the specialty of anesthesiology, what is almost more important is how willing physicians and dentists were to

use ether in this new way. Consider for a moment that outside of Boston, none of the recipients of the news that ether produced insensibility to the surgeon's knife had actually witnessed the event. Many accounts, especially those reaching South Africa and Australia, were newspaper articles or letters to the editor, often signed by a pseudonym. The hope that these medical professionals had, their desperation at their inability to alleviate pain, and their desire to help patients may well have motivated them to try this new technique. Yet, when viewed from the perspective of current early 21st century medical practice, this willingness to go on purely written accounts, often in the lay press, without the collaborating voices of the medical profession, seems to be dangerous, and without regard for the basic principle of medicine: first do no harm.

And what of the surgeons? Tolerance of the pain of surgery limited operations to those that could be performed quickly. Anesthesia obviated the need for speed, presenting the possibility of operating within the visceral cavities for hours rather than seconds. But as the physician responsible for the patient, long before the specialty of anesthesiology would be defined, why were these professionals willing to risk lives to find an anesthetic? What does this behavior say to the modern student of medical professionalism?

JOHN SNOW, SPECIALIZATION, AND EARLY PROFESSIONALISM

As reprehensible as Morton's actions appear in patenting his "discovery," Morton was acting within the ethics of his time. The American Medical Association (AMA) was only just beginning to be formed. Meeting for the first time in May 1846, 5 months before the public demonstration, the National Medical Convention adopted a resolution to write a code of medical ethics. A year later, the code was adopted. Morton's actions were covered under section 4:

> Equally derogatory to professional character is it, for a physician to hold a patent for any surgical instrument, or medicine, or to dispense a secret nostrum, whether it be the composition or exclusive property of himself or others. For, if such nostrum be of real efficacy, any concealment regarding it is inconsistent with beneficence and professional liberality;...[14]

FIGURE 1–1. John Snow. (Photograph courtesy of the Wood Library-Museum of Anesthesiology.)

Thus, at the time when Morton was trying to patent either ether or the apparatus for its vaporization, medicine was starting to organize and promulgate statements against such behavior.

In contrast, John Snow (Fig. 1–1), a London physician, became very interested in this new state of anesthesia. He began to study the chemical and physical properties of ether, and by 1847 had developed a vaporizer. "Snow never patented any apparatus he designed. On the contrary, he published clear descriptions, including engraved figures, so that others could copy them if they chose."[15] Snow, by careful observation worked out the vaporization characteristics of ether. His vaporizer (Fig. 1–2) was temperature compensated, being made of coiled copper (Fig. 1–3), an excellent heat-conducting metal, housed in a water bath to ensure constant temperature of the ether. Thus, Snow was able to calculate the amount of ether a patient required for anesthesia within a decade of the discovery of anesthesia.[13]

Following the introduction of chloroform as an anesthetic in 1847 by Edinburgh obstetrician James Young Simpson, Snow began to investigate this second anesthetic agent. Snow used his experience with ether as a guide for investigating the properties of chloroform. He concluded that it was far safer to give this new anesthetic in measured quantities through an inhaler. He did not favor the handkerchief method, whereby chloroform was applied to a cloth and held close to the nose and mouth, as being too difficult to adequately control the anesthetic depth of the patient. His deliberate nature and strong powers of observation allowed Snow to create a calibrated, temperature-compensated vaporizer for this agent as well.[13]

Snow is unique among his colleagues in the 1850s in London. A physician with many interests, it was the giving of anesthetics that accounted for the vast majority of Snow's clinical income throughout the decade. In a day when operations were still rarely performed, Snow specialized in anesthetics. In some ways, his expert knowledge al-

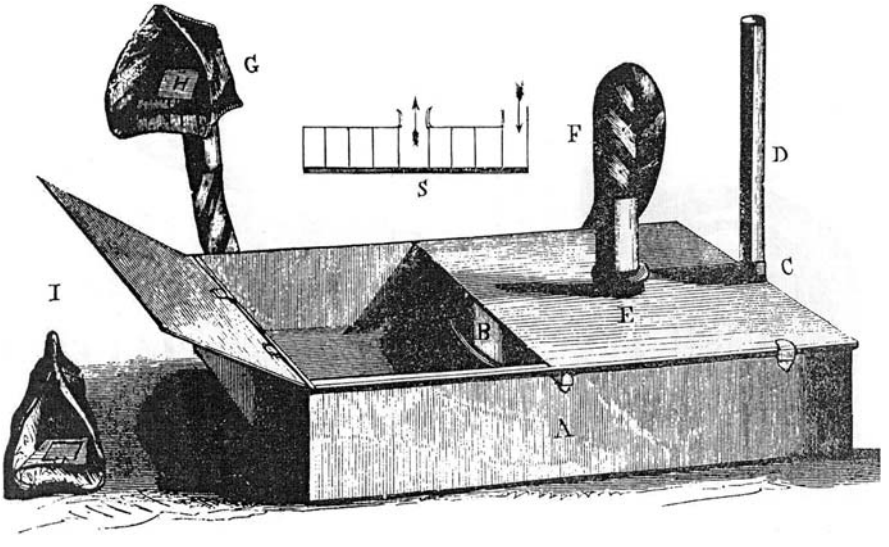

FIGURE 1–2. Snow's vaporizer. (Image courtesy of the Wood Library-Museum of Anesthesiology.)

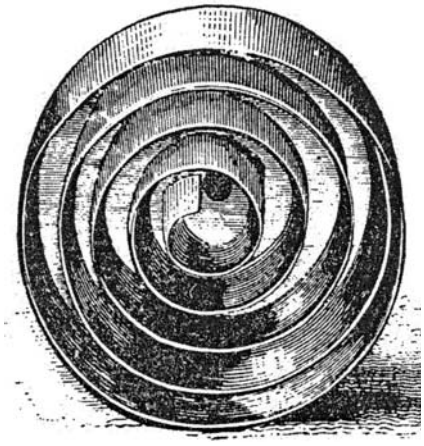

FIGURE 1–3. Coil from Snow's vaporizer. (Image courtesy of the Wood Library-Museum of Anesthesiology.)

lowed him entrée into the upper echelons of both social and physician circles, a status he could not have obtained had he not limited his practice. Perhaps this is best illustrated by his attendance upon Queen Victoria for the birth of her last two children. While Snow did not use his inhaler, he also did not induce the full anesthetic state in the Queen. Rather, he strove for analgesia with chloroform, and in so doing, created a form of obstetrical analgesia, *chloroform a la reine*, which would persist in various forms over the next century.[13]

Aside from working out the physics of vaporization, Snow was intensely interested in outcome data. He studied every report concerning a death under anesthesia, and often times had data in advance of the published reports of death. He commented extensively on the death of Hannah Greener, thought to be the first death under anesthesia in the world.[16] In his posthumous book, *On Chloroform and other Anesthetics,*[17] published in 1858, Snow compiled the first 50 deaths under chloroform, with comments about the pathophysiology present. Snow's spirit of inquiry, which went from the bench top to the pathologic findings at death, helped him to understand the nature of the anesthetic process and the agents that produced insensibility. In following his inquiring mind, Snow created the scientific underpinnings for a specialty.[18]

A PROFESSION EMERGES

After Snow's untimely death, anesthesia faded into the medical background again. In larger cities, there were those who made a majority of their clinical income from providing anesthesia, yet it would not be until the advent of Listerism and the "taming" of infection that operations would become more frequent. As the number of operations increased, so did the need for anesthesia and, unfortunately, mortality became an issue. Chloroform was responsible for deaths that seemed unexplainable. Ether appeared to be safer, yet the side effects of nausea and vomiting, and the prolonged induction when compared to chloroform, made ether a less-than-ideal agent. Surgeons began to search for alternative methods for the administration of anesthetics.

In 1884, Carl Koller, a resident in ophthalmology in Vienna, was introduced by Sigmund Freud to a new crystalline substance called cocaine. Koller sought a local anesthetic to replace ether anesthesia for operations on the eye; because fine suture material to close the eye wound did not exist, any postoperative retching potentially could cause the loss of vision. Thus, when Koller's tongue became numb from droplets of a solution containing cocaine, he made the conceptual leap that this same solution could be applied to the cornea with similar anesthetic effects on the eye. Using the facilitates of the laboratory in which he worked, Koller soon numbed the eyes of several animals, a fellow investigator, and himself. He took this new topical anesthetic to the clinic and used it with great success. On September 15, 1884, Koller had a paper on the subject on the program at the German Ophthalmological Society meeting in Heidelberg. Because Koller was too poor to travel, his colleague, Dr. Josef Brettauer presented the paper for him.[19]

While Koller continued his career in ophthalmology, eventually immigrating to the United States, other physicians modified this new form of anesthesia into an alternative to general narcosis. One of the early practitioners was William Halstead, future chair of surgery at Johns Hopkins University, who was in Vienna at the time of Koller's discovery. Using cocaine topically, Halstead eventually learned to dissect down to a nerve, and to anesthetize it directly. Much of the work he did on himself, becoming addicted to cocaine in the process.[20] Another of the pioneers of regional anesthesia was the German surgeon Carl Ludwig Schleich, who developed the technique of infiltration anesthesia.[21] Combining infiltration techniques with the newly discovered lumbar puncture, August Bier, another academic German surgeon, initiated spinal anesthesia in the late 1890s. Working with his fellow August Hildebrandt, Bier successfully cannulated the subarachnoid space of Hildebrandt and produced a satisfactory anesthetic state. Hildebrandt was unsuccessful in cannulating Bier's subarachnoid space; however, both men suffered postdural-puncture headaches.[22] Ten years later, Bier described his intravenous regional anesthetic technique, which is still referred to as the Bier block.[23]

At the same time that regional anesthesia was being developed in Germany, concern over the safety of chloroform, especially when compared to ether, was developing. In India, then a colony of England, a Chloroform Commission was seated in Hyderabad to attempt to determine which anesthetic agent was safest. Funded by the Nizam of Hyderabad, the 1888 study of anesthetic agents was an effort to find out if there was an intrinsic mortality associated with chloroform. The findings were tainted by the British medical officer in charge, Dr. Edward Lawrie, who was a strong chloroform proponent, having trained in Edinburgh, chloroform's birthplace. The findings of the Hyderabad Chloroform Commission were not conclusive, and a second was ordered, which also was inconclusive. But what was important in these commissions, like the drive to discover regional anesthetic techniques, was that physicians were studying anesthesia and trying to increase patient safety. For many physicians, it was slowly becoming apparent that there was a need for a specialty practice of anesthesia.[24]

Early in the 20th century, the American Medical Association set up a commission to study anesthetics. A preliminary report was issued in 1908.[25] All forms of anesthesia were accounted for, including spinal anesthesia, and various combinations of inhalational agents. The conclusions of the report are interesting, for they foreshadow the development of a separate specialty:

> ...[A]ll the newer methods demand expertness, experience, and special apparatus. They appeal especially to the surgeons who are equipped with the paraphernalia of expensive and

> highly specialized clinics. They are little suited to physicians in general practice. For the latter great class of practitioners, the old general anesthetics, chloroform and ether, will probably hold their own until increasing experience has enabled us to simplify and to make safe the newer and more novel methods.[25]

The commission had three very interesting recommendations:

1. That for the general practitioner, and for all anesthetists not specially skilled, ether must be the anesthetic of choice—ether administered by the open-drop method.
2. That the use of chloroform, particularly for the minor operations, be discouraged, unless it is given by an expert.
3. That the training of skilled anesthetists be encouraged and that undergraduate students be more generally instructed in the use of anesthetics.[25]

The third suggestion of the commission would take almost the entire 20th century to implement.

THE RISE OF THE SPECIALIST

In 1905, in Brooklyn, New York, a group of 8 physicians and a medical student, led by Adolph Frederick Erdmann (Fig. 1–4), gathered to discuss the problem of anesthetics. These young physicians thought, like the AMA commission, that there was more to the giving of an anesthetic than simply dropping ether on a cloth held near the patient's face, and that there needed to be discussions and a free exchange of scientific and practical information about anesthesia.[26] This was the second specialty group in the world that was created, the first being the London Society of Anesthetists in 1893, and it would become the catalyst for the development and recognition of physicians who were specialists in anesthesia.[27] Thus, the Long Island Society of Anesthetists was born. The society met quarterly, in the evening, with a short business meeting followed by the presentation of 2 or 3 papers, or a couple of papers and a demonstration of a new anesthetic technique or apparatus. Science aside, the society provided a "support" group for those seeking to improve their anesthetic skills, and a forum at which to exchange ideas and deal with problems beyond the science of anesthesia.[26]

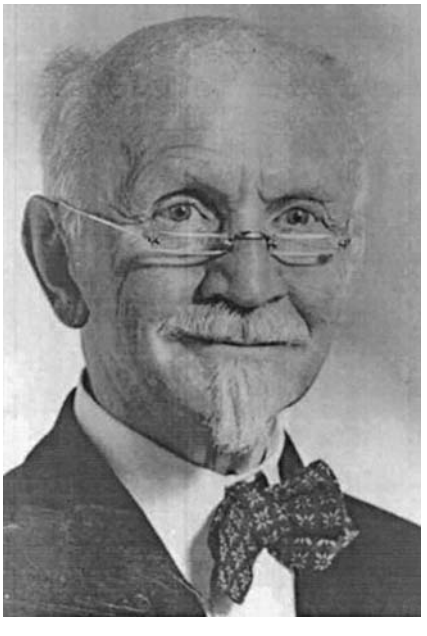

FIGURE 1–4. Adolph Frederick Erdmann. (Photograph courtesy of the Wood Library-Museum of Anesthesiology.)

The group flourished and, in 1912, moved across the river to New York City, changed the organization's name, and became the New York Society of Anesthetists. Over the next 24 years, the society would grow, both in membership and in scope. Starting out as a New York City group, by the mid 1920s, the group encompassed all of the state. By 1936, it had become a national organization.[28] The transformation focused on the recognition of physicians who primarily anesthetized patients as specialists.

The first significant political move of the New York Society was a motion put before the House of Delegates of the American Medical Association asking for a Section on Anesthetics in 1912. The members of the society were concerned about nonphysicians giving anesthetics, and echoed some of the findings of the AMA's Commission on Anesthetics some 6 years earlier.[28] James Gwathmey (Fig. 1–5), the society's president, was developing a new method of anesthesia—rectal ether. Like chloroform, rectal ether could be unpredictable and needed to be administered by someone very familiar with its use and with the effects of anesthesia in general.[29] The quest for a section within the AMA was, in some ways, the beginning of a quest for patient safety in anesthesia, a movement that would take the specialty by storm in the latter half of the 20th century.

FIGURE 1–5. James Tayloe Gwathmey. (Photograph courtesy of the Wood Library-Museum of Anesthesiology.)

The motion was denied by the AMA House of Delegates. However, Gwathmey and Francis Hoeffer McMechan (Fig. 1–6) gathered the defeated physician anesthetists and created the American Association of Anesthetists (AAA). This was the first national group of physician anesthetists in the United States. The following year, 1913, the group met for a day of papers, mostly clinical in origin, and a dinner, with spouses (Fig. 1–7). The

First Regular Meeting
OF THE
American Association
of
Anesthetists
AT
Minneapolis, Minnesota
June 18, 1913
Organized June 12, 1912
Atlantic City, N. J.

FIGURE 1–7. Program of the first meeting of the American Association of Anesthetists, June 18, 1913, Minneapolis, Minnesota. (Image courtesy of the Wood Library-Museum of Anesthesiology.)

science presented at the meeting is memorable in that the day was devoted to anesthesia; the evening meal signified a group, however small, that was willing to be recognized as specialists in anesthetics and by uniting, to move the field forward.[28]

The AAA, and its successor, the Associated Anesthetists of the United States and Canada, were run by Francis Hoeffer McMechan. A third-generation physician who entered anesthesia against the advice of his father, McMechan had crippling rheumatoid arthritis, and was out of clinical practice by 1911. McMechan was a visionary who desired to see, on a worldwide scale, the elevation of anesthesia to "stand shoulder to shoulder" with surgery and internal medicine. He realized that without a place to publish papers on the specialty, and without a place to gather the news of the various societies and names of physicians practicing anesthesia, the specialty would be doomed. Convincing his friend Joseph McDonald, the editor of the *American Journal of Surgery* to publish a supplement on anesthesia gave the specialty its first U.S. quarterly. McMechan also edited the *Yearbook of Anesthesia* between 1914–1919, compiling all the papers published in the specialty in the preceding year into a single volume.[30]

McMechan also understood that the specialty would never develop as a discipline within medicine without a strong scientific underpinning. To that end, first nationally, and internationally in the mid 1920s, McMechan organized a society devoted to research in anesthesia. The International Anesthesia Research Society brought together basic science researchers and the physicians most in need of their talents. Most importantly, the IARS sponsored the first journal in the world devoted to anesthesiology, *Current Researches in Anesthesia and Analgesia*.[31]

The education of physician specialists, especially in the postgraduate period, was another of McMechan's concerns. Partnering with Ralph Waters, an opportunity emerged at the University of Wisconsin in 1926, as the medical school transformed itself from a 2-year institution offering only basic science education into a 4-year curriculum with all the clinical sciences. One addition was a section on anesthesia, headed by Waters, in the department of surgery. Waters immediately began to teach anesthesia to medical students and interns. He collaborated with the basic science researchers, at first on problems of carbon dioxide absorbance, and later, through various members of his department, on all aspects of anesthesiology. Perhaps most importantly, Waters established the first residency training program in an academic center. The training was 3 years beyond the intern experience. Years 1 and 3 were clinical in nature, with year 2 devoted to laboratory research. Two weekly conferences were established, one discussing the week's cases in a format similar to current morbidity and mortality conferences, and another devoted to the current literature in anesthesia. By 1933, the teaching program was the envy of the world, and Waters understood that the final step had to be taken. He sent one of his faculty members, and an early graduate of the program, Emery Rovenstine, to Bellevue Hospital and New York University to try to replicate the University of Wisconsin department. Rovenstine was successful beyond any expectation and, in some ways, his graduates would eclipse the contributions of Waters' graduates in the development of academic anesthesiology across the country.[32]

In 1929, the year of the stock market crash and the beginnings of the Great Depression, another pivotal event occurred in anesthesiology. The Anaesthetists Travel Club was organized by John Lundy at the Mayo Clinic. The group was organized along the lines of the Society of Clinical Surgery, with members going to other members' institutions to see their anesthetic practice in action. It was a young man's group, with the oldest member being Lahey Clinic anesthesiologist Lincoln Sise at 55 years of age, and the youngest being Philadelphian and future first editor of *Anesthesiology* Henry Ruth at 30 years of age, and Mayo resident Ralph Tovell at 28 years of age. The average age was just 40 years. These young, influential anesthesiologists were those "standing in line" in the McMechan organization, or those who believed that McMechan's international vision of the specialty, while important, would not solve domestic issues. The Travel Club would come to dominate the New York Society, and become the nidus of leadership for the effort to create the American Board of Anesthesiology.[33]

THE CREATION OF THE AMERICAN BOARD OF ANESTHESIOLOGY

Once there was an organization in place to address national issues, regular meetings of a society devoted to the specialty, a university presence, ongoing research into clinical problems, and a residency training program to continue to retain and transmit the knowledge already gained, some recognition of a physician practicing the specialty was important. The gains in clinical practice in the 1920s and 1930s are best summed up by Harold Griffith, a leading Canadian physician-anesthetist of the time when he wrote, in 1939, the following:

> Seventeen years ago when I began to give anesthetics, the anesthesia equipment in the small hospital which has ever since been my hospital home, consisted of bottles of ether and chloroform and a few face masks. This was typical of the fairly well-equipped hospitals of that time. Today in that hospital there are eight gas machines of various models, suction equipment in every room, oxy-

gen- and helium-therapy equipment, at least fifteen different anesthetic agents, and much technical equipment for their administration. This transformation has been taking place everywhere in anesthesia.[34]

Economic reasons played a role in the need to define a specialist in anesthesia, for physician anesthetists were not well compensated and faced competition from a number of groups. Surgeons, for example, could hire a nurse to help in the office and give anesthetics. The surgeon could then charge each patient a fee for anesthesia in addition to the fee for surgery. The income generated from the anesthetic fee was in excess of what he paid the nurse, and thus profitable. Likewise, hospitals could hire nurses to give anesthetics, charge a fee that cumulatively was in excess of the salaries, and make a profit. Finally, general practitioners would refer cases to surgeons with the caveat that they could give the anesthetic and collect the anesthetic fee.[35]

McMechan proposed an International College of Anesthetists and certified the first fellows in 1935. There were two serious problems with his certification process. First, and foremost, the clinical criteria were weak. The applicant only had to document 10 anesthetic cases, with lessons learned, to be eligible. In one instance, an intern on the anesthesia service for 1 month wrote up the necessary cases and was certified. In another, a surgeon who occasionally gave an anesthetic, completed the necessary paperwork and was certified. With certificate in hand, he attempted to become the head of a hospital division of anesthesia. Second, the college had no standing with the AMA, and the certificate meant nothing "official" in the United States.[36]

Members of the Anaesthetists Travel Club, especially Paul Wood, John Lundy, and Ralph Waters, believed that certification was essential if anesthesiology was going to be recognized as an equal with all other specialty practices. Using AMA criteria, which included documentation of either postgraduate training in the specialty, or 2500 cases where the applicant had administered the anesthetic, Wood and his colleagues at the New York Society created a special classification of members called "fellows." This new form of membership was extremely popular, and the membership of the New York Society skyrocketed. Now

FIGURE 1–8. Erwin Schmidt. (Photograph courtesy of the Wood Library-Museum of Anesthesiology.)

national in membership, the society changed its name to the American Society of Anesthetists in February of 1936.[37] In 1945, the American Society of Anesthetists became the American Society of Anesthesiologists.

The AMA took note largely through Lundy's efforts, and Waters, working closely with Erwin Schmidt (Fig. 1–8), the chair of surgery at the University of Wisconsin, was able to secure an agreement for the American Board of Anesthesiology (ABA) to be created as a subboard of the American Board of Surgery. Using AMA criteria, which included, in addition to the heavy clinical training, the stipulation that the physician had to be in full-time practice of the specialty the ABA was created in 1938. The first written examination of the ABA was held in March 1939. It was an essay format, with 5 subject subheadings: pharmacology, anatomy, physics and chemistry, pathology, and physiology. There was an oral examination and a practical one at the candidate's place of practice.[38] Thus, there was a heavy emphasis on the clinical practice of anesthesiology.

WORLD WAR II AND BEYOND

The New York World's Fair opened on April 30, 1939, the eve of World War II. In the Hall of Man, an anesthesiology exhibit (Fig. 1–9) allowed the general public to learn more about the specialty. The exhibit was paid for by the Winthrope Chemical Company at a cost equivalent to several million dollars today. This is important for two reasons; first, it demonstrated that anesthesia had enough of a market impact that industry was willing to spend lavishly to support such a display. Second, the clinical practice of anesthesiology had become both complex and commonplace enough that the lay public needed to learn about it.[39]

At the same time, Lewis Wright was hired by Squibb Pharmaceuticals to investigate new anesthesia drugs, among them, curare. Wright was a self-taught anesthesiologist who, in midcareer, took a leave of absence from his job at Squibb and did a residency with Emery Rovenstine at Bellevue Hospital.[40] It was to Rovenstine and Emmanuel Papper that he gave some of the first commercially prepared curare. Papper felt that the agent was a poor anesthetic, as all the test animals stopped breathing when it was administered to them.[41] It was Harold Griffith and Enid Johnson, of Montreal, who discovered the true value of curare in anesthesia.[42]

As the United Sates plunged into World War II, the anesthesia community was determined not to repeat the mistakes of World War I. Physician anesthetists had been in short supply and often ran from unit to unit training corpsmen in the administration of ether by open drop.[43] By the early 1940s, anesthesia had become too complex for this to be successful. The leaders of the American Society of Anesthetists worked with the advisors to the armed forces and developed short courses, 90 days in length, to train medical officers in the basics of anesthesia. These young physicians managed many horrific clinical situations and, applying what they learned, were able to decrease mortality.[44] The case of Samuel Lieberman, who won the Legion of Merit for his work in the South Pacific, is illustrative. By using continuous spinal anesthesia he decreased the mortality from abdominal wounds from 46–12.5%.[45]

Returning from the war, these physicians had tremendous clinical experience, especially with regional anesthesia. Nerve blocks were invaluable, because corpsmen could take vital signs and talk to the soldier while the operation was ongoing, freeing the anesthesiologist to treat others. Likewise, these military anesthesiologists had

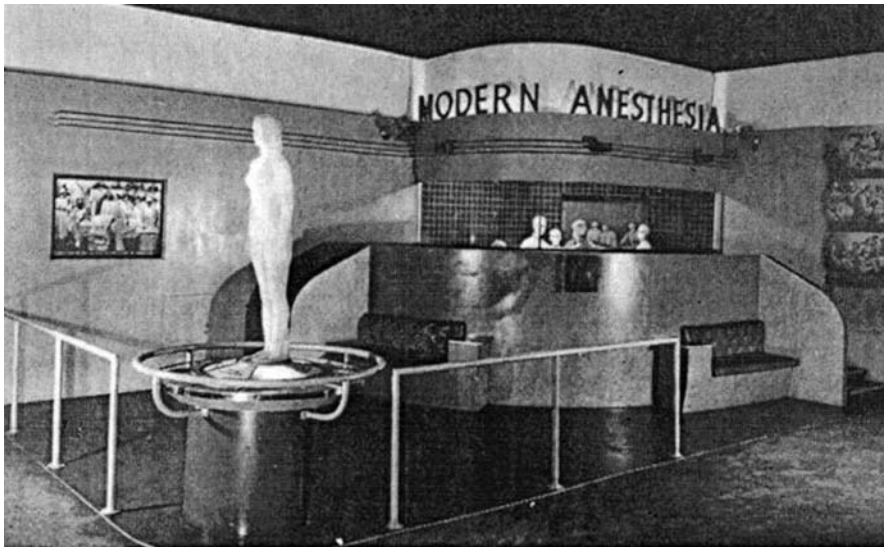

FIGURE 1–9. Postcard image of the anesthesia exhibit at the 1939 World's Fair. (Image courtesy of the Wood Library-Museum of Anesthesiology.)

extensive experience with transfusion and fluid therapy. Returning to the United States, approximately 40% sought additional formal training as anesthesiologists. Thus, the specialty expanded tremendously after the end of the war, not only because of the returning physicians, but because surgeons exposed to the field work of the anesthesiologists demanded physician involvement in the anesthesia.[44]

THE SECOND HALF OF THE 20TH CENTURY

McMechan's vision of an international community of anesthesiologists came to fruition in the 1950s. The first world meeting of anesthesiologists had been scheduled for Paris in the spring of 1940, but was canceled as the German army took the city. By the early 1950s, Europe was starting to recover from the effects of the war and the original French organizers were still interested in seeing the meeting become a reality. Working within the European community and Canada, and with help from the World Heath Organization, preliminary meetings were organized and the structure of the WFSA was created. The first World Congress, held at The Hague in the Netherlands in 1955, was a success despite the absence of the Americans. The WFSA wanted to bring the best clinical practice of the specialty to the fore; the World Congress was a way to bring first-, second-, and third-world anesthesiologists together to discuss problems and to seek solutions. The WFSA set up programs to share information with those in need of it.[46]

However, it would not be until the end of the decade of the 1950s that the American Society of Anesthesiologists would join the WFSA. The reluctance on the part of the Americans was multifactorial. First, because dues to the WFSA were on a per capita basis, the American Society of Anesthetists felt that they would be providing the majority of the finances of the organization without an equal voice in its government. There was also reluctance on the part of some American anesthesiologists to join an organization that contained communists. Time, dialogue, and the performance of the WFSA eliminated those fears.[47]

Along with the international concerns, the specialty faced a challenge in the United States as well. There was a significant part of the anesthesiology community that felt that no physicians should accept a contract for services and allow a third party, such as a hospital or other employer, to bill in the physician's name. Enforcement of this edict was done by the component societies of the American Society of Anesthetists. An anesthesiologist could not be a member of the American Society of Anesthetists if the anesthesiologist wasn't a component society member. If the anesthesiologist was not an American Society of Anesthetists member, the anesthesiologist was ineligible to take the American Board of Anesthesiology examination.[48] In response to this, the Association of University Anesthesiologists (AUA) was formed. The majority of academic anesthesiologists were employed by the university for a salary, in violation of the American Society of Anesthetists rules. The establishment of the organization is important not only as a protest, but because it underscores how important academics had become to the fledgling field in the 30 years between the creation of the Waters department to the first AUA meeting.[49] It was a rapid expansion and one that continued to delineate the scientific underpinnings of the specialty.

In the 1960s, the U.S. federal government sought to support medical research and created the National Institutes of Health (NIH). Emmanuel Papper (Fig. 1–10) was invited to Washington, DC to help organize the new agency. Dr. Papper worked tirelessly to see that anesthesiologists were treated fairly by the NIH and were eligible for funding. However, he was unable to secure an independent study section for anesthesia, and the battle to obtain this for the specialty remains a leading agenda item for many.[41]

The 1970s were a decade of crisis for anesthesiology. To assure billing that was commensurate with services, the American Society of Anesthesiologists had endorsed a relative value guide that

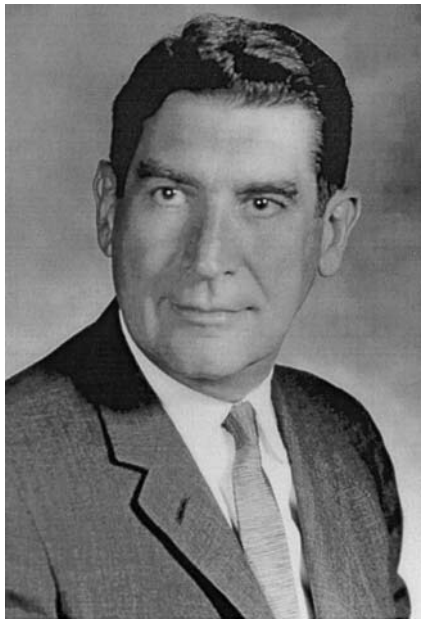

FIGURE 1–10. Emmanuel Papper. (Photograph courtesy of the Wood Library-Museum of Anesthesiology.)

helped place a unit value on work done by the physician. Other specialties, including orthopedics and radiology, had adopted similar guides, but the Federal Trade Commission (FTC) thought this was a monopolistic practice. All of the specialties but anesthesiology agreed to cease and desist; the American Society of Anesthetists went to court. After a 2-week trial, the judge ruled that the relative value guide did not represent a monopolistic practice; rather, it was simply a tool that applied monetary value differently in different parts of the country. In one of history's little ironies, 30 years after the verdict, the federal government now states the relative value guides are the preferred billing methodology. The 1970s also saw another federal government suit against the American Society of Anesthetists for the fee-for-service rule. Here there was little chance of a successful suit, yet the federal government, cautious after its defeat, agreed to a cease-and-desist order.[50]

The 1980s, by contrast, witnessed the development of two organizations that have served anesthesiology well. The Foundation for Anesthesia Education and Research (FAER) is devoted to the promotion of research within the specialty. The group has a special interest in those just beginning their careers, and has supported a successful starter grant program. Indeed many of the leaders of academic anesthesiology in the early 21st century began their careers with a FAER grant. At the same time FAER was being established, the Anesthesia Patient Safety Foundation (APSF) was created. Its mission is simple: no patient should ever be harmed by an anesthetic. APSF has partnered the academic, private practice, and industrial communities to work toward decreasing anesthetic risk. The establishment of the Harvard standards of monitoring, at the beginning of the APSF, was an important step in this direction. APSF and its work is the model for the patient safety movement across the country, and is used by the AMA as a model for its patient safety foundation.[51]

CONCLUSIONS

By comparison with most other medical specialties, the history of clinical anesthesia is short. Perhaps Francis Hoeffer McMechan summed it best when he wrote, in 1935, the following:

> Anesthesia was the gift of pioneer doctors and dentists to suffering humanity, and every significant advance in its science and practice has been contributed by doctors, dentists, and research workers of similar standing. In contrast, technicians have added nothing of any consequence. Anesthetics are among the most potent and dangerous drugs used in the practice of medicine; they penetrate to every cell and organ of the body and may cause almost instant or delayed death by their toxic effects. The dosage of general inhalation anesthetics cannot be prescribed in advance but must be determined from moment to moment during administration. The dosage of local and other anesthetics must be determined by the risk of the patient, the nature and duration of the operation to be done—certainly a challenge to the knowledge and experience of the keenest doctor. No patient should ever be given an anesthetic whose condition and risk has not been diagnosed in advance of the operation, so that every resource of medical science can be used to lessen the risk and make the recovery more assuring. Certainly in this preoperative evaluation and the selection of the safest anesthetic and best method of administration, the medical anesthetist is more in a position to act as a consultant than a technician....
>
> The safety of the patient demands that the anesthetist be able to treat every complication that may arise from the anesthetic itself by the use of methods of treatment that may be indicated. The medical anesthetist can do this, the technician cannot. More recent developments have extended the field of medical anesthesia to include resuscitation, oxygen therapy, and therapeutic nerve block for intractable pain, and treatment of various conditions of disease, and the rehabilitation of the disabled—all fields of practice quite beyond the capacity of the technician.[52]

McMechan's vision of professionalism, and its 21st century equivalents, needs to continue to guide the specialty. The history of anesthesia is interesting, filled with fascinating events and people, and it is replete with the highest examples of professionalism.

CHAPTER 2

The Scope and Future of Anesthesia Practice

Michael S. Avidan, MBBCh, DA, FCA, and Alex S. Evers, MD

Anesthesiology arose as a medical specialty because the dangers associated with anesthetic drugs and techniques demanded that they be administered by skilled and knowledgeable physicians. As safer drugs were developed and physiologic monitoring improved, the need for anesthesiologists was propelled by increasing surgical complexity and severity of patient illness, as well as by increasing expectations for patient safety. Whereas the original raison d'être for the specialty remains today, a variety of professional and economic factors have challenged anesthesiology and produced large "swings of fortune" during the past few decades.

During the 1970s and 1980s the emergence of critical care attracted many talented medical students to American anesthesiology training programs. However, these were halcyon days for anesthesiologists practicing in the operating room, where professional income was high, job opportunities were ample and increasing surgical complexity demanded an increasing level of medical knowledge and skills. Thus there was little incentive for anesthesiologists to expand their roles beyond the confines of the operating suites and most of the trainees who were initially attracted by critical care subsequently practiced operating room anesthesia only. In contrast, during this same period, anesthesiologists in Europe and Canada were consolidating their positions in the burgeoning subspecialties of pain, intensive care, and resuscitation.

In the mid 1990s, gloom beset anesthesiology in the United States as predictions, widely reported in lay press such as the *Wall Street Journal*, suggested that the need for anesthesiologists would decrease dramatically in an anticipated managed care environment. Medical graduates were discouraged from pursuing careers in anesthesiology, and residency programs contracted dramatically. Anesthesiologists in other parts of the world have also experienced fluctuating fortunes. Currently there is a shortage of doctors in general, and of anesthesiologists in particular, in many countries. The future of anesthesiology depends on several factors, including changes in surgery and interventional medical practice, technological advances in anesthesiology, the evolving scope of anesthesia practice, and the role of nonphysicians (e.g., nurse anesthetists and anesthesia physician assistants) and physicians trained in other specialties in the provision of anesthesia care; healthcare financing will also influence trends in anesthesia practice. This chapter briefly reviews the current scope of anesthetic practice and offers some possible scenarios for future directions of the specialty.

OPERATING ROOM ANESTHESIA

The operating room remains the primary focus for the vast majority of anesthesiologists. The anesthesiologist's primary responsibility in this arena is to ensure the patients' comfort and safety when they are exposed to the trespass of surgery; this includes protecting the patient from pain, undesired awareness and organ system injury, and fostering full recovery from the surgical and anesthetic interventions. Over the past decades it has become increasingly clear that the intraoperative conduct of anesthesia has a profound effect on patient safety and comfort in the postoperative period. For example, modest intraoperative hypothermia can either decrease the incidence of wound infection[1] or provide neuroprotection,[2] depending on the clinical situation. Anesthesiologists are increasingly sophisticated in their understanding of patient safety and they are focusing on such issues as appropriate perioperative medications, antibiotic prophylaxis and infection control, multimodal analgesia, maintenance of normothermia and normoglycemia, and appropriate fluid and electrolyte therapy. Recent findings raise the intriguing possibility that anesthetic management may contribute to postoperative cognitive decline and to long-term outcomes.[3] This growing responsibility for overall postoperative outcomes raises new expectations for knowledge and skills of the practicing anesthesiologist and challenges our

KEY POINTS

1. The operating room remains the primary focus for the vast majority of anesthesiologists.
2. The anesthesiologist's primary responsibility is to ensure patients' comfort and safety when they are exposed to the trespass of surgery.
3. The intraoperative conduct of anesthesia has effects on patient safety and comfort in the postoperative period.
4. The provision of safe anesthetic care across geographically dispersed sites and encompassing wide ranges of patient health, in an economically responsible manner, is a challenge that anesthesiologists need to address proactively.
5. It is arithmetically impossible to provide a fully trained anesthesiologist for every anesthetic procedure.
6. Meeting the manpower, safety, and cost demands of the future requires overcoming the political infighting between organized anesthesiology and nurse anesthesia.
7. It is important for the future of the specialty that anesthesiologists increase their commitment to critical care medicine.
8. Recent advances in knowledge and technology create an enormous opportunity for anesthesiologists to address the scientific questions at the core of the specialty as well as a variety of important clinical problems.
9. Apart from traditional areas of involvement, such as operating room anesthesia, critical care, pain medicine, teaching, research, and resuscitation, there will be future opportunities for anesthesiologists in pharmacogenomics, healthcare systems management and new technologies.

previously narrower definitions of anesthetic outcome.

Despite the demands imposed by increasing severity of illness in surgical patients, growing surgical complexity and more comprehensive postoperative considerations, anesthesiology is often viewed as a victim of its own perceived success. One widely cited study from the United Kingdom, the Confidential Enquiry into Perioperative Deaths (CEPOD) study, reports that patients undergoing general anesthesia have a 1 in 185,000 chance of dying as a consequence of anesthetic misadventure.[4–6] This finding was highlighted in the Institute of Medicine report on medical errors[7] and anesthesiology was cited as the specialty that had best addressed safety issues (see Chap. 3 for a more comprehensive review of quality and safety in anesthesia practice). Unfortunately, this widely publicized perception that anesthesia is "safe" has encouraged nonphysician anesthesia providers to advocate for independent practice and has suggested to insurers that anesthetic care by an anesthesiologist is needlessly expensive. However, studies from other countries have reported much higher rates of death attributable to anesthesia than those reported in the CEPOD study.[8] In a large French study, the perioperative mortality directly attributable to anesthesia was found to be 1 in 13,000.[9] In studies reported from Australia,[10] Denmark,[11] Finland,[12] and the Netherlands,[13] perioperative death attributable to anesthesia ranged from 1 in 2500[11] to 1 in 67,000.[12] The mortality attributable to anesthesia is probably much greater in developing countries. For example, a 1992 study from a Zimbabwean teaching hospital reported an alarming incidence of death or coma—1 in 388—attributable to anesthesia.[14] Whereas the bulk of evidence suggests that anesthesia is not nearly as safe as publicized,[15] it is undoubtedly true that advances in anesthetic practice in developed countries have rendered the care of healthy patients undergoing low- or intermediate-risk surgery much safer than in the past (see Chap. 24 for a more detailed review of anesthesia risk).

The challenges to anesthesiology are exacerbated by the massive expansion in demand for anesthesia services for a variety of nonoperative procedures, ranging from cerebral aneurysm coiling to general anesthesia for screening colonoscopy, and by the introduction of freestanding ambulatory surgery centers and office-based surgical suites where anesthesia is administered. The demands for safe anesthesia care provided in numerous remote locations, present significant challenges to the workforce, and to the financing and practice of anesthesiology.

Current practice models vary widely both in the United States and worldwide. In the United States, some anesthesiologists (or practice groups) personally provide all anesthetic care regardless of complexity, an approach that is also common in the United Kingdom, Canada, and Australia. In other practices, anesthesiologists supervise ancillary providers (e.g., nurse anesthetists, residents, or anesthesia assistants) in more than one operating room; a practice model that is also common in the Netherlands. The provision of safe anesthetic care across geographically dispersed practice sites and encompassing wide ranges of severity of patient illness, in an economically responsible manner, is a major challenge that anesthesiologists need to address proactively.

The expectations for operating room anesthesia can be simply stated: we need to provide an ever-increasing quality of perioperative care for a lower cost. In turn, these expectations and predictions require that the anesthesiologist community consider who will, or should, provide each component of anesthesia care, what levels of knowledge and skill will be required of each provider, and how the responsibility for care will be organized, managed, and rewarded.

Currently, at least 50% of anesthesia care in the United States involves nurse anesthetists; in several states, physician supervision is not mandatory. Worldwide, anesthesia practice often includes some form of nonphysician provider, or a physician provider who is not a fully trained anesthesiologist. For example, staff-grade noncertified anesthetists provide a significant proportion of anesthesia care in the United Kingdom. One report asserts that nonanesthesiologists can safely provide anesthesia for selected procedures (e.g., colonoscopy) and patients.[16] It is also clear that patients with minimal physiologic reserve, those undergoing major interventions, and those with complex medical problems require the direct involvement of a skilled anesthesiologist to enhance patient safety.[17,18] Unfortunately, practitioner skill and experience are often not matched to these factors, but determined by availability of providers, or a fixed model of care delivery, rather than one that is tailored to the specific clinical situation. This is a fruitful area for further work by anesthesiologists to assure proper matching of resources to the clinical needs.

It is arithmetically impossible to provide a fully trained anesthesiologist for every anesthetic procedure. Furthermore, the increasing demands for anesthesia services (aging population, proliferation of ambulatory surgery centers, escalating demand for nonsurgical anesthesia and sedation) will outstrip even the most aggressive output of anesthesiologists. Medical schools simply do not have the capacity to train sufficient numbers of doctors to feed exponentially increasing anesthesia programs. For reasons of both anesthesiologist availability and cost, it is apparent that the future of anesthesia practice will involve an increasing role for nonphysician providers.

How can this be made compatible with the demands for increasing safety and quality? By involving skilled anesthesiologists in the cognitive aspects of *every* anesthetic. This will require coordination and cooperation with nonphysician providers, allowing them to perform at the highest levels their training allows, while ensuring that a fully trained specialist is involved in planning and managing care for high-risk cases and is readily available for complex diagnostic and therapeutic decision making. Technologic developments in monitoring and information systems should facilitate these changes. The development of telemedicine could make this model of care feasible even in communities where an anesthesiologist is not physically present.[19] Meeting the manpower, safety and cost demands of the future will require that we overcome the political infighting between organized anesthesiology and nurse anesthesia. Furthermore, the training of anesthesiologists will increasingly need to encompass the development of skills in supervising other anesthesia providers. It is in the interests of public safety and healthcare delivery that unity be forged among anesthesia providers under the leadership of specialist anesthesiologists, whose medical training and education is required for

complex medical decision making, supplemented by the skills and abilities of nonphysician providers who enhance this team approach.

OUTSIDE THE OPERATING ROOM

Preoperative Care

Perioperative morbidity is frequently attributable to poor preoperative patient assessment and optimization. These roles have always been integral to the anesthesiologist's practice. However, as patients increasingly present to the hospital on the day of surgery, it has become necessary to ensure that patients are properly evaluated well before the immediate preoperative interval. Recognizing this need has led to burgeoning preoperative assessment clinics, where problems such as ischemic heart disease, pulmonary disease or sleep apnea may be evaluated and appropriate perioperative interventions may be planned. (See Chap. 4 for a more detailed discussion of the benefits and operation of preoperative clinics.) In some practice settings, preoperative assessment of complicated patients has been largely relegated to nonanesthesiology trained physicians or physician extenders. In other settings, the challenge of same-day surgery admission has left preoperative assessment as a day-of-surgery activity; neither of these approaches is optimal. From the standpoint of continuity of care and so that anesthesiologists can implement best practices that contribute to the continuum of care and long-term outcomes, it is essential that anesthesiologists continue to play an integral role in preoperative assessment clinics. This should also be a key component of anesthesia resident training programs, for it represents an important aspect of future anesthesia practice.

Pain Medicine

Doctors cannot always cure disease but they should always try to alleviate suffering. Physical pain is among the most unpleasant of human experiences. Anesthesiologists are often involved in the management of severe pain associated with surgery and the perioperative use of analgesics constitutes an important component of anesthetic care. Anesthesiologists are more comfortable with opiate administration than many other physicians, because of their knowledge of pharmacology (especially opioid pharmacology), as well as their skill and experience in managing side effects such as respiratory depression. Anesthesiologists pioneered regional anesthetic techniques, many of which are applicable to the treatment of chronic intractable pain. Increasing numbers of anesthesiologists are specializing in pain management and the effective relief of pain will remain an important component of the anesthesiologist's role even for those who do not subspecialize specifically in pain medicine.

Critical Care Medicine

Anesthesiologists pioneered the development of critical care medicine.[20] In many countries, anesthesiologists constitute the bulk of the physician workforce in critical care. In most of Europe, full training in critical care is an integral component of an anesthesia residency and critical care anesthesiologists are responsible for organizing and staffing most hospital critical care units. In contrast, U.S. anesthesia residents receive only a few months of critical care training and anesthesiologists constitute a minority of the nation's critical care physicians. Many believe it is important for the future of the specialty that anesthesiologists increase their commitment to critical care medicine. Consistent with this view, there is impetus in the United States to increase the minimum duration of critical care training to 6 months during the anesthesia residency. The intent is to broaden the scope of expertise of anesthesiologists, thus partially addressing the marked shortage of critical care physicians in the United States.[21] Clearly, this would enhance the perception of anesthesiologists as broad-based physicians who can contribute additionally to the general healthcare needs of the United States, but the feasibility of this proposal requires both redesign of the residency programs (including either modifying the duration of the residency or altering the duration of specific rotations in the current residency continuum) and the commitment of future trainees to embrace the practice of critical care medicine.

Clinical Services Administration

The operating suite is a complex environment that is inefficiently managed. Anesthesiologists are an integral component of this important but unwieldy organization. The need for effective management and administration is being increasingly recognized and anesthesiologists are often sought for this management function. In many countries, including in Europe and North America, anesthesiologists are acquiring formal training in management and business administration. Today's doctors, even in academic institutions and national health services, cannot afford to isolate themselves from the realities of reimbursement, cost, efficiency, patient satisfaction, and overall system performance. There appears to be a bright future for physician leaders in healthcare organizations; anesthesiologists are, and will continue to be, an important part of this management evolution.

Patient Safety

Anesthesiologists are at the forefront of pioneering patient safety. So dramatic have been the improvements implemented by anesthesiologists that liability insurance for anesthesia practice has decreased, while that for most other specialties has steadily increased (some dramatically). The Anesthesia Patient Safety Foundation (APSF) was founded in the United States in 1984 with the expressed purpose of assuring *"that no patient shall be harmed by the effects of anesthesia."* Since 1985, the American Society of Anesthesiologists' (ASA) Committee on Professional Liability has been studying records of closed malpractice claims files for anesthesia-related patient injuries.[22] More than 5000 claims have been studied. In 1987, the Australian Patient Safety Foundation was established and the Australian Incident Monitoring Study initiated.[23] More than 4000 critical incidents have been reported through 2000. Analysis of these incidents has reinforced the value of technological advances, such as capnography and oximetry, in improving patient safety. The results also confirm the value of structured algorithms in anesthesia care, by documenting favorable outcomes in a range of life-threatening crises during anesthesia. CEPOD was started in the United Kingdom in 1989. Changes in consultant practice, an increase in the number of medical audits, improvements in physiologic monitoring, appropriate matching of specialist expe-

rience to patient's medical conditions, and increasing awareness of the need for critical care services are believed to have been influenced by this inquiry.[24] Critical events occur within the context of complex system failures, and anesthesiologists have been developing safeguards to decrease the likelihood that human error may result in patient harm. Examples include written "check lists," audible alarm settings, and automated anesthesia machine checks. This expertise in patient safety should be developed and translated into the broader medical context, including application in areas not historically viewed as the purview of anesthesia practice (such as diagnostic and treatment suites, obstetrical suites, intensive care units and intermediate care units).

Research

Anesthesiology has a vibrant history of research and intellectual contributions to clinical medicine. Historically anesthesia research has focused on laboratory investigations in physiology and pharmacology and their application to patient care. These contributions have improved the safety of anesthesia and surgery, and constituted pioneering efforts in the initial application of scientific principles to individual patient care. Until recently many of the scientific questions at the core of anesthesiology have been relatively inaccessible to investigation; this stems from the absence of tools to study the mechanisms of the complex behaviors (e.g., consciousness, memory, pain) that anesthesiologists manipulate. Recent advances in cellular physiology (e.g., patch clamp recording), molecular biology, genetics, functional imaging, and behavioral sciences have enabled serious investigation of these complex behaviors. It is thus now possible that the fundamental mysteries of anesthesia (including the molecular mechanism of the hypnotic, amnestic, and analgesic effects of anesthetics agents) will be solved. These same new scientific tools also make it feasible to define the mechanisms of hyperalgesia and chronic pain and to design effective treatments. Finally, advances in the understanding and manipulation of inflammation and the immune response provide a new opportunity to delineate how organ system injury occurs in the perioperative period and to identify strategies for protection of the brain, heart, kidneys and other organs. Collectively, recent advances in knowledge and technology create an enormous opportunity for anesthesiology to address the scientific questions at the core of the specialty, as well as a variety of important clinical problems.

The application of information technology and epidemiologic techniques (often referred to as outcomes research) to the perioperative period has also created new research opportunities for anesthesiology. These approaches quantify and describe perioperative morbidity and mortality, facilitating recognition of patterns and causes of adverse patient outcomes. Outcomes research has already identified a variety of problems with the process and substance of anesthetic care; it has also led to identification of previously unrecognized adverse patient outcomes (e.g. postoperative cognitive decline). The broad application of information technology coupled to epidemiologic analysis will provide the opportunity to define and monitor "best practices" and to systematically evaluate the efficacy of new technologies, techniques and approaches.

Academic anesthesia has been challenged in recent years, with decreased academic funding of some departments, a decreasing share of extramural grant funds,[25] and a contraction in the number of young anesthesiologists embarking on rigorous research training and careers. One reason put forward for reducing funding for anesthesia research is that the current safety of anesthesia implies that anesthesia research is not a pressing public health concern. As noted earlier, this may be a misconception; although intraoperative mortality is rare, postoperative mortality and major morbidity still occur commonly, and anesthesia care has been shown to contribute to this process, both positively and negatively. There is much room for improvement before any field can conclude that we have overcome the hurdles in surgical care that challenge the extremes of age, those with significant comorbidities or those undergoing extensive surgical procedures. Many of the advances in these areas will come from improved perioperative care, built on evidence-based techniques that are confirmed by careful clinical investigation and innovation. One of the priorities for research, as identified by the National Institutes of Health, is for investigators to embark on more multidisciplinary and multicenter research initiatives. It is also crucial to foster translational research where advances in the basic sciences, including genetics, can lead to progress in the clinical arena. A strong commitment to research will be necessary to ensure the continued advance of the specialty, and to insure that anesthesiology remains a mainstream medical discipline that contributes to the overall good of society.

EDUCATION AND TRAINING

Clearly, the future of the specialty requires a robust commitment to education and training at all levels, from undergraduate medical education through the most advanced subspecialty levels. Strong training programs depend on an excellent teaching faculty, ample and diverse clinical cases, a well-organized teaching program and an emphasis on the knowledge required for future as well as current practice. One challenge facing academic anesthesia in the United States is that reimbursement is halved when a resident provides anesthesia supervised by a teaching anesthesiologist. This reduces the funds available to the academic department for support of nonclinical teaching time, educational resources such as simulators, libraries, or administrative support staff, and compensation for the teaching faculty. The American Society of Anesthesiologists has engaged in a major legislative effort to remedy this funding problem, but resolution of this issue is far from assured because of overall funding limitations and political maneuvering among medical and surgical specialties. Adequate funding for anesthesiology education by the federal government, by teaching hospitals and by our specialty societies is an imperative if the specialty is to flourish in future decades. The current shortfall in anesthesiologists (particularly in teaching hospitals) creates a temptation to increase training numbers and churn out many more anesthesiologists; this may be particularly true in training programs that need to use residents primarily as work force. The danger is that this approach will decrease the selectivity of training programs and downgrade the quality of anesthesiolo-

gists. Training must be broadened as well; if the next generation of anesthesiologists is to be prepared for the future, anesthesiology training programs must emphasize preoperative assessment, critical care, pain management, supervision of nonphysician providers and operating room administration, among others. Also important will be an increased emphasis on fellowship programs, with formal recognition of fellowships in areas such as regional anesthesia, transplant anesthesia, and obstetric anesthesia.

To attract high-caliber applicants to anesthesiology, it is important that medical students continue to receive adequate exposure to the specialty. In addition to perioperative medicine and pain medicine, anesthesiologists are well placed to teach medical students applied respiratory and cardiovascular physiology, several aspects of neuroscience and numerous aspects of pharmacology, in addition to their more traditional educational roles in resuscitation and emergency airway management. The model of academic anesthesia care facilitates excellent learning, with medical students able to spend high quality one-on-one time with experienced anesthesiologists.

SIMULATION

The aerospace industry has long appreciated the value of simulation in increasing safety and decreasing errors. Within the medical profession, anesthesiologists were among the first to recognize the potential role of simulation in improving both education and patient safety. Anesthesiologists established simulation facilities to train anesthesiologists in the management of infrequent but life-threatening problems that arise in the operating room. It rapidly became apparent that simulation might be useful for teaching other topics that are not unique to anesthesia practice (e.g., diagnosis and management of pneumothorax, hemorrhagic shock, myocardial infarction, insertion of central vascular catheters). Computer modeling also can be employed in research. Speculation is rife about a role for simulation in credentialing and recredentialing in various medical specialties. Increasingly, physician and nursing professionals, including those in critical care and emergency medicine, are seeking time in simulation facilities for purposes of training and honing their skills in crisis management. Simulation centers are mushrooming internationally and are also being embraced by medical schools. Anesthesiologists have led this initiative, and it is important that we continue to lead innovation in this field of evolving technology.

Public Perception of Anesthesiologists

Anesthesiology is one of the largest physician based specialties, but few mainstream medical specialties are as poorly understood by members of the public and by other health professionals.[26] Many patients do not realize that anesthesiologists are doctors or that they have responsibilities outside the operating room.[26] In Swiss and Austrian studies 93–99% of patients knew that anesthesiologists are qualified physicians. In addition, many of the patients were aware that the anesthesiologists are engaged in activities outside the operating room. However, many patients also thought that the anesthesiologists played a subservient role to the surgical team.[27,28] In studies from Singapore, Pakistan, and the West Indies, only 56–66% of patients were aware that anesthesiologists are physicians, and most patients had a limited knowledge of the anesthesiologists' roles.[29–31] In contrast to these findings, a Finnish study reported that anesthesiologists were generally recognized as specialist physicians and were held in high esteem.[32] In the United Kingdom, the bodies representing anesthesiologists initiated National Anaesthesia Day in an attempt to increase the profile of anesthesiologists. Clearly, there is variation among countries in the way anesthesiologists are perceived. Heightening public awareness and improving public perception about anesthesiologists and their many essential functions may be important to the future of the specialty in several respects, including allocation of research funding, quality of applicants to residencies and the future role of anesthesiologists within healthcare in general.

A recent Scandinavian study explored perceptions of the anesthesiologist's role. The study was titled: "Professional artist, good Samaritan, servant and co-coordinator: four ways of understanding the anesthetist's work."[33] According to these authors, the current scope of anesthesia practice encompasses:

1. The provision of safe anesthesia while controlling patients' vital functions.
2. Helping patients including the alleviation of pain and anxiety.
3. Providing service to the whole hospital, including support to other doctors and nurses who are caring for severely ill patients.
4. Participation in the organization and direction of the operating suites to ensure that lists run smoothly.

Whereas these are essential and important components of the specialty, even collectively they do not encompass the spectrum of anesthesiology as we view it currently, or as we look to the future, which seems particularly attractive if we maintain a comprehensive view of the opportunities for our discipline.

THE FUTURE OF ANESTHESIA PRACTICE

The future of the specialty depends on several key drivers: (a) the vision and actions of organized anesthesiology; (b) technological changes in surgery and anesthesiology and; (c) the directions chosen by academic institutions, the trainers of future practitioners. These drivers will influence the attractiveness of anesthesiology as a specialty choice for medical students, the career paths of young anesthesiologists, and the scope and organization of anesthetic practice.

There will be tough choices faced by future anesthesiologists. New drugs and increasingly sophisticated monitoring will facilitate safer anesthesia. Such technological advances will allow more effective remote supervision of anesthesia providers. There is likely to be a steady growth in the demand for anesthesia. Anesthesiologists will have to decide whether to try to expand their ranks at all costs and to defend their turf, or refine their training according to future conditions. It is highly unlikely that anesthesiologists alone will be able to meet all the demands for anesthesia.

Anesthesiology faces many challenges in the years ahead. To meet these challenges, perioperative medi-

cine, which includes the spectrum of care from preoperative assessment to postoperative care, may offer the best chance for the specialty to survive and prosper.[34] While there is a vision that future anesthesiologists will practice as much outside as inside operating rooms,[35] the expansion of anesthesiologists' activities could lead to dilution of the specialty's identity, endangering the vitality of anesthesiology in an era of sweeping changes in healthcare-delivery systems.[36] An expansion of anesthesiology practice into nonoperative domains of perioperative medicine may also be challenged by other specialties. The role of perioperative physician may fall to hospitalists, the role of critical care physicians to intensivists and the role of pain management to pain specialists. Anesthesia may grow and acquire new tentacles or it may have its subspecialties amputated, leaving it as a restricted operating room bound specialty (Fig. 2–1). In the United Kingdom, there was a recent struggle in which the Royal College of Anaesthetists opposed efforts to establish a fully autonomous College of Intensive Care Medicine; it is likely that this will be revisited in the United Kingdom and other countries in future.

As an academic specialty, anesthesiology evolved out of fundamental contributions to healthcare, including the prevention of pain from surgery and the development of critical care medicine, cardiopulmonary resuscitation, and pain medicine.[37] In recent years, many advances have occurred in the basic science of anesthesiology, including mechanisms of pain, receptor physiology, modes of action of anesthetic agents, and cellular responses to sepsis. If anesthesiology is to flourish as an academic specialty, it is crucial that research is pursued and encouraged. Without intellectual advances, anesthesiology is in danger of becoming a sterile technical discipline.[37] University departments of anesthesiology are increasingly experiencing pressure to emphasize clinical delivery at the expense of academic pursuits. Succumbing to these pressures will threaten undergraduate perioperative medicine teaching, development of critical appraisal skills among anesthesiologists, and the future of research programs.[38] The irony would be that by immersing themselves entirely in the clinical arena, anesthesiologists would neglect the education of medical students and trainees, thus jeopardizing the future of clinical anesthesiology practice.

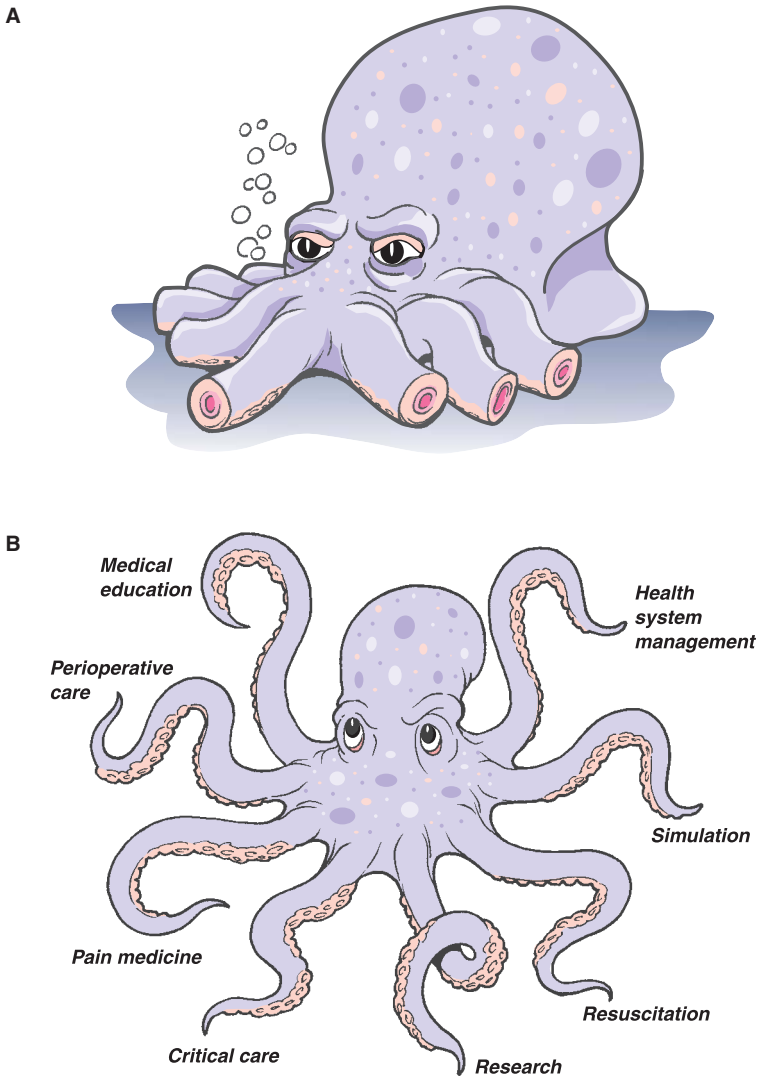

FIGURE 2–1. The future of anesthesiology—two possible outcomes. **A.** The specialty may come to resemble a bloated octopus, based only in the operating room with all its tentacles amputated. **B.** Anesthesiology may retain its integral role in the operating room (lean body), but expand its tentacles in other areas, such as critical care, pain medicine, medical education, health system management, simulation, resuscitation, and research.

Although it is easy to teach others as we were taught, or as we practice today, focus on the future is an essential element of education. Long-term success for the specialty will depend on our efforts in undergraduate and graduate medical education, whereas short-term success will depend on our efforts in the continuing medical education of current practitioners.[39] A different approach may be required to redefine the scope of the practice with broadened training to provide increased expertise in the evolving medical marketplace. This approach could include solid training in business, informatics, data management, and critical thinking on outcomes. This paradigm shift may be challenging, and requires redirection, reallocation of assets, reeducation, and a new mindset. If successfully applied, however, it presents a means to strengthen the respected position of the specialty and to promote the medical care and practice of perioperative specialists in the rapidly changing landscape of modern medicine.[40]

VISIONS OF THE FUTURE

Scenario 1: To Each Patient a Dedicated Anesthesiologist

This is the current model of anesthesia care in much of the developed world

and many in the United States are adherents of this model. Most American residency programs are structured to train anesthesiologists to practice in this model. As discussed earlier, it is unlikely that this model of anesthesia care will be sustainable given the mismatch between surgical demand and anesthesiology manpower and the inevitable pressure to reduce the cost of anesthesia.

Scenario 2: Physicians for the Perioperative Period

Many advocate that anesthesiologists should play a greater role in perioperative care. This is an appealing option, but is fraught with difficulties. An expansion of anesthesiologists' roles will mean that even more anesthesiologists must be trained. There is simply a limited capacity to achieve this. It also is not clear whether anesthesiologists are prepared to financially compete in many perioperative roles. Anesthesiologists are accustomed to high remuneration for their procedure-driven roles, whereas hospitalists are willing to accept lower compensation. Thus far anesthesiologists have not shown enthusiasm in adopting the mantle of perioperative physicians. Tremendous inertia will have to be overcome for this to become a possibility.

Scenario 3: Process Managers and Perioperative Care Directors

To achieve this, anesthesiologists will require formal training in business, management and finance. They will also need to broaden their medical knowledge and experience. Perhaps, most importantly, anesthesiologists would have to be trained to supervise others effectively and to utilize physician extenders throughout the perioperative period. Certified registered nurse anesthetists (CRNAs) are also expensive, and other physician extender roles should be explored. This model runs counter to the current training process. There are anesthesia programs that are offering novel fellowships, such as operating room management. The philosophy behind this model is that anesthesiologists would receive broader training, where operating room anesthesia would be only a component. Fellowships and academic tracks would also increase. If this model is to succeed, residencies will have to undergo major paradigm shifts.

Meeting the Challenge of Change

At the ASA's 2005 Rovenstein Lecture, Mark Warner opined that as long as anesthesiologists remain steadfast in their commitment to the specialty's core values, the specialty would continue to develop as a vibrant academic medical specialty.[41] Dr Warner identified two quintessential values of anesthesiology[41]:

1. Commitment to the care of critically ill patients as well as those experiencing acute and chronic pain.
2. Promoting and improving patient safety in the operating room and in the perioperative period.

Change will be driven by several imperatives, including shifting demographics, technological advances, patterns of surgery, and economic realities. There will be an increasing number of elderly people, high-risk obstetric patients, and children with complex medical problems requiring surgery. It is important to further increase the safety of surgical, anesthetic, and perioperative care to minimize both short-term morbidity and long-term deterioration when vulnerable patients undergo surgery and anesthesia.

Improved monitoring, safer drugs, less-invasive surgery, and sophisticated communication networks may allow anesthesiologists and other anesthesia providers to extend their roles without compromising patient safety. Intensive care units may serve as a useful model. Typically, one nurse attends to 1 or 2 critically ill patients. Usually a small number of physicians, with 1 experienced intensivist, regularly assess all the patients and modify treatment plans over the course of the day. A derivative of this model could be conceptualized for future operating room anesthesia care. As individual patients present with their genetic profiles, it may become possible to tailor anesthetic and analgesic therapy with increased efficacy and decreased side effects. This pharmacogenomic model would represent a major advance in patient safety.

CONCLUSION

Healthcare systems are evolving at a rapid rate. Anesthesiology as a specialty must adapt to the changes so that anesthesiologists remain invaluable and irreplaceable members of the healthcare team. Anesthesiologists must extend their physician skills and increasingly pursue subspecialty fellowships. Anesthesiologists should have a meaningful presence in all areas of medicine. Apart from traditional areas of involvement, such as operating room anesthesia, critical care, pain medicine, teaching, research and resuscitation, there will be future opportunities for anesthesiologists in pharmacogenomics, healthcare systems management, and new technologies.

CHAPTER 3

Safety and Quality: The Guiding Principles of Patient-Centered Care

Jeffrey B. Cooper, PhD, and David Longnecker, MD, FRCA

Anesthesia providers develop a comfort with their craft, despite its inherent dangers. Over time, the administration of potentially lethal drugs, the management of apnea, and the control of altered physiologic systems become almost routine. As experience grows, they may even take for granted the inherently hazardous art and science of rendering patients insensible to pain, unconscious, and paralyzed. Yet, patients do not take anesthesia for granted. To the contrary, many fear it. They fear the possibility of experiencing pain or awareness, as well as the potential for death or other serious complications.[1,2] They also fear what professionals might consider "minor complications." Anesthesia providers may view postoperative nausea and vomiting as minor side effects that pale when compared with the potential life-threatening complications that can occur during complex surgical and medical procedures, but patients often view postoperative nausea and vomiting as dreaded and prominent complications associated with the procedure.

Although this chapter focuses on patient safety and quality, it is firmly based on the concept that the patient is the center of care. The person or team performing the procedure has requirements that must be accommodated in the anesthetic plan. But the patient's concerns, fears, values, and expectations also must be addressed. Although that may seem obvious, historically, the design of healthcare systems, including anesthesia care, has been centered on the needs and convenience of the providers and the facility. The underlying concept was that quality of care alone was enough, whereas quality of service (i.e., "patient centeredness") was relatively insignificant in the process. That concept is changing, but it is not yet fully addressed in many approaches to teaching, education, and practice in anesthesia. Thus, to establish the foundation for talking about patient safety and quality, this chapter begins by emphasizing that patient perceptions must be considered in the design of a safe, high-quality anesthetic experience.

The patient's most fundamental needs are for high quality and complete safety. Meeting these expectations demands knowledge, skills, and continuous vigilance. Equally important is a system that ensures safe practitioners; provides the appropriate drugs, technologies, policies, and procedures to foster safe practice; monitors performance of the entire process (including both outcomes and patient satisfaction); identifies safety and quality problems; and implements corrections. All of these demand a culture of safety and quality at all levels of the system, a culture that supports these needs not just in word, but in deeds and actions.

In 2001, an Institute of Medicine (IOM) committee identified patient safety, quality of care, and patient-centered care (i.e., individualized care) as progressively increasing levels of excellence in the overall healthcare process.[3] This view is consistent with the tenants of other organizations that serve the public while dealing with potentially lethal outcomes (e.g., the commercial aviation industry). In short, safety is the foundation upon which quality (e.g., the application of evidence-based approaches) and then patient-centeredness are built, but all are required to meet the goal of highest-quality care.

The demands for quality and safety start with the patient's needs guided by the needs of the physicians performing the procedure (medical, surgical, or diagnostic) that requires anesthesia care. Quality and safety goals must be met before, during, and after application of the anesthetic, including the various transport processes. Within this framework, constraints are introduced by the needs of all parties in the care process, including the expectations of other clinicians (e.g., surgeon or other operator, medical consultants), facilities (e.g., hospital or ambulatory care site), and the patient (or family or guardian, for example). Sometimes these are competing expectations, requiring thoughtful tradeoffs based on essential priorities. When balancing these tradeoffs, involvement of the patient is a key to positive patient satisfaction with the overall process.

Every subsequent chapter in this text has the delivery of safe and high-quality care as its primary objectives. This chapter defines a strategy and generic principles for achieving these objectives, centering on the patient while also meeting the other demands of modern perioperative care. Subsequent sections in this book provide specific elements of evidence-based anesthesia care that are required to meet these strategic objectives.

KEY POINTS

1. The patient should be the center focus of anesthesia care.
2. The goal of anesthesia care must be to ensure that *no* patient is harmed.
3. Preventing harm is challenging because care is complex, serious adverse events are relatively rare and almost always the result of many causes rather than a single one.
4. Serious adverse events are usually the result of weaknesses in the "system" of anesthesia care, not the fault of incompetent clinicians.
5. To prevent adverse events, a strategy is needed, not simply vigilance.
6. Organizations, departments, and groups must employ a top-down approach and a commitment to creating a safe environment and system for safety.
7. Safety must be the number 1 organizational priority to create an organization that operates at the highest level of reliability.
8. Anesthesia professionals must employ a broad array of safety tactics.
9. Teamwork and communication among the perioperative caregivers are critical components of patient safety.

DEFINING QUALITY AND SAFETY

The key terms commonly used to discuss quality and patient safety are as follows:

- *Patient-centered care* encompasses the qualities of compassion, empathy, open and complete communication, and responsiveness to the needs and preferences of each patient.[3]
- *Quality of care* is the extent to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge.[4]
- *Patient safety* is the avoidance, prevention, and amelioration of adverse outcomes or injuries stemming from the processes of healthcare. These events include "errors," "deviations," and "accidents." Safety emerges from the interactions among the components of the system; it does not reside in a single person, device, or department. Improving safety depends on learning how safety emerges from the interactions of the components through analysis of "near misses" and adverse outcomes or injuries. Patient safety is a subset of healthcare quality.[5]
- *Quality assurance* is the formal and systematic monitoring and reviewing of medical care delivery and outcome; designing activities to improve healthcare and to overcome identified deficiencies in providers, facilities, or support systems; and the carrying out of followup steps or procedures to ensure that actions have been effective and no new problems have been introduced.[6]
- *Adverse event* is an injury that was caused by medical management that results in measurable disability.[7]
- *Accident* is an unplanned, unexpected, and undesired event, usually with an adverse consequence.[8]
- *Error* is when a planned sequence of mental or physical activities fails to achieve its intended outcome and these failures cannot be attributed to the intervention of some chance agency.[9]
- *Human factors* refers to the scientific discipline concerned with understanding interactions among humans and other elements of a system, and to the profession that applies theory, principles, data, and methods to design so as to optimize human well-being and overall system performance.[10]
- *Risk management* is the clinical and administrative activities undertaken to identify, evaluate, and reduce the risk of injury to patients, staff, and visitors, and to identify, evaluate, and reduce the risk of loss to the organization itself.[11]

The concepts of quality and safety are a continuum. There is no uniform agreement on their differences in the larger healthcare community. Some view safety as a subset of quality; most agree that quality care must be founded on safe care. There is perhaps more of an argument for that in the larger world of healthcare and less in anesthesia. One important difference is that quality is generally measured in terms of success in achieving desired outcomes, whereas safety is measured in failures, particularly catastrophic failures. Success in achieving the desired outcomes includes not only a safe experience, but also one that incorporates the elements of evidence-based medicine, especially because personal provider experience is almost never adequate to evaluate either the overall positive or negative consequences of a specific drug, technique, or procedure. Because anesthesia is generally not therapeutic, complete safety must be the most important goal of every anesthetic. Simply stated, this means a goal that *no patient is caused any injury or complication from the effects of the overall anesthesia encounter.* This may seem unattainable. But, as described below, adopting such lofty goals and committing to achieve them leads to greater safety and better care. The concept of healthcare quality has broader implications than safety alone. In the context of anesthesia, quality can be thought of as a balance between providing the patient a healing experience with the least possible pain and discomfort, optimal conditions for surgery, smooth flow of patient care for the organization, and absolutely no injury or unwanted complication caused by the anesthetic.

Because safety focuses on preventing rare events, it is much harder to develop an evidence base for actions that create safety. Randomized controlled trials, while possible for testing many types of quality improvement measures, are almost unheard of for trials of safety measures. Many safety measures arise from investigation of serious adverse events. More intuitive arguments and judgments guide the implementation of safety principles.

To the benefit of all, quality and safety have attained increasing importance in modern healthcare. There is a rich history of attention to quality assurance; that is, attention to the processes of improving care. Those activities can be traced to the work of Donebedian, who developed principles by which quality can be measured and improved for healthcare in general, but with specific applications to hospital care.[12] It was only in the late 1990s that the concept of patient safety was raised to prominence in the broad healthcare environment, a result of a landmark study of medical error.[13] Yet, in anesthesia, patient safety has a much richer history. Indeed, the specialty of anesthesiology is often identified as the earliest adopter of patient safety principles, and lauded for achieving dramatic improvements in outcomes (see Anesthesia Risk and Accidents below for the history of patient safety in anesthesia).

The concepts of patient safety, quality assurance, and risk management are related but have important distinctions. Patient safety is focused on prevention of injury. Quality assurance generally deals with the broader spectrum of quality, including the success of treatments. Risk management historically was directed at managing the aftermath of adverse outcomes, especially to manage legal issues, malpractice, and avoidance of financial loss for insurers. But modern risk management is focused on proactive patient safety, based on the principle that prevention of injuries via error reduction and system improvements reduces the adverse events from which malpractice awards arise.

ANESTHESIA RISK AND ACCIDENTS

The roots of safety run deep in anesthesiology. Dating to the first survey of anesthetic deaths,[14,15] there has been a regular and continuous self-examination within the anesthesia profession

to understand the causes of harm and how to prevent them. In the modern era of healthcare, anesthesia was the specialty that coined the term "patient safety," which is now in the lexicon of healthcare and broadly applied to all medical disciplines.

History of Patient Safety in Anesthesia

The history of safety in anesthesiology may have begun with the first description of an anesthetic death—that of Hannah Greener, who died during administration of chloroform for amputation of her large toe in 1848.[16] This examination of cause illustrates the early focus of anesthesia providers on understanding mechanisms of adverse outcomes and their prevention. Although outcome studies were reported over the years, it was not until the landmark study of Beecher and Todd that a large population was sampled and specific causality suggested.[17] Although that study drew the wrong conclusion from the data, ascribing inherent toxicity to curare, the stage was strongly set to document and enhance the safety of anesthesia care through frequent reviews of outcome and revisions in practice based on these reviews. Other studies followed during the 1950s and 1960s, with a focus generally on the morbidity and mortality associated with general or regional anesthesia, and the cause of death or serious injury in surgical patients.[18,19]

One of the earliest safety interventions of relatively modern times was the development of safety features of anesthesia equipment. Safety features incorporated into anesthesia machines in the 1950s and 1960s are still in use today, including the fail-safe system for protecting against loss of oxygen supply pressure and pin-indexing of gas cylinders to prevent their being interchanged.

The concept of "patient" safety arose in the early 1980s, in response to several factors. The first study of the contribution of human error in anesthesia was reported in 1978, and was followed by later studies of a larger cohort and specific issues of how errors occur and strategies for their prevention.[20,21] In these studies, Cooper et al. studied "critical incidents" gathered in interviews with anesthesiologists, residents and nurse anesthetists from four hospitals. The findings elucidated the mechanisms of what were then called anesthesia "mishaps" as being multidimensional in that a number of errors and other factors contributed to each event. Other reports described attributes of a specific event, disconnection in the breathing circuit, and a generic contributor to critical events, the relief of one anesthesia provider by another. Several studies replicated the methods and general findings in other settings and countries.[22,23]

A "crisis" of increasing costs for malpractice insurance for many medical specialists, especially anesthesiologists, prompted intense interest in reducing settlements for claims through tort reform. More importantly, leadership among the anesthesia community took a then unique approach of concentrated efforts to reduce the number of adverse events that led to claims. The American Society of Anesthesiologists (ASA), under its then president, Ellison C. Pierce, Jr., MD, created a committee on Patient Safety and Risk Management, which likely was the first use of the term "patient safety."[24] In 1984, an International Symposium on Preventable Anesthesia Mortality and Morbidity was held in Boston, and the concept of a directed effort toward anesthesia patient safety was conceived. The Anesthesia Patient Safety Foundation (APSF) was formed in 1985. Its newsletter, research program, and other activities represented the first organized efforts in healthcare to address patient safety as a single topic. The ASA later sponsored studies of closed malpractice claims, which led to numerous reports about causes of the most severe adverse events and their trends.[25]

Many efforts contributed to what appears to be a substantial reduction in catastrophic adverse anesthesia outcomes among relatively healthy patients.[26] Among these were improvements in educational programs, safer drugs and equipment, more intense patient monitoring (especially oxygen analyzers, pulse oximetry, and capnography), and new technologies for managing difficult airways (a specific contributor to numerous severe adverse outcomes). Standards and guidelines for anesthesia care also played a role in reducing adverse events. The Harvard Medical School Department of Anaesthesia promulgated the first standards for care in 1986;[27] these were later adopted by the ASA as national standards. It is claimed that these standards are associated with a reduction in serious outcomes among ASA physical status (ASA-PS) 1 and 2 patients in the ensuing years.[30] Many other standards and guidelines followed. Box 3–1 summarizes key milestones in the path to safer anesthesia care.

BOX 3–1.

Key Influences Leading to Increasing Patient Safety in Anesthesia

- Research in human error, human factors, and closed claims.
- Development and routine use of pulse oximetry.
- Development and routine use of capnometry.
- Enhanced alarms and safety features in anesthesia machines/workstations.
- Development of safer anesthetic drugs.
- Anesthesia Patient Safety Foundation focus on patient safety.
- ASA adoption of standards and guidelines for safe practice.
- Development of new airway-management tools such as fiberoptic bronchoscopy.

Data from American Society of Anesthesiologists: Standards, Guidelines and Procedures. http://www.asahq.org/publicationsAndServices/sgstoc.htm. Accessed May 23, 2006.

A national movement in patient safety was catalyzed by the 1999 publication of the IOM report *To Err is Human: Building a Safer Healthcare System*.[13] This landmark study identified failures in the healthcare system to be an important public health issue and the eighth leading cause of death in the United States. It and subsequent reports recommended fundamental changes in the healthcare system to combat a problem with deep roots in the way patient care is organized (or disorganized), particularly the culture of healthcare that did not place a high priority on the overall safety of patients relative to the delivery of specific services. A federal agency was later assigned to direct U.S. government initiatives to improve safety. Patient safety became a higher priority in the mission of numerous health-related organizations, and the sole mission of others. Anesthesiology was singled out in the IOM's report, and in other writings, as the one specialty that addressed patient safety early and with positive results.

Current State of Knowledge of Anesthesia Risk and Relationship to Error

There is a general belief that the risk of preventable death or injury from anesthesia is relatively low compared to many other medical and nonmedical risks. Yet, there are no accurate estimates of the rate of adverse outcomes in general or for an individual patient presenting with specific risk factors. One reason is that there are no standard methods for assigning causality appropriately among numerous factors that include anesthesia, surgery, the facility (and its systems), and the patient's disease. Particularly in the United States, the fear of malpractice claims hinders reporting and open, candid discussion of errors. Federal legislation, similar to that enacted in Australia in the late 1980s, now protects voluntary reporting, although the process for doing that has not been implemented as of this writing.[28] Despite the absence of strong evidence, estimates of the risk of untoward outcome to a relatively healthy patient are believed to be on the order of 1:100,000 patients.[29,30] However, for patients presenting at greater risk, the risk may be on the order of 1:10,000, which is not different from early estimates for all patients.[29,31] Thus, there remains substantial room for improvement in overall safety of anesthesia. Chapter 24 has a comprehensive discussion of risk, mortality, and morbidity.

ACCIDENT MODELS

Most people, both in and out of healthcare, seek to assign blame to specific individuals for specific lapses in performance associated with an adverse event. Yet, the evidence demonstrates that most injurious accidents are typically complex events for which there is no single cause.[32–34] Although it would be possible to envision a scenario wherein a specific act by one individual led to an accident, assigning such pinpoint causality is not a useful approach to accident prevention. Substantial research is targeted at learning how accidents occur and how humans are involved in that process. The science emerging from that research supports the concept that there are few simple solutions for prevention of accidents. However, it offers possible strategies and tactics for lowering the potential for accidents, by preventing human error and its precursors (i.e., the factors that promote and propagate errors), and by creating resilience in systems to respond to those errors that will inevitably occur despite the best of intentions and preventive actions.

When moving toward a goal of zero failures in patient care, we must consider models for both organizational and individual failure. The goal of adverse event-free anesthesia care can be achieved only by applying a broad spectrum of prevention strategies and building resilience throughout the entire system of anesthesia care, for the overall system is no stronger than its weakest links. This section examines several models and issues at the organizational and human levels to inform our thinking about designing for failure.

The "System" of Anesthesia Care

Before examining models for failure, we need a model for anesthesia practice. Whereas anesthesia could be viewed simply as a single provider administering drugs to a single patient, that narrow perspective does not represent the much more intricate and multidimensional processes that characterize care delivery. Rather, the anesthesia encounter consists of several components that comprise the "system of anesthesia care." The anesthesia processes can be thought of broadly in three phases: preanesthetic planning and preparation, provision of anesthesia for the procedure, and postanesthesia care. Within each of these phases, the anesthesia provider (or providers) performs a set of tasks that are intended to provide quality care for the patient, surgeon, or other operator, and the healthcare organization. Achieving patient care quality and safety requires that these anesthesia activities not be independent from the needs of other providers, allied health professionals, technical staff, support staff, hospital or organization programs, and, especially, not independent of the patient's needs and expectations. The interactions between all of these components comprise a "system" of care that has yet to be fully modeled for the perioperative experience. Furthermore, this "anesthesia system" takes place within a system of systems that comprise the overall course of care, and numerous elements of this larger system may interact with anesthesia care at multiple points in the delivery process; such interactions often contribute to a less-than-optimal experience for the patient.

The Accreditation Council for Graduate Medical Education (ACGME) has established a set of 8 competencies that must be met for all medical trainees.[35] One competency is to understand and know how to practice within a system of healthcare. That requirement arose in recognition of the interdependencies among all the members of the care team and the larger system in which they all operate. In the case of anesthesia, that implies having an understanding of the requirements and needs of all other participants in the perioperative system and implementing an anesthesia plan that appropriately meets these various needs, rather than acting individually in an introverted fashion.

Models of Organizational Failure

Several models offer generic explanations of how accidents occur. James T. Reason is perhaps the most widely cited author for overall conceptual thinking about the mechanisms of human error and system failures, although his work is founded on the basic work of Rasmussen. Their thinking derives from research in high-hazard industries, such as nuclear power, aviation, and chemical manufacture. Gaba has offered insightful interpretations of this work and other research as it applies specifically to anesthesia practice.[34] The basic concepts are relatively simple: Accidents are not one-dimensional; rather, they are the result of the interaction of several elements. There are generic, individual elements that influence the evolution of accidents, but each accident is somewhat unique in the way that elements combine to result in injury. (Note that in the context of "safety," we are addressing only those adverse outcomes that could be prevented given the application of current knowledge; death or injury that appears to be caused primarily by the patient's disease process or the unpredictable influences of drugs or operation, likely cannot be altered by safety

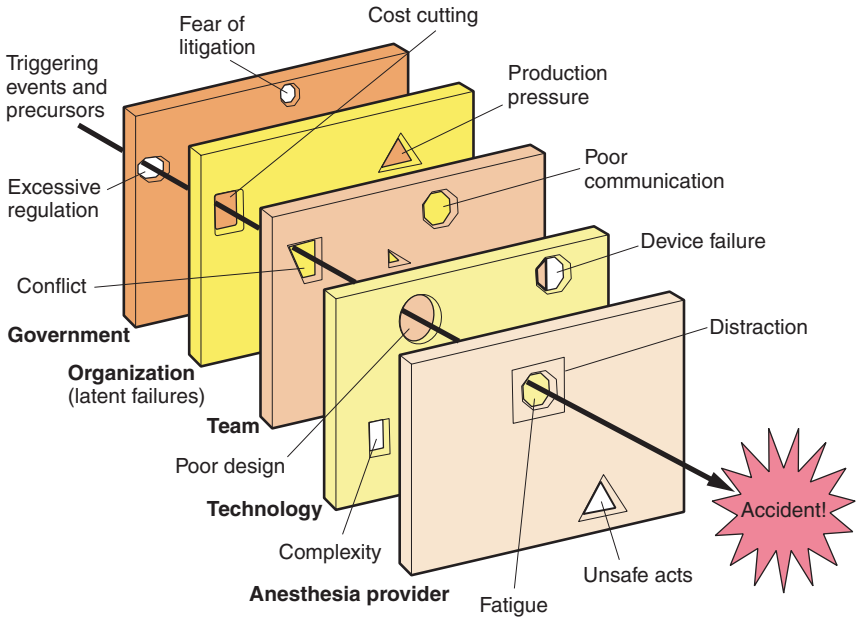

FIGURE 3–1. "Swiss cheese" model of accidents in anesthesia. Reason J. *Managing the Risk of Organizational Accidents*. Aldershot, Hants, UK: Ashgate Publishing; 1997.

interventions.) Reason depicted the process of accident evolution in what is widely referred to as the "Swiss cheese" model (Fig. 3–1).[9]

The "Swiss cheese" model illustrates that accidents are typically the result of a series of events that include precursors, which trigger or allow the chain of events that result in the final (active) adverse event. Reason termed these precursors *latent errors*. This concept is now widely accepted in understanding healthcare system failures. Latent factors are situations that exist on a regular basis within any work environment. They have the potential for influencing the initiation or propagation of an evolving accident. Examples are failure to maintain equipment or replace obsolete equipment; selection of low-quality supply items; poor scheduling practices that promote haste or fatigue; and case scheduling and staffing models that allow assignment of relatively inexperienced clinicians to unfamiliar cases or high-risk patients. Cultural influences are an important source of latent failures. Examples include the pressure to proceed with cases in remote locations where the resources are insufficient to meet minimal anesthesia safety requirements; pressures to move rapidly to avoid "turnover delays;" pressures to assign an experienced provider to a case in order to "keep the schedule moving;" a hostile atmosphere within an operating room that limits preemptive communication of care concerns; and failure to heed a patient's warnings or concerns. Latent errors rarely lead to an immediate accident. Rather, they can be seen as a lurking enemy, or, as Reason called them, "resident pathogens," awaiting the circumstances that will combine to produce a catastrophic outcome, often in ways that are unusual and what may be called "unpredictable." Avoiding the consequences of latent errors requires a broad set of defenses and resilience throughout the system, to mitigate evolving failure that results from alignment of the "holes in the cheese."

Reason's model highlights the need for broad and varying mechanisms to trap errors and failures during the patient's healthcare encounter and thus mitigate or prevent the full cascade from unfolding. His work on managing risk begins at the organizational level and offers a spectrum of strategies and tactics for accident prevention. Both the attitude and actions of the organization and each individual in the chain of care can either bolster or undermine those defense mechanisms.

There is a competing theory that postulates that prevention is not always possible or even probable. The normal accident theory (NAT), as described by Perrow,[32] characterizes some industrial systems as being particularly resistant to strategies for prevention of catastrophic accidents if the systems are both complex and "tightly coupled"; that is, the connections between processes are such that one quickly affects the other in ways that can evolve into an accident that is not predictable by deterministic analysis. NAT does not offer much hope for prevention of accidents in many high-risk industries. Fortunately, although human physiology and all of the processes involved in anesthesia administration may together create a "complex" system, there is not usually the extent of "tight coupling" that is necessary in Perrow's model, although it may occur in certain high-risk patients whose disease processes present a less-stable condition. Still, the NAT view of accidents and how they evolve provides many lessons for anesthesia practice, and for constructing resilient systems to minimize the potential for accidents. Of special concern is that some protections and safety features can actually make systems more complex, mask impending problems, and impart a false sense of security. This concept is an example of how certain prevention or mitigation strategies may affect other parts of the system in unanticipated ways and thus lead to new, unexpected risks. Anesthesia has many examples: Pulse oximetry can lead to practicing closer to the edge of acceptable levels of oxygenation or inappropriate assumptions that a functioning pulse oximeter implies adequate blood flow as well; automated noninvasive blood pressure monitors can fail to cycle and thus continue to present falsely high readings even in the presence of blood loss; or alarms on anesthesia monitors may be turned off to avoid "distraction" during the procedure. Moreover, the relative safety of anesthesia itself has been called an "insidious hazard," for some become complacent about anesthesia care and vigilance and assume that nothing will go wrong, based on prior experience.[21] The development of complacency about safety, based on prior experiences, has led to major disasters in a variety of organizations; a prime example is the loss of the orbiter ("shuttle") *Columbia* on February 1, 2003. The Columbia Accident Investigation Board identified a number of contributing latent factors that resulted in complacency within the

National Aeronautics and Space Administration (NASA), including the acceptance of "normal deviation" and the loss of checks and balances that should have guided NASA safety efforts; many of these latent factors resulted from the lack of serious events in the years immediately preceding the loss of *Columbia*.[36]

Reason's commentary about creating effective defenses against accidents fits well for anesthesia:

> If eternal vigilance is the price of liberty, then chronic unease is the price of safety. Studies of high-reliability organizations—systems that have fewer than their share of accidents—indicate that the people who operate and manage them tend to assume that each day will be a bad day and act accordingly. But this is not an easy state to sustain, particularly when the thing about which one is uneasy has either not happened or has happened a long time ago, and perhaps in another organization. Nor is this Cassandra-like attitude likely to be well received within certain organizational cultures....[33]

Models of Human Error/Failure

The modern theory of accident causality and safety views the human as a component of a system. Most experts now tend to play down the operator's responsibility for accidents, perhaps because so often the attention and blame has been so heavily directed at those who are at what Woods and Cook term the "sharp end" of the pyramid of accident control.[37] In fact, there is substantial evidence about human error and how humans interact with systems in diverse ways to either help or hinder the accident process. This is a topic of serious study that applies to all of society, and numerous textbooks of general and specific areas are available.[9,38] Whereas the vast majority of research has been in industry, most notably aviation and nuclear power applications, there has been substantial study in anesthesia specifically, where the earliest studies and discussions of human error and human factors in healthcare are found.

The studies of critical incidents mentioned earlier identified the basic issue of human error as a component of what were termed "mishaps." Factors associated with mishaps, what would now be called latent factors, were identified, such as lapses in training, equipment design weaknesses, and the contribution of fatigue. In these and other areas, the science of human performance and human factors has revealed much more about the weaknesses of humans and the many ways in which we can fail, including how system design and other factors can influence our performance and conspire to weaken even the most expert clinician.

There has been a strong reliance on "vigilance" during anesthesia as the primary approach to error prevention, so much that the word is the motto of the ASA. Vigilance means sustaining attention.[39] It has been defined as having 3 components: alertness, selection of information, and conscious effort. It is a much more complex process than is immediately apparent, and vigilance is the subject of much investigation in many fields that require sustained attention to assure safety and performance. The observant practitioner is aware of some of the many ways that vigilance can be thwarted and performance degraded. Furthermore, vigilance is only one task of a complex set of tasks that compromise safe anesthesia practice.

Human error in general is the subject of intense investigation in the fields of human factors, ergonomics, and industrial psychology. Again, we look to James Reason for a overview of the subject.[9] Reason built on the work of Rasmussen in defining and characterizing human performance and error. Performance is defined in 3 levels: skill based, rule based, and knowledge based. Error is defined as the failure of planned actions to achieve their desired ends without the intervention of some unforeseeable event. Errors are divided into 2 main types: slips and mistakes (Box 3–2).

These definitions do not of themselves help prevent errors, but the thoughtful practitioner will consider that his or her slips and mistakes vary in type and cause, most of all recognizing that all forms of error require efforts toward prevention and mitigation of the consequences of those errors that occur despite the best of efforts.

Many factors influence vigilance and performance (performance-shaping factors), including fatigue and sleep deprivation, environmental influences, production pressures, human-interface design, and teamwork. Other factors associated with adverse events in anesthesia that either may promote errors or foster their propagation have been identified.[20,21] We consider some as examples of the kinds of issues that anesthesia providers must address to maintain accident-free performance throughout a professional career. Measures to prevent performance decrement or to help maintain optimal performance are described in Creating Safety at the Organizational and Department Level below.

BOX 3–2.

Slips and Mistakes

Slip: The plan is adequate but the actions fail to go as planned. These are unintended failures of execution, also referred to as lapses, trips, or fumbles. They are further divided into attentional slips of action and lapses of memory.

Mistake: The actions conform to plan but the plan is inadequate to achieve its intended outcome. Mistakes are divided into rule based (e.g., misapplication of normally good rules but not correct for this situation) and knowledge based (e.g., incorrectly thinking out a solution for which there is not a prepackaged solution).

Fatigue and Sleep Deprivation

There is recent evidence (in trainees) that shows a clear association between sleep deprivation and human errors, including lack of attention to task, serious auto accidents, and medical errors involving both diagnosis and treatment.[40–42] There are many examples of large-scale industrial accidents where sleep deprivation or fatigue was identified as a major contributing factor.

Howard et al. reviewed the literature on sleep and fatigue with particular reference to anesthesia.[43] Among the key findings were the following: (a) Inadequate sleep degrades performance; (b) Individuals require different amounts of sleep to feel awake and alert; (c) The failure to obtain adequate sleep results in a sleep "debt" that is cumulative and can only be diminished by sleep to pay back the debt; (d) Circadian rhythms have an important influence both on the tendency to sleep and the ability to sleep. The circadian lull associated with degraded performance is between 2 and 6 A.M. and 2 and 6 P.M.; and (e) Stimu-

lants such as caffeine can aid in maintaining alertness and wakefulness, but side effects must be understood in order to use these effectively.[44]

Transitions Among Care Providers ("Handoffs")

There are conflicting findings about the impact of handoffs among anesthesia providers to mitigate the effects of fatigue, boredom, hunger, and so forth. Cooper et al. examined critical incidents associated with relief of one anesthesia provider by another.[45] They concluded that, overall, relief provided more benefit from detecting undiscovered problems than harm from transferring responsibility to a provider with less serial knowledge of the specific patient and procedure. These conclusions were verified by interpretation of data from a similar study by Short et al.[46] More recently, Arbous et al. found that a change of anesthesiologists was associated with a greater incidence of severe morbidity and mortality.[47] Yet, routine breaks are generally found to be useful and necessary in anesthesia and in high-hazard industries. Provisions for adequate transfer of critical information and situational awareness are required. Cooper suggested a specific set of guidelines for conduct of handoffs, which was recently updated.[48,49] The hazards of transitions in care are now more widely recognized in healthcare and receiving increasing attention for remediation. More handoffs now occur among trainees as a result of the recent ACGME work-limitation requirements that are intended to mitigate the consequences of sleep deprivation and fatigue.

Environmental Factors

Many environmental factors can affect the performance of the anesthesia provider. Among these are noise, extremes of temperature and humidity, lighting, and toxic vapors.[39] Listening to music or reading during anesthesia administration are controversial issues with conflicting tradeoffs.[50,51] There are no robust studies in healthcare, nor simple extrapolations from studies in other fields, to guide the development of evidence-based standards. Rather, good judgment appears to be the best guideline. Background music can alleviate stress and boredom, but different musical tastes may lead to different effects among all on the operating team. Loud music or other noises can obscure verbal communications and be especially disruptive during periods of high workload or management of critical events. Similarly, reading in the operating room could alleviate boredom during uneventful intervals, but it could also foster a lack of vigilance and alertness. Reading appears especially problematic intuitively, and would be difficult to justify during an accident investigation involving pilots, air traffic controllers, or anesthesia providers, among others.

Human Factors and Human Interface Design

Human factors engineering (HFE) is a broad topic that encompasses all of the different aspects of the ways in which humans interact with systems.[38] The importance of human factors, especially the design of the human–machine interface, is well known in other fields, but greatly underappreciated in healthcare.[10] Human error can be either encouraged or discouraged, depending on the attention given to understanding human limitations and the ways in which humans interact with the machines and technologies. The goal of HFE is to "design tools, machines, and systems that take into account human capabilities, limitations, and characteristics."[52] Given that anesthesia is very technology-intensive, human factors issues play an important role in prevention of errors and adverse outcomes.

Several studies have examined the anesthesia work environment, the tasks of anesthesia providers, and how the design of displays and alarms impact on ease of use and errors.[39,53,54] The results indicate that technology is not generally well designed to accommodate the ways people use it. There are numerous examples of how the design of a device interface can be especially dangerous.[55–57] The design of anesthesia monitors is particularly problematic, especially when the anesthesia provider works in facilities that have various models or different suppliers of devices. Software complexity, for example, the depth of menus, excessive flexibility in options for alarms, and displays, can cause confusion and distract the provider from other important tasks that should be higher priority.

Production Pressure

Production pressure refers to "overt or covert pressures and incentives on personnel to place production, not safety, as their primary priority."[58] Based on a survey of anesthesiologists in California, Gaba et al. reported that nearly half of the respondents had witnessed instances of what they believed to be unsafe actions by an anesthesiologist because of production pressure.[58] These included internal pressures (e.g., to foster good relations with a surgeon, accrue personal income) and external pressures (e.g., proceed rather than cancel a case to appease patient or family, accept an unfamiliar patient or procedure to foster facility throughput).

Teamwork

The importance of good teamwork and communication is now more widely recognized in healthcare, especially for surgical teams. A substantial body of literature from high-hazard domains, especially aviation, and in healthcare, demonstrates the value of teamwork for successfully preventing and managing critical situations.[59–61] Gaba et al. were the first to develop teamwork and crisis management training techniques for healthcare, adapting crew resource management (CRM) techniques from aviation for applications in anesthesia.[62] These approaches have since been extended to nearly all healthcare settings but are particularly applicable to those where rapid action is required to successfully treat acute complex events, such as dire surgical emergencies.[63]

A team can be defined as "two or more individuals who have specific roles, perform interdependent tasks, are adaptable, and share a common goal."[59] Box 3–3 lists some characteristics of effective teams.[59,64,65] These definitions and characteristics, derived from other industries, generally apply to healthcare and to anesthesia practice. Anesthesia providers have a varying dependency on others, depending on the setting and circumstances. Good teamwork can prevent errors or prevent them from propagating. Teamwork is vital to the successful management of critical events. The team within which anesthesia providers work varies depending on the setting, but it typically has a surgeon, a circulating nurse, a surgical technician, and other support personnel, including environmental workers, technicians (e.g., blood bank, laboratory, or radiology), and clerical personnel. Within the broad system of care, the team can include those who provide care pre- and postoperatively and specialists,

BOX 3–3.

Some Effective Practices of High-Performance Teams

- Introduce all members of the team to each other at the start of each procedure.
- Regularly conduct *preoperative briefings* with the entire operative team, which can be done via a specific checklist as described by Lingard.[64]
- Use specific *communication protocols* within the team (SBAR is gaining increasing acceptance. It calls for a specific sequence for describing the patient's status: describe the Situation, the Background, Assessment, and Recommendations [SBAR]).[65]
- Establish communication standards such as "read-back" of all verbal orders, e.g., medications.
- Conduct *debriefings* with the team following unusual occurrences, near misses, or critical events.
- Establish an environment that encourages cross-monitoring and backup behaviors across the entire team.
- Create a language that signifies recognition of potential hazards.
- Practice for emergency situations (Box 3–4).

such as radiologists, pathologists, and intensivists. The immediate operative team has been given the most attention for training and research.

Surgical teams have several distinguishing features that create obstacles to effective performance. The hierarchy in surgical care places physicians above other workers. It is common for surgeons to be accorded higher status and to assume a self-designated role of "captain of the ship." Whereas leadership is a key feature for team success, the person in that role should vary depending on the situation. Similarly, anesthesia providers may treat other team members as subordinates rather than colleagues. High-reliability organization (HRO; see The Elements of Safe, High-Quality Anesthesia Care/The High-Reliability Organization Model) theory, which is based on characteristics of organizations that function at high levels of safety, calls for a nonhierarchal culture in which the leader is the one with the most expertise, not the highest status. Conflict among these roles can be problematic in management of acute operative events, especially when the care team does not work together regularly (e.g., during nights and weekends when the care team consists of "night call" personnel from various work rosters).

CRM techniques have been applied for training teamwork skills and performance. There are now many different approaches to such training but the principles are generally the same. Teamwork needs should be assessed for the specific environment; all team members must be motivated and engaged in accepting the need for teamwork and agree about skills and behaviors they will adopt; those behaviors must be taught and practiced via drills; and the behaviors assessed and periodically reinforced via more drills and didactic sessions.[59]

In anesthesia, simulation of the patient and environment in which anesthesia is administered has been employed, both for motivation and for training of technical and nontechnical teamwork skills.[66,67] The level of realism (fidelity) employed varies depending on the training objectives and philosophy.[68] One of several models of computer-controlled mannequin is used to simulate the patient, whose physiology, anatomy and life signs can be varied to simulate normal or abnormal situations.[66,69] In high-fidelity simulation, props and actors are employed to create realism, which is believed to strengthen the engagement of the learners. The early applications were for the anesthesia "crew" of the larger surgical team. More recently, simulations have involved training for entire operative teams. CRM concepts are the basis for training in behavioral skills. Prominent among these is the concept that all team members are expected to communicate openly, ranging from confirming a directive (e.g., "heparin, *xx* units, has been administered," "I'm confirming that these are Mrs. Jones' radiographs"), to speaking out when a concern for safety exists (e.g., "Are you sure you should be prepping the right hand? The consent says left." or "Have you noticed that this patient's blood pressure has been falling over the past several minutes?"). Training sessions use patient-care scenarios to elicit treatment responses from the individuals or teams being trained. Debriefing using videotapes of the session are conducted to review actions. There is some evidence that such sessions can effectively instill good team behaviors.[70] Team training without simulation also is effective, as is the combination of both approaches.[61,71]

SOME SPECIFIC HAZARDS ASSOCIATED WITH ANESTHESIA

There are a seemingly infinite number of case reports of specific hazards and complications of anesthesia that were largely preventable, although a litany of isolated cases is perhaps less helpful than a series of organized observations. Studies of closed malpractice claims, funded by the ASA, have examined many of these events in a more systematic manner, one that assists in developing action plans for reducing risks. These closed claims studies have explored several categories of adverse outcomes, the most notable addressing errors related to airway management, monitoring, sudden cardiac arrest during spinal anesthesia, equipment failures, or nerve injuries.[25,72,73]

The Australian Incident Monitoring project analyzed 4000 critical events and developed an algorithm (COVER ABCD: A Swift Check) that accounts for the majority of common anesthetic emergencies (Box 3–4)[74]. Use of the mnemonic will prevent injury in the majority of cases if specific practices are followed. A detailed review of even a substantial subset of these concepts is beyond the scope of this chapter. Rather, we present here examples of the types of failures that establish an argument for having organized principles for general prevention of errors. Analysis of these types of events also suggests tactics that could reduce the likelihood that these would become a trigger or propagator of an accident chain.

Adverse Respiratory Events

Events associated with management of respiration are the most serious remaining hazards in anesthesia, as evidenced by data from the ASA closed claims analyses.[73] The three most common causes of death and brain damage are inadequate ventilation, esophageal intubation, and difficult tracheal intubation. The large majority of cases in the first 2 causes were judged to have been preventable

BOX 3–4.

Crisis Management Algorithm—Memorize and Practice: An Explanation of Each Cue in the Mnemonic COVER ABCD[74]

C1	Circulation	Establish adequacy of peripheral circulation (rate, rhythm, and character of pulse). If pulseless, institute cardiopulmonary resuscitation (CPR). The core algorithm must still be completed as soon as possible.
C2	Color	Note saturation. Examine for evidence of central cyanosis. Pulse oximetry is superior to clinical detection and is recommended. Test probe on own finger, if necessary, while proceeding with O1 and O2.
O1	Oxygen	Check rotameter settings, ensure inspired mixture is not hypoxic.
O2	Oxygen analyzer	Adjust inspired oxygen concentration to 100% and note that only the oxygen flowmeter is operating. Check that the oxygen analyzer shows a rising oxygen concentration distal to the common gas outlet.
V1	Ventilation	Ventilate the lungs by hand to assess breathing circuit integrity, airway patency, chest compliance, and air entry by "feel," careful observation, and auscultation. Also inspect capnography trace.
V2	Vaporizer	Note settings and levels of agents. Check all vaporizer filler ports, seatings, and connections for liquid or gas leaks during pressurization of the system. Consider the possibility of the wrong agent being in the vaporizer.
E1	Endotracheal tube	Systematically check the endotracheal tube (if in use). Ensure that it is patent with no leaks or kinks or obstructions (see suggested protocol in Anaesth Intensive Care 1993;21:615). Check capnograph for tracheal placement and oximeter for possible endobronchial position. If necessary, adjust, deflate cuff, pass a catheter, or remove and replace.
E2	Elimination	Eliminate the anesthetic machine and ventilate with self-inflating (e.g., Ambu®) bag with 100% oxygen (from alternative source if necessary). Retain gas monitor sampling port, but be aware of possible problems.
R1	Review monitors	Review all monitors in use (preferably oxygen analyzer, capnograph, oximeter, blood pressure, electrocardiograph, temperature and neuromuscular junction monitor). For proper use, the algorithm requires all monitors to have been correctly sited, checked, and calibrated.
R2	Review equipment	Review all other equipment in contact with or relevant to the patient (e.g., diathermy, humidifiers, heating blankets, endoscopes, probes, prostheses, retractors, and other appliances).
A	Airway	Check patency of the nonintubated airway. Consider laryngospasm or presence of foreign body, blood, gastric contents, or nasopharyngeal or bronchial secretions.
B	Breathing	Assess pattern, adequacy, and distribution of ventilation. Consider, examine, and auscultate for bronchospasm, pulmonary edema, lobar collapse, and pneumo- or hemothorax.
C	Circulation	Repeat evaluation of peripheral perfusion, pulse, blood pressure, electrocardiograph, and filling pressures (where possible) and any possible obstruction to venous return, raised intrathoracic pressure (e.g., inadvertent peak end-expiratory pressure) or direct interference to (e.g., stimulation by central line) or tamponade of the heart. Note any trends on records.
D	Drugs	Review intended (and consider possible unintended) drug or substance administration. Consider whether the problem may be a consequence of an unexpected effect, a failure of administration, or wrong dose, route, or manner of administration of an intended or "wrong drug." Review all possible routes of drug administration.

Runciman WB, Kluger MT, Morris RW, et al. Crisis management during anaesthesia: the development of an anaesthetic crisis management manual. Qual Saf Health Care 2005;14(3):e1. With permission from the BMI Publishing Group.

if "better monitoring" had been employed. For management of the difficult airway, prevention is more challenging. Peterson et al. reported that "Persistent failed attempts at intubation were associated with an outcome of death or brain damage in claims in which a 'cannot ventilate and cannot intubate' emergency situation developed prior to surgical incision." [75] They concluded that this was confirming evidence for limiting conventional ventilation efforts to 3 attempts before using other strategies. Despite substantial advances in technologies that aid endotracheal intubation and some helpful, although far from foolproof, methods of airway assessment, there remain many opportunities for unanticipated difficulties with airway management, tracheal intubation, and effective ventilation (see Chaps. 12 and 35). Each is an opportunity for a serious adverse outcome. Although airway management skills are greatly emphasized during training, there is great variance in experience and abilities among anesthesia providers, as are the opportunities to practice emergency skills. Thus, periodic retraining and practice in the application of difficult airway management protocols is prudent. (This is an example of the value of simulation as a tool for learning and maintaining skills that may be needed infrequently, but which are essential for patient safety.)

Monitoring and Alarms

Failure to monitor the patient adequately is an important contributor to anesthesia adverse events, both in critical incident studies and in the closed claims studies. Aside from failures of vigilance, which are often related to performance-shaping factors, monitoring technology design and lack of experience with technology can contribute

to adverse outcomes. There are numerous ways in which pulse oximetry, capnometry, and automated noninvasive blood pressure monitors can give false information, leading to missed or incorrect diagnoses. The failure to use alarms has led to a requirement in the relevant standard that when a pulse oximeter is used, the variable pulse pitch tone and low-threshold alarm of the oximeter must always be audible.[76] Similarly, when capnography or capnometry is used, the end-tidal CO_2 alarm must be audible.

Medication Errors

Medication errors are among the most frequent errors in anesthesia, and in healthcare practice in general.[21] Similarity of drug names, containers, and label colors contribute to the ease by which such errors can be made, especially during periods of high stress. Dosing errors are also common and related to the frequent need for individual numerical calculations when drawing and mixing drugs for bolus administration or intravenous infusion. Choosing the wrong form of drug (e.g., among various insulin formulations), flushing a catheter with a solution containing another potent drug, and confusion in the programming of infusion pumps are other examples of ways in which patients can be injured.

An obvious recommendation for prevention of some medication errors is to admonish the provider to read the label carefully.[77] Another tactic is to read each label 3 times. Yet, human factors issues are widely recognized as contributing greatly to medication errors, especially because of similarity of drug names, the small or obscure print on vials or ampules, and the failure to organize medication carts optimally to avoid errors. Distractions and production pressure also are likely contributors to medication errors. No universal remedy for prevention has been identified. There is a standard for label colors and grouping by drug type, but some argue that it is unlikely to be effective and, if anything, all drug labels should be in black and white to force careful reading of the drug identity and concentration.[78]

Errors in Diagnosis

Diagnostic errors are likely underreported because of the difficulty in their identification. Yet it is likely that diagnostic errors occur, especially during the management of critical events. Gaba has described 3 forms of fixation errors, including "this and only this" (fixating on a single diagnostic possibility to the exclusion of others, a form of "tunnel vision"), "everything but this" (searching among many possibilities but not including the real explanation) and "everything's OK" (persistent belief that there is no problem in spite of substantive signs that there is a problem).[62]

Equipment Errors and Failures

Current anesthesia machines and associated technology incorporate substantial safety features (see Chap. 38), which have been developed over decades in response to specific series of patient injuries associated with failure or misuse of equipment. Equipment failure is frequent and can occur in many ways, but rarely causes injury directly.[21,79,80] When there is an equipment-associated injury, it is more likely to be from misuse than from overt failure of a device. Whereas the end user may be at fault, human factors research dictates that causes related to the design of technology and the lack of training and practice are equally, if not more, responsible. Among the legendary failures associated with poor human factors are the failure to turn on a ventilator that was briefly suspended during measurement of cardiac output or performance of radiologic studies, or the accidental, unnoticed disconnection of an intravenous or arterial pressure cannula leading to blood loss or failure of fluid or drug administration. Users can reduce hazards by ensuring they obtain adequate training before using a new device, conducting a systematic preuse inspection of devices, and using backup monitoring devices as aids to vigilance. Never turning off an alarm is an essential precept to safe care.

Errors Associated with a Lack of Standard Practice and Unusual Situations

The complexities of anesthesia create many opportunities for preventable adverse events caused by unusual circumstances or pitfalls. Goldhaber-Feibert and Cooper, taking from a convenient sample of clinician experiences, offers numerous examples)[49]:

- A Passy-Muir valve (PMV), a form of "talking" tracheotomy tube, left on a tracheostomy when inflating the cuff to deliver positive-pressure ventilation causes repeated inflation of the patient's lungs with no mechanism for exhalation.
- An emergency can arise during transport of the intubated patient if the tracheal tube is accidentally dislodged.
- Administration of undiluted phenytoin (Dilantin) by rapid intravenous infusion can cause refractory hypotension, arrhythmias, and death.
- Administration of undiluted potassium by rapid intravenous infusion can cause ventricular fibrillation and cardiac arrest.
- Neostigmine given without an antimuscarinic drug (e.g., glycopyrrolate) can cause asystole/severe bradycardia and atrioventricular (AV) block, and can be fatal.
- Inadvertent intravascular injection of local anesthetics during a nerve block can cause neurologic and cardiac toxicity, which can be fatal (especially with bupivacaine).
- Air embolism can occur during the placement or removal of central venous catheters.
- Limb necrosis can develop if the tourniquet used for intravenous placement or blood draw is left on the anesthetized patient for a prolonged period.
- Intracranial pressure (ICP) may be increased if a ventriculostomy drain is connected to a pressurized bag of heparinized saline (in a patient who likely already has a high ICP).

Even though these situations are likely obvious to experienced clinicians, they might occur under periods of stress and might not be obvious to the uninformed neophyte. Learning may arise haphazardly in the absence of a systematic approach to training.

THE DIMENSIONS OF QUALITY

Despite the widespread use of the term by both the public and the professions, *quality* in healthcare continues to have multiple meanings, depending especially on the views of the beholder. However, few would deny that the concept of quality care has gained increasing importance over the past 2 decades, as both health professionals and the public have focused greater

attention on this aspect of healthcare delivery. A discussion of all aspects of quality goes beyond the bounds of this chapter, but focus on some of the key concepts is appropriate if anesthesia providers are to become full participants in the quality movement, a prominent force in the early 21st century. Our comments are limited to some of the essential features of quality and its application to anesthesia practice.

What is quality as applied to healthcare? "Quality" is an abstract concept, with little intrinsic meaning. Rather, it represents the extent to which the expectations of healthcare consumers are met by healthcare providers, whether that consumer is the patient, a professional colleague, the payer, or the facility that provides resources for the care delivery. In this context, the "consumer" of anesthesia services includes not only the patient, but the surgeon or other operator who requires anesthesia services to perform a diagnostic or therapeutic procedure.

Numerous definitions of quality exist, but perhaps the most widely accepted definition is that of the IOM, which we noted earlier: Quality is the "extent to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge."[4] Thus quality represents not a distinct entity or end point, but a continuum in the process of meeting the rational expectations of others who interact with the providers of healthcare services. Two major concepts are inherent in the IOM definition of quality: measurement (i.e., "outcomes") and evidence-based care (i.e., "current professional knowledge"). Inherent in the definition of quality is the view that safety is the essential foundation for quality, and that high quality practice cannot be achieved in the absence of safe practice. Figure 3–2 illustrates these concepts.

Donabedian, a leader in the genesis of the quality movement, proposed that quality could be evaluated by examining its major components: structure, process, and outcomes.[12] Structure involves the facilities and environment in which care is delivered (e.g., governance, policies and procedures, and specific details, such as cleanliness, attractiveness, ease of access, noise levels, privacy); process involves how care is actually delivered, including the interactions between clinicians and patients (e.g., the elements of communication including listening, sensitivity, compassion, the development of trust); outcomes involves measures of results of the care provided (e.g., mortality, morbidity, speed of recovery). Inherent in these evaluations of quality are the patients' perspectives on each of these areas, whereas historically, both clinicians and facilities focused primarily on the technical aspects of care delivery. Thus the role of the consumer (especially the patient) in the evaluation of healthcare quality has increased considerably in recent years.

Building on these concepts, the IOM has gone further in defining quality, by identifying 6 desired characteristics of healthcare. Thus high-quality care should be safe, timely, effective, efficient, equitable, and patient-centered (often abbreviated as STEEEP, for ease of recall). Here, also, the concepts of measurement and current knowledge are apparent throughout.

Although recent quality initiatives have focused on the patient–provider relationship, there are other dimensions of healthcare delivery that require attention for both safe and high quality practice. The relationships among providers are key elements in the care process, especially in an era when complex care management is provided by specialists and subspecialists who focus on specific aspects of care. That complexity often leads to communication lapses and fragmentation without subsequent integration into a coordinated system of care that focuses on the patient's needs for understanding, planning, and decision making. Thus patients often rate communication as one of the most important components in the evaluation of quality healthcare, whereas physicians often rate technical abilities as considerably more important than communication.[81]

Eliminating these lapses in communication is essential for both patient compliance and patient satisfaction; eliminating the lapses benefits both process and outcome in the delivery of care. Furthermore, it minimizes the frustrations that patients and families experience as a result of conflicting or inadequate communications among professionals, leading to mistrust of the provider by the consumer. Finally, the development of relationship-centered care teams, wherein all parties have developed a pattern of open communication and mutual respect and trust, increase both safety and quality in multiple industries, including healthcare.[82]

These concepts apply as much to the discipline of anesthesiology as to other disciplines in the healthcare delivery process. Anesthesia providers, as individuals and departments, must institute these principles, including practical measurement of outcomes

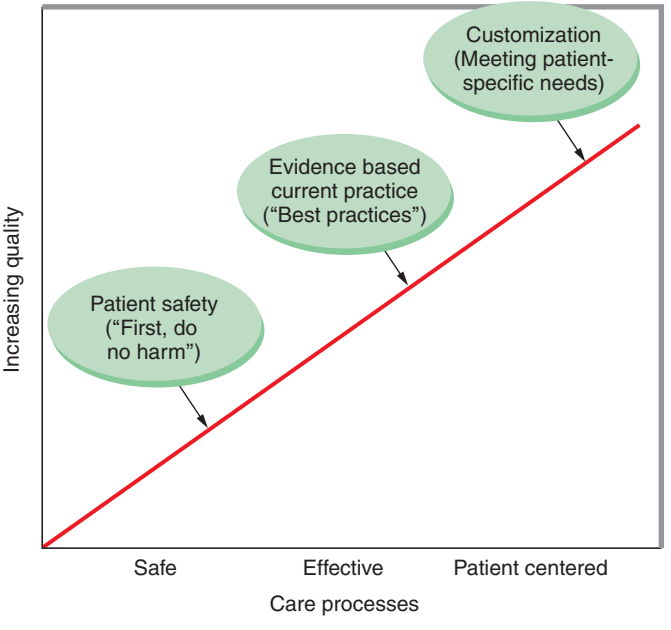

FIGURE 3–2. The relationship between safety and quality and the process of care.

and the development of relationship-centered clinical teams, if they expect to practice at the higher levels of the quality spectrum (i.e., beyond the fundamental level of safe practice).

THE ELEMENTS OF SAFE, HIGH-QUALITY ANESTHESIA CARE

Creating a safe, high-quality practice of anesthesia depends on a combination of broad strategies and effective tactics for day-to-day work. Many models for establishing safe environments and practices and for ensuring quality have been described, but there is no empirical evidence from controlled studies to demonstrate that a specific model is superior to other models. Still, there is face validity from qualitative studies in specific industries and organizations to suggest that having an overall systematic approach leads to both safer and higher quality care. Indeed, a recent combined report from the National Academy of Engineering and the IOM emphasized that systems approaches to healthcare delivery were most likely to transform healthcare to deliver the goals of safe, timely, effective, efficient, patient-centered care in the future.[83]

The High-Reliability Organization Model

Although several models have been promulgated for managing quality (see Chap. 25), there are fewer directed primarily at safety. For the latter, the concept of the HRO was formulated from observations in highly hazardous industries that, despite operating under conditions of high risk, have many fewer serious accidents than expected.[84,85] Such industries included naval aviation, nuclear power, and offshore oil platforms. Weick and Sutcliffe further describe how organizations can be successful if they appropriately "manage uncertainty."[86] Gaba applied these concepts to healthcare.[34] Although there is no single, accepted model of an HRO, Weick lists the following elements that characterize a typical highly reliable organization:

- *Preoccupation with failure*—Despite its good safety records, an HRO will constantly be on the lookout for any signs of weak systems or impending failure. An HRO assumes that failure is imminent and plans for the worst. In anesthesia, this extends to organizational and individual planning for potential failures or problems in every procedure.
- *Reluctance to simplify interpretations*—Managers often look for simple answers to problems. In an HRO, interpretations are more nuanced and skepticism about apparent explanations is encouraged. Rather than simply blaming the people who are the proximal agents in a causal chain of events, an HRO seeks to understand the latent failures that led to an individual's failure to perform flawlessly.
- *Sensitivity to operations*—An HRO pays close attention to how work actually gets done on the frontline rather than merely proposing solutions that appear reasonable from a distance. Cook wrote about the danger of ignoring the ways in which workers must act to do their jobs, often needing to circumvent rules made by managers or regulators who do not understand the complexity and challenges in healthcare systems.[37]
- *Commitment to resilience*—The HRO understands that regardless of its best efforts, things do go wrong and people do make mistakes. An HRO "develop[s] capabilities to detect, contain, and bounce back from those inevitable errors that are part of an indeterminate world." In the operating room, this translates to ensuring adequate backup of personnel, supplies, and equipment.
- *Deference to expertise*—During a crisis in an HRO, decision making falls to the person most experienced in dealing with that kind of problem, not to the most senior person. A good leader seeks out that expertise rather than squelching disagreement or demanding loyalty.

Another critical feature of an HRO is that safety is the highest priority over all other concerns. That is, the interests of production and speed are not allowed to supersede the need to ensure safety.[34] Another element of HROs, one that has direct implications for anesthesia practice, is the need for intensive and regular training, especially with simulation.[87] For high-hazard industries that face rare events requiring expertise to avoid an adverse outcome, frequent training and practice are essential; all of these conditions are met in the practice of anesthesiology.

HROs are also noted for organizational learning, especially from accidents and near misses. Healthcare recently embraced the process of root cause analysis (RCA).[11] An RCA is applied to unusual, potentially harmful events in an effort to understand the many elements that contribute to an event and use the findings to design and implement corrective interventions (see Chap. 25 for more detail on RCA). Failure mode and effect analysis (FMEA) is one of several industry techniques to study new processes proactively, before an adverse event occurs.[88] The FMEA is used to identify potential failure modes and key points where barriers are needed to minimize the potential for failure (see Chap. 25 for a more detailed discussion of RCA and FMEA as risk-reduction strategies).

Vaughan described the concept of "normalization of deviance" that arises when an otherwise safe organization drifts into unsafe conditions.[89] In analyzing the sociologic features of the disintegration of the *Challenger* orbiter ("shuttle") in 1988, Vaughan identified how NASA, under intense financial and political pressures, evolved from an organization that had once highly valued safety to one that gave production a higher priority. This led to what she called a "normalization of deviance" in the way engineers made decisions about safety issues. Rather than demanding that assurance of safety was the highest priority at each step, the "burden of proof" had shifted—to cancel or delay a launch, engineers were asked to prove that conditions were unsafe, where previously, to allow a launch, they were required to prove that each item was safe. This critical shift in emphasis has direct applications to anesthesia and surgery.

To ensure safety, strategies and tactics must be implemented at all levels throughout an organization, from senior management to bedside provider. That process has 2 major elements of responsibility: the organization and the individual.

Creating Safety at the Organizational and Department Level

The organization is responsible for creating a safe culture throughout its various levels.

Culture is the "shared values and beliefs that interact with an organiza-

tion's structures and control systems to produce behavioral norms."[33] More simply stated, it is "the way we do things around here." Cultural characteristics are usually deeply ingrained, not immediately visible, and often difficult to modify. Yet, it is the culture that defines the overall commitment to safety of an organization. Although highest reliability can likely only be achieved within a consistent culture of safety across an organization, the perioperative subcultures and anesthesia practices and departments can establish strong safety cultures within their sphere of influence. Batalden refers to these smaller elements as "microsystem environments," and emphasizes that safety and quality must be applied at these levels, as well as in the more global "macrosystems environments" (i.e., it must be brought from the corporate or departmental office to the bedside to be effective).[90] In contrast, the individual practitioner working in various environments (e.g., *locum tenems* practice), will find it difficult to achieve an overall high-quality, safe practice in an organization that gives only lip service to safety.

There is a growing literature about safety culture (also referred to as "climate"; the terms are similar but not synonymous) in healthcare.[91,92] One means to assess the organizational culture is to conduct periodic surveys. Little is written about the perioperative or anesthesia department patient safety culture or what should be its defining characteristics. Helmreich reported on use of one survey instrument, the Operating Room Management Questionnaire, and compared attitudes of surgeons to pilots, whose safety culture is generally believed to be superior to that found in many industries as a result of long-standing attention to safety training and interventions.[93] (Others, less reverently, attribute the safety focus of pilots to the observation that they are usually first on the scene of aviation accidents!). Although there are many similarities with pilots, surgeons appear to have attitudes that are not aligned with safety science, such as a perception that their performance is not affected by fatigue. Flin reported on results of a survey from anesthesia departments in the United Kingdom with a similar finding about the effects of stress and fatigue.[94] Also, for example, although perceptions of teamwork were generally positive, only 65% of respondents perceived that operating room personnel worked well together as a team. Respondents also reported variable compliance with procedures and policies.

The Joint Commission on Accreditation of Healthcare Organizations (JCAHO) presumes to assess the organizational and department level of safety through its process of accreditation, which lists many requirements for anesthesia services. Included among those are processes to credential individual practitioners, processes for evaluating unusual clinical events (quality assurance or quality improvement), policies and procedures for common procedures, and a program for ensuring that individuals are trained on the technologies they use.[95] Periodic inspections are used to assess the compliance with the JCAHO requirements, but these requirements are generally viewed by practitioners as bureaucratic and of limited value in ensuring that safety is deeply ingrained in ongoing practices.

Extrapolating from the earlier descriptors of an HRO, we can imagine that a safe perioperative culture demonstrably places safety as its priority with regular meetings of the group and teams; organizational learning via reporting systems that are open, fair, and nonpunitive; a formal and active quality improvement process; by implementing corrective actions on learning of unsafe practices; having policies and procedures defining standard operations; have regular training for common emergencies; being nonhierarchical during emergencies; rewarding those who raise safety concerns and have open discussions about those concerns; having processes for briefing and debriefing about near misses and adverse events; having standard processes for communication among providers especially for transitions in care; and use other similar processes and attributes. Amazingly, few organizations have these attributes, especially those related to multispecialty analyses of the causes of errors and adverse events; too often these analyses take place in parallel processes that result in the allocation of blame rather than resolution of the root causes that are embedded in the larger system, or the interfaces between services or providers.

The safe organization ensures that its workers practice safety and provides the support and resources to enable them to do so. It is then the responsibility of the individual to develop and maintain a continuous personal commitment to safety by adopting a spectrum of safe practices as outlined in the next section.

Practical Elements for the Practitioner for Producing Safe, High-Quality Patient Care

Importance of Instilling Values of Patient Safety, Quality and Patient Centeredness

Safety demands that each individual, as well as the organization, make preventing any injury or harm to the patient the highest priority. For the individual clinician, a continual commitment to safe practice includes avoidance of unnecessary risk taking and avoidance of corner cutting, an almost unending anticipation of what might go wrong, projection of actions in anticipation of failure and, above all, mindfulness. Weick describes mindfulness for HROs as organizing in such a way as to "better notice the unexpected in the making and halt its development."[86] The concept applies equally well to the individual practitioner or member of the perioperative care team. Weick goes on to say that "[m]indfulness preserves the capability to see the significant meaning of weak signals and to give strong responses to (them). This counterintuitive act holds the meaning to managing the unexpected." Being patient-centered includes placing the patient's needs above all others, especially protecting the patient from harm. Thus, patient safety and patient centeredness are intimately connected and the hallmarks of high-quality practice.

Maintaining Vigilance and Mitigating Performance Decrement

Although vigilance cannot be relied on solely to protect the patient from harm, it remains the strongest underpinning of safety in anesthesia. This means that the anesthesia provider must maintain alertness and be aware of, compensate for, and counteract the forces working against vigilance. This, too, requires mindfulness about the state of one's own vigilance.

Fatigue and sleep deprivation are probably the most common causes of lapses in vigilance. Howard et al. have recommended several "fatigue

countermeasures."[43] Among these are education about the effects of fatigue on vigilance, employing good sleep hygiene (regular bedtime and wake-up time; restricting alcohol, caffeine, and nicotine use; creating good conditions for sleep), rest breaks, strategic napping, and selected medications, if necessary.

There is no evidence to support any specified time between breaks, but awareness of a fatigued state can suggest when a break is needed. Naps are often inconsistent with daily clinical routines, but may be appropriate when routines are disrupted or during "on call" intervals. Optimal nap times are on the order of 45–60 minutes to improve alertness while minimizing sleep inertia on awakening. Napping is best done when circadian rhythms are enabling sleep (between 2:00 and 6:00 P.M. and 2:00 and 6:00 A.M.), and is more difficult to do when circadian rhythms are encouraging wakefulness. The evidence that napping improves performance of flight crews is strong enough that appropriate napping is recommended during long duration flights.[96] Caffeine can be used judiciously to compensate for fatigue.[43] Excessive use or inappropriate timing of caffeine use can have the negative consequence of preventing subsequent sleep.

Relief breaks, either during a procedure or at a change of shift, are a double-edged sword, providing an opportunity to identify an undiscovered problem or to create a new problem because of lesser situational awareness by the relieving provider.[45,46] A preplanned protocol should be followed to optimize information transfer during the handoff.[48,49]

Practice in a System of Care

Anesthesiologists must identify and integrate into the larger system of care in which they operate. Safe care depends on the effective work of many others working as a team, and understanding their constraints and processes can go far toward creating an environment of safety. This includes learning how to operate within a team rather than primarily as an individual. If the anesthesiologist can determine how the surgeon, consultant physicians, nurses, allied health professionals, and laboratory support personnel and systems function, and where "glitches" may develop in these systems, then the anesthesiologist can be prepared to mitigate or interrupt cascades that lead to adverse events. For example, understanding how and under what conditions delays in delivery of laboratory information might occur, knowing when nursing turnovers occur, and understanding what factors affect surgical judgment can alert the anesthesia practitioner to strategies that might reduce errors. An example is failure to transfuse when blood loss is excessive (e.g., a system of events where estimation of blood loss by the nurses is interrupted by change of shift, laboratory reports are delayed due to time pressures in the laboratory and the surgeon "hopes" that the bleeding is controlled; this sequence is a classic example of the "holes in the Swiss cheese" aligning in a way that fosters medical error). Integrating anesthesia practices into the overall system, rather than acting in isolation, is more likely to result in safe and efficient processes for the entire patient-care experience.

Teamwork

Although teamwork can be seen as a subset of working within a system of care, it also includes specific practices for optimizing safety. Box 3–3 lists some of the recommended practices of high-performance teams in nonhealthcare domains.

Preparation

The failure to adequately prepare for anesthesia administration often contributes to anesthesia critical incidents.[20,21,97] Preparation encompasses a large set of issues, including complete preoperative assessment (see Preoperative Assessment and Planning below); ensuring availability of emergency drugs, equipment, and supplies; checking out the function of equipment (especially using the FDA recommended procedure for ensuring functionality of the anesthesia machine[98]); and ensuring communication pathways in the event of an emergency.

Preoperative Assessment and Planning

Preoperative assessment and planning involves evaluation of the patient and development of the anesthesia plan that includes the anesthetic technique, the requirements for monitoring, and the plans for postoperative care, all of which must be consistent with the wishes of the patient and the needs of the surgeon or other operator (e.g., radiologist, cardiologist), and the resources of the facility.

The evaluation must be thorough and appropriate for the procedure and the patient; most especially, it must include a systematic evaluation of comorbidities or other factors that might lead to adverse outcomes. Even in healthy patients, there may be conditions that can lead to adverse events, such as difficult airway access, family history of relevant disease, or the recent use of nonprescription or illicit drugs. (Preoperative evaluation is considered in Chap. 4, and for specific conditions in Chaps. 6–23.) Similarly, an anesthetic plan must be developed that is consistent with both patient wishes and operator requirements, and with the plans for postoperative care. The anesthetic plan should never be based on a rote formula that depends on the procedure only; it should be tailored to the needs of patient, operator, and facility, including the environment and plans for postoperative care. Chapter 5 addresses the development of the anesthetic plan in detail.

Monitoring

Because failure to monitor is so often associated with adverse outcomes, this issue deserves special attention. The safe practitioner follows the standards promulgated by the ASA except in truly extraordinary situations, and should those occur, documents the reason for noncompliance. Critical alarms should never be disabled.

Control for Human Factors

Although the individual anesthesia provider has little control over the design of equipment and local systems, he or she does have substantial control over many of the human factors features that are part of the environment. Attention to the organized arrangement of supplies and drugs, especially adherence to consistent labeling of drugs, and establishing and adhering to local standards are examples. Care to keep arterial and intravenous cannulae and monitoring cables orderly, ensuring reasonable lighting, and reducing clutter, noise, and distractions are general, sound, safety practices. Control of noise levels and background music can be contentious issues among staff, surgeons, and anesthesia providers, who sometimes are urged to compromise the principle that patient safety takes preeminence.

Reasonable efforts should be made to reach compromise and music should be discontinued during management of critical events.

Applying Systematic Crisis Management Techniques

Anesthesia crisis resource management (ACRM) is an organized set of principles for managing crisis situations in anesthesia. Adapted by Gaba et al. from CRM in aviation, it consists of several founding principles for effective management of acute events.[62,70,99,100] Although there is no single adopted standard, the following principles are generally applicable:

- Seek assistance early and quickly—inform others on the surgical team and call for extra assistance as soon as unusual circumstances are recognized.
- Establish clarity of roles for each person involved in management of the event; especially identify who will manage the event (event manager).
- Use effective communication processes, including reading back of instructions, being clear to whom directions are being given.
- Use resources effectively and identify what additional resources (people, supplies, equipment, transportation, etc.) are available to manage the situation.
- Maintain situational awareness and avoid fixations, which is perhaps the most challenging task as situational awareness is difficult to retrieve once it is lost. Having one person act as event manager, observing the big picture rather than becoming immersed in the details, is thought to be effective.

The algorithm of ABCD COVER swift check discussed earlier (Box 3–4) should be available for reference.

Infection Control

Care in the safe use and sterility of all anesthesia systems is essential, especially in the modern hospital environment where hospital-acquired infections with resistant organisms (e.g., methicillin- or vancomycin-resistant *Staphylococcus aureus* organisms) are increasingly common. Adherence to carefully timed protocols for antibiotic administration in the perioperative interval reduces postoperative wound infection.[101] Surgical wound infection rates are increased 3-fold by hypothermia and reduced by increased perioperative oxygen administration.[102,103]

Following Standards and Practice Guidelines

The ASA has established a large set of practice standards and guidelines.[104] Standardizing practices across providers is widely accepted as a critical component for safety and reliability. Box 3–5 lists common practice standards. Each practitioner is obligated to be familiar with such guidelines and apply them appropriately in his or her practice. Similarly, healthcare facilities are required to establish local polices and procedures to ensure standardization of basic practices. These, too, must be known and followed.

Periodic Training

Because critical events are relatively rare and demand expert and effective treatment, it is important to practice skills periodically. Schwid demonstrated that advanced cardiac life support (ACLS) skills are generally maintained for only approximately 6 months.[105] Periodic training includes practice in management of the unanticipated difficult airway, generic skills in ACRM, and drills for operating room fires and other specific anesthetic emergencies, such as malignant hyperthermia. Simulation is increasingly used for such training. Some practice can be achieved via computer-based simulators and trainers, which are effective for obtaining knowledge in management of acute events.[106] Simulation using various forms of simulators, from basic to the most realistic environment, is effective for imparting generic, nontechnical (behavioral) skills in managing critical events.[66] Resources for obtaining such training are expanding and the ASA is encouraging its members to maintain their skills in this way. In the future, simulation may become part of evaluation processes of accrediting agencies.

INVOLVING THE PATIENT IN SAFETY AND QUALITY

Patients increasingly are being urged to take a role in ensuring the safety of their own care, as well as being involved in patient safety by their healthcare providers.[107] Anesthesia professionals should encourage and assist in this because it benefits everyone. Providers should also be concerned with the patient's perceptions of the quality of care and consider more than just the needs of the direct surgical process. There are several ways in which these goals can be achieved.

To encourage patient involvement, actions can be taken to foster "patient-centered communication," which has been defined as including the following:[108]

- Eliciting and understanding the patient's perspectives—concerns, ideas, expectations, needs, feelings, and functioning.
- Understanding the patient within his or her unique psychosocial context.
- Reaching a shared understanding of the problem and its treatment with the patient that is concordant with the patient's values.

- Helping patients share power and responsibility by involving them in choices to the degree that they wish to be involved.

What specific things can anesthesia providers do to involve patients in their own care that will not just improve satisfaction but also safety? Consider the following:

- Tell the patient as much as practical (assessing how much the patient can handle knowing) about the process of anesthesia care the patient will experience.
- Provide information preoperatively about the process of anesthesia care and expectations; several references are available on the Internet in addition to books and pamphlets.
- Encourage the patient to speak up if the patient doesn't understand something or believes something is inappropriate, such as drugs being given, absence of handwashing or glove wearing.
- Involve the patient's family members in care whenever practical.
- Advise the patient to contact you if there are any concerns or possible side effects after the anesthetic.
- In concert with other providers, disclose errors and adverse events (a strategy that enhances trust and decreases skepticism in concerned patients).
- Involve patients on committees that involve the design of anesthetizing locations, and in the process of patient flow and family communication in such facilities.

SUMMARY AND CONCLUSIONS

The concepts of quality, safety, and patient centeredness are prominent themes throughout American healthcare, and they have been embraced by patients and affirmed by third-party payers, specialty societies, and healthcare organizations, both governmental and private. Despite the increased focus on these factors, the goals have yet to be met, especially because most initiatives have focused on individual practitioners or within specific disciplines. To achieve the full goals of quality and safety, the processes must include systematic approaches that cross the boundaries of specialties, clinical services, and facilities. In short, the delivery of care must be recognized as a complex matrix of interactions among multiple providers, including both clinicians and facilities, all interacting with one another in a system of systems. The specialty of anesthesiology is a leader in the development of patient safety approaches within its discipline; the next steps involve building safety and quality into this larger system of care. Anesthesia providers can contribute significantly to achieving these goals by participating fully in the system-of-systems approach, as well as by building highly reliable microsystems within their department or group. These approaches are best understood by adopting a patient-centered approach, whereby all providers interpret the integrated care process from the patient's viewpoint, and include that viewpoint in the design and delivery of care.

PART 2

PREPARING FOR ANESTHESIA

SECTION A

Approach to the Anesthesia Patient

CHAPTER 4

Overview of Preoperative Assessment and Management

Bobbie Jean Sweitzer, MD

GOALS AND BENEFITS

As the practice of medicine becomes increasingly outcomes-driven and cost-conscious, clinicians need to reevaluate and streamline methods of patient care. Preoperative assessment and management have evolved as the role of the anesthesiologist has expanded outside of the operating theater and as an increasing number of procedures are performed on patients who are not hospitalized the night before. Reasons for preoperative assessment may entail some or all of the following:

1. To screen for and properly manage comorbid conditions.
2. To assess the risk of anesthesia and surgery and lower it.
3. To identify patients who may require special anesthetic techniques or postoperative care.
4. To establish baseline results for perioperative decisions.
5. To educate patients and families about anesthesia and the anesthesiologist's role.
6. To obtain informed consent.
7. To facilitate timely care and avoid cancellations on the day of operation.

KEY POINTS

1. Comprehensive preoperative evaluation and management improves patient satisfaction, outcomes, and safety.
2. Inadequate preoperative evaluation and management increase perioperative adverse events.
3. At a minimum, the preanesthesia visit should include an interview with the patient to review the medical history (including medications, allergies, comorbid conditions, and previous operations), an appropriate physical examination, review of diagnostic data, assignment of an American Society of Anesthesiologists physical status score, and a formulation and discussion of the planned anesthetic with the patient.
4. The medical history is the most important component of preoperative assessment.
5. Findings from the history and physical examination determine the need for further diagnostic testing.
6. Diagnostic tests should only be ordered if the results will alter the planned anesthetic or procedure or establish an already suspected diagnosis. "Screening" tests are never appropriate.
7. A determination of functional capacity or the patient's cardiorespiratory fitness can guide further testing and predict a wide range of complications and outcome.
8. Cardiovascular morbidity and mortality are the leading cause of significant perioperative adverse events.
9. Identification and optimization of cardiovascular disease is an important goal of preoperative evaluation.
10. Knowledge of risk factors for cardiovascular disease and familiarity with the American College of Cardiology–American Heart Association guidelines for cardiovascular evaluation for noncardiac surgery is essential.
11. Other "high-risk" patients include those with the following conditions:
    a. Congestive heart failure
    b. Murmurs
    c. Pacemakers and implantable cardioverter-defibrillators (ICDs)
    d. Pulmonary disease
    e. Obstructive sleep apnea
    f. Obesity
    g. Diabetes mellitus
    h. Poorly controlled hypertension
    i. Renal disease
    j. Hepatic disease
    k. Substance abuse
    l. Geriatric patient
    m. Difficult airway
12. Poor communication is a common source of medical errors and patient dissatisfaction.
13. Practice guidelines can standardize care, decrease delays, and improve outcomes.
14. Anesthesia-directed preoperative evaluation centers can be cost-effective, improve care and patient safety, and offer services beyond history acquisition, physical examinations, and diagnostic testing.

8. To motivate patients to stop smoking, lose weight, or commit to other preventive care.
9. To train personnel in the art and science of preoperative assessment and optimization of a patient's condition.

The Australian Incident Monitoring Study (AIMS) found that 3.1% (197 of the first 6271 reports) of adverse events were unequivocally related to insufficient, and 11% to inadequate, preoperative assessment.[1] More than half of incidents were considered preventable. An analysis of the first 2000 reports to AIMS found a 6-fold increase in mortality in patients who were inadequately assessed preoperatively.[2] Davis concluded that 53 (39%) of 135 deaths attributed to anesthesia involved inadequate preoperative assessment and management.[3] Delays, complications, and unanticipated postoperative admissions are significantly reduced by preoperative screening and patient contact. Others have shown that preoperative health status can predict both operative clinical outcomes and resource use. Preoperative preparation and education can facilitate recovery and reduce the incidence of postoperative morbidity. Anxiety, postoperative pain, and length of stay have been positively affected by comprehensive preoperative care. From the patient's perspective, an opportunity to meet an anesthesiologist (preferably the one providing anesthesia on the day of surgery) is very important. In a study conducted in Canada and Scotland, patients rated meeting the anesthesiologist as the highest priority—above that of information on pain relief, alternative methods of anesthesia, and complications.[4]

Preoperative evaluation must be efficient for both patient and hospital personnel. It can be cost-effective and can reduce turnover times, cancellations, length of hospital stays, and postoperative complications. Preoperative visits should be comprehensive, including plans for postdischarge patient care. As the numbers of patients undergoing surgery on an outpatient basis or presenting to the hospital on the day of operation increases, anesthesiologists have to adapt to provide patients with the best preoperative services. Many anesthesiologists perform preoperative evaluations, review diagnostic studies (chosen and ordered by someone else), discuss anesthetic risks, and obtain informed consent moments before a patient undergoes a major, potentially life-threatening or disfiguring procedure. This choice offers little opportunity to manage comorbid conditions or alter risk. Legally, morally, and psychologically anesthesiologists and patients are in awkward, and often unpleasant, situations. The effects of extensive disclosure are stressful for patients and families at a time when they may be ill-prepared to consider the implications rationally. An increase in preoperative anxiety may adversely affect postoperative outcomes because increased anxiety correlates with increased postoperative analgesic requirements and prolonged recovery and hospital stay. Anxiety impairs retention of information, which could result in legal action because of inadequate communication or discussion of the risks of anesthesia.

At a minimum, the guidelines of the American Society of Anesthesiologists (ASA) indicate that a preanesthesia visit should include the following[5]:

1. Interview with the patient to review medical, anesthesia, and medication history
2. Appropriate physical examination
3. Review of diagnostic data (laboratory, electrocardiograms, radiographs)
4. Assignment of ASA physical status score
5. Formulation and discussion of anesthesia plan with patient or responsible adult

Table 4–1 outlines the criteria and medical conditions of patients likely to benefit from evaluation in a preanesthetic clinic before the day of surgery.

RISK ASSESSMENT AND REDUCTION

The current ASA risk classification system was developed in 1941 by Meyer Saklad at the request of the ASA (Table 4–2). This classification was the first attempt to quantify risk associated with anesthesia and surgery. The type of anesthesia and the operation were not even considered in this classification system. Moreover, this system attempted to estimate the mortality rate based only on the patient's preoperative medical condition. Since then other studies have corroborated an association of mortality and morbidity with ASA physical status (ASA PS) scores. Studies also have shown a correlation between ASA PS and unanticipated intensive care unit admissions, longer hospital stays for some procedures, and adverse cardiopulmonary outcomes. No correlation was shown between ASA PS class and cancellations, unplanned admissions, and other perioperative complications and cost.[6] Fewer studies have evaluated the effect of combining the risk of the surgical procedure and the ASA PS score. Among the first was the Johns Hopkins Risk Classification System.[7] Many institutions use a more simplified version of high, intermediate, and low risk.[8] Table 4–3 offers one definition of these risk stratifications.

Goldman et al. further advanced risk assessment by identifying risk factors and cardiac complications in noncardiac surgery. Several studies followed, culminating in the joint guideline publication by the American College of Cardiology and the American Heart Association (ACC/AHA) in 1996, which was updated in 2002.[8] (See Heart Disease below and Chap. 7 for more detailed discussions of the ACC/AHA guidelines.)

Some assessment of risk is important to prepare for the anesthetic and surgical procedure. The need for invasive monitoring, blood salvage and hypothermic techniques, postoperative care in the intensive care unit, and special monitoring must be considered. Patients must be informed during the consent process. Risk assessment is useful to compare outcomes, control costs, allocate compensation, and assist in the difficult decision of canceling or recommending a procedure not be done when the risks are too high. Yet risk assessment, at its best, is hampered by individual patient variability.

TIMING OF ASSESSMENT

The Practice Advisory for Preanesthesia Evaluation commissioned by the ASA determined that the time of the preanesthesia assessment depends on the patient's condition, the type of procedure, the health care system, and the patient's access to care providers.[5] The recommendations, which were based on the opinions of experts and random-

TABLE 4–1.

General Criteria and Medical Conditions for Which Preoperative Evaluation is Recommended Before the Date of Surgery

Medical Condition	Criteria
General	Age
Normal activity inhibited	>75 years, unless surgery is minor (e.g. cataract) and under monitored anesthesia care
Monitoring or medical assistance at home within 6 months	Language
Hospital admission within 2 months	Patient or parent/guardian cannot hear, speak, or understand English
Obesity >140% ideal body weight	Anesthesia Effects
Cardiovascular	Patient or family has had previous difficult intubation, elevated temperature during anesthesia, is allergic to succinylcholine, has malignant hyperthermia or pseudocholinesterase deficiency or paralysis or nerve damage during surgery
Angina	Procedure related
Coronary artery disease	Intraoperative blood transfusion likely
History of myocardial infarction	ICU admission likely
Symptomatic arrhythmias	High risk surgery
Poorly controlled hypertension	Pregnancy
Systolic blood pressure >180 mm Hg or diastolic blood pressure >110 mm Hg	Patient is pregnant (unless the procedure is dilation and evacuation or dilation and curettage)
Congestive heart failure	
Respiratory	
Asthma	
Chronic obstructive pulmonary disease (COPD) requiring medication	
Exacerbation or progression of COPD within 6 months	
Previous airway surgery	
Unusual airway anatomy	
Airway tumor or obstruction	
Home ventilatory assistance or monitoring	
Endocrine	
Diabetes	
Adrenal disorders	
Active thyroid disease	
Neuromuscular	
Seizure disorder	
CNS disease (e.g., multiple sclerosis)	
Myopathy or other muscle disorders	
Hepatic	
Active hepatobiliary disease or compromise	
Renal	
Renal insufficiency or failure	
Musculoskeletal	
Kyphosis or scoliosis compromising function	
Temporomandibular joint disorder	
Cervical or thoracic spine injury/disease	
Oncology	
Chemotherapy	
Significant physiologic compromise	

The medical condition portion of this table has been adapted with permission from Pasternak LR. Preoperative evaluation of the ambulatory surgery patient. Ambulatory Surgery. Anesthesiol Rep 1990;3(1):8.

ly selected ASA members, favor assessments on or before the day of surgery for low to medium invasive procedures and before the day of operation for highly invasive procedures. The consensus is for assessments before the day of surgery for patients with less-severe disease if they are scheduled for highly invasive procedures and for less-invasive procedures in patients with severe disease. For selected patients, evaluations on the day of surgery can be safe and effective.

The importance of a visit to the preoperative clinic before a surgical procedure cannot be overstated.[9] A Canadian survey found that more than 60% of patients thought it was important to see an anesthesiologist preoperatively, more than 30% thought it was ex-

TABLE 4–2.

American Society of Anesthesiologists Physical Status Classification

P1	Healthy patient without organic, biochemical, or psychiatric disease.
P2	A patient with mild systemic disease, e.g. mild asthma or well-controlled hypertension. No significant impact on daily activity. Unlikely impact on anesthesia and surgery
P3	Significant or severe systemic disease that limits normal activity, e.g. renal failure or dialysis or class 2 congestive heart failure. Significant impact on daily activity. Likely impact on anesthesia and surgery.
P4	Severe disease that is constant threat to life or requires intensive therapy, e.g. acute myocardial infarction, respiratory failure requiring mechanical ventilation. Serious limitation of daily activity. Major impact on anesthesia and surgery.
P5	Moribund patient who is equally likely to die in the next 24 hours with or without surgery.
P6	Brain-dead organ donor.

"E" added to the above (P1–P5) indicates emergency surgery.
Adapted from American Society of Anesthesiologists. ASA physical status classification system. Available at: *www.asahq.org*.

TABLE 4–3.

Preoperative Testing Guidelines for Healthy Patients, American Society of Anesthesiologists Physical Status 1

Procedure Type	Invasive Status	Tests[a,b,c]
Low risk, e.g., breast biopsy, knee arthroscopy, cataracts	Minimal	Baseline creatinine if procedure involves injection of contrast dye
Intermediate risk, e.g., inguinal hernia or lumbar laminectomy	Moderate	Baseline creatinine if procedure involves injection of contrast dye
High risk, e.g., thoracotomy, colectomy, or other procedures with expected fluid shifts or significant blood loss	High	Complete blood count with platelets, electrolytes, blood urea nitrogen, and creatinine

[a]Results from laboratory tests within 6 months of surgery are acceptable unless major abnormalities are present or patient's condition has changed.
[b]Routine pregnancy test before surgery is not recommended before the day of surgery. A careful history and local practice determine whether a pregnancy test is indicated.
[c]Age alone is not an indication for an electrocardiogram (ECG). Reimbursement for an ECG depends on indication (pallor, dizziness, hypertension) or a diagnosis documented by history or physical examination. No new ECG is needed if results from an ECG within 6 months of surgery are normal and the patient's condition has not changed.

tremely important, and more than half indicated that the visit should be before the day of operation.[10] Anesthesiologists at Massachusetts General Hospital demonstrated that a preoperative visit before the day of surgery was as good as or better than medication in reducing preoperative anxiety and postoperative pain.

DETECTING DISEASE

It has been written that the history and physical examination, often referred to as the *clinical examination*, frequently are all that are required for a diagnosis or elimination of alternative hypotheses.

Several studies have proved the usefulness of the history and physical examination in deciding a diagnosis. A study of patients in a general medical clinic found that 56% of correct diagnoses were made with the history alone and rose to 73% with the physical examination. In patients with cardiovascular disease, the history established the diagnosis 66% of the time, and the physical examination contributed to 25% of diagnoses. Moreover, routine investigations, mainly chest radiography and electrocardiography (ECG), helped with only 3% of diagnoses, and special tests, mainly exercise ECG, assisted with 6%.[11] History is also the most important diagnostic method in respiratory, urinary, and neurologic conditions. The skill of performing a clinical examination derives from pattern recognition learned by seeing patients and listening to the stories of their illnesses. The diagnostic acumen of the physician is a result of the ability to assimilate and develop an overall impression, rather than just reviewing a compilation of facts.

Medical History

One common problem is the variability of the medical history. Asking and recording symptoms in ordinary words leads to greater interobserver agreement between practitioners. History taking is not simply asking the questions; history taking includes interpreting and carefully recording the answers. Complete and thorough histories not only assist in planning appropriate and safe anesthesia care, but also are more accurate and cost-effective in establishing diagnoses than are screening laboratory tests.

The patient's medical problems, past operations, previous anesthesia-related complications, allergies, and use of tobacco, alcohol, or illicit drugs should be documented. Equally important to identifying the presence of a disease is establishing the severity, the stability, and prior treatment of the condition. A screening review of systems needs special emphasis on airway abnormalities, personal or family history of adverse events related to anesthesia, and cardiovascular, pulmonary, endocrine, or neurologic symptoms.

The patient's medical problems, previous operations, and responses to questions should elicit further questions to establish the severity of disease, its stability, current or recent exacerbations, and recent or planned interventions. Rarely is a simple notation of diseases or symptoms such as hypertension (HTN), diabetes mellitus (DM), coronary artery disease (CAD), shortness of breath (SOB) or chest pain sufficient. The severity, extent, degree of control, and the activity-limiting nature of the problems are equally important.

A determination of the patient's cardiorespiratory fitness or functional capacity is useful in guiding additional preanesthetic evaluation and predicting outcome and perioperative complications.[8,12] Exercise or work activity can be quantified in metabolic equivalents (METS), which refer to the volume of oxygen consumed during an activity. One's ability to exercise is two-pronged in that better fitness decreases mortality through improved lipid and glucose profiles and reductions in blood pressure and obesity. An inability to exercise may be a *result* of cardiopulmonary disease. Several studies show that inability to perform average levels of exercise (4–5 METS) identifies patients at risk of perioperative complications.

Table 4–4 shows the important components of an anesthesia history. The form can be completed by the patient in person (paper or electronic version), via Internet-based programs, via a telephone interview, or by anesthesia staff. A more detailed discussion of important components of the history for specific medical conditions is presented below (see Medication Instructions).

Physical Examination

At a minimum, the preanesthetic examination should include the airway, a heart and lung examination, vital signs, including oxygen saturation, and height and weight. Body mass index (BMI) is one of many factors associated with development of chronic diseases such as heart disease, cancer, and diabetes, and can be calculated from an individual's height and weight. The two formulas for calculating the BMI are the English and the metric.

TABLE 4–4.

Sample Patient Preoperative History

Patient's Name _____ Age _____ Sex _____
Planned Operation _____ Date of Surgery _____
Surgeon _____ Primary Doctor _____
Cardiologist? _____

1. Please list **all operations** (and approximate dates)

a.	d.
b.	e.
c.	f.

2. Please list any **allergies** to medicines, latex, or other (and your reactions to them)

a.	c.
b.	d.

3. Please list **all medications** you have taken in the last month (include over-the-counter drugs, inhalers, herbals, dietary supplements, and aspirin)

Name of Drug	**Dose and how often**	**Name of Drug**	**Dose and how often**
a.		f.	
b.		g.	
c.		h.	
d.		i.	
e.		j.	

(Please check YES or NO and circle specific problems)	**YES**	**NO**
4. Have you taken steroids (prednisone or cortisone) in the last year?	☐	☐
5. Have you *ever* smoked? (Quantify in ___ packs/day for ___ years)	☐	☐
Do you still smoke?	☐	☐
Do you drink alcohol? (If so, how much?) _____	☐	☐
Do you use or have you ever used any illegal drugs? (We need to know for your safety.)	☐	☐
6. Can you walk up one flight of stairs without stopping?	☐	☐
7. Have you ever had any problems with your heart? **(circle)** (chest pain or pressure, heart attack, abnormal ECG, skipped beats, heart murmur, palpitation, heart failure [fluid in the lungs], require antibiotics before routine dental care)	☐	☐
8. Do you have high blood pressure?	☐	☐
9. Have you had any problems with your lungs or your chest? **(circle)** (shortness of breath, emphysema, bronchitis, asthma, tuberculosis [TB], abnormal chest x-ray)	☐	☐
10. Are you ill now or were you recently ill with a cold, fever, chills, flu, or productive cough?	☐	☐
Describe recent changes _____		
11. Have you or anyone in your family had serious bleeding problems? **(circle)** (prolonged bleeding from nosebleed, gums, tooth extractions, or surgery)	☐	☐
12. Have you had any problems with your blood (anemia, leukemia, sickle cell disease, blood clots, transfusions)?	☐	☐
13. Have you ever had problems with your: **(circle)**		
Liver (cirrhosis, hepatitis, jaundice)?	☐	☐
Kidney (stones, failure, dialysis)?	☐	☐
Digestive system (frequent heartburn, hiatus hernia, stomach ulcer)?	☐	☐
Back, neck, or jaws (temporomandibular joint, rheumatoid arthritis)?	☐	☐
Thyroid gland (underactive or overactive)?	☐	☐
14. Have you ever had: **(circle)**		
Seizures, epilepsy, or fits?	☐	☐
Stroke, facial, leg or arm weakness, difficulty speaking?	☐	☐
Cramping pain in your legs with walking?	☐	☐
Problems with hearing, vision, or memory?	☐	☐
15. Have you ever been treated for cancer with chemotherapy or radiation therapy? **(circle)**	☐	☐
16. Women: Could you be pregnant?	☐	☐
Last menstrual period began: _____		
17. Have you ever had problems with anesthesia or surgery? **(circle)** (severe nausea or vomiting, malignant hyperthermia [in blood relatives or self], prolonged drowsiness, anxiety, breathing difficulties, or problems during placement of a breathing tube)	☐	☐

English formula:

$$\text{BMI} = \left(\frac{\text{Weight in pounds}}{\left(\text{Height in inches}\right) \times \left(\text{Height in inches}\right)} \right) \times 703$$

Metric formula:

$$\text{BMI} = \left(\frac{\text{Weight in kilograms}}{\left(\text{Height in meters}\right) \times \left(\text{Height in meters}\right)} \right)$$

or

$$\text{BMI} = \left(\frac{\text{Weight in kilograms}}{\left(\text{Height in centimeters}\right) \times \left(\text{Height in centimeters}\right)} \right) \times 10{,}000$$

See Obesity below for further discussion and for definitions of BMI for adults.

Components of the airway examination should include the following[13]:

- Length of upper incisors
- Condition of the teeth
- Relationship of upper (maxillary) incisors to lower (mandibular) incisors
- Ability to protrude or advance lower (mandibular) incisors in front of upper (maxillary) incisors
- Interincisor or intergum (if edentulous) distance
- Visibility of uvula
- Presence of heavy facial hair
- Compliance of mandibular space
- Thyromental distance
- Length of neck
- Thickness of neck
- Range of motion of head and neck

Because of the relatively frequent incidence of dental injuries during anesthesia, a thorough documentation of preexisting tooth abnormalities is useful. Either a tooth chart (Fig. 4–1) or standard nomenclature (e.g., right upper central incisor, left lower lateral incisor, or right lower bicuspid) can be helpful.

A good time to discuss with patients variant options of airway management or techniques other than general anesthesia when applicable, and to prepare patients for possible awake fiberoptic intubation, is after examination of the airway. When challenging airways are identified, advance planning ensures that necessary equipment and skilled personnel are available.

The physical examination contributes 25% of diagnoses in patients with cardiovascular disease. Auscultation of the heart and inspection of the pulses, peripheral veins, and extremities for the presence of edema are important diagnostically and for risk assessment in development of care plans. One should auscultate for murmurs, rhythm disturbances, and signs of volume overload. Murmurs, without a clear etiology (anemia, hyperthyroidism, or pregnancy, with confirmation that the murmur was not present prior to these conditions), warrant further evaluation (see Heart Disease below).

The pulmonary examination should include auscultation for wheezing, decreased or abnormal breath sounds, notation of cyanosis or clubbing, and effort of breathing.

Observing whether the patient can walk up 1–2 flights of stairs can predict a variety of postoperative complications, including pulmonary and cardiac events and mortality, and aid in decisions regarding the need for further specialized testing such as pulmonary function tests (PFTs) or noninvasive cardiac stress testing.[14]

For selective patients (e.g., those with deficits or disease who are undergoing neurologic surgery or regional anesthesia) a neurologic examination is necessary to document preexisting abnormalities that may aid in diagnosis or that can interfere with positioning, and to establish a baseline in defense of potential malpractice claims of adverse events.

Obesity, HTN, and large neck circumference predict an increased incidence of obstructive sleep apnea (OSA). See Obstructive Sleep Apnea below.

PREOPERATIVE TESTING

Preoperative testing is performed to evaluate existing medical conditions and to diagnose asymptomatic conditions based on known risk factors for particular diseases. Diagnostic tests can aid in the assessment of the risk of anesthesia and operation, guide medical intervention to lower this risk, and provide baseline results to direct intra- and postoperative decisions. The choices of laboratory tests should depend on the probable impact of the test results on the differential diagnosis and on patient management. A test should be ordered only if the results will impact the decision to proceed with the planned procedure or alter the care plans. The history and physical examination should be used to direct test ordering. Tables 4–3 and 4–5 contain recommendations for testing based on specific medical conditions.

Preoperative tests without specific indications lack clinical usefulness and may actually lead to patient injury because of unnecessary interventions, delay of surgery, anxiety, and even inappropriate therapies. The history is

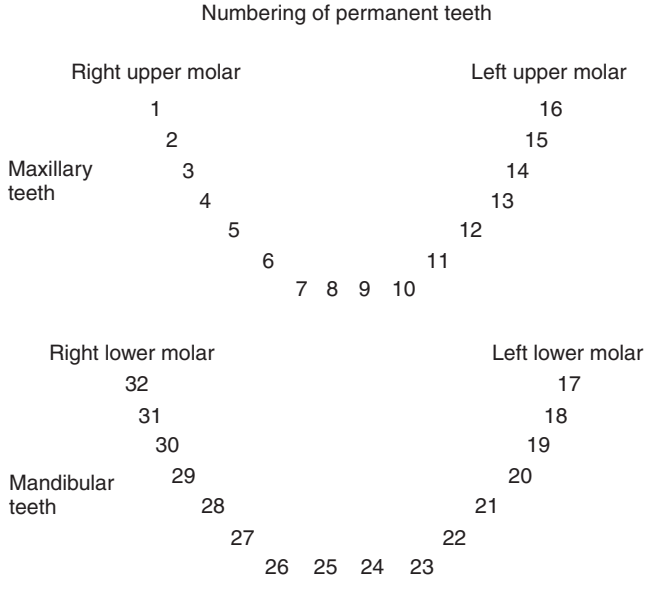

FIGURE 4–1. Dental chart.

TABLE 4–5.

Preoperative Diagnostic Testing Order Form

		Healthy patient
☐	Standard Order CBC w/plt; BUN/Creat; glucose	Standard order for healthy patients having procedure with significant blood loss or in a high-risk category
		Disease/therapy/procedure-based indications
☐	AST/AlkP	Alcohol abuse; exposure to hepatitis; hepatic disease; personal or family history of bleeding
☐	β-hCG	Possible pregnancy
☐	BUN/Creat	Cardiovascular, hepatic, intracranial, peripheral vascular, or renal disease; diabetes; morbid obesity; poor exercise tolerance; systemic lupus; use of digoxin, diuretics, steroids; procedures with significant blood loss, with radiographic dye, or in a high-risk category
☐	CBC w/plt	Alcohol abuse, anemia; cardiovascular, intracranial, pulmonary, or renal disease; malignancy; malnutrition; personal or family history of bleeding; poor exercise tolerance; radiation therapy; rheumatoid arthritis; sleep apnea; smoking >40 pack-years; anticoagulant use; procedures with significant blood loss or in a high-risk category
☐	CXR	Only for active, acute symptoms especially with cardiovascular or pulmonary disease; rheumatoid arthritis; smoking >40 pack-years; systemic lupus; radiation therapy
☐	ECG	Alcohol abuse; cardiovascular, cerebrovascular, intracranial, peripheral vascular, pulmonary, or renal disease; diabetes; morbid obesity; poor exercise tolerance; rheumatoid arthritis; sleep apnea; smoking >40 pack-years; systemic lupus; radiation therapy to chest or breasts; use of digoxin
☐	Electrolytes	Cerebrovascular, intracranial, or renal disease; diabetes; malnutrition; use of digoxin, diuretics, or steroids; high-risk procedure
☐	Glucose	Cerebrovascular or intracranial disease; diabetes; morbid obesity; poor exercise tolerance; steroid use
☐	PT/PTT	Alcohol abuse; hepatic disease; malnutrition; personal or family history of bleeding; use of anticoagulants
☐	Thyroid tests	Thyroid disease; use of thyroid medications
☐	T&S	Procedure with significant blood loss or high-risk category
☐	Urinalysis	Suspected urinary tract infection

Abbreviations: AST/AlkP = aspartate transaminase/alkaline phosphatase; β-hCG = β-human chorionic gonadotropin; BUN/Creat = blood urea nitrogen/creatinine; CBC w/plt = complete blood count with platelets; CXR = chest radiograph; ECG = electrocardiogram; PT/PTT = prothrombin time/partial thromboplastin time; T&S = type and screen.
With the exception of β-hCG for pregnancy, all tests are valid for 6 months before surgery unless abnormal or patient's condition has changed. Guidelines may not apply for low-risk procedures where testing is only indicated if the medical condition is newly diagnosed or unstable.

responsible for the diagnosis 75% of the time and is more important than the physical examination and laboratory investigations combined. In addition, the evaluation of abnormal results is costly. Many studies have evaluated the benefits of disease/condition-indicated testing versus screening batteries of tests. Few abnormalities detected by nonspecific testing resulted in changes in management, and rarely have such changes had a beneficial patient effect.[15] At most 1 in 1000 patients has benefited from findings derived from nonindicated testing.[16] Blery et al. found that 0.4% of tests without specific indications provided useful clinical information.[15] However, 1 in 2000 preoperative tests resulted in patient harm from pursuit of abnormalities detected by those tests; only 1 in 10,000 was of benefit to the patient.[6] It has been suggested that not following up on an abnormal result is a greater medicolegal risk than not identifying the abnormality to begin with.

Preoperative ECGs are one of the most frequently ordered and costly noninvasive tests. Preoperative ECGs are ordered because occult heart disease is common in the middle-age population and increases with advancing age; preexisting heart disease increases perioperative risk; and establishing a baseline value is desirable.

However, a *resting* ECG is not a reliable screen for CAD and is a poor predictor of heart disease (without a supporting history) in nonsurgical patients. It appears that only some ECG abnormalities are important in the perioperative period (e.g., new Q waves and arrhythmias). One study found only 2% of patients had one or both of these abnormalities.[17] It has been estimated that the frequency of silent Q-wave infarctions found *only* by ECG in men age 75 years or older (the highest risk group) is 0.5%. Gold et al. found that in ambulatory surgical patients, the incidence of abnormal ECGs was 43%. Only 1.6% (12/751) of patients had an adverse perioperative cardiac event and in only half (6/751) of these was the preoperative ECG of potential value.[18]

Many abnormalities may have implications for anesthesia care beyond the detection of CAD. Arrhythmias, such as atrial fibrillation, which should be detected on physical examination and confirmed by ECG, conduction abnormalities, and left ventricular hypertrophy, may alter anesthesia plans. Adjustments may be necessary to avoid hemodynamic instability, ischemia, or pulmonary edema because of drug interactions or the stress of surgery combined with previous, but not necessarily clinically significant, disease. Plans can be made on the day of operation when monitors are placed in the preoperative area or the operating room rather than incurring the expense of a 12-lead ECG beforehand.

Unfortunately, the specificity of an ECG abnormality for predicting postoperative cardiac complications is

only 26%; consequently, a normal ECG does not exclude cardiac disease.[19] The ACC/AHA *Guidelines for Perioperative Cardiovascular Evaluation for Noncardiac Surgery* consider ECG abnormalities (other than Q waves) as a minor predictor of complications.[8] History is far more important. An abnormal ECG will be found in 62% of patients with known cardiac disease, in 44% of patients with strong risk factors for ischemic heart disease, and in only 7% of patients older than 50 years with no risk factors. Even more significant is that results are abnormal in only 3% of patients between ages 50 and 70 years without risk factors for heart disease.[20] Tait et al. suggested that routine preoperative ECG testing is not indicated in patients without a history of cardiovascular disease and no significant risk factors.[21] In summary, the prevalence of abnormalities on ECG may incur costly evaluation, delaying necessary surgery, and the yield of these workups is quite low. Tables 4–3 and 4–5 list the indications for ECG testing.

Coagulation studies (platelet count, prothrombin, or activated partial thromboplastin time) are not recommended unless the patient history suggests a coagulation disorder or the procedure is high risk. Given a patient's negative history for a bleeding disorder, the cost of screening coagulation tests before minor surgery outweighs the benefit. Many practitioners mistakenly believe that a *screening* prothrombin time (PT) is more likely to be abnormal because of the numbers of patients with liver disease, malnutrition or warfarin use, conditions that should be readily identified by history. If "screening" tests (not based on history) are ordered, a platelet count and activated partial thromboplastin time (aPTT) are indicated to detect the uncommon patient with thrombocytopenia, an acquired anticoagulant (e.g., lupus anticoagulant) or a reduced level of a contact activation factor (e.g., von Willebrand disease or factor VIII, IX, XI, or XII deficiencies). Additionally, a *short* aPTT may be equally as important as a prolonged aPTT. A short aPTT increases the risk of postoperative thromboembolism. The Centers for Medicare and Medicaid Services (CMS) does not reimburse for "routine" or "preoperative" PT/partial thromboplastin time (PTT) without an appropriate International Classification of Diseases (ICD-9) code.[22]

There are few data to recommend age-based testing. No correlation has been established, independent of coexisting disease, a positive history, or findings on physical examination, between age and abnormalities in hemoglobin (Hgb), serum chemistries, radiographs, or PFTs.[16,23,24] Chest radiographs are indicated only in patients with pulmonary signs or symptoms of undetermined cause or severity. Hgb and hematocrit (Hct) levels are frequently abnormal in otherwise healthy patients, but rarely impact anesthetic care or management unless the planned procedure involves the potential for significant bleeding.

Even though ECG abnormalities are more common with advanced age, abnormalities alone do not predict postoperative cardiac complications in the elderly.[18,19] Significant abnormalities that impact care are rare in the absence of a history or symptoms of cardiac disease.[18] Even the ASA Practice Advisory for Preanesthesia Evaluation states, "The Task Force recognizes that age alone may not be an indication for an electrocardiogram."[5] CMS will not provide coverage for age-based ECGs or simply as a "preoperative" test; one must provide a supporting diagnosis with an acceptable ICD-9 code.[22]

There is much controversy about and no consensus regarding routine pregnancy testing, especially in adolescents. Surveys show that 30–50% of practitioners mandate testing in females of childbearing age, primarily because of the unreliability of the history, especially from minors, and the concern over the potential harm to the pregnancy or fetus with anesthesia and surgery, with the attendant medicolegal implications.[25] Opponents of mandatory testing cite the false-positive rate, cost, the belief that history is reliable if taken in privacy, and the paucity of data establishing risks of anesthesia in early pregnancy. When minors are pregnant, their privacy is governed by state laws. One must be familiar with local statutes and how unexpected positive pregnancy results will be handled. With the high reliability of urine testing, it is best to delay testing until the day of operation instead of testing in the preoperative clinic, unless the patient suspects pregnancy or the menstrual period is delayed. This delay in testing will obviate a negative test days before surgery that may be positive on the day of surgery. The ASA Preoperative Evaluation Practice Advisory "[r]ecognizes the literature is insufficient to inform patients or physicians on whether anesthesia causes harmful effects on early pregnancy. Pregnancy testing may be offered to female patients of childbearing age and for whom the result would alter the patient's management."[5]

Healthy patients of any age undergoing low- or intermediate-risk procedures without expected significant blood loss are unlikely to benefit from any tests (Table 4–3). Exceptions are a procedure with the injection of contrast (screening blood urea nitrogen [BUN] and creatinine levels are indicated), or the possibility of pregnancy (a pregnancy test should be done). Table 4–5 contains the recommendations for diagnostic tests for patients with coexisting diseases, and taking certain medications, or who are scheduled for a high-risk operation or one in which there is anticipated blood loss. In general, tests are recommended only if their results may

- Change, cancel, or postpone the surgical procedure.
- Change anesthesia and medical management.
- Change monitoring or intra- or postoperative care.
- Confirm an abnormality suspected from the history or physical examination.

The ASA Task Force states that test results are valid and acceptable for up to 6 months prior to the operation if the medical history has not changed substantially.[5]

Many facilities have developed diagnostic testing guidelines to improve patient care, standardize clinical practice, improve efficiency, and reduce costs. With implementation of guidelines, one facility reduced the tests ordered by 60%, improved testing by 81%, and saved almost $80,000 per year. The Mayo Clinic reduced preoperative testing and its costs without a change in outcomes. A cost-to-benefit analysis found that routine urinalysis for all knee replacement surgery in the United States would cost $1.5 million to prevent 1 wound infection.[26] Interestingly, one study found 50% more routine ECGs and 40% more chest radiographs were done in a fee-for-service versus a prepaid practice.[27]

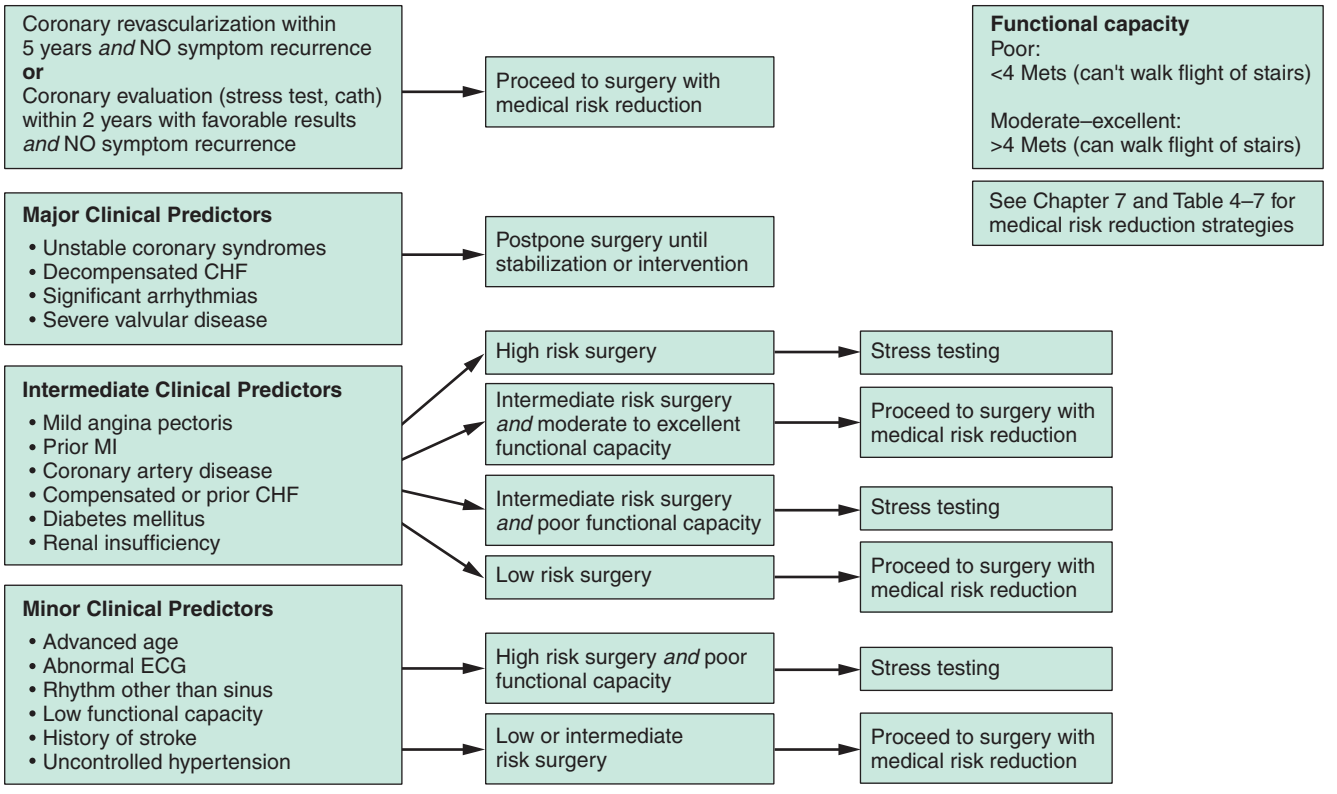

FIGURE 4–2. Simplified cardiac evaluation for noncardiac surgery.

HIGH-RISK PATIENTS

Although many of these conditions are discussed in greater detail in other chapters of this text, here is a brief review of some conditions commonly seen in the preanesthetic assessment clinic and for which preoperative intervention is important. Identification of patients with these comorbid conditions often presents an opportunity for the anesthesiologist to intervene to lower risk. The following conditions are best managed before the day of surgery, which allows ample time for thoughtful evaluation, consultation, and planning.

Heart Disease

Cardiovascular complications are the most common serious adverse event perioperatively. It is estimated that 1–5% of unselected noncardiac surgical patients will suffer a cardiac morbidity. Below is a brief discussion of a few high-risk issues that are likely to be encountered in the preoperative clinic. The patient with ischemic heart disease, heart failure, a rhythm disturbance, an abnormal ECG, an undiagnosed murmur, or a cardiac rhythm management device is discussed. Chapter 7 provides a comprehensive review of cardiovascular disease.

Ischemic Heart Disease

The goals in the preanesthetic encounter are to

- Identify the risk of heart disease based on comorbid diseases (Fig. 4–2);
- Identify the presence and severity of heart disease from symptoms, physical findings, or diagnostic tests;
- Determine the need for preoperative interventions; and
- Modify the risk of perioperative adverse events.

The basis of cardiac assessment is the history, the physical examination, and the ECG. The guidelines for cardiac evaluation before noncardiac surgery published by the ACC/AHA are the national standard of care.[8] Figure 4–2 presents a simplified approach to the evaluation of patients with a history of heart disease before noncardiac surgery. The complete ACC/AHA algorithm is found in Chapter 7. The goal is to identify patients with heart disease who have a significantly high risk of cardiac morbidity and mortality perioperatively. Clinical predictors, functional or exercise capacity, and level of surgical risk guide further diagnostic and therapeutic interventions. Not included in the ACC/AHA guidelines are conditions such as chronic inflammatory diseases (e.g., rheumatoid arthritis, systemic lupus erythematosus), chronic steroid use, and chest irradiation, either alone or associated with more traditional risk factors, identifies patients at risk for CAD and cardiac complications.[28–30]

Anesthesiologists in preanesthetic clinics who apply the ACC/AHA recommendations and develop practice guidelines (Fig. 4–2) are well positioned to initiate evaluation with stress tests. Results may obviate the need for a cardiac consultation or be available at the time of consultation. Exercise treadmill testing is indicated for patients with normal ECGs who can exercise. Pharmacologic tests, such as dobutamine echocardiography or nuclear perfusion imaging, are necessary for those unable to exercise or who have significant ECG abnormalities that may interfere with the interpretation of ischemia via ECG.

Currently, the benefits versus risk reduction of coronary revascularization before noncardiac surgery are controversial.[31] Factors to consider are the urgency of the noncardiac surgery (e.g., in cancer cases) and the potential long-term benefits of revascular-

ization. Noncardiac surgery soon after revascularization (bypass grafting and percutaneous coronary intervention with or without stents) is associated with high rates of perioperative cardiac morbidity and mortality.[32]

Patients who have had a percutaneous coronary intervention, especially with newer, drug-eluting stents, require several weeks, if not months, of antiplatelet therapy to avoid restenosis or acute thromboses. These patients must be identified in the preanesthetic clinic and managed in collaboration with a cardiologist. Given that up to half of all perioperative myocardial infarctions and cardiac deaths can be attributed to plaque rupture in noncritical coronary stenoses, intensive medical management in revascularized patients is likely to be helpful and may account for the lack of benefits of revascularization.[31,33]

Decisions to revascularize patients before noncardiac surgery should be made only after evaluating the risk of perioperative cardiac adverse events, the risks and benefits of the various methods of risk reduction, the benefits of the noncardiac surgery, and the patient's preferences. A face-to-face dialogue with all involved parties, similar to "tumor-board" discussions, may assist decision making. Because cardiac complications are the leading cause of perioperative morbidity and mortality, anesthesiologists must be current on the latest evidence-based recommendations and be active in decision making and in the management of patients at risk.

Heart Failure

Heart failure affects 4–5 million people in the United States and is a significant risk factor for postoperative adverse events. The goal in the preoperative clinic is to identify and minimize the effects of heart failure. Recent weight gain, complaints of shortness of breath, fatigue, orthopnea, paroxysmal nocturnal dyspnea, and edema, recent hospitalizations, and recent changes in management are all significant. Physical findings should focus on examination for third or fourth heart sounds, rales, jugular venous distension, ascites, hepatomegaly, and edema. Classifying the patient's medical status according to the New York Heart Association's (NYHA) categories is useful.[34]

- Class I—no limitation of physical activity; ordinary activity does not cause fatigue, palpitations, or syncope
- Class II—slight limitation of physical activity; ordinary activity results in fatigue, palpitations, or syncope
- Class III—marked limitation of physical activity; less than ordinary activity results in fatigue, palpitations, or syncope; comfortable at rest
- Class IV—inability to do any physical activity without discomfort; symptoms at rest

Diastolic dysfunction may be as common as systolic dysfunction and predicts a poor prognosis outside the perioperative period. The significance of diastolic dysfunction for anesthesia and surgery is less-well defined.

Preoperative ECG, electrolytes, BUN, and creatinine tests are indicated (Table 4–5). An objective measure of left ventricular ejection fraction (LVEF) and ventricular performance is helpful, especially in patients with NYHA class III or IV heart failure. Normal LVEF is >50%; mildly diminished, 41–49%; moderately diminished, 26–40%; and severely diminished, <25%. Patients with class III or IV heart failure should be evaluated by a cardiologist before undergoing general anesthesia or any intermediate- or high-risk procedure. Very minor procedures under monitored anesthesia care (MAC) can proceed as long as the patient's condition is stable.

Rhythm Disturbances and ECG Abnormalities

Arrhythmias and conduction disturbances are common in the perioperative period. Supraventricular and ventricular arrhythmias are associated with a greater risk of perioperative adverse events because of the arrhythmia itself and because they are markers for cardiopulmonary disease. Because uncontrolled atrial fibrillation and ventricular tachycardia are high-risk clinical markers, elective surgery should be postponed until evaluation and stabilization are complete.[8] Rhythms other than sinus are minor clinical predictors (Fig. 4–2).

New-onset atrial fibrillation, symptomatic bradycardia, or high-grade heart block (second or third degree) identified in the preoperative clinic warrant postponement of elective procedures and referral to cardiology for further evaluation. Left bundle-branch block (LBBB) is highly associated with CAD and a recent onset or no previous evaluation of LBBB requires stress testing or cardiology consultation. Right bundle-branch block (RBBB) is likely to be congenital, either a result of calcification and degeneration of the conduction system or secondary to pulmonary disease. Brugada syndrome is a congenital disease characterized by RBBB with ST-segment elevation in the right precordial leads and is associated with a risk of sudden death and lethal arrhythmias. If the history and physical do not suggest significant pulmonary or congenital heart disease, no further evaluation is warranted because of an isolated RBBB. However, RBBB in a patient with pulmonary symptoms is suggestive of severe respiratory compromise that warrants a pulmonary evaluation and echocardiography if an intermediate- or high-risk operation is planned. If congenital heart disease or Brugada syndrome is suspected, a cardiology consultation is indicated.

Left ventricular hypertrophy (LVH) and ST-segment depression on preoperative ECG are associated with a greater risk of myocardial infarction and cardiac death perioperatively.[35] LVH may be associated with diastolic dysfunction and poorly controlled hypertension. Prolonged QT intervals should prompt an evaluation of electrolytes, magnesium, and calcium and a cardiology referral.

Murmurs

The quandary in the preoperative clinic is to determine the cause of cardiac murmurs and to distinguish between significant murmurs and clinically unimportant ones. Diastolic murmurs are always pathologic and require further evaluation. Regurgitant disease is tolerated perioperatively much better than stenotic disease.

Aortic stenosis is the most common valvular lesion in the United States, affecting 2–4% of adults older than 65 years of age; severe stenosis is associated with a high risk of perioperative complications.[8] Once considered a degenerative lesion increasing with age or a congenital bicuspid valve, aortic stenosis is now thought to have much in common with CAD and is an independent marker of CAD.[36]

Aortic *sclerosis,* which also causes a systolic ejection murmur similar to that of aortic stenosis, is present in 25% of adults 65–74 years of age and almost half of those older than 84 years of age.[36] Aortic sclerosis is associated with a 40% increase in the risk of myocardial infarction (MI) and a

50% increase in the risk of cardiovascular death in patients without a history of CAD.[37] There is no hemodynamic compromise with aortic sclerosis.

The cardinal symptoms of severe aortic stenosis are angina, heart failure, and syncope, although patients are much more likely to complain of a decrease in exercise tolerance and exertional dyspnea. Aortic stenosis causes a systolic ejection murmur that is best heard in the right upper sternal border, which often radiates to the neck. Any patient with a previously undiagnosed murmur needs an ECG, and any ECG abnormality warrants an echocardiogram. Because of the difficulties noncardiologists have in distinguishing murmurs of aortic stenosis from those of aortic sclerosis, an echocardiogram should be ordered even without ECG abnormalities, especially if general anesthesia or an intermediate- or high-risk procedure is planned. Current guidelines recommend echocardiography annually for patients with severe aortic stenosis, every 2 years for moderate stenosis, and every 5 years for mild stenosis.[38]

Mitral stenosis is much less common than aortic stenosis and is usually associated with a history of rheumatic heart disease. Mitral stenosis causes a diastolic murmur and should always be further evaluated with ECG and echocardiography. Patients with hypertrophic obstructive cardiomyopathy are often young and male, and may be asymptomatic and without murmurs. An ECG and echocardiogram should be done if there is a personal or family history of syncope with exertion or sudden death, or if a murmur is detected. LVH and ST-segment and T-wave abnormalities on an ECG in an otherwise healthy nonhypertensive patient need to be further evaluated with echocardiography.

Patients at risk for bacterial endocarditis (e.g., those with valvular abnormalities, valve replacements, or complex congenital heart disease but not coronary revascularization) who are scheduled for procedures with the potential for transient bacteremia should be identified preoperatively to plan for treatment.[39]

Cardiac Rhythm Management Devices: Pacemakers and Implantable Cardioverter-Defibrillators

It is estimated that more than 100,000 new cardiac rhythm-management devices (CRMDs) are implanted yearly in the United States. Electromagnetic interference is likely to occur with electrocautery, radiofrequency ablation, magnetic resonance imaging (MRI), and radiation therapy, and can result in malfunction or adverse events.[40] Some patient monitors and ventilators may cause electromagnetic interference in patients with CRMDs with rate-adaptive mechanisms. The preoperative evaluation should determine the type of device and the features (e.g., rate-adaptive mechanisms) likely to malfunction if electromagnetic interference should occur perioperatively. Consultation with the device manufacturer, cardiologist, or the electrophysiology or CRMD service may be needed. Ideally, patients with CRMDs should have these devices interrogated preoperatively. Special features, such as rate adaptive mechanisms and antitachyarrhythmia functions, need to be disabled or the device reprogrammed to an asynchronous pacing mode before surgical procedures and anesthesia where electromagnetic interference is anticipated.[40] Newer-generation devices are more complex and reliance on a magnet, except in emergency situations, is not recommended. Planning ahead is important.

Pulmonary Disease or Patients with Risk Factors for Postoperative Pulmonary Complications

Postoperative pulmonary complications develop in 5% of patients undergoing nonthoracic surgery and as many as 1 in 4 deaths occurring within a week of operation are pulmonary related, making it the second most common serious morbidity after cardiovascular adverse events.[41] Established risk factors for an increased risk of pulmonary complications include the following:[42]

- History of cigarette use (current or >40 pack-years)
- ASA PS scores >2
- Age older than 70 years
- Chronic obstructive pulmonary disease
- Neck, thoracic, upper abdominal, aortic, or neurologic surgery
- Anticipated prolonged procedures (>2 hours)
- Planned general anesthesia (especially with endotracheal intubation)
- Albumin less than 3 g/dL.
- Exercise capacity of less than 2 blocks or 1 flight of stairs
- BMI >30 kg/m^2

Surprisingly absent predictors in the above list are asthma or results from arterial blood gas (ABG) analysis or PFTs. Risk of complications is surprisingly low in well-controlled asthma and in patients treated preoperatively with corticosteroids.[43] Risk is greater in asthmatics with recent exacerbations, a history of postoperative pulmonary complications, recent hospitalizations, or recent intubations for asthma. ABGs are useful in predicting pulmonary function after lung resection surgery but do not predict risk for complications. The degree of airway obstruction, measured by the forced expiratory volume in 1 second (FEV_1) is not predictive of pulmonary complications.[44]

The focus in the preoperative clinic should be on identifying patients at risk for postoperative pulmonary complications and on optimizing those patients with preexisting pulmonary disease (Table 4–5). PFTs may be indicated to diagnose disease (dyspnea caused by lung disease or heart failure?) or assess management (can dyspnea or wheezing be improved further?), but *not* as a risk assessment tool or to deny a beneficial procedure.[44]

The pulmonary status of patients with recent exacerbations or infections should be improved whenever possible. Prescriptions for antibiotics, bronchodilators, and steroids, referral to pulmonologists or internists, or delay of surgery might be necessary. Training patients preoperatively in lung expansion maneuvers, such as deep-breathing exercises and incentive spirometry, reduces pulmonary complications more than giving the training postoperatively.[45] Additionally, a change in perioperative management, including altering the planned surgical procedure if possible, discussing alternatives to general anesthesia, and educating the patient about the benefits of epidural pain management, may provide effective measures to decrease pulmonary complications.[46]

Patients with pulmonary arterial hypertension have a high rate of perioperative morbidity and mortality. The patient's care should be coordinated with a pulmonologist. An ECG and echocardiogram are useful in patients with more than mild disease. Signs and symptoms of disease severity include the following[47]:

- Dyspnea at rest
- Metabolic acidosis
- Hypoxemia
- Right heart failure (peripheral edema, hepatomegaly, jugular venous distension)
- History of syncope

Traditionally, especially with children, cases scheduled for elective procedures were cancelled for patients with current or recent upper respiratory tract infections. With modern anesthetic practices, cancellation is not routine. In patients with severe symptoms, especially those with underlying conditions that may further compromise a safe anesthetic, elective surgery should be postponed for at least 4 weeks.[48] When infection is mild or uncomplicated in healthy patients, there is little risk in proceeding with a procedure to avoid the inconvenience of a cancellation. The dilemma lies with the patients between these extremes. Decisions regarding suitability to proceed should be made on an individual basis. Chapter 19 discusses the pediatric patient with an upper respiratory tract infection in greater detail. Chapter 9 discusses the patient with pulmonary disease in detail.

Obstructive Sleep Apnea

Sleep-disordered breathing affects up to 9% of middle-age women and 24% of middle-age men; less than 15% of these cases have been diagnosed. OSA, the most common serious manifestation of sleep-disordered breathing, is caused by intermittent airway obstruction. OSA is characterized by total collapse of the airway with complete obstruction for more than 10 seconds. Obstructive hypopnea is partial collapse (30–99%) associated with at least a 4% arterial oxygen desaturation. OSA severity is measured on the apnea–hypoxia index (AHI), the number of apneic and hypopneic episodes per hour of sleep. Patients with severe OSA have >30 episodes per hour.

Cardiovascular disease is common in patients with OSA. These patients have an increased incidence of hypertension, atrial fibrillation, bradyarrhythmias, ventricular ectopy, endothelial damage, stroke, heart failure, dilated cardiomyopathy, and atherosclerotic CAD.[49] Mask ventilation, direct laryngoscopy, endotracheal intubation, and even fiberoptic visualization of the airway are more difficult in patients with OSA than in healthy patients.

The Berlin Questionnaire is useful to identify patients with undiagnosed OSA.[50] The presence of any two of the following is considered a high risk for sleep apnea:

- Snoring
- Daytime sleepiness
- Hypertension
- Obesity

Preoperative evaluation should focus on identification of patients at risk for OSA and improving associated comorbid conditions. Table 4–5 identifies the testing guidelines. Echocardiography may be indicated if heart failure or pulmonary hypertension is suspected. Patients should be instructed to bring their continuous positive airway pressure (CPAP) devices to the hospital on the day of operation. Chapter 9 discusses OSA in detail.

Obesity

A BMI of ≥ 40 kg/m^2 defines extreme obesity; obesity is defined as a BMI of 30–39.9 kg/m^2. An overweight person has a BMI of 25–29.9 kg/m^2 (see Physical Examination above for BMI calculation formulas). It is estimated that 64% of adults in the United States are overweight or obese and that 4.7% are extremely obese. Annually 300,000 U.S. adults die of obesity-related issues, and almost 10% of healthcare expenditures in the United States are associated with obesity and inactivity. Obesity is an independent risk factor for heart disease. Hypertension, stroke, hyperlipidemia, osteoarthritis, diabetes mellitus, cancer, and OSA are more common in obese people.

Extremely obese patients may have challenging airways that require specialized equipment, techniques and personnel. They may need prophylaxis for deep venous thrombosis (DVT) with advanced techniques such as inferior vena cava filter placements. They require special operating room tables and gurneys to support excessive weight. Venous access and invasive and noninvasive monitoring can be difficult. Preoperative identification and planning for these contingencies will avoid delays on the day of the operation. Preoperative evaluation should be directed toward coexisting diseases (Table 4–5). Chapter 22 discusses this in greater detail.

Diabetes

An estimated 18 million U.S. adults have diabetes mellitus, which increases the risk of CAD, is considered a CAD equivalent, and is an intermediate-risk factor for perioperative cardiac complications on a par with angina or a previous myocardial infarction.[8,51] Figure 4–2 and Chapter 7 address cardiac evaluation for noncardiac surgery.

Heart failure is twice as common in males and 5 times as common in females with diabetes as in those without diabetes. Poor glycemic control is associated with an increased risk for heart failure and both systolic and diastolic dysfunction may be present. Diabetics are also at increased risk for renal failure perioperatively (see Chap. 13 and Renal Disease below), and for postoperative infections. Recent studies suggest that tighter perioperative control may be warranted. Patients with poor preoperative management of glucose are likely to be more out of control intra- and postoperatively.[52] Obtaining a glycosylated hemoglobin ($HgbA_{1c}$) concentration preoperatively can guide glucose management with intensification of therapy before the procedure. Aggressive management of hyperglycemia decreases postoperative complications. The American College of Endocrinologists position statement recommends a target fasting glucose of <110 mg/dL in noncritically ill patients.[53]

In the preoperative clinic, the focus should be on assessing organ damage and the control of blood sugar. Cardiovascular, renal, and neurologic systems should be evaluated. Ischemic heart disease is often asymptomatic in the diabetic. Table 4–5 has testing suggestions. The goals of perioperative diabetic management include avoidance of hypoglycemia and marked hyperglycemia. Table 4–6 has suggestions for hypoglycemic medication management on the day of the operation.

Hypertension

HTN, defined by 2 or more measurements of blood pressure greater than 140/90, affects 1 billion individuals worldwide. The incidence of HTN increases with age. In the United States, 25% of adults and 70% of patients older than age 70 years have HTN and fewer than 30% are adequately treated. The degree of end-organ damage and morbidity and mortality correlate with the duration and severity of HTN.

TABLE 4–6.

Preoperative Medication Guidelines

- Continue on the day of the operation[a]
  - Antidepressant, antianxiety, and psychiatric medications
  - Antihypertensive medications, except angiotensin-converting enzyme inhibitors or angiotensin receptor blocking agents, which may be selectively discontinued on the day of the operation
  - Antiseizure medications
  - Asthma medications
  - Birth control pills
  - Cardiac medications (e.g. digoxin)
  - Diuretics, such as triamterene or hydrochlorothiazide, for hypertension
  - Heartburn or reflux medications
  - Insulin—all intermediate, combination, and long-acting insulins
    - Type 1 diabetics should take a small amount (usually one-third) of their usual morning long-acting insulin (e.g., lente or NPH) on the day of the operation
    - Type 2 diabetics should take none or up to one-half of long-acting or combination (70/30 preparations) insulins on the day of the operation
    - Patients with an insulin pump should continue only their basal rate on the day of the operation
  - Narcotic pain medications
  - Ophthalmic drops
  - Statins
  - Steroids, oral or inhaled
  - Thyroid medications
  - Cyclooxygenase-2 inhibitors, unless surgeon is concerned about bone healing
- Discontinue 7 days before the operation
  - Aspirin, except for vascular patients and patients having cataract surgery
  - Clopidogrel (Plavix), except for vascular patients and patients having cataract surgery
  - Herbals and nonvitamin supplements
  - Hormone replacement therapy
- Discontinue 4 days before the operation
  - Warfarin (Coumadin), except for patients having cataract surgery without a bulbar block
- Discontinue 48 hours before the operation
  - Nonsteroidal antiinflammatory drugs
- Discontinue 24 hours before the operation
  - Erectile dysfunction medications
- Discontinue on the day of the operation
  - Diuretics, except triamterene or hydrochlorothiazide for hypertension, which should be continued
  - Insulin—all regular insulins
    - Type 1 diabetics should take a small amount (usually one-third) of their usual morning long-acting insulin (e.g., lente or NPH) on the day of the operation
    - Type 2 diabetics should take none or up to one-half of long-acting or combination (70/30 preparations) insulins on the day of the operation
    - Patients with an insulin pump should continue only their basal rate on the day of the operation
  - Iron
  - Oral hypoglycemic agents
  - Topical medications (e.g., creams or ointments)
  - Vitamins
- Special considerations before the operation
  - Monoamine oxidase inhibitors—patients taking these antidepressant medications need an anesthesia consultation before the operation (preferably 3 weeks before)

[a]Patients should take medications with a small sip of water even if otherwise nothing by mouth (NPO).

Ischemic heart disease is the most common form of organ damage associated with HTN. *Uncontrolled* HTN is an ACC/AHA *minor* cardiac risk factor and the odds ratio for an association between HTN and perioperative cardiac risk is 1.31.[8,54] There is little evidence of an association between preoperative blood pressures <180/110 mm Hg and perioperative cardiac risk. Heart failure, renal insufficiency, and cerebrovascular disease are more common in hypertensive patients.

It is generally recommended that elective surgery be delayed for severe HTN (diastolic blood pressure >115 mm Hg; systolic blood pressure >200 mm Hg) until the blood pressure is <180/110 mm Hg. If severe end-organ damage is present, the goal should be to normalize blood pressure *as much as possible* before the operation.[54] There is no evidence to justify cancellation of an operation when blood pressure is <180/110 mm Hg, although interventions preoperatively are appropriate. Severely elevated blood pressure should be lowered over several weeks.

Testing should be determined by the history and physical examination (Table 4–5). Guidelines suggest that cardioselective β-blocker therapy is the best treatment preoperatively because of a favorable profile in lowering cardiovascular risk (Table 4–7).[8] Effective lowering of risk may require 6–8 weeks of therapy to allow regression of vascular changes and too rapid or extreme lowering of blood pressure may increase cerebral and coronary ischemia. The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack (ALLHAT) trial showed that effective treatment of HTN is not simply a matter of lowering blood pressure.[55] Continuation of antihypertensive treatment preoperatively is critical (Table 4–6). Chapter 7 has more information on the hypertensive patient.

Renal Disease

A normal creatinine level is often not an accurate indicator of renal function. A doubling of serum creatinine from 0.8 to 1.6 mg/dL represents a halving of glomerular filtration rate (GFR). Creatinine does not exceed the normal limits until GFR has fallen below 50 mL/min. GFR decreases with age and the renal reserve of a healthy 80-year-old is less than half that of a

TABLE 4–7.

β-Blockers: Preoperative Instructions

Rationale. The pre- and postoperative administration of β-blockers reduces morbidity and mortality in patients at risk for cardiac complications after surgery of intermediate or high risk. The purpose of this protocol is to identify at-risk patients for prophylactic treatment with β-blockers preoperatively.

Inclusion criteria

1. Patients scheduled for surgical procedures of moderate to high risk such as
   - All vascular surgical procedures: aortic, peripheral, carotid
   - Major orthopedic, total joints, open back
   - Open abdominal or pelvic, GI, urologic, gynecologic
   - Open thoracic or procedures requiring one-lung ventilation
   - Major neurosurgical such as craniotomy, spinal
   - Major head and neck

and

2. Known coronary artery disease

or

3. At least 2 of the following risk factors for coronary artery disease
   - Age >70 years
   - Diabetes mellitus
   - Poorly controlled hypertension (systolic >160 mm Hg; diastolic >100 mm Hg)
   - Peripheral vascular or carotid arteriosclerosis
   - Renal insufficiency (creatinine ≥2.0)
   - Cerebrovascular disease (stroke, transient ischemic attack)
   - Poor functional status (fewer than 5 METS; i.e., unable to walk up a flight of stairs or walk 2 blocks without stopping) (Table 4–4)

Exclusion Criteria

1. Pulmonary disease with significant reactive component, taking β-agonists daily or oral steroids, unless already taking a β-blocker
2. Acute congestive heart failure or severe left ventricular dysfunction (ejection fraction <0.30) or recent (<1 month) hospitalization for congestive heart failure unless already taking a β-blocker
3. Second- or third-degree heart block
4. β-Blocker allergy
5. Systolic blood pressure <90 mm Hg or heart rate <50 beats/min

Preoperative Instructions

1. Start atenolol or metoprolol 25–50 mg/d titrating heart rate to <65 beats/min
2. Patients already taking a β-blocker should continue until the day of the operation; titrate to target heart rate of 65–80 beats/min

healthy 40-year-old. The focus of the preoperative evaluation of patients with renal insufficiency or failure should be on the cardiovascular and cerebrovascular systems, fluid volume, and electrolyte status. Chronic metabolic acidosis is common but usually mild and compensated for by chronic hyperventilation. Table 4–5 has testing recommendations.

Chronic renal disease is a significant risk factor for cardiovascular morbidity and mortality and is an ACC/AHA intermediate cardiac risk factor equal to a history of known CAD. The annual incidence of death from CAD in patients with both diabetes and end-stage renal disease who are on hemodialysis is 8.2%. A creatinine ≥ 2.0 mg/dL should trigger an assessment of cardiac risk using the ACC/AHA guidelines (Fig. 4–2).[8] Chapter 7 provides a more detailed discussion of these guidelines.

In elective cases, hemodialysis should be performed within 24 hours of the operation, but not immediately before. Hemodialysis is associated with fluid and electrolyte (sodium, potassium, magnesium, phosphate) imbalance and shifting of electrolytes between intra- and extracellular compartments. Hemodialysis should be performed to correct volume overload, hyperkalemia, and acidosis.

Patients at risk for perioperative renal failure include those with preexisting renal insufficiency and diabetes, especially in combination, and those undergoing procedures with the administration of contrast medium. If all 3 conditions are present, the risk of renal failure may be as high as 50%. Preoperative identification of at-risk patients may change management, such as administration of sodium bicarbonate, a change in type of contrast medium, and avoidance of hypovolemia or even vigorous hydration. Chapter 13 has a complete discussion of the patient with renal disease.

Hepatic Disease

Predictors of poor perioperative outcome in patients with liver disease include the following[56]:

- Acute hepatitis (viral or alcoholic)
- Chronic active hepatitis with jaundice, encephalopathy, coagulopathy, or elevated liver enzymes
- Child's C cirrhosis (bilirubin >3 mg/dL, albumin <3 g/dL, PT >6 seconds more than control, poor nutritional status, large amount of ascites, and moderate encephalopathy)
- Abdominal surgery
- PT >3 seconds prolongation refractive to vitamin K therapy

Salt and water restriction, diuretic therapy (spironolactone is preferred), enteral nutritional supplements, and oral vitamin K (1–5 mg daily for 3–5 days) are indicated preoperatively to correct deficiencies. Delaying elective surgery until after an acute episode of hepatitis or an exacerbation of chronic disease has resolved is appropriate. Table 4–5 suggests the appropriate tests; Chapter 14 discusses the patient with liver disease in detail.

Anemia

Consequences from moderate levels of anemia and Hgb levels ≥ 6.0 g/dL in patients without CAD are minimal. The ASA Task Force on Blood Component Therapy concluded that red blood cells should not be transfused solely because of a Hgb level but rather because of risk for complications from inadequate oxygenation.[57] Transfusion is rarely indicated when the Hgb is >10 mg/dL, and almost always needed when the Hgb is <6 mg/dL. The goal in the preoperative clinic is to determine the etiology, duration, and stabil-

ity of the anemia, and to consider the extent and type of surgery, the anticipated blood loss, and the patient's comorbid conditions that may impact oxygenation, such as pulmonary, cerebrovascular, or cardiovascular disease. Type and screen testing before the day of operation and planning for the availability of blood will avoid delay of the procedure. This can ease the burden on the blood bank personnel for same-day admission or outpatient surgery. A protocol can be instituted with the department of surgery and the blood bank. In special circumstances, such as a patient's refusal of perioperative blood transfusions or for elective procedures with expected significant blood loss in anemic patients, postponement of surgery to treat with recombinant human erythropoietin and iron may be warranted.

Sickle cell disease is a hereditary hemoglobinopathy and vasoocclusion is responsible for most of the associated complications. Preoperative assessment should focus on identification of organ dysfunction and acute exacerbations.[58] Frequent hospitalizations or a recent increase in hospitalizations, increasing age, preexisting infections, and pulmonary disease predict perioperative vasoocclusive complications.[58] The preoperative history and physical examination should focus on the frequency, severity, and pattern of vasoocclusive crises and the degree of pulmonary, cardiac, renal, and central nervous system damage. Measurement of pulse oximetry, Hct, BUN, and creatinine, ECG, and a chest radiograph are indicated. Additional testing (e.g., echocardiogram, arterial blood gases) may be needed. Prophylactic transfusion may be beneficial, especially before intermediate- to high-risk operations. Preoperative prophylactic transfusion is controversial and the decision to transfuse should be made in concert with a hematologist familiar with the disease. Chapter 15 discusses in detail the patient with anemia.

Neurologic Disease

For a patient with neurologic disease (e.g., stroke, seizure disorder, multiple sclerosis), a detailed history is required with focus on recent events, exacerbations, or evidence for poor control of the medical condition. A basic neurologic examination documenting deficits in mental status, speech, cranial nerves, gait, and motor and sensory function is important. This baseline enables postoperative comparison and evaluation of new deficits. If a stroke or transient neurologic deficit is not fully evaluated or occurs within 1 month before the operation, elective surgery should be delayed pending complete evaluation. A newly discovered carotid bruit requires a careful history of related symptoms and carotid Doppler studies, especially if the procedure is likely to involve manipulation of the neck or if the patient has a potentially difficult airway. Significant abnormalities on Doppler studies should prompt a referral to a vascular surgeon or neurologist.

Routinely ordering tests for serum drug levels of antiseizure medications is not indicated unless toxicity is a concern or the patient is having breakthrough seizures. Patients with good control of seizures may have levels outside the therapeutic range and results may be confounded if the timing of the administration of the drugs in relation to when the test is drawn is not considered. Table 4–5 has testing suggestions and Chaps. 10 and 11 discuss neurologic diseases in detail.

Cancer Patients

Patients with a history of cancer may have complications related to the disease or the treatment. Preoperative evaluation should focus on evaluation of the heart, lungs, and neurologic and hematologic systems. Previous head and neck irradiation may cause carotid artery disease, hypothyroidism, or difficulty with airway management.[59] Auscultation for bruits, thyroid function tests (thyroid-stimulating hormone levels), and carotid Doppler studies are recommended.

Mediastinal, chest wall, and left breast irradiation can cause conduction abnormalities, cardiomyopathy, valvular abnormalities, and premature CAD even without traditional risk factors.[60] Cardiovascular disease is the second most common cause of mortality in survivors of Hodgkins disease. One study found that 88% of patients had echocardiographic abnormalities 5–20 years after treatment, most of them asymptomatic. Treatment at a younger age increases risk. These risk factors were not considered in the ACC/AHA *Guidelines for Cardiac Evaluation for Noncardiac Surgery* but they may be important predictors of CAD.[60] ECG, echocardiography, and stress testing may be indicated. Table 4–5 lists suggested diagnostic testing.

Substance Abuse

Patients who use alcohol to excess or illicit drugs may not give a reliable history. Addicts may be at risk for a myriad of perioperative complications, including withdrawal, acute intoxication, an altered tolerance to anesthetic and opioid medications, infections, and end-organ damage. Preferably, patients with drug or alcohol dependence should be drug-free well before an elective operation. Acute preoperative abstinence in alcoholics, however, is associated with a poorer outcome postoperatively than if drinking is continued.[61]

Preanesthesia clinic staff should be prepared to refer patients to addiction specialists or programs or prescribe medications to prevent withdrawal in the preoperative period if patients agree to abstinence. Intravenous drug use should prompt an evaluation for cardiovascular, pulmonary, neurologic and infectious complications. Because intravenous access is often limited in users, interventional radiology may be needed to help with line placement. Alcoholics need assessment of cardiovascular, hepatic, and neurologic alterations. Testing depends on symptoms and findings from the history and physical. ECG, echocardiography, chest radiography, and chemistry and hepatic panels may be needed. Table 4–5 and Chap. 23 provide additional information.

Patients with or at Risk of Thromboembolism and/or Pulmonary Emboli

Recent arterial or deep venous thromboembolism requires postponement of non–life-saving procedures. Without anticoagulation, the risk of recurrent DVT within 3 months of a proximal deep venous thromboembolism is approximately 50%. A month of warfarin treatment reduces the risk to 10%; and 3 months of warfarin treatment reduces the risk to 5%. Patients with a hereditary hypercoagulable state, cancer, or multiple episodes of DVT are at higher risk indefinitely. Patients with nonvalvular atrial fibrillation who have had a previous cerebral embolism also are at high risk. Patients with mechanical heart valves, especially

multiple valves, are at risk for embolism. Risk is greater with mitral than with aortic valves. Surgery increases the risk of deep venous thromboembolism, but there is no evidence that surgery increases the risk of arterial embolism in patients with atrial fibrillation or mechanical valves.[62]

An elective operation scheduled for the first month after an episode of venous or arterial thromboembolism should be postponed. If postponement is not possible, then the patient should receive preoperative heparin while the international normalized ratio (INR) is below 2.0.[62] Ideally, 3 months of anticoagulation is recommended before an elective operation. See the section on Medication Instructions and Table 4–6 for further discussion of warfarin management preoperatively. Chapter 15 discusses patients with coagulation disorders.

Smokers and Those Exposed to Secondhand Smoke

Exposure to tobacco, directly or through "secondhand" smoke, increases the risk of many perioperative complications. Smokers are more likely to experience wound infections, respiratory or airway complications (including oxygen desaturation), and severe coughing.[63] Smoking decreases macrophage function, negatively impacts coronary flow reserve, and causes vascular endothelial dysfunction, hypertension, and ischemia. Smokers require longer hospital stays and more often need postoperative intensive care than do nonsmokers.

The greatest benefit of smoking abstinence is probably only realized after several months of cessation. In studies reporting a greater perioperative risk in recent quitters than in smokers, selection bias may have contributed to the results. The patients who were motivated to stop or advised to quit smoking may have been at greater risk because of health status. Soon after a patient quits smoking carbon monoxide levels decrease, which improves oxygen delivery and use. Cyanide levels decrease, which benefits mitochondrial oxidative metabolism. Lower nicotine levels improve vasodilatation and many toxic substances that impair wound healing decrease. Patients without a history of ischemic heart disease who smoked shortly before operation had significantly more episodes of rate-pressure product-related ST-segment depression than did nonsmokers, former smokers, or chronic smokers who did not smoke in the immediate preoperative period.[64]

A preoperative smoking cessation intervention in patients who underwent knee and hip replacements decreased rates of surgical-site infections from 23% in the conventional group to 4% in those who stopped smoking. The U.S. Public Health Service recommends that "*all* physicians should strongly advise every patient who smokes to quit because evidence shows that physician advice to quit smoking increases abstinence rates."[65] Nearly 70% of smokers want to quit.

Effective interventions include medical advice and pharmacotherapy, such as nicotine-replacement therapy, which is safe in the perioperative period. Nicotine patches, gum, and lozenges are available without a prescription; nasal spray and bupropion (Wellbutrin) require prescriptions. Clonidine is also effective. Bupropion or clonidine should be started 1–2 weeks before a quit attempt; nicotine replacement therapy is effective immediately.[66] Individual and group counseling may increase rates of long-term abstinence. Many hospitals, insurance companies, and communities offer smoking cessation programs. Excellent resources are available on the Internet and from the U.S. government. Advice and guidelines are available at *http://www.surgeongeneral.gov/tobacco/default.htm*. Tobacco-intervention training during medical school and residency can significantly improve the quality of physician counseling and rates of abstinence.

The Elderly

By the year 2030 almost 70 million persons older than 65 years of age will be alive in the United States and a significant portion of these will be 85 years of age or older. The number of patients older than 65 years of age who will undergo noncardiac surgery will increase from 7 to 14 million by 2025. Chronological age, however, is a less important determinant of operative outcome than are comorbid conditions and physiologic age. Age >70 years is an independent predictor of postoperative mortality, cognitive dysfunction, major perioperative complications, and longer hospital stays.[67] Organ function declines in the elderly, who respond differently to medications and have a greater number of comorbid conditions. Among the conditions are arthritis, hypertension, heart disease, and diabetes. One study found coexisting disease in 95% of geriatric patients scheduled for surgery. Postoperatively 35% of patients had cardiac or pulmonary complications that were associated with comorbid conditions, and many could have been predicted preoperatively.[68] Other studies have found that the rate of perioperative complications among the very elderly (>85 years of age) is not prohibitive.[67]

Elderly individuals often do not return home immediately after an operation for various reasons. They need rehabilitation, their recovery takes longer, they have a high incidence of postoperative delirium (26% prevalence at 1 week, 10% at 3 months), or support services are lacking. Discharge planning in advance may lessen the costs of perioperative elder care. Preoperative clinics can be designed to offer multidisciplinary care and after-discharge planning that coordinates with surgical, nursing, and social service departments.[69]

Testing in the elderly patient should be based on disease indications rather than age alone (see Tables 4–3 and 4–5 and the section in this chapter on age-based testing under Preoperative Testing). Chapter 20 presents an expanded discussion of the evaluation of the geriatric patient.

Cataract Patients

Patients undergoing cataract surgery are often elderly with extensive comorbid disease. The procedure is minor, however, without expected systemic physiologic disturbances or significant postoperative pain. Topical anesthesia is commonly used and because general anesthesia is rarely required, the risk is lessened. Elective cataract surgery has the enormous benefits of allowing individuals to drive, read, avoid isolation, watch television, and decrease the incidence of falls. The cost of routine medical testing before cataract surgery is estimated at $150 million annually. In a study of more than 18,000 patients randomly allocated to no *routine* testing before cataract surgery or to a battery of tests, including ECG, complete blood count (CBC), and electrolytes, BUN, creatinine, and glucose levels, no differences in postoperative adverse events were found between the two groups.[70]

The results of this study do not suggest that patients undergoing cataract surgery require no laboratory testing.[70] The study of cataract patients eliminated routine tests, not tests indicated for a new or worsening medical problem. The group that crossed over from no testing to some testing had significantly more coexisting illness and poor self-reported health status. This finding suggests that the preoperative care provider screen patients to order tests for those who require them. In the study described, exclusion criteria were general anesthesia or a myocardial infarction within 3 months. *All* patients underwent a *preoperative medical assessment*. More than 85% of enrollees reported good to excellent health status, almost 25% reported no coexisting illnesses (including hypertension, anemia, diabetes, and heart or lung disease), almost 30% were <70 years old, and 65% were ASA PS 1 or 2 status, suggesting a fairly healthy group.[70] If patients are comparable to those in the study, are routinely evaluated by primary care physicians, have stable mild disease, and will undergo cataract operation under topical or bulbar block, then no special testing is required because of cataract surgery. Serious, poorly controlled conditions must be normalized before surgery, and selective testing suggested by history and physical examination may be necessary. Although testing is rarely necessary *because* of cataract surgery, patients with limited access to healthcare services may benefit from medical evaluation. The ACC/AHA *Guidelines for Cardiac Evaluation for Noncardiac Surgery* consider cataract surgery to be low risk.[8] Tables 4–3 and 4–5 list testing indications for particular diseases.

The Difficult Airway

An important part of preoperative evaluation is assessment of the airway. If a patient with a difficult airway can be identified before the day of operation, special equipment or personnel with advanced training and skills in airway management can be available without delaying or postponing procedures or compromising patient safety.[1] Patients with the following characteristics may have a challenging airway:

- Obstructive sleep apnea
- Snoring
- Obesity
- Facial and neck deformities from previous operation
- Head and neck radiation
- Head and neck trauma
- Congenital abnormalities
- Rheumatoid arthritis
- Down syndrome
- Scleroderma
- Cervical spine disease or previous operation

The ease or difficulty of laryngoscopy and intubation are discussed extensively in the literature. However, equally, if not more, important is the ability to predict difficulty with mask ventilation.[71] The following patient characteristics independently suggest difficulty with mask ventilation:

- Age >55 years
- BMI >26 kg/m^2
- Lack of teeth
- A beard
- Snoring history

Patients with Down syndrome or rheumatoid arthritis may have asymptomatic atlantoaxial subluxation and cervical spine instability. A careful history may elicit neurologic deficits or neck and shoulder pain. Patients with neurologic deficits or symptoms, and rheumatoid arthritis patients with long-standing, severely deforming disease need cervical spine radiographs with special flexion, extension, and open-mouth odontoid views.

Chapter 8 discusses the evaluation of the patient with a difficult airway. The goals in the preoperative clinic should be documentation of an airway examination, including Mallampati score, status of teeth (Fig. 4–1), range of motion of the neck, thyromental distance, body habitus, and pertinent deformities. Previous anesthetic records should be obtained and a discussion of awake fiberoptic intubation with the patient may be appropriate. See Physical Examination above for components of the airway examination.

Anesthesia-Specific Concerns

A personal or family history of pseudocholinesterase deficiency should be identified preoperatively. Records from previous anesthetics may clarify an uncertain history. If time allows, a dibucaine number and pseudocholinesterase, chloride, and fluoride levels should be obtained. A history of malignant hyperthermia (MH) or a suggestion of it (hyperthermia or rigidity during anesthesia) either in a patient or family member should be clearly documented and arrangements made before the day of operation.

Ambulatory Surgery

Approximately 60–70% of surgical procedures are performed on an outpatient basis, and of these, 5–8% are performed in an office setting. A study of ambulatory surgery in Medicare beneficiaries older than 65 years of age found no deaths on the day of operation when the procedure was performed in a physician's office; 2.3 deaths per 100,000 procedures when performed in a freestanding ambulatory surgical center; and 2.5 deaths per 100,000 when performed at an outpatient hospital. The 7-day mortality was 35 per 100,000, 25 per 100,000, and 50 per 100,000 respectively. Age >85 years, significant comorbidity, and type of procedure predicted adverse events.[72]

Almost half of ambulatory surgical procedures are performed in patients age 65 years and older. Elderly patients may bring specific problems to the ambulatory setting as they often have multiple chronic conditions and poor eyesight, and may be unable to perform activities of daily living such as feeding themselves or driving. Some patients have limited support during the stress of recovery from anesthesia and surgery.[69] Chapter 20 and The Elderly above discuss preoperative evaluation of this population in greater detail.

Patients with OSA may require skilled and specialized airway management. They are typically sensitive to anesthetic agents (less airway muscle tone than normal, which leads to airway collapse) and narcotics (greater than average respiratory depression). They may require longer postoperative monitoring and the American Sleep Apnea Association suggests that some patients with sleep apnea might not be candidates for ambulatory surgery.

Obese patients may require specialized equipment to accommodate their weight, which might not be readily available in ambulatory facilities. Patients with a history or family history of MH may require prolonged observa-

tion in the recovery period, so planning is important. Whether a patient susceptible to MH is a candidate for ambulatory surgery should be decided well before the day of operation. Patients with a history or who are at risk of a difficult airway may need specialized equipment and personnel that might not be available. Individuals with pacemakers and ICDs may not be candidates for freestanding ambulatory facilities if electromagnetic interference is likely.

PATIENT MANAGEMENT

Management of comorbid conditions and interventions to reduce risk are as important as identification and diagnosis of medical disease. If anesthesiologists are not going to intervene to improve new or chronic disease states, then close collaboration with primary care physicians, specialists, and surgeons are essential. Far too many anesthesia practices collect information without having processes in place to follow through to manage patients and risk so as to improve outcomes and reduce adverse events.

Consultations

Collaborative care of patients is often necessary and beneficial. Consultation initiated by the preoperative physician should seek specific advice regarding diagnosis and status of the patient's condition(s). Asking specific questions such as "Does this patient have CAD?" or "Is this patient in the best medical condition for planned thoracotomy with lung resection under general anesthesia?" is the first step. Letters or notes stating "cleared for surgery" are rarely sufficient to design a safe anesthetic. A letter summarizing the patient's medical problems and condition, along with the results of diagnostic tests, are necessary.

Close coordination and good communication among the preoperative anesthesiologist, surgeon, and consultant is vitally important. Miscommunication among care providers was central to most reported incidents in the Australian Incident Monitoring Study (AIMS) whenever preoperative assessment was implicated.[1]

In many practices the cardiology service is most frequently consulted perioperatively. In one survey, however, the usefulness of such consultations was questioned by anesthesiologists. Unfortunately, only 17% of anesthesiologists felt obligated to follow the consulting cardiologist's recommendations. Forty percent of the consultations contained only the recommendation to "proceed with the case," "cleared for surgery," or "continue with current medications." Recommendations regarding intraoperative monitoring or cardiac medications were largely ignored. Part of this responsibility lies with the consulting physicians (be that surgeons or anesthesiologists) and the long-standing practice of asking for or receiving cardiac "clearance." This is a vague request and a response (often scribbled on a prescription pad) simply stating "low risk" or "cleared for surgery" is meaningless and unhelpful. In general, preoperative consultations should be sought for diagnosis, evaluation, and improvement of a new or poorly controlled condition, and for creation of a clinical risk profile that the patient, anesthesiologist, and surgeon use to make management decisions.

Detailed discussions and communication, preferably oral, are essential for the best management of complicated patients. Copies of diagnostic studies that accompany the consultation letter help the anesthesiologist to make an independent decision about patient risk and to plan anesthetic care. Chapter 6 has a detailed discussion of consultations.

Practice Guidelines

An important element for a successful preoperative evaluation system is a uniform, consistent method for assessment and management. Even though individual judgment is necessary, guidelines and policies for the group should be developed. Cancellations, delays, or demands for additional diagnostic testing on the day of operation after a patient has been evaluated and deemed acceptable for anesthesia by the preoperative clinic is detrimental to the success of a preoperative assessment program.

Practice guidelines improve the process of preoperative evaluation and management and affect surgical outcomes. Guidelines minimize variation in clinical practice and make good use of resources. They may help to avoid cancellations or delays on the day of operation when the anesthesiologist in the preanesthetic clinic and the one performing the anesthesia have differences in opinion about the patient's fitness for operation. This will prevent patient inconvenience and disappointment and surgeon dissatisfaction. Guidelines synthesized from the best, most current sources help practitioners stay up-to-date with recommendations and the literature by assimilating treatments and diagnostics into their practices. Guidelines can be as simple as an organization of the type and timing of care delivered to typical, uncomplicated patients, or as complex as instructions for dealing with a specific issue expressed by decision trees in branching logic format.[73] Acceptance is more likely when disease-specific algorithms are developed and agreed to by all stakeholders. The intent is not to design inflexible standards, but to provide a consistent, straightforward method to evaluate a particular disease such as hypertension or CAD; a finding such as a murmur; or a symptom such as chest pain. Practice guidelines recommend care based on scientific evidence and broad consensus, but leave room for justifiable variations in practice.

Practice guidelines typically rely on evidence-based medicine that examines the data from clinical research. Intuition, personal clinical experience, and pathophysiologic rationale are less important. The practice and teaching of evidence-based medicine requires skills that are not part of traditional medical training. Precisely defining a problem and the information required to resolve the problem are important first steps. The pertinent studies from a well-conducted literature search are selected and applied to the treatment of medical conditions found in patients.

Algorithms such as in Figure 4–2, and guidelines such as those in Tables 4–3, 4–5, and 4–7, are examples.

Nothing by Mouth Guidelines

Historically, patients have been told to abstain from oral intake (nothing by mouth [NPO]) after midnight regardless of the time of their procedure to reduce the risk of aspiration. Twenty years ago Miller found that a light breakfast (of tea and toast) 2–4 hours before an operation did not negatively impact gastric pH or volume. In many European countries today, patients are allowed to eat a "light breakfast" if an operation is scheduled for noon or after. However, this practice has not received widespread adoption in the

United States. Because oral fluids have short gastric transit times many, if not most, departments of anesthesia modified the "nothing after midnight" approach. The ASA recommends that healthy patients who will undergo elective procedures be allowed to drink clear liquids (e.g., water, juice without pulp, coffee or tea without cream or milk) until 2 hours before anesthesia; breast milk until 4 hours before anesthesia; and nonhuman milk, infant formula, or a light breakfast until 6 hours before procedures requiring anesthesia (Table 4–8).[74]

Medication Instructions

Some medications should be continued on the day of operation because of their beneficial effects; others may be harmful or contraindicated.[75] Medications associated with withdrawal effects (e.g., β-blockers, centrally acting sympatholytics, benzodiazepines, and opioid analgesics) should be continued through the preoperative period. Table 4–6 describes in detail drugs to be continued or discontinued before an operation.

Most antihypertensive medications, with the possible exception of angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin receptor-blocking agents (ARBs) should be taken before operation.[76] ACEIs and ARBs may be associated with greater risk for hypotension upon induction of general anesthesia. For significant procedures with planned neuraxial blockade or general anesthesia in well-controlled hypertensive patients, it may be beneficial to hold these drugs on the day of operation. In our preoperative clinic patients who will undergo minor procedures with monitored anesthesia care, and those with poorly controlled hypertension are advised to continue these drugs on the day of operation to reduce the risk of significantly elevated blood pressure in the pre- and postoperative periods. β-Blockers and centrally acting sympatholytics (e.g., clonidine) can be associated with rebound hypertension when withdrawn.

Consensus is lacking on the recommendations to discontinue diuretics preoperatively. Diuretics (e.g., hydrochlorothiazide) to treat HTN may help to control blood pressure when continued on the day of operation. Withholding potent loop diuretics (e.g., furosemide) on the day of operation may decrease the risk of hypokalemia, volume depletion, and renal insufficiency. Intravenous admission by the anesthesiologists on the day of operation is an option.

TABLE 4–8.

Guidelines for Food and Fluids Before Elective Surgery

Time Before Surgery	Food or Fluid Intake
Up to 8 hours	Food and fluids as desired
Up to 6 hours[a]	Light meal (e.g., toast and clear liquids[b]), infant formula, nonhuman milk
Up to 4 hours[a]	Breast milk
Up to 2 hours[a]	Clear liquids[b] only; no solids or foods containing fat in any form
During the 2 hours	No solids, no liquids

[a]This guideline applies only to patients who are not at risk for delayed gastric emptying. Patients with the following conditions are at risk for delayed gastric emptying: morbid obesity; diabetes mellitus; pregnancy; a history of gastroesophageal reflux; a surgery limiting stomach capacity; a potential difficult airway; opiate analgesic therapy.

[b]Clear liquids are water, carbonated beverages, sports drinks, and coffee or tea (without milk). The following are not clear liquids: juice with pulp, milk, coffee or tea with milk, infant formula, and any beverage with alcohol.

Medications used by patients with a history of or who are at risk for heart disease, such as β-blockers, digoxin, antiarrhythmics, and statins, should not be withdrawn before operation. Not only are they beneficial, but risk may be increased when they are not taken.[8]

Pulmonary medications, such as theophylline, inhaled β-agonists, inhaled anticholinergics, and inhaled or oral steroids, should be continued preoperatively.

Oral hypoglycemic agents should be held the day of operation to avoid hypoglycemia. Taking small amounts of long-acting insulin on the day of operation presents little risk of hypoglycemia, but results in improved perioperative control. Patients with types 1 and 2 diabetes should discontinue all short-acting insulins on the day of operation. Type 2 diabetics should take none or up to one-half dose of long-acting (e.g., lente or neutral protamine Hagedorn [NPH]) or combination (70/30 preparations) insulins on the day of operation. Type 1 diabetics should take a small amount (usually one-third to one-half) of their usual morning long-acting insulin (e.g., lente or NPH) on the day of operation to avoid diabetic ketoacidosis. Patients with an insulin pump should continue their basal rate only.

Warfarin may be associated with increased bleeding except for minor procedures such as cataract surgery without bulbar blocks. There is no consensus on the optimal perioperative management of patients on warfarin. The usual recommendation is to withhold 4 doses of warfarin before operation (if the INR is 2.0–3.0) to allow the INR to decrease to <1.5, a level considered safe for surgical procedures and neuraxial blockade.[6,77] If the INR is >3.0, it is necessary to withhold warfarin longer than 4 doses. If the INR is measured the day before the operation and remains >1.8, a small dose of vitamin K (1.0–5.0 mg orally or subcutaneously) can reverse anticoagulation.[63]

Substitution with shorter acting anticoagulants such as unfractionated or low-molecular-weight heparin, referred to as bridging, is controversial and should be individualized.[62] Kearon recommends preoperative bridging with intravenous heparin only for patients who have had an acute arterial or venous thromboembolism within 1 month before operation if the procedure cannot be postponed.[62]

Most medications for neurologic and psychological problems should be continued on schedule in the preoperative period. Antiepileptics, antiparkinson medications, antidepressants, including monoamine oxidase inhibitors (MAOIs), antipsychotics, benzodiazepines, and drugs to treat myasthenia gravis are best maintained to avoid exacerbations of symptoms. Antianxiety and psychiatric medications should be continued up until the time of the procedure. Communication is crucial to alert the day of operation caregivers because alterations in anesthesia may be necessary when caring for patients on these medications, especially for patients taking MAOIs.

Highly active antiretroviral regimens to treat human immunodeficien-

cy virus require regular dosing to prevent drug resistance. It is important to maintain these as scheduled. Antibiotics should be taken to complete a prescribed course of therapy.

Patients taking narcotic pain medications should be told to continue these medications as needed, including on the day of operation. Missed doses may result in withdrawal symptoms and significant pain with the associated stress response and hemodynamic perturbations.

Aspirin and other nonsteroidal antiinflammatory drugs (NSAIDs) are generally discontinued before the day of operation. Circumstances may dictate otherwise to prevent myocardial infarction or stroke, to improve patency of vascular grafts, and to achieve better pain control. There is a lack of consensus about discontinuing these medications. Stopping aspirin and NSAIDs may be more important for intracranial, spinal, and some ophthalmologic (other than cataract) procedures. Aspirin may be continued for patients at high risk for cardiovascular and cerebrovascular complications and for those scheduled for vascular reconstruction. Discontinuation of nonaspirin NSAIDs may benefit patients at risk for renal insufficiency and continuation may be preferred to improve pain management. Aspirin and other NSAIDs do not need to be discontinued for planned neuraxial or regional anesthesia techniques. If the decision to discontinue these agents is made, aspirin should be stopped 5–7 days before the operation and other NSAIDs 24–48 hours before the operation.[78] Many cold preparations and over-the-counter drugs (e.g., Alka-Seltzer and Pepto-Bismol) may contain aspirin.

More potent antiplatelet agents, such as clopidogrel (Plavix) may be associated with a substantial risk of perioperative bleeding. These drugs should be discontinued 7 days before the operation.

Thyroid replacement drugs and antithyroid medications should continue on schedule.[75] Patients taking steroids regularly should take their usual dose on the day of operation.[79] Patients who have taken more than the equivalent of 7.5 mg of prednisone a day for at least 2 weeks within the previous year may be at risk for stress-associated adrenal insufficiency.

Postmenopausal hormone replacement therapies containing estrogen increase the risk of perioperative thromboembolic complications and should be discontinued before operation.[80] Estrogens must be stopped approximately 1 month before the operation to return coagulation to baseline. Most modern oral contraceptives have low doses of estrogen that increase thromboembolic risk minimally. The risk of unanticipated pregnancy may outweigh the benefits of discontinuing oral contraceptives.

Herbals and supplements may interact with anesthetic agents, alter the effects of prescription medications, and increase bleeding. Many patients do not consider supplements to be medications and will not report them in a list of their medications unless asked. Gingko biloba, echinacea, garlic, ginseng, kava, St. John's wort, and valerian may be associated with increased bleeding, or a resistance or increased sensitivity to anesthetic and sedative agents.[81] Herbals and supplements should be discontinued 7–14 days before the operation. The exception is valerian, a central nervous system depressant that may cause a benzodiazepine-like withdrawal when discontinued. If time permits, valerian should be tapered before a planned anesthetic.

Patients who are particularly anxious should be offered a prescription for a short course of benzodiazepines, such as lorazepam, to be taken in the days preceding the operation, as well as on the day of operation.

Therapies to Modify Cardiac Risk

Perioperative β-blockers may reduce adverse cardiac events in patients who will undergo intermediate- to high-risk operation, if significant clinical predictors are present.[82,83] One survey found that almost 60% of surgeons and 50% of cardiologists thought that the best place to institute or coordinate a β-blocker protocol is in a preoperative anesthesiology clinic.[84] Anesthesiologists, especially those working in preoperative clinics, need to participate in this effort to identify at-risk patients and prescribe these drugs. Although these drugs can be given in the immediate preoperative period on the day of operation, patients may derive added benefit from starting these drugs sooner. Starting β-blockers preoperatively allows more time to titrate to effect and provides an opportunity to identify intolerance. Table 4–7 lists β-blocker prescribing guidelines.

A combination of β-blockers and statins reduced cardiovascular complications and mortality in vascular surgery patients, and statins alone were beneficial in patients who had other high-risk procedures.[85] Elective operations should be postponed for at-risk patients scheduled to undergo vascular or other high-risk procedures to implement statin therapy (see Chap. 7 and Heart Disease above).

β-Blockers should not be started in patients with an acute or recent (within 1 month) exacerbation of heart failure (although they are beneficial for patients with chronic heart failure), in patients with high-degree heart block or significant bradycardia, or in patients with reactive airways disease who are dependent on daily β-agonists or who have an acute exacerbation of bronchospasm. β-Blockers are *not* contraindicated in patients with stable, mild to moderate chronic obstructive lung disease or asthma.[86] Table 4–7 lists exclusion criteria.

Chapter 7 discusses this topic in greater detail.

CLINICAL MODELS AND MANAGEMENT

As the practice of surgery has moved into the outpatient arena with the majority of patients presenting to the hospital within minutes to hours of undergoing complex procedures anesthesiologists have struggled with how best to accomplish their evaluations. Various models exist. Lee originally proposed an anesthesia-based outpatient clinic in 1949. Some clinics do no more than document information provided by the patient, the medical record, or others who have seen the patient. Some anesthesiologists rely on other physicians operating independently to prepare patients for operation, either based on anesthesia-derived guidelines or not. This allows for review of information but little direct oversight of the process. Practices that do not have preanesthesia clinics need to develop guidelines to direct testing and to prepare patients for anesthesia (Tables 4–3, 4–5, 4–6, 4–8, and 4–9).

Many surgeons and anesthesiologists rely on prior screening of patients or referrals to primary care physicians, internists, or specialists to "clear" patients or to manage comorbid conditions. Although this reliance

TABLE 4–9.

Surgeon's Checklist

If the patient has not had an anesthesia consultation before the day of surgery, please adhere to the following guidelines:

- ☐ 1. Surgical history and results of physical examination are available on the day of the operation.
- ☐ 2. Preoperative Questionnaire (Table 4–4) is given to the patient with instructions to fill it out and bring it on the day of surgery or fax it before hand to _____
- ☐ 3. Appropriate diagnostic tests are completed and are available. You are responsible for followup on any tests that you order (Tables 4–3 and 4–5 and Fig. 4–2).
- ☐ 4. Medical information from outside our healthcare system (diagnostic tests, blood work, cardiac stress tests, echocardiograms, catheterizations, pulmonary function tests, consultations) is available on the day of the operation.
- ☐ 5. Patient has been given preoperative medication instructions (Table 4–6).
- ☐ 6. Patient has been given NPO guidelines (Table 4–8).
- ☐ 7. "Clearance" letters or notes are rarely sufficient to design a safe anesthetic. A letter summarizing the patient's medical problems and condition and verifying that the patient's medical status is optimized is necessary. Surgery may be delayed or postponed for patients with chronic medical conditions if they have not been evaluated in the Anesthesia Preoperative Medicine Clinic (APMC) and necessary information is not available preoperatively, or their medical status is not optimized. The staff of APMC encourage you to use the clinic for complex patients or those undergoing major operations (Tables 4–1 and 4–3).

may be appropriate for a few, very select diseases and patients, the management of conditions for everyday life and for reducing long-term complications is very different from the stresses of a surgical procedure and anesthesia. Proficiency in preoperative care is a prerequisite for board certification in anesthesia; internists who are not specifically trained in preoperative care may "feel insecure when called on to evaluate the preoperative patient because this important aspect of medicine is not formally taught in many training programs."[87] Anesthesiologists are best suited to do preoperative assessments because of our comprehensive understanding of surgical procedures, anesthetic techniques, and the pharmacologic and physiologic responses of patients during procedures.

Anesthesiologist-staffed preoperative clinics improve the satisfaction of patients and physicians, reduce operating room cancellations and delays, and decrease unnecessary testing and costs.[88] To expand the anesthesiologist's responsibilities beyond the operating room, an educational system must be developed to train anesthesiologists in preoperative care. Concern has been expressed that current anesthesiology training programs are inadequately preparing practitioners to evaluate and manage patients with complicated medical conditions prior to anesthesia and operation.[89] During residency training, honing the cognitive aptitude for preoperative medicine is not emphasized because of the inordinate amount of time anesthesiologists spend in the operating room learning technical and procedural skills. One study found that fewer than half of residency programs have a formal preoperative management curriculum.[89] Anesthesiology often attracts physicians who either do not want to work in clinic settings, or do not want to develop proficiency in preoperative medicine, communication, and multidisciplinary management of care. Kluger, from the AIMS study, stated: "Anaesthetists must recognize they are responsible for the overall clinical management of the patient rather than simply providing a technical service."[1]

As anesthesiologists assume a greater out-of-operating room presence and take on the tasks of evaluating and managing patients before operation and anesthesia, expert practices using cost-efficient management, outcomes measures, and practice guidelines must be developed. Diagnostic expertise and clinical decision making should be emphasized. It would be unrealistic to expect anesthesiologists to manage the administrative and clinical roles of perioperative medicine without training in these skills during residency.[89] Greater involvement of anesthesiologists in preoperative medicine has potential benefits to patients, institutions, the healthcare system, and the specialty. Preoperative clinics enable anesthesiologists to be responsible for perioperative care resources, to attract a diverse population of healthcare providers to the specialty, and to establish an expertise beyond the operating suite.

Preanesthesia clinics vary widely in services offered and the personnel involved in preoperative evaluation. They are staffed by anesthesiologists, internists, or physician extenders, such as nurse practitioners, physician assistants, registered nurses, or some combination (M. Higgins, personal communication, Vanderbilt University December 2005).[73] Little difference has been shown in patient outcomes when those cared for by physicians and other health practitioners were compared. Little data from preanesthetic clinics exist to guide staffing. When outcomes were compared between patients cared for by nurse practitioners versus primary care physicians, no difference in health status of patients or quality of care was found. In one study, a physician's diagnostic accuracy was improved 20–30% after a physician's assistant took a detailed history.[90]

Anesthesiologists are highly qualified to perform preoperative assessment and management because of their intimate knowledge of anesthesia, the planned surgical procedures, and the associated physiologic perturbations. For the sake of cost-efficiency, physician extenders, such as registered nurses, physician assistants, advanced nurse practitioners, and medical assistants, can contribute to evaluation under the direction of the anesthesia department. Depending on services that are offered, additional staff might include clerks, phlebotomists, ECG technicians, administrators, social workers, case managers, and physical therapists.

Scheduling

Scheduling should be based on the anticipated requirements of the preoperative visit, such as the numbers and types of practitioners (e.g., nurses, physicians, physical therapists, phlebotomists) who will be seeing the patient, required diagnostic studies, and the general health of the patient. The general health of the patient is estimated by the ASA PS or a screening mechanism offered by various Internet-based tools, a previsit telephone call, or a patient-completed information form sent from the surgeon's office (Table 4–4). Standardized appointment times for all patients inherently result in delays and long waits. Facilities should consider open-access scheduling that accommodates walk-ins for those patients traveling long distances or who have physical disabilities or unexpected scheduling of operation to prevent inconveniencing them with a return appointment. Reserving a block of time to coordinate appointments with high-volume office visits to surgeons might be useful. Scheduling patients far enough in advance allows time for ordering tests, improving the patient's medical condition, and recruiting social services. Evening and weekend hours afford patients the least disruption from work or family responsibilities.

Because long wait times contribute to patient dissatisfaction, strategies should lessen wait times to improve satisfaction. If patients arrive early or late for an appointment, if practitioners take longer than an appointment time, or if patients without appointments delay the evaluation of other patients, wait times will increase. Scheduling appointments that reflect time needed, using longer appointment intervals, providing necessary clinical information, using a computerized anesthesia record, accepting provider idle time, scheduling breaks, and deliberately expecting many "no-show" patients might decrease wait time.

Improving Patient Experience with Preoperative Evaluation

Patients who are scheduled for operation want information, want to have their concerns addressed, and want their questions answered.[91] Patient anxiety is reduced when a patient's coping style is not threatened. Too much information, especially detailed information about the dangers of anesthesia and operation, creates anxiety in patients who prefer to cope by avoidance. Patients without prior anesthetic exposure desire more information than patients who have had previous anesthetics. Patients desire information in layperson language. Respecting a patient's feelings, explaining complex issues in a simple manner, and learning effective communication skills can improve patient satisfaction.[92] Nonverbal communication, dress, and avoidance of jargon are important. Videos about anesthesia can be time-efficient and well received. Written instructions, especially regarding NPO guidelines, medications, and when and where to go on the day of operation, are essential.

Patient satisfaction questionnaires should be designed and used to improve the processes.[93] Some questions that might be asked in such a survey are as follows:

- Did the anesthesiologist explain the planned anesthetic in terms you understood?
- How well did the anesthesiologist answer your questions and address your concerns?
- How well did the anesthesiologist explain what you could expect after your anesthesia?
- Did you have to wait long?
- Was the staff courteous and respectful to you?
- Overall, how satisfied were you with your preanesthetic visit?
- How might we improve our services?

Informatics

Modern, up-to-date information systems streamline acquisition, storage, and transfer of data about patients among primary care providers, the laboratory, consultants, surgeons, and operating room and clinic personnel. Many institutions have developed their own computer-based programs (Figs. 4–3, 4–4, and 4–5) and a variety of commercial products are available. These can be as simple as a questionnaire (Table 4–4) or as advanced as complex systems that include decision support tools for diagnostic testing, suggestions for consultations, physician computer order entry, direct links to laboratory databases, and the capability of printing patient preoperative instructions, as well as a summary of the evaluation.

Computerized order-entry, prescription generation, and management programs can improve patient care and reduce costs. Patients can transfer information via e-mail, facsimile machines, and interactive telephone systems. Simple telephone reminders improve appointment keeping, patient satisfaction, patient compliance, use of services, and medication compliance, and decrease use of alcohol and tobacco (prevention programs).

Computer-program patient interviews save valuable physician time and may be convenient for the patient. Computer programs that gather information directly from patients allow planning for needed services in advance, and can provide patient education and instruction. Internet-based sites such as www.onemedicalpassport.com and tools such as HealthQuest and telemedicine have been used for preoperative evaluation.[73] Airway evaluation is particularly enhanced with telemedicine.

Electronic technology has enhanced the ease and efficiency of data acquisition and this data can be accessed for patient care simultaneously by multiple providers in diverse locations. Technology can improve management of clinical studies, be used for cost analysis, and used for staffing, resource allocation, and managed care or capitated contract negotiations.

A computerized preanesthetic evaluation system can improve hospital (not just preoperative clinic) reimbursement by improved documentation of diagnosis-related group (DRG) codes when ICD-9 codes are changed.[94]

Medicolegal Culpability

As anesthesiologists broaden their scope of practice and responsibilities, concerns over medical liability arise. Professional negligence, or malpractice, is generally characterized as a failure on the part of the physician to possess or exercise reasonable skill or diligence in the diagnosis or treatment of a patient. The essential elements of a medical malpractice claim include a duty toward the patient, a breach of that duty, and an injury to the patient because of the breach of duty. A physician's responsibility is to act in accordance with *national* standards of care established by the profession, which are defined in terms of care delivered by an average practitioner, not the *best* practitioner.

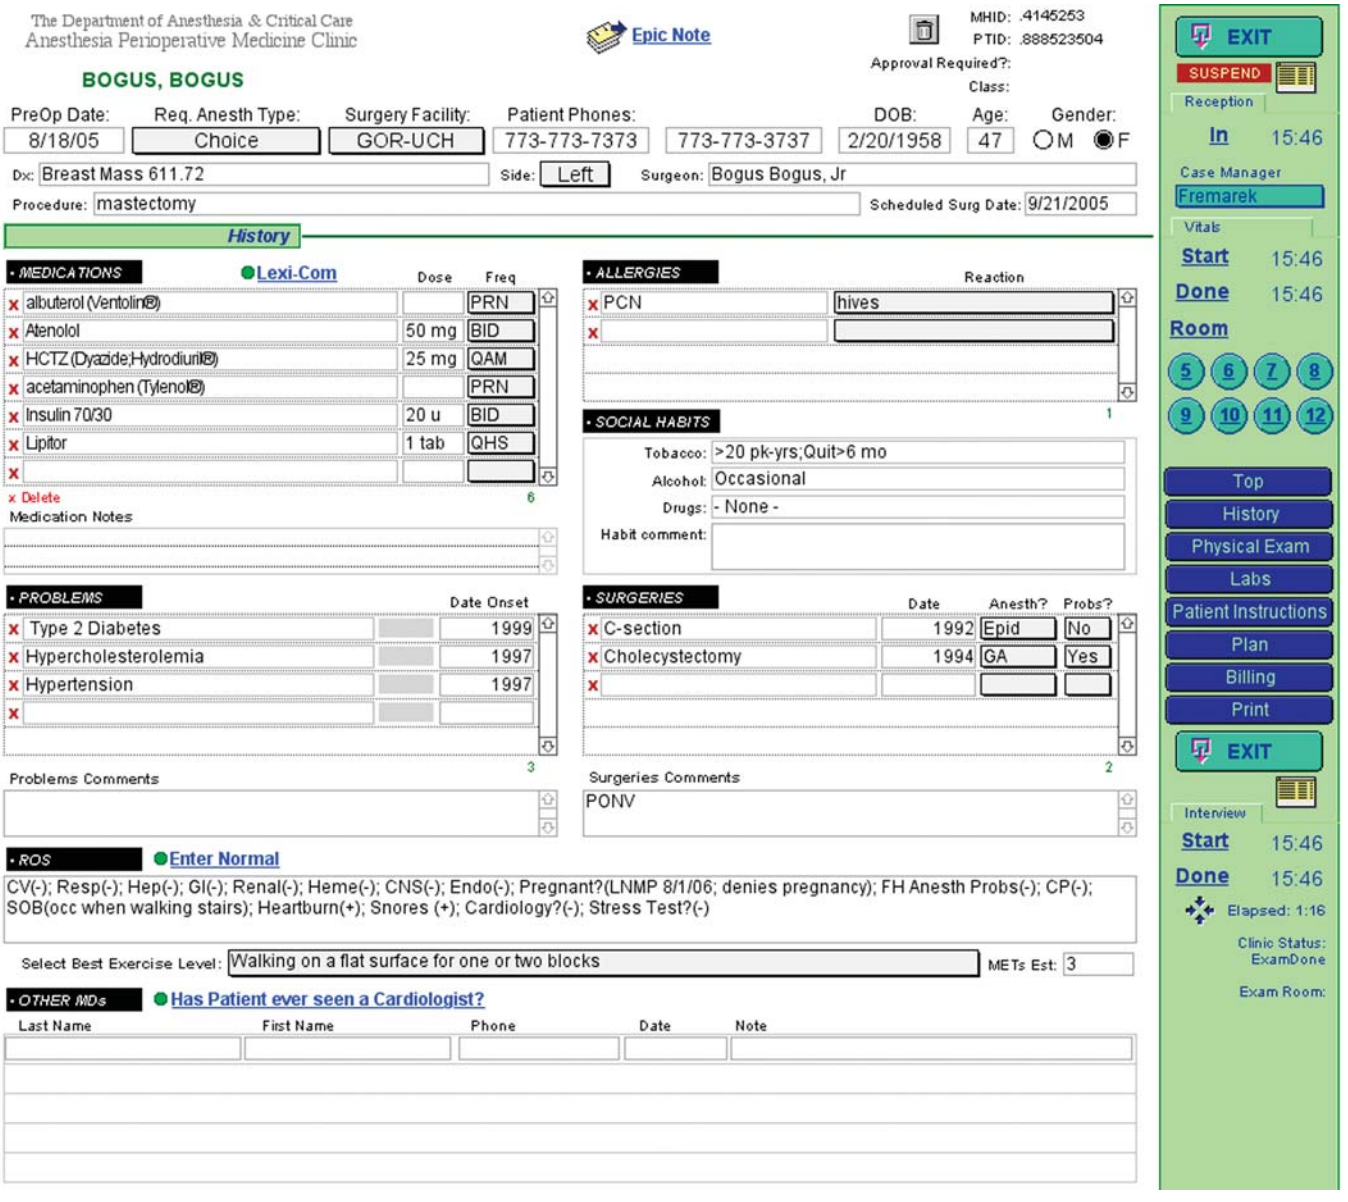

FIGURE 4–3. Computerized patient history.

Duties of the preoperative physician include examination of the patient and referral to a specialist if necessary. Part of the examination requires the use of diagnostic information or techniques that an average, reasonable practitioner would use in similar circumstances.

Often physicians are concerned about failure to diagnose a condition by failing to order a diagnostic screening test. The traditional system of ordering preoperative tests routinely evolved from the mistaken belief that more information, no matter how irrelevant or expensive, will improve care, enhance safety, and decrease liability. In reality, nonselective screening may increase legal culpability. Unanticipated abnormalities on laboratory test results are uncommon. The relationship between these abnormalities and surgical and anesthetic morbidity is weak at best. More than half of all abnormal test results obtained in routine preoperative screening are ignored or not noted in the medical record, which is the document of interest to the courts. Failure to followup an abnormal result is, from a legal point of view, probably riskier than failure to order the test in the first place.

Physicians without malpractice claims are more likely than physicians with malpractice claims to encourage patients to talk and give their opinions. The physicians clarify what has been discussed, and keep patients informed about what to expect during a visit. One study found that communication problems were predominant in most of the reported incidents involving a failure of preoperative preparation.[1] Chapter 95 discusses legal issues in anesthesiology in greater detail.

Economics

It has been said that anesthesiologists do not get paid to do preoperative evaluations. In reality, the fee for preoperative assessment is part of the total operating room payment, and preoperative assessment by an anesthesiologist is required by both regulatory bodies and CMS.[24] One study showed that preanesthetic care can reduce delays and cancellations on the day of operation.[88] This can improve revenues by

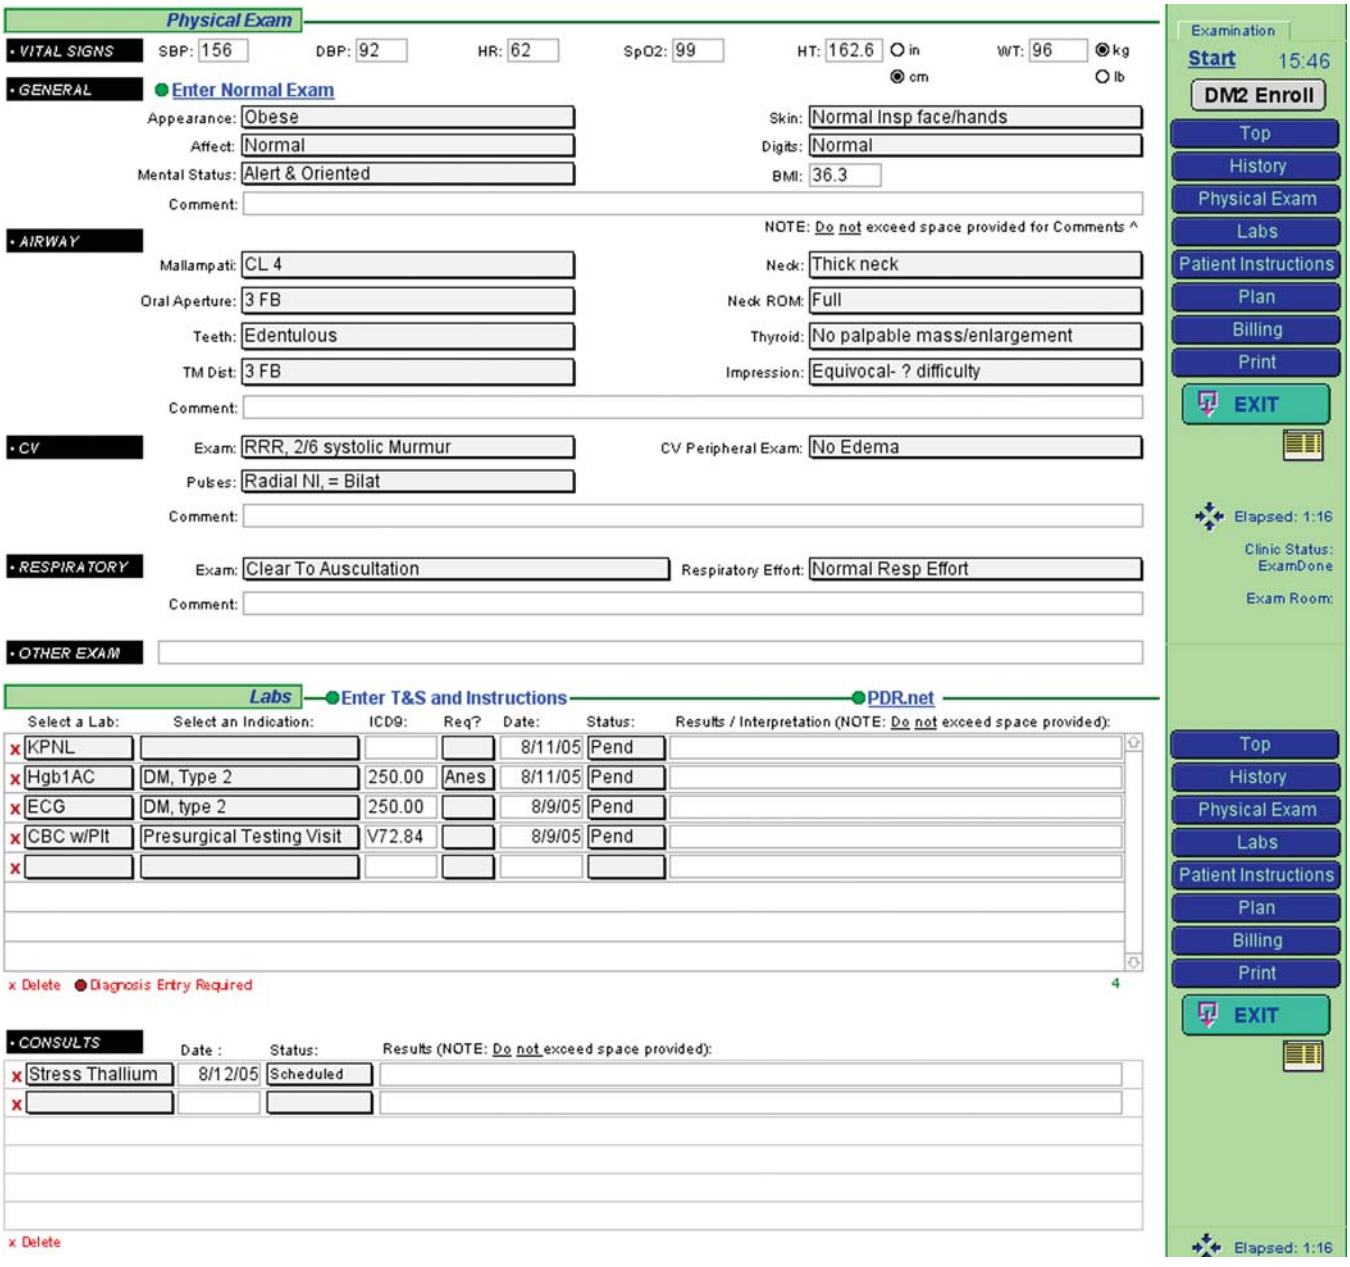

FIGURE 4–4. Computerized patient physical examination and diagnostic test ordering.

increasing time spent on billable cases rather than incurring personnel costs with an empty operating room. Avoiding delays and cancellations on the day of operation eliminates waste associated with unnecessary setups with disposal products. Preoperative assessment clinics also reduce costs by decreasing unnecessary testing and identifying patients with special needs on the day of operation.

According to CMS, preoperative assessments by anesthesiologists can be billed separately as visits or consultations "if medically necessary" and "beyond a routine preanesthetic assessment."[24] When anesthesiologists perform at the level of a perioperative physician by ordering diagnostic studies such as echocardiograms or stress tests; by identifying problems and requesting consultations with specialists; by prescribing therapies such as β-blockers or bronchodilators; and by coordinating care beyond a simple anesthetic plan, they are offering care "beyond a routine preanesthetic assessment" and should bill for consultative services. Chapter 97 describles the criteria required to bill for preoperative consultations.

Physicians working in or administering preanesthetic clinics must become familiar with the CMS Advance Beneficiary Notice (ABN) billing rules. These rules govern whether physicians and other Medicare Part B providers can bill beneficiaries directly if Medicare does not cover services because of a lack of medical necessity. In the past, under Medicare, liability for uncovered services was the responsibility of the beneficiary. Recent changes to the rules relieve beneficiaries from financial liability if the provider did not disclose that the service was not reimbursed by CMS. Unless the physician or facility has followed the ABN rules, payment may not be sought from the patient. ABN rules apply only to outpatient services. Additional information can be obtained from http://www.cms.hhs.gov.

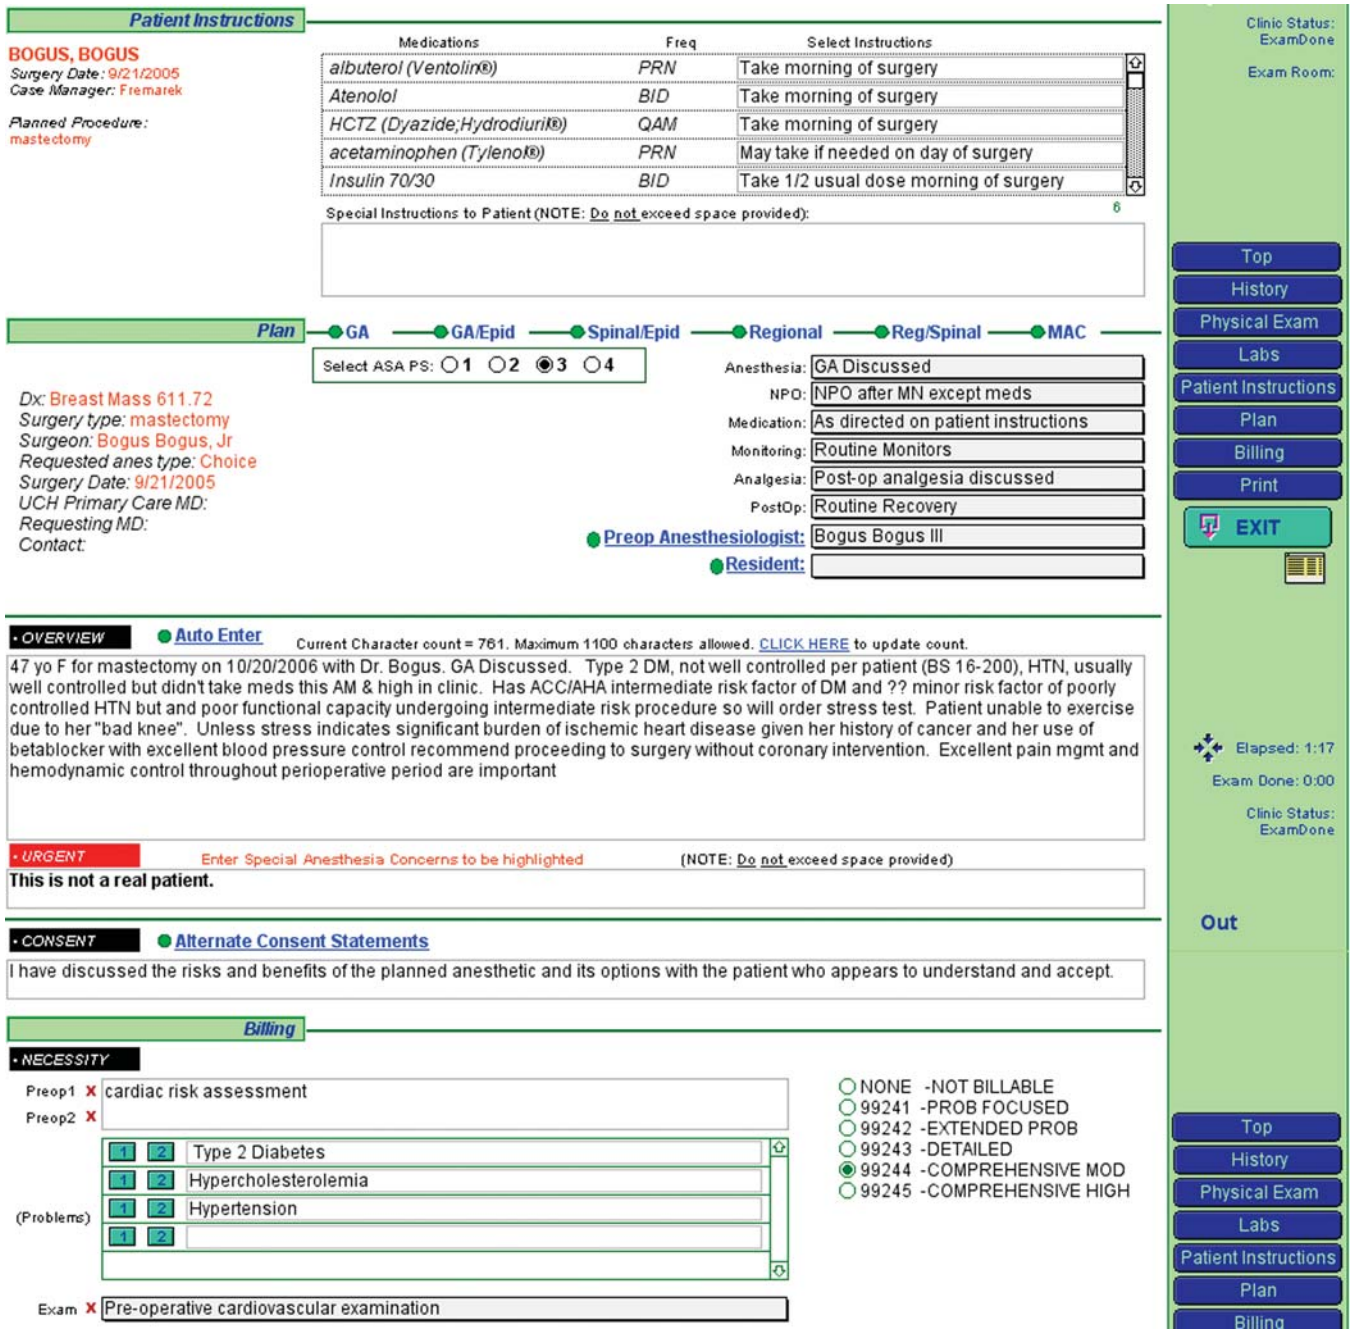

FIGURE 4–5. Computerized patient assessment and plan, patient medication instructions, and billing documentation.

THE FUTURE OF PREOPERATIVE CLINICS

Preoperative clinics are ideal settings for offering comprehensive care beyond anesthesia evaluation. Advanced care and postdischarge planning, respiratory therapy training, counseling about smoking and substance abuse, vaccinations, and end-of-life care discussions have been effectively implemented in preanesthesia clinics.[67,95] When a patient is scheduled for operation, the patient may be more focused on health issues and improvement interventions may be particularly successful. These times have been called "teachable moments."[95]

Warner has rightfully challenged the anesthesia community to do its part in reducing the substantial burden of tobacco abuse.[67] Physical therapists can offer crutch training, social workers can begin postdischarge planning, especially for patients requiring rehabilitation services, and case managers can coordinate care across many disciplines. A 5-minute intervention in a preoperative clinic significantly increased and improved discussions of advance care planning and increased completion of a durable power of attorney to 25%, compared to 10% by controls.[96]

Some day it may be possible to identify patients with genetic polymorphisms linked to adverse outcomes during the preoperative assessments. Then pharmacologic interventions and management can directly alter morbidity and mortality.[97] Molecular biology is rapidly changing our ability to identify genetic variability and its effects on diseases and responses to therapies. This new approach could dramatically alter the way

we perform risk assessment and how we design management plans. It would allow us to move away from expectations of results based on population studies to treatments based on individual patient characteristics. Pharmacogenetics may eventually lead to genetic screening tests to identify patients who are at risk for adverse perioperative outcomes, such as patients with pseudocholinesterase deficiency, halothane hepatitis, and susceptibility to malignant hyperthermia, as well as less familiar traits associated with the duration and response to drugs such as benzodiazepines, opioids, anesthetics, and NSAIDs, and pain tolerance.[97]

CONCLUSION

The prevention of complications during and after procedures requiring anesthesia is the most important task for preoperative anesthesiologists. Identification of risk requires fundamentally good medicine, systems of care, clinical and laboratory assessment, and experienced, knowledgeable, and dedicated healthcare providers. Risk reduction and outcome improvement are the ultimate goals of preoperative assessment and management.

CHAPTER 5

The Anesthetic Plan for Healthy Patients

Patrick E. Benedict, MD, and
Kevin K. Tremper, PhD, MD

This chapter focuses on the development of an anesthetic plan for healthy adults undergoing elective surgery. Like their medically ill counterparts, healthy patients undergo a variety of surgical procedures. By virtue of their favorable physical status, however, healthy patients generally undergo shorter and simpler operations. This is fortunate as the complexity of surgical procedures is one determinant of overall perioperative risk.[1] Additionally, healthy patients, by definition, are free of major medical comorbidity, a major contributor to perioperative risk.[2] For purposes of this chapter, "healthy" patients are defined as American Society of Anesthesiologists[3] (ASA) physical status (PS) 1 or 2. Despite the fact that perioperative risk is low in healthy patients, development of an anesthetic plan is, in many respects, the same as that for patients with serious comorbidities. Development of a successful anesthetic plan in any patient consists of several important steps. The first is a thorough evaluation of the patient via history and physical examination. In healthy patients, a key component of this evaluation is the history of perioperative, and specifically anesthetic, problems and complications. Any successful plan must also take into account the exact nature of the proposed surgical procedure. Finally, expectations and needs of both the patient and the surgeon must be taken into consideration. Of these expectations, safety and efficacy are of utmost importance. This chapter reviews the evaluative phase of the anesthetic plan, with a special focus on recognition and avoidance of complications that can occur in healthy patients. This is followed by a review of the implementation phase, with specific emphasis on meeting the needs of both the patient and the surgeon, within the bounds of safety and efficacy. Finally, we review the use of routine and specialized monitors in healthy patients undergoing elective operations.

EVALUATION OF THE HEALTHY PATIENT

History

Formulating an anesthetic plan begins with a thorough evaluation of the patient. The starting point for this evaluation is the complete history and physical examination. In October 2001, the ASA published a Practice Advisory for Preanesthesia Evaluation.[4] This practice advisory provides guidelines regarding the minimum requirements with respect to the history, physical examination, testing, and timing of the preoperative assessment. Throughout this chapter, the principles of this advisory are invoked when specific issues relate to the healthy patient, whether they are undergoing simple or complex surgical procedures.

In the context of the healthy patient, the purpose of the history and physical examination is fourfold:

- To fully elucidate the nature of the proposed operation and the problem for which the operation is being performed.
- To investigate for the presence or absence of comorbidities or conditions that can heighten perioperative risk (to verify that the patient is, in fact, healthy).
- To ascertain whether the patient has a history of perioperative complications.
- To educate the patient and determine the patient's preferences.

The preoperative history and physical examination are typically a joint effort between the surgeon and the anesthesiologist. The following sections are specific goals and methods for the conduct of such a preoperative history and physical examination, which are also well summarized in the American Society of Anesthesiologists Practice Advisory for Preoperative Evaluation.[4]

Nature of the Surgical Disease and the Planned Surgical Procedure

In planning a successful anesthetic, the primary goals of the anesthesiologist are patient safety, patient satisfaction, and the provision of ideal operating conditions. The starting point for the development of this plan is a thorough understanding of the surgical problem. In many cases, the physical problem that necessitates an operation can have a significant impact upon the provision of safe anesthesia. For example, patients presenting for surgical correction of temporomandibular joint disease may have significant issues with airway management. In addition, operations that achieve the same end point are often performed using differing approaches and techniques. For example, otherwise healthy men may undergo prostatectomy using either a laparoscopic or an open approach. Surgical

KEY POINTS

1. The main objectives in anesthetizing healthy patients are safety and efficacy.
2. The purpose of the anesthetic history and physical examination in healthy patients is fourfold:
   - To fully elucidate the nature of the surgical problem and the specific requirements of the operation being performed.
   - To ensure that the patient is, in fact, healthy.
   - To identify patient features that could potentially complicate the anesthetic.
   - To interview the patient and determine the patient's preferences.
3. A successful anesthetic plan must take into account the needs of the patient, the surgeon, and the anesthesiologist.
4. Healthy patients can undergo most of their preoperative evaluation and preparation immediately prior to surgery.
5. Extensive evaluation and testing are rarely necessary in healthy patients undergoing uncomplicated surgical procedures.
6. Anesthetic monitoring has evolved greatly and is believed to prevent complications and improve outcomes.
7. Healthy patients rarely require more than basic, noninvasive intraoperative monitoring.
8. Healthy patients occasionally undergo complicated surgical procedures that require additional and more invasive monitoring.

technique alone can have a profound impact upon the choice of anesthesia.

Much information regarding the surgical condition and planned procedure is obtained from the surgical history and physical, which is performed by the surgeon or an agent of the surgeon (physician assistant, resident, nurse practitioner). It is critical that effective communication be established and maintained between members of the surgical and anesthesia teams at all times. Computerized medical records aid greatly in achieving this goal. Most healthy patients do not require a visit with an anesthesiologist prior to their operation date. It is important, however, that the surgical team recognize when an advance visit with an anesthesiologist is appropriate, and that the opportunity for the visit be made available. To this end, preoperative anesthesia assessment clinics have evolved, along with screening criteria[5] to aid surgical teams in deciding who needs this consultation. Preoperation clinics are discussed in subsequent sections.

Defining "Healthy"

For purposes of this chapter, "healthy" patients are considered to be ASA physical status (PS) classifications 1 and 2.[6] Hence, by definition, these patients either have no disease, or minor disease processes that are well controlled and cause no physical limitation. In 1993, Menke et al. demonstrated that ASA classification independently predicted overall perioperative risk, and that this risk was low in ASA PS 1 and 2 patients.[7] Similar findings have been verified by other authors, and the classification is still in common use (Table 5–1), demonstrating low perioperative risk in healthy patients.[8]

Once the surgical condition and the specifics of the operation are clarified, the next goal of the anesthesiologist is verification that the patient is, in fact, free of disease. This constitutes the bulk of the preoperative history and physical in healthy patients, and again, should be a joint venture between surgical and anesthesia teams. A comprehensive review of systems is the tool of choice for this purpose, and this is generally obtained by a member of the surgical team. It is good practice for anesthesiologists to verify and further explore these findings, especially when they are pertinent for provision of safe anesthesia. The use of assessment tools or guidelines is helpful for this purpose. The American College of Cardiology/American Heart Association guidelines are extremely useful for evaluating patients with suspected cardiovascular disease.[9] Similar guidelines exist for evaluation of the respiratory system.[10] The review of systems is also a valuable tool for careful screening of hepatic and gastrointestinal, neurologic, musculoskeletal, endocrine, genitourinary, and blood coagulation systems.

Occasionally, findings from the review of systems (e.g., history of gastroesophageal reflux disease, neuropsychiatric disorders, clotting abnormalities), can alter the anesthetic plan in otherwise "healthy" patients. In addition, medical disease (e.g., hypertension, diabetes, coronary artery disease, asthma, obstructive pulmonary disease) will occasionally be diagnosed in surgical patients previously assumed to be "healthy." It is critical that these patients be referred for definitive evaluation and potential optimizing therapy. Communication with the referring surgeon is important, as this evaluation and treatment can delay the planned procedure. A full discussion of the impact of comorbidity on perioperative risk is beyond the scope of this chapter.

TABLE 5–1.

American Society of Anesthesiologists Physical Status Classification

Class	Description	Examples
P1	No organic, physiologic, biochemical, or psychiatric disturbances	Otherwise healthy patient
P2	Mild to moderate systemic disturbance(s)	Hypertension; well-controlled diabetes; mild obesity; age <1 or >70 years; malignancy without evidence of significant spread or physiologic disturbance
P3	Severe systemic disturbance that may or may not be related to the reason for surgery	Angina; poorly controlled diabetes; massive obesity; uncontrolled thyroid dysfunction
P4	Severe systemic disturbance that is life-threatening	"Unstable" angina; congestive heart failure; debilitating respiratory disease; hepatorenal failure
P5	Moribund patient who has little chance of survival	Septic patient with multiorgan failure; patient in cardiac arrest with major trauma
P6	Brain-dead patient for organ harvesting	
E	Any patient in whom an emergency operation is required	

Data from American Society of Anesthesiologists Physical Status Classification.[6]

Identification of Potential Anesthetic Complications

Even patients who are free of comorbidity are susceptible to a range of anesthetic complications (Table 5–2).

In healthy patients, a primary determinant of the success of an anesthetic is avoidance of these complications. Hence a major focus of the anesthesiologist's portion of the medical history in healthy patients is identification of potential complications. Patients may have a personal or a family history of such complications. When a history of complications is suspected, the patient should always be asked to provide a thorough account of the events and their consequences. It also is important to obtain medical records if possible. This is usually a simple process, but consent is required. Once the com-

TABLE 5–2.

Potential Anesthetic Complications in Healthy Patients

Complication	Frequency (Reference)
Postoperative nausea and vomiting	1:3[11]
Ocular injury	1:600–1:1600[103,104]
Unanticipated difficult airway	1:8–1:1000[45]
Intraoperative awareness	1:100–1:500[25,105]
Malignant hyperthermia	1:30,000[16,106]

TABLE 5–3.

Risk Factors for Postoperative Nausea and Vomiting

Patient	Surgical	Anesthetic	Postoperative
Female gender	Longer duration	Nitrous oxide use	Pain
History of PONV or motion sickness	Gynecologic operation	Gastric distension	Dizziness
High preoperative anxiety level	Laparoscopic operation	Reversal of neuromuscular blockade	Early oral intake
Obesity	Middle ear operation	Opioid use	Opioid use
Delayed gastric emptying			
Nonsmoking patient			
Younger age			

PONV, postoperative nausea and vomiting.
Reprinted and adapted from Golembiewski JA, O'Brien D. A systematic approach to the management of postoperative nausea and vomiting. J Perianesth Nurs 2002;17:363–376, with permission from The American Society of PeriAnesthesia Nurses.[107]

plication is identified and fully elucidated, the anesthetic plan should be altered so as to minimize the risk of the particular complication. This plan should be clearly documented, and the patient informed that steps have been taken for prevention of the complication. Below is a discussion of common anesthetic complications and steps that can be taken to minimize or eliminate them.

Postoperative Nausea and Vomiting The most common complication that patients experience in relation to anesthesia is postoperative nausea and vomiting (PONV). This complication is highly distressing, yet relatively amenable to prevention.[11] Recognition of this problem, followed by alterations in the anesthetic plan has resulted in marked improvements in patient outcome and satisfaction.[12] Untreated, nausea occurs in as many as 40% of patients undergoing general anesthesia.[13] Golembiewski's excellent review of this subject outlines patient characteristics that have been shown to heighten risk (Table 5–3).

When these characteristics, or a strong history of PONV are encountered, the anesthetic plan should include use of anesthetic agents with less likelihood of causing the disorder (e.g., consideration of total intravenous anesthesia [TIVA] with propofol).[12] In addition, strong consideration should be given to use of prophylactic preventative agents, which are highly effective.[12] Figure 5–1 illustrates the PONV algorithm used at the University of Michigan.

Note that postinduction droperidol (0.625 mg IV) is included as a primary prophylactic agent in high-risk patients. The U.S. Food and Drug Administration (FDA) recently placed a "black box" warning on droperidol, noting its propensity to prolong the QT interval, which may be associated with serious cardiac rhythm disturbances.[14] Subsequent investigations have challenged this measure by the FDA, citing remarkable safety at the typical dosages used in modern anesthetic practice.[15] It is therefore controversial whether there should be any limit on the use of droperidol, given its long track record of safety and efficacy in anesthetic use. Finally, anxiety, as a possible causative factor, can be effectively addressed by a frank acknowledgment to the patient that the problem has been recognized and that steps are in place for prevention.

History of Difficult Airway An important potential complication that must be recognized prior to elective surgery is a history of difficult airway management. When this problem is known or suspected, a thorough account of the findings and management must be sought from both the patient and old medical records. In this regard, a thorough, legible account of the intraoperative events is critical for subsequent management. "Difficult airway" usually means that airway anatomy was such that standard laryngoscopy was either difficult or impossible. When this is identified in the preoperative history, subsequent management via an awake technique must be considered. Patients with difficult airways, temporomandibular joint disorders, congenital airway disorders, etc are often otherwise healthy. The prospect of awake airway management can be anxiety provoking, and it is best that this possibility be communicated well in advance of the operative date. Explaining this plan in a slow, reassuring fashion serves to inform and prepare the patient so that the patient can present on the day of the operation with minimal anxiety. A brief review of airway assessment is found in Physical Examination below; airway evaluation and assessment are considered in greater detail in Chap. 35.

Malignant Hyperthermia A rare anesthetic complication that must be recognized and planned for is malignant hyperthermia (MH). Estimates of the incidence of this complication range from 1:20,000 to 1:70,000.[16] Recognition, prevention, and treatment of MH are a major success story in anesthesia. What used to be a nearly uniformly fatal disorder now has a mortality rate of less than 10%.[17] When patients present with either a personal or family history of the disorder, the evaluating anesthesiologist is confronted with decisions regarding testing and perioperative management. Muscle biopsy testing for the disorder is available at a diminishing number of centers and is costly, time-consuming, and not completely reliable.[18] This test is characterized by excellent sensitivity, but marginal specificity.[19] Although genetic testing appears promising, it is currently not widely available. Consequently, many anesthesiologists proceed on the assumption that the patient is at risk and provide a nontriggering anesthetic. In certain cases, regional anesthesia, or even conscious sedation, may be appropriate. In cases where this is inappropri-

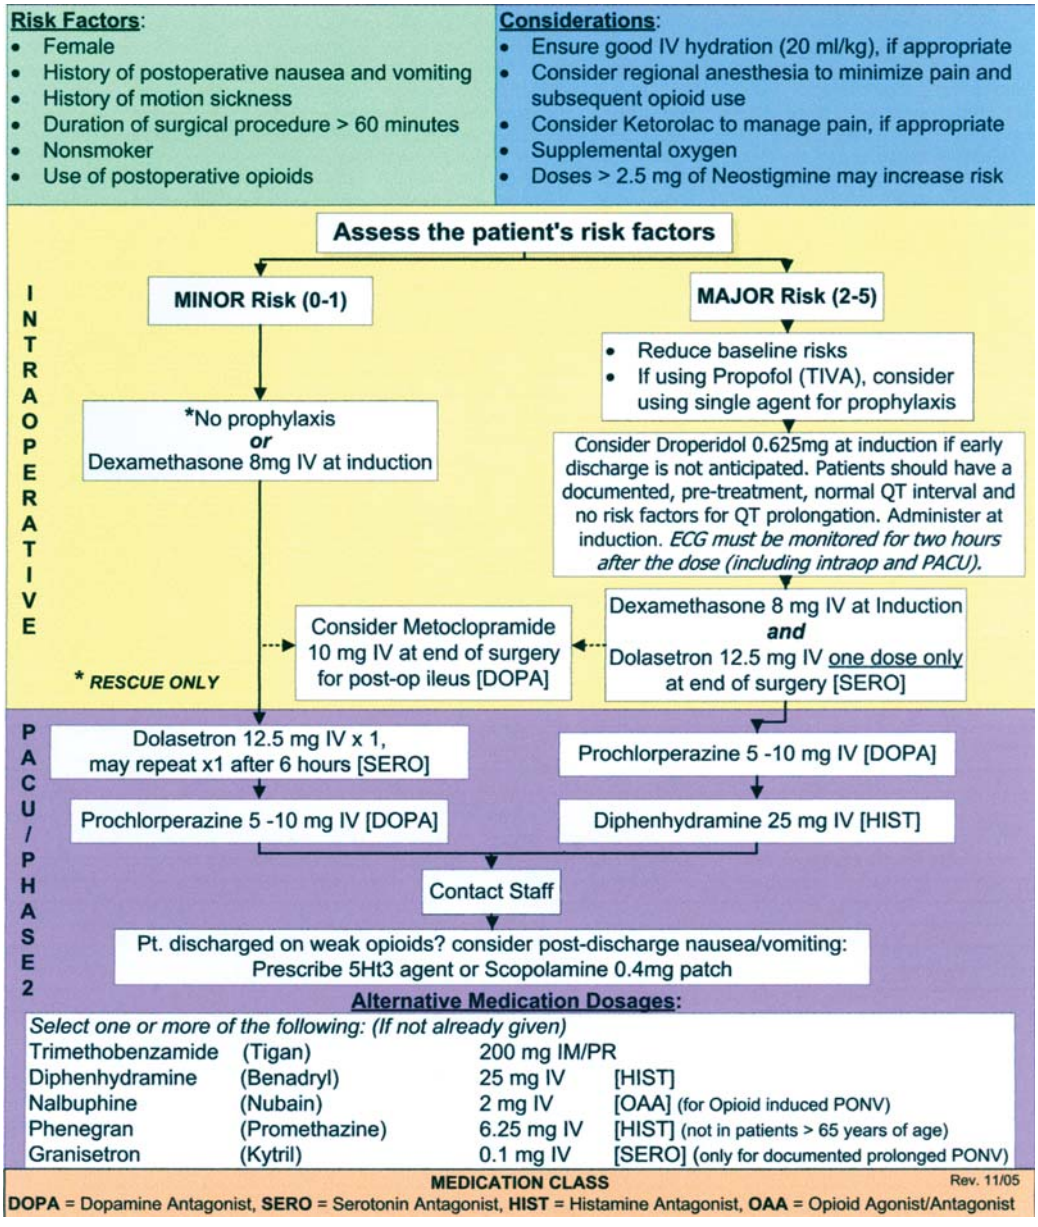

FIGURE 5–1. Guidelines for the prevention of postoperative nausea/vomiting in the adult patient.

ate, however, a nontriggering general anesthetic is provided. Bryson et al. demonstrated recently that general anesthesia could be safely provided to MH-susceptible outpatients as long as triggers were avoided.[20] "Nontriggering" in this sense means avoidance of the only two reliable MH triggers: succinylcholine and the potent inhaled anesthetics. This is typically accomplished with TIVA, which includes propofol, nondepolarizing neuromuscular blocking agents, and opiates. A minimum of 4 hours of observation are recommended following an uneventful anesthetic.[21] It is appropriate that patients with potential MH risk be seen well in advance of surgery so that an accurate clinical history can be obtained and a plan can be devised and communicated to the patient.

Pseudocholinesterase Deficiency Pseudocholinesterase (butyrylcholinesterase) is a plasma enzyme that has no known physiologic function. Most cases of deficiency of this enzyme are attributable to alterations in the gene that codes for it. In 2003, Yen et al. estimated the incidence of homozygous (affected) individuals to be approximately 1:1800.[22] Deficiency is usually identified when an anesthetized patient has prolonged recovery from the depolarizing neuromuscular blocking agent succinylcholine. Suspicion of this deficiency first arose in 1953, when Nilsson gave succinylcholine to a patient who then failed to resume spontaneous ventilation after completion of a short operation.[23] Hence the colloquial name "suxamethonium apnea." Mivacurium, a short-acting, nondepolarizing, neuromuscular blocking agent, also depends on this enzyme for elimination.[24] Despite being far more common than its inherited counterpart MH, pseudocholinesterase deficiency should pose far less danger to patients. In addition, testing for the disorder is far simpler and more widely available than that for MH. Once identified, safe management simply entails ventilatory sup-

port, combined with sedation until the drug is eliminated via the kidney (after several hours in homozygous recessive patients). Identification of this condition in advance allows for alteration of the anesthetic plan so that use of these drugs can be avoided.

Awareness A great deal of public concern has been expressed about intraoperative awareness. Recently, Matthey identified the concept of "awake paralysis," the subject of much recent media attention, to be a top concern in patients undergoing general anesthesia. Unfortunately, the true incidence of intraoperative awareness under general anesthesia, reported to range from 0.2–1.0%, is probably underestimated.[25] Not all patients who are aware in the operating room remember the fact afterward. This can be a particularly bothersome experience for many patients and lasting adverse sequelae are common.[26] Domino et al., using an analysis of litigation records, identified awareness as a common root cause for legal action against anesthesiologists.[27]

As with other complications, a thorough account of the events from both the patient and the patient's records should be sought. Occasionally, a patient misinterprets the goals of conscious sedation and labels this as intraoperative awareness. It is important to clarify this distinction to patients, so that expectations are realistic. In light of the recent focus that intraoperative awareness has received, a new monitor, the bispectral index (BIS) has evolved.[28] Although use of BIS monitoring may reduce the incidence of awareness, recent reports by Mychaskiw and Rampersad cast doubt on this technology. Both demonstrated awareness, despite BIS values being maintained in the low (anesthetized) range.[29,30] Use of this device is more thoroughly reviewed in Monitoring in Healthy Patients below. Whenever strong suspicion of awareness under general anesthesia exists, plans must be made to alter the anesthetic to prevent its recurrence. Kazanjian provides an excellent list of methods (Table 5–4) to reduce the incidence of awareness, and of steps to take in response to this complication.[31]

Recent ASA guidelines on intraoperative awareness and brain-function monitoring also provide practitioners with useful information for evaluation and treatment plans to prevent this worrisome complication.[32] These include careful preoperative evaluation, as certain patient features, such as drug resistance, may be predictive.[27] In addition, various types of surgery (cardiac, obstetric, trauma), as well as anesthetic techniques, may place patients at particular risk.[33] The ASA recognizes that processed electroencephalogram (EEG) devices, which assign a numeric value to a patient's level of sedation, are marketed to help minimize the risk of intraoperative awareness, and the ASA states "we are interested in following their continued evolution and in conducting further research in this area." Hence, the ASA concludes, "[b]rain function monitors are an *option* to be used when the anesthesiologist deems it appropriate, just as he or she makes choices about specific drugs, dosages, warming devices, and other types of monitors depending on the individual patient."

TABLE 5–4.

Intraoperative Awareness

Prevention	Followup
Consider amnestic premedication (midazolam, scopolamine)	Punctual postoperative checks with inquiries about awareness
Routine equipment checks: e.g., correct placement of vaporizer	Precise documentation of suspected events, as reported by patient
End-tidal monitoring of volatile anesthetics with low-concentration alarm	Attempt to corroborate patient's account with actual events
Adequate dosing of induction agents	Do not trivialize or deny patient's assertion
Use of appropriate volatile anesthetic concentration or propofol dose for maintenance	Provide a full explanation of events to patient
Realize potential for awareness with hypotension/hypovolemia	Offer patient appropriate followup, e.g., psychological support, if desired
Judicious use of neuromuscular blocking agents combined with careful monitoring	Try to determine a cause
Frequent checks of intravenous lines and pumps when using total intravenous anesthesia	Assure patient that risk of awareness is still low with subsequent anesthetics
Clear labeling of all syringes	Notify hospital risk management
Quiet, professional operating room atmosphere: minimize auditory input	Notify surgeon and primary care physician
Consider use of anesthetic depth monitor (Bispectral Index)	
Calm reassurance when strong possibility of awareness suspected	

Data from Kazanjian P.[31]

Additional Complications A variety of additional perioperative complications exist and early recognition of these complications is critical in preventing their reoccurrence. In a recent review, Mertes et al. found that serious drug reactions are surprisingly common in anesthetic practice,[34] and that in many cases, alternative drugs could have been selected (antibiotics, local anesthetics, opiates, others) or avoided altogether (succinylcholine in the case of pseudocholinesterase deficiency). Pulmonary aspiration of acidic gastric contents has the potential to complicate any anesthetic, even in otherwise healthy patients. Gastroesophageal reflux disease (GERD) and a full stomach are potential risk factors in healthy patients. If general anesthesia is being contemplated when aspiration risk exists, the anesthetic plan is altered in two ways:

1. Prophylactic antiaspiration measures should be taken (gastric motility drugs, pharmacologic stomach acid reduction, and rapid sequence induction), and
2. Laryngeal mask airway should not be used.

Finally, even in the absence of anticipated risks or complications, many patients simply have high-anxiety levels. It is appropriate for these patients to visit with an anesthesiologist,

TABLE 5–5.

Pharmacologic Effects and Potential Perioperative Complications of 8 Commonly Used Herbal Remedies

Name of Herb	Common Uses	Pharmacologic Effects	Potential Perioperative Complications
Echinacea, purple coneflower, root	Treatment of viral infections	Immune system stimulation	Reduced effectiveness of immunosuppressants; infection with long-term use; potential hepatotoxicity
Ephedra, ma huang	Weight loss, athletic performance	Indirect- and direct-acting sympathomimetic	Dose-dependent increase in heart rate and blood pressure with potential for perioperative myocardial infarction and stroke; arrhythmias with halothane; tachyphylaxis with intraoperative ephedrine
Garlic, ajo	Antihypertensive, antithrombus-forming	Inhibits platelet aggregation	Concerns for perioperative bleeding
Gingko, maidenhair, fossil tree	Circulatory stimulant	Inhibits platelets	Concerns for perioperative bleeding; may potentiate platelet inhibitors
Ginseng, ajo	General well-being	Poorly understood	Concerns for perioperative bleeding
Kava-kava	Anxiolytic, sedative	Anxiolytic, sedative	Potentiates sedative effects of anesthetic agents
St. John's wort	Depression, anxiety	Inhibition of serotonin, noradrenaline and dopamine; cytochrome P450 enzyme induction	Decreased effectiveness of multiple medications
Valerian, vandal root, all heal	Anxiolytic and sleep aid	Sedation	Potentiates anesthetic agents

Data from Skinner, CM and Rangasami J.[108]

in advance of their operation date, to address and ameliorate this anxiety. There is even evidence to suggest that nonpharmacologic strategies may play a significant role in treating both pain and anxiety.[35]

Medication Review

A thorough and meticulous drug history must be obtained from all patients undergoing elective surgery. Even healthy patients may take a variety of prescription and nonprescription medications. All medications must be recorded, and the reasons for their use must be assessed. Patients must also be questioned carefully about drug allergies and drug intolerances, and a clear distinction between the two must be documented in the medical record. When obtaining a drug history, it is important to ask that *all* regularly ingested exogenous compounds, including over-the-counter medications, herbal preparations and vitamin supplements be reported. Several of these compounds have been associated with serious perioperative complications and drug–drug interactions.[36] The ASA recommends avoidance of these preparations (generally for a period of 2 weeks) prior to administration of an anesthetic.[37] Table 5–5 lists common herbal preparations and adverse interactions that are associated with them.

Finally, it is important to determine whether the patient is using any illicit drugs, as many of these drugs are also associated with anesthetic complications.[38] Patients must be advised to abstain from all forms of illicit drugs as soon as possible prior to an elective operation.

Physical Examination

The purpose of the physical examination in healthy surgical patients is to corroborate and augment findings from the medical history. Thus the first goal of the physical examination is to rule out disease. The second goal is to identify physical features that may make provision of anesthesia difficult, or potentially lead to complications. In actuality, the physical examination begins while the history is being obtained. This direct interaction is a good time to observe the gross physical appearance and mental status of the patient. It is also a good time to look for any obvious skin (jaundice, cyanosis, signs of dehydration, rashes) or musculoskeletal abnormalities (especially spine deformities) that may be clues to underlying pathologic conditions. This examination begins with a set of vital signs, including room air oxygen saturation. Even if previously documented from the surgical history and physical examination, it is important for anesthesiologists to perform baseline examinations of both the cardiovascular and respiratory systems prior to an elective operation. Finally, a meticulous examination of the airway must be performed to assess for features that predict difficult airway management if the need for general anesthesia should arise.

Vital Signs

Even in the presence of a negative medical history, abnormal vital signs can be an important first clue to the presence of underlying disease. In fact, potential medical risks, such as hypertension and thyroid disease, are occasionally diagnosed during the preoperative history and physical examination. The "white coat" phenomenon is responsible for hypertension in many preoperative patients.[39] Significant elevations in blood pressure or heart rate, however, especially on repeated measures, warrant further investigation and possible therapy. Rather than simply asking, height and weight should be accurately measured. Arterial blood pressure should be determined either via sphygmoma-

nometry or oscillometry, using an appropriate-size cuff. It is desirable to obtain blood pressure in both arms. We feel strongly that baseline room air oxygen saturation should be measured via pulse oximetry on every patient.

Cardiorespiratory Examination

Examination of cardiovascular and respiratory systems also begins with observation of the patient, which is conveniently accomplished while obtaining the history. Findings such as labored breathing, wheezing, coughing, clubbing of the nails, jugular venous distension, and cyanosis are typically identified while simply conversing with a patient. Obviously, these are signs of potentially serious pathologic conditions, and should be investigated further by more in-depth examination. Physical examination of the cardiovascular system should aid in ruling out hypertension, valvular heart disease, and heart failure. Palpation and auscultation of the heart should be performed to identify heaves, rubs, extra heart sounds, and murmurs. Peripheral pulses should be assessed for both quality and magnitude. The chest should be examined for wheezes, rales, and rhonchi.

Airway Evaluation

Regardless of the anesthetic that is ultimately chosen for a particular operation, it is important that a careful examination of the airway be performed in every patient. While much of the remainder of the physical examination represents a combined or even redundant effort between anesthesiologists, surgeons, and internists, a complete airway examination is generally not the purview of other medical specialists. The anesthesiologist is solely responsible for securing the airway and establishing ventilation. Difficulty with these processes may place the patient in great peril. This is borne out by the fact that airway management problems account for a relatively large proportion of anesthesia-related morbidity and mortality. In ASA closed claims analyses, both Caplan and Domino demonstrated that loss of the airway is a frequent cause of litigation associated with severe injury or death.[40,41] If a patient is known to have a difficult airway, alternative management plans are available (e.g., awake fiberoptic intubation) to the anesthesiologist. Identifying patients with difficult airways, followed by these alternative induction techniques, should eliminate the "unconscious patient, can't intubate, can't ventilate" scenario. Consequently, it is a major goal of anesthesiologists to predict the potentially difficult airway in advance of anesthetic induction.

TABLE 5–6.

Features Associated with Difficult Laryngoscopy

Feature	Likelihood Ratio (LR) That Laryngoscopy Will Be Difficult
Difficult mask ventilation	>2 Factors, LR = 2.5[46]
Body mass index >26	
Edentulous	
Age >55 years	
History of snoring	
Facial hair	
Mouth opening/jaw protrusion	Limited jaw protrusion (Mallampati Class III), LR = 6.5[44]
Mallampati classification	Mallampati Class III, IV, LR = 1.5–6.0[109,110]
Mandibular space	Thyromental distance <6 cm, LR = 2[111]
Obesity	Body mass index >35, LR = 2[112]

Data from Pearce A.[43]

Tests to Predict Difficult Laryngoscopy Preoperative airway assessment, with the aim of detecting the anticipated difficult airway, has evolved over the years. Currently, a number of strategies exist for systematic evaluation of the airway and various guidelines endorse the use of such strategies.[42] Key elements of the airway examination include neck anatomy, neck flexion and extension, thyromental distance, mouth opening, Mallampati score, and, more recently, jaw protrusion and the presence of a beard. Excellent reviews are available of various tests and strategies commonly used by anesthesiologists to assess physical and symptomatic features that may predict difficult laryngoscopy (Table 5–6).[43]

Mandibular displacement (upper lip bite test) recently was correlated with difficulty of laryngoscopy and may have clinical usefulness.[44] Although these various tests and maneuvers are typically simple to perform, they usually have poor sensitivity and specificity, and hence unreliable predictive value.[45] This explains the occasional finding of the "unanticipated difficult airway" after seemingly reliable testing preoperatively predicted otherwise.[45] Typically, these tests have attempted to correlate symptomatic (e.g. sleep apnea) and anatomic patient features with difficulty of laryngoscopy.[43]

Difficult Mask Ventilation

Although successful laryngoscopy followed by endotracheal intubation constitutes definitive management for an unconscious and apneic patient, ventilation by mask can be a lifesaving maneuver. Despite this fact, the historical precedent for investigators with an interest in predicting the difficult airway has been to focus on laryngoscopy alone. With the potentially lifesaving importance of mask ventilation in mind, however, investigators are beginning to stress both laryngoscopy and mask ventilation in their predictive strategies. In 2000, Langeron et al. estimated the incidence of difficult mask ventilation and identified several predictive physical features: history of snoring, body mass index (BMI) >26, lack of teeth, age >55 years, and beard.[46] In 2004, Han et al. devised a scale for categorizing difficulty of mask ventilation. This 4-point scale elaborates on Langeron's work , which only noted difficult and impossible ventilation, whereas Han's scale describes four degrees of assessment of ventilation, similar to scales used for laryngoscopy (Table 5–7).

Han et al. noted an incidence of difficult mask ventilation of approximately 1.5% in the 3000 patients studied.[47] More recently, a study of more than 41,000 patients confirmed the incidence of difficult ventilation to be approximately 1.5% and that the incidence of impossible ventilation was 0.5%.[48] This large study by Kheterpal

TABLE 5–7.

Mask Ventilation Scale

0	Not attempted
1	Easy mask ventilation (with and without neuromuscular block)
2	Ventilated by mask with oral airway or other adjuvant (with or without neuromuscular block)
3	Difficult mask ventilation—inadequate, unstable, or required two practitioners
4	Unable to ventilate

Data from Han R, Tremper KK, Kheterpal S, and O'Reilly M.[47]

et al. noted 6 preoperative independent predictors (four of Langeron's) of difficult mask ventilation: history of snoring, age >58 years, BMI >30, Mallampati class III or IV, limited jaw protrusion, and the presence of a beard (Table 5–8).

It should be noted that the only modifiable risk factor is the presence of a beard. These results suggest that the anesthesiologist might consider recommending that the patient shave

TABLE 5–8.

Independent Predictors of Difficult Ventilation and Intubation

Difficult Mask Ventilation	P-Value
Beard	0.0001
History of snoring	0.001
BMI >30	0.0001
Mallampati III or IV	0.001
Age >50 years	0.01
Severely limited jaw protrusion	0.03
Difficult Mask Ventilation[a] and Difficult Intubation[b]	
Severely limited jaw protrusion	0.0001
Thick neck/mass	0.02
History of sleep apnea	0.04
BMI >30	0.05
History of snoring	0.05

prior to an elective procedure, especially if the patient has several other risk factors for difficult mask ventilation. Table 5–9 illustrates the standard preoperative airway features that we assess and record via electronic data entry at the University of Michigan.

Anticipated Difficult Airway Strategy

When a potential difficult airway is identified, it is the anesthesiologist's responsibility to develop a strategy to manage the airway in the event that general anesthesia becomes necessary. When a truly difficult airway is known or strongly suspected, and general anesthesia is necessary, the usual management plan entails placement of an oral or nasal endotracheal tube while the patient is awake and spontaneously breathing. Several important steps in planning and patient preparation for this process are worth mentioning.

The very thought of a potential airway problem can be anxiety provoking. Often, the source of this anxiety stems from the patient's perception that theirs is a rare problem that places them in grave danger. To allay much of this anxiety, it is helpful to have a frank discussion with the patient and fully inform the patient about the nature of the problem, and the rationale and plan for safely dealing with it. Patients are reassured knowing that the difficult airway is relatively common and that appropriate management poses no untoward danger. Careful anxiolytic sedation is appropriate preoperatively, to the extent that airway compromise is avoided. Antisialagogue premedication (typically glycopyrrolate 0.4–0.6 mg IV) aids greatly in the ability to anesthetize airway mucosa (typically with 2–4% lidocaine). Profound topical anesthesia of upper airway mucosa, combined with judicious sedation, are the key elements in conducting a safe, effective, and comfortable awake intubation.

Special Preoperative Considerations

Preoperative Anesthesia Assessment Clinics Currently, the vast majority of patients who present for elective operations are admitted to the hospital on the day of their procedure. Fortunately, most healthy patients can be seen and assessed by the anesthesia team immediately prior to their operation. The ASA Practice Advisory on Preanesthesia Evaluation recommends the timing of the preoperative evaluation based on not only the health of the patient, but the invasiveness of the surgical procedure.[49] The ASA recom-

TABLE 5–9.

Airway Physical Exam Elements

Test	Findings
Dentition	Normal Dentures Edentulous Poor dentition
Beard	Yes/no
Mouth opening	≥3 cm <3 cm Unable to assess
Mallampati class	Class I, II, III, IV, Unable to assess
Hyoid to mentum	≥6 cm <6 cm
Cervical spine	Normal Limited flexion Limited extension Limited flexion and extension Known unstable Possible unstable Unable to assess
Existing airway	None Tracheostomy Endotracheal tube Unable to assess
Neck anatomy	Normal Laryngeal mobility limited status Postradiation therapy Mass Previous tracheostomy scar Radiation changes Thick, obese Thyroid cartilage not visible Tracheal deviation Unable to assess
Jaw protrusion	A: Normal, lower incisors can protrude past upper B: Limited, lower incisors can only be advanced to meet upper C: Severely limited, lower incisors cannot protrude to meet upper

Patient Information Report: Sample Questions

Question	Criteria	Answer	Action
Do you have or have you had any of the following heart-related conditions?	Heart disease	Yes or No	If yes, send patient for ECG and preoperative anesthesia visit
	Heart attack within the last 6 months	Yes or No	If yes, send patient for ECG and preoperative anesthesia visit
	Angina (chest pain)	Yes or No	If yes, send patient for ECG and preoperative anesthesia visit
	Irregular heartbeat	Yes or No	If yes, send patient for ECG and preoperative anesthesia visit
	Heart failure	Yes or No	If yes, send patient for ECG and preoperative anesthesia visit
Do you have or have you ever had any of the following?	Rheumatoid arthritis	Yes or No	If yes, send patient for preoperative anesthesia visit
	Kidney disease	Yes or No	If yes, send patient for electrolytes, creatinine, BUN, CBC, and preoperative anesthesia visit
	Liver disease	Yes or No	If yes, send patient for SGOT/ALT, PT/PTT, and preoperative anesthesia visit
	Diabetes	Yes or No	If yes, send patient for ECG and preoperative anesthesia visit

BUN, blood urea nitrogen; CBC, complete blood count; PT, prothrombin time; PTT, partial thromboplastin time; SGOT (ALT), serum glutamic oxaloacetic transaminase.
Data from Tremper KK, and Benedict P.[5]

mends that all patients undergoing highly invasive surgical procedures be seen prior to the day of surgery. These patients require evaluation, counseling, or therapy in advance of their surgical date. An appropriate and convenient place to coordinate this workup is the preoperative anesthesia assessment clinic (PAC). To derive the most benefit from PACs, surgeons need to use them discriminately. We find it helpful to provide screening criteria to our surgeons in the form of a patient self-assessment sheet.[5] This screening questionnaire (Table 5–10) is filled out by the patient using a series of check boxes. The boxes are aligned to a back page such that positive answers will check (via carbon copy) the recommended preoperative laboratories and whether a PAC consultation is suggested. For example if an affirmative answer is recorded for the question "Do you have heart disease?", an electrocardiogram is ordered (if not recently done) and the patient is referred. Chapter 4 provides a detailed account of the role, functioning, and benefits of PACs.

Obesity and Obstructive Sleep Apnea Obesity is a well-established public health problem in developed countries. More specifically, obesity presents a major problem for all practitioners who care for patients in the perioperative period. Obese patients not only have alterations in physiology at baseline that result in major lifestyle limitations, they also have a well-documented elevation in perioperative risk.[50] This would seem to justify (by convention) ASA classification of at least PS 2, and perhaps PS 3. Multiple physiologic comorbidities tend to exist in obese patients (diabetes mellitus, obstructive sleep apnea, cardiovascular disease, osteoarthritis, others).[51] In addition, anatomical alterations of the airway also place these patients at increased risk for difficult mask ventilation and laryngoscopy.[48] Intravenous access can be extremely difficult in obese patients and in some cases central access must be considered. Many consider obesity to be a risk factor for gastric aspiration and preventative measures should be considered. Obesity clearly heightens risk for adverse perioperative respiratory outcomes.[52] Blum et al. reviewed the quality assurance events recorded from 25,767 anesthetics. They found a statistically significant increase in failed intubation, reintubation, dental injury, and airway obstruction associated with increasing body mass index.[50]

Short of substantial weight loss prior to elective surgery (with a poor success rate, as shown recently by Coe et al.),[53] however, the aforementioned perioperative risks are generally not modifiable. Hence, a key element for practitioners to consider in preparation for an elective operation in obese patients is counseling, specifically with regard to weight loss (if time permits) and full disclosure of significantly heightened perioperative risks.[53]

It might also be beneficial to prepare obese patients for practical issues such as difficult IV access and the possible need for awake intubation and extubation. Obstructive sleep apnea (OSA) is a syndrome that is commonly associated with obesity and is characterized by periodic, partial, or complete airway obstruction during sleep. It is estimated that approximately 9% of women and 24% of men have some degree of OSA, while the severe, symptomatic disease is present in approximately 2% of women and 4% of men.[54] In October 2005, the ASA published a practice guideline on the *Perioperative Management of Patients with Obstructive Sleep Apnea (OSA)*. This practice guideline comprehensively reviews the preoperative and postoperative management of patients with this disorder.[55] On occasion, patients who are considered to be healthy may have undiagnosed OSA; thus it is important to get a complete history, specifically as it relates to snoring and daytime somnolence. If the patient is, indeed, suspected of having the syndrome, then the patient should be worked up prior to an elective procedure as recommended by the practice guideline.

Old Age Another well-established public health concern that has specific perioperative implications is aging. This is critical for anesthesiologists because of the rapid aging of the population, combined with the fact that an increasing proportion of surgical procedures are performed in the elderly. In 1986, Tiret et al. provided evidence that the elderly have higher perioperative complication rates and higher risk than their younger counterparts, even in the

absence of comorbidities.[56] The issue of perioperative risk, as it relates solely to advancing age, however, is far from settled.[57] Some would therefore assert that anesthetizing "healthy" elderly patients poses no significant elevation in perioperative risk. It must be remembered, however, that even "healthy" elderly patients have marked diminution in the function of all major organ systems.[58] This would cause some to assign the ASA classification of PS 2 or even PS 3 to all such patients. Aside from the universal physiologic changes seen in all elderly patients ("aging"), elderly patients definitely tend to accumulate coexisting disease, which Kim et al. clearly demonstrated to be a strong predictor of complications.[59]

Elderly patients often have additional and unique perioperative challenges. Many have poor hearing and eyesight, and some suffer from cognitive impairment. This can make communication difficult. Simple issues like transportation home after conscious sedation can become logistical problems in the elderly. An important result of the aforementioned physiologic changes is markedly altered drug disposition in the elderly. Elderly patients have diminished volumes of distribution, decreased clearance, and heightened sensitivity to nearly all medications.[58] This explains why elderly patients are more sensitive to the therapeutic actions of most drugs, and markedly more susceptible to side effects. In summary, despite changes attributable to normal aging, there is no strong association between age itself and perioperative risk. Thus, chronologic age should not be a contraindication to surgery. The elderly tend to accumulate coexisting disease, however, so anesthesiologists should be especially vigilant in the detection of such disease. Finally, to avoid complications and dissatisfaction in the elderly, anesthesia providers need to understand the altered pharmacology, physiology, and special needs that accompany the normal aging process.

Smoking Approximately 1 in 5 adult Americans currently smoke and millions of elective surgical procedures are performed each year on these individuals.[60] This is unfortunate, as cigarette smoking is independently responsible for an alarming elevation in the rate of serious perioperative pulmonary complications.[61] Cigarette smoking is definitely an addictive disease that adversely alters the lifestyle of those affected. This fact, coupled with the well-known perioperative risks that smoking confers,[62] should result (again, by convention) in otherwise healthy smokers being classified as at least ASA PS 2, and in many cases, ASA PS 3. A recent United States Public Health Service guideline has advised *all* physicians to "strongly advise every patient who smokes to quit because evidence shows that physician advice to quit smoking increases abstinence rates."[63] Furthermore, anesthesiologists are uniquely positioned to give such advice. The preoperative interaction has been described by Warner as a "teachable moment" that not only lowers their immediate perioperative risk, but also is of great benefit to their long-term health.[60] Quitting smoking immediately prior to surgery does not heighten risk, produce untoward anxiety, or consistently precipitate nicotine withdrawal.[64] Hence, patients who smoke should not be considered "healthy." These patients should be advised of the elevation in perioperative risk that is attributable to their habit, and be encouraged to quit as soon as possible prior to their elective surgical procedure.

Preoperative Testing in Healthy Patients

Billions of dollars are wasted in the United States each year on unnecessary preoperative testing.[65] In the case of healthy patients, this testing is almost always unnecessary.[66] It is generally accepted that healthy patients undergoing low-risk surgical procedures require no specific laboratory testing unless clinically indicated.[67] Little evidence exists regarding the propriety of such routine testing in healthy patients undergoing more complicated procedures with the potential for major blood loss (e.g., major corrective orthopedic procedures, brain aneurysm clipping). Many recommend obtaining a preoperative hematocrit level in menstruating women, but there are little data to support this.[67] Women of childbearing age should be given pregnancy tests if it cannot be ascertained for certain whether or not they are pregnant. It is our institutional policy that women 18 years of age and older be asked, "Is it possible that you could be pregnant?" If they answer "no," they are not tested. This is in general agreement with the ASA stance on this issue: "The task force believes that the literature is inadequate to inform patients or physicians on whether anesthesia causes harmful effects on early pregnancy. Pregnancy testing may be offered to female patients of childbearing age and for whom the result would alter the patient's management."[49]

The indiscriminate ordering of batteries of routine tests, even in patients with serious comorbidities, has been the subject of intense review, and has been found to be excessively expensive and ineffective.[36] In fact, batteries of routine tests and their subsequent interpretations were found to predict morbidity more poorly than the simple use of either the ASA physical status classification, or the ACC/AHA[9] guidelines. What is recommended by the ASA Practice Advisory is that "specific tests and their timing should be individualized and based upon information obtained from sources such as the patient's medical record, interview, physical examination, and the types and invasiveness of the planned procedure."[49] Halaszynski et al. well-summarized these concepts in their recent article addressing this issue (Table 5–11).[36]

They suggest that age be used as a basic indication for testing, with the additional components of surgical complexity and medical illness allowing for layers of flexibility. According to this paradigm, healthy patients < 45 years of age, having uncomplicated operations require no testing. As patients deviate from this healthy/uncomplicated baseline, testing may be indicated, but in a directed and temporally related fashion (if a test was recently done, it does not generally need to be repeated). Thus, if it can be ascertained from the preoperative history and physical examination that a patient is healthy, "routine" testing is rarely indicated in patients having uncomplicated surgical procedures. At the University of Michigan, the only "screening" test that we routinely order preoperatively is an electrocardiogram (ECG) in asymptomatic men older than 45 years of age and in women older than 55 years of age if they have any cardiovascular risk factors.[1,68]

IMPLEMENTATION OF THE PLAN

Type of Anesthesia: General, Regional, Monitored Anesthesia Care

Once the goal of preoperative evaluation has been achieved, the anesthesi-

ologist and patient must devise an anesthetic plan. This is where surgeon requirements and patient preference directly interface. Surgeon requirements vary widely, but most patients simply want their surgical experience to be safe and comfortable. Surgeons want the best conditions possible to perform their operations and it is advisable that surgeons and anesthesiologists communicate in advance of the operation to express their requirements and limitations. Anesthesiologists have direct control over many variables that surgeons require to carry out their operations safely and swiftly, including degree of consciousness, blood pressure control, ventilatory control, and level of consciousness at the conclusion of surgery. If other factors are equal (patient has no particular preference, perceived safety is equal), surgeon preference must be taken into consideration. Patient safety, however, is always of paramount importance and at times may outweigh surgeon preference (e.g., performing a regional anesthetic for a lower-extremity procedure in a patient with severe pulmonary disease).

Keeping safety in mind, the anesthetic choice is often influenced by two key patient features: coexisting disease and aging. A completely acceptable technique for a particular operation (e.g., a subarachnoid block for a total-knee arthroplasty) may be contraindicated in patients presenting with certain disease states (e.g., aortic stenosis). Whereas general anesthesia is performed rather indiscriminately in young, healthy patients, regional, or even local anesthesia with sedation might be the safest option in patients with severe respiratory disease. The same holds true for the elderly patient. Even "healthy" elderly patients have well-documented diminutions in the function of renal, hepatic, cardiorespiratory, and drug-metabolizing systems[58] that are progressive. Drugs and doses that are innocuous in young, healthy patients can have long-lasting, debilitating effects in the elderly. Consequently, it may be desirable, whenever possible, to consider regional, or even local anesthesia with minimal sedation in the elderly.

Type and location of surgery play an important role in planning for anesthesia, but patient preference and the destination of the patient in the postoperative phase also must be considered. Newer, more rapidly eliminated anesthetics have made postoperative destination less of an issue than in times past, but one that still must be considered. For example, long-lasting regional blocks and long-acting intravenous medications may be inappropriate for patients scheduled on an outpatient basis. Following is an overview of common surgical operations and factors that influence the anesthetic plan.

Type of Procedure

Head and Neck Procedures

Head and neck procedures range from minor, superficial operations to complex resections and reconstructions involving nerve monitoring, large fluid shifts, and blood loss. Many simple, superficial operations are performed for skin cancer excision, followed by closure of the defect. Unless these lesions are deep or large, the cases can usually be safely and comfortably managed with conscious sedation combined with local anesthetic applied by the surgeon. Unless brief and superficial, ear surgery usually necessitates general anesthesia to achieve suitable patient comfort. It is common for these procedures to be performed on an outpatient basis. Cosmetic facial surgery is often performed with conscious sedation combined with local anesthesia to preserve awake muscle tone. Complex head and neck operations are often performed for invasive (mouth, throat, neck) cancers. These operations can be very complex and involve much fluid shifting and blood loss. In addition, these lesions can compromise the airway, necessitating non-

standard (awake) airway management techniques. Presence of a tracheostomy is relatively common at completion of these operations. Because of the length and complexity of these procedures, invasive monitoring (arterial lines) is common. Communication with the patient and family is important in achieving realistic expectations.

On occasion, intracranial neurosurgery is performed in the awake patient, but the majority of these operations are performed under general endotracheal anesthesia. Anesthesia for awake craniotomy is beyond the scope of this chapter. Success in these cases depends on an intimate surgeon–patient–anesthesiologist interaction with much preoperative communication. Because operating conditions for intracranial operations depend on and, conversely, can impact on vasomotor control, invasive (particularly arterial) monitoring is common. Neurologic function (somatosensory evoked potentials) monitoring is common and the anesthesiologist must be knowledgeable in the interactions of anesthetic agents and these monitors. Additionally, neurosurgeons will often request (if feasible) that a rapid wake-up be accomplished at the conclusion of surgery so that early assessment of neurologic function can be carried out.

Thoracic Procedures Thoracic surgical procedures range from outpatient thoracoscopic procedures (minor pulmonary resections and biopsies, sympathectomy) to major pulmonary and upper gastrointestinal tract procedures involving major body cavity and cardiovascular trespass, blood loss, and fluid shifting. The majority of these procedures require single-lung ventilation, and this must be planned for. Open thoracic procedures are typically associated with a high degree of postoperative pain, which is best controlled with postoperative epidural analgesia. Because of their proximity to major vascular structures and potential for adverse ventilatory interactions these procedures often necessitate invasive intravascular lines and monitors, which must be discussed with the patient as part of the preoperative plan.

Abdominal Procedures Increasingly, abdominal procedures are being performed laparoscopically. General anesthesia with endotracheal intubation must be employed for patients to safely and comfortably tolerate this technique. Regional techniques can be used successfully for open intraabdominal procedures, but these operations are frequently long and complex, so general anesthesia is often favored. When general anesthesia is employed, endotracheal intubation is indicated to provide abdominal muscle relaxation and to protect against gastric aspiration. Epidural is an excellent option for postoperative analgesia in open abdominal operations, but is usually not necessary when procedures are performed laparoscopically. Because of the potential for vascular involvement, major blood loss, and fluid shifting, invasive monitors are sometimes indicated, even in otherwise healthy patients.

Urologic Procedures Many urologic procedures are performed through a cystoscope and are of relatively short duration. In these cases, short-acting regional and general anesthetics are equally safe and effective options. Patient preference can play a major role in devising a plan for these cases. Both nephrectomy and prostatectomy typically have been performed via large, open approaches, but are increasingly being performed laparoscopically. Open prostatectomy has been performed successfully under both general and regional anesthesia, but the laparoscopic approaches for these procedures necessitate general anesthesia with endotracheal intubation.

Gynecologic Procedures As with abdominal and urologic procedures, gynecologic procedures are being performed increasingly via the laparoscopic approach. The same principles as for abdominal and urologic procedures apply. When performed via an open abdominal approach, gynecologic procedures generally require general anesthesia with endotracheal intubation to allow profound muscle relaxation. Vaginal, cervical, and hysteroscopic procedures can be completed safely and comfortably using either general or regional anesthesia. Thus patient preference combined with anesthetist experience must be taken into account when planning for these cases.

Orthopedic Procedures At one extreme, orthopedic operations can be brief and minor peripheral extremity procedures amenable to either regional or local anesthesia with sedation. At the other end of the spectrum are long, complicated procedures that involve large blood losses, fluid shifting, and intraoperative nerve monitoring. Total knee and hip joint replacement operations are very common and can be carried out with either general or regional anesthesia. Epidural anesthesia is an effective choice and can be continued into the postoperative period to provide excellent analgesia. Some patients are extremely anxious about the prospect of being awake during orthopedic procedures. Serious consideration must be given to general anesthesia in these patients. Major spine surgery, operations for major orthopedic malignancies and revision hip operations can be long and complex, so general anesthesia with endotracheal intubation and invasive monitoring should be considered. Upper-extremity nerve blocks are increasingly common for procedures on the shoulder and arm. Interscalene blocks and catheters are useful for shoulder surgery. Infraclavicular blocks and/or catheters are useful for procedures on the forearm and hand. Chapter 74 discusses the use of these techniques more fully. Because of the significant pain associated with shoulder reconstructive surgery and the need for postoperative manipulation as part of the rehabilitation, interscalene catheters are very popular. They can be used as the sole anesthetic, or in combination with general anesthesia. These blocks have proven efficacy in the successful treatment of immediate postoperative pain.[69]

Ocular Procedures Many surgical procedures on the eye can be carried out safely and comfortably using local anesthesia. When formulating the anesthetic plan preoperatively with the patient, this technique must be fully explained so that the patient has realistic expectations. Some ocular procedures can be very long, necessitating use of general anesthesia to provide optimal operating conditions. In these cases, plans may need to be devised for "deep" extubation to avoid coughing and elevation of intraocular pressure on emergence from anesthesia.

Regional Anesthesia versus General Anesthesia

Whether general anesthesia or regional anesthesia should be used for major surgical operations is controversial.

TABLE 5–12.

Perceived Advantages of Regional Anesthesia

Regional anesthesia
Very targeted site of drug action
Necessitates far less intravenous sedations and analgesia (especially important in elderly patients)
Profound analgesia and relaxation
No need for airway management or mechanical ventilation
Possible decreased blood loss, decreased risk of thromboembolism[70]
General anesthesia
Indiscriminate drug administration to entire body
Far greater requirement for intravenous and potentially long-acting medications
Intravenous drugs with potential side effects required to achieve same effect
Airway management is always necessary and mechanical ventilation is often necessary
Patients at risk for hemorrhage, venous thromboembolism

Both techniques have advocates and detractors from both a safety and efficacy standpoint. Table 5–12 identifies the advantages commonly cited for general and regional anesthetic techniques.

Although there is no convincing evidence that morbidity and mortality are decreased with either technique, there is a suggestion of improvement in specific outcomes with use of regional anesthesia.[70] Despite the common perception that regional anesthesia is generally "safer" than general anesthesia, its principal advantage is in providing analgesia postoperatively. For certain operations, regional anesthesia offers distinct advantages compared to general anesthesia,[71] but some of the perceived benefits of regional anesthesia recently have been questioned.[72] For regional techniques to be successful, the patient must be accepting of the technique, a skilled clinician must be available to perform it, and the block must be effective. If long-lasting blocks or indwelling catheters are to be used, educational efforts must be made regarding the special care that these techniques necessitate. Lastly, patients must be informed of the potential complications that can result from the use of regional anesthesia. Chapters 45–49 provide a more in-depth analysis of this controversial subject.

Monitored Anesthesia Care: Potential Pitfalls

Superficial operations are commonly performed in healthy patients using the monitored anesthesia care (MAC) technique. This entails use of anxiolytic, sedating, and analgesic medications administered by anesthesia personnel, combined with local anesthesia administered by the surgeon. In a recent editorial, Hug describes the attitude of anesthesia providers regarding such cases as "routine, simple, and low-risk."[73,74] In addition, these operations are often performed hastily, in remote locations, and involve positioning that provides anesthetists poor access to the airway. This can result in a situation where "diligence is less by both the anesthetist and the surgeon."[73] Combined with liberal use of sedating respiratory-depressant medications, MAC has the potential to result in life-threatening anesthetic-related complications.

Complications attributable to MAC anesthesia have been reported in the literature, and a recent closed claims analysis by Bhanaker et al. sheds new light on this devastating, yet uncommon problem. In this study, MAC anesthesia represented a "liability profile similar to claims associated with general anesthesia." This led the authors to conclude that "oversedation leading to respiratory depression was an important mechanism of patient injury during MAC. Appropriate use of monitoring, vigilance, and early resuscitation could have prevented many of these injuries."[74] Hence, anesthesia providers need to be cognizant of the potential for serious complications associated with MAC anesthesia and avoid the pitfall of trivializing this technique to the extent of compromised vigilance and potential serious complications.

Preoperative Instructions

A clear, concise set of preoperative instructions can contribute greatly to patient safety and operating room efficiency. Provision of these instructions can be carried out in a variety of ways, but we feel that a combination of both verbal and written communication is most likely to achieve the desired result. At our institution the verbal communication is carried out in either the preoperative clinic, or via a combination of surgical and nursing preoperative "teaching." Our written preoperative instructions are in the form of a folder, or "packet," that is periodically reviewed by perioperative surgical, anesthesia, and nursing teams. The most important elements of preoperative instruction that relate to the provision of safe anesthesia are dietary (nothing by mouth [NPO]) and medication instructions. Even when general anesthesia is not the primary anesthetic plan, it is an eventual possibility in many cases. Consequently, it is important that patients fast appropriately so that the risk of aspiration is minimized. Fasting guidelines for elective surgery are clearly delineated by the ASA,[75] and we tend to instruct patients conservatively (e.g., interpreting "clear liquids" to mean "water").

ASA PS 1 and PS 2 patients may be taking a variety of prescription and nonprescription medications. To avoid potential complications, clear instructions must be given regarding continuation and avoidance of various medications prior to elective surgery. Medications that are typically continued include antireflux, cardiovascular, and antihypertensive (with the possible exception of angiotensin-converting enzyme inhibitors and angiotensin receptor blockers),[76] pain (with the possible exception of aspirin and nonsteroidal antiinflammatory medications), psychotropic (with the exception of monoamine oxidase inhibitors), asthma, and antiseizure medications. Medications taken on the day of surgery should be consumed with as little water as possible. Alternative medications and herbal preparations deserve special consideration. Many patients do not consider these to be medications and hence must be specifically asked about their use. These products are poorly regulated and often contain unknown quantities of substances that can lead to serious perioperative drug interactions and complications.[77] Because of the lack of data on many of these preparations, the ASA recommends that practitioners continually familiarize themselves with alternative medications and advise the discontinuation of all such products for at least 2 weeks prior to elective surgery.[78]

Premedication

It is difficult to find consensus on what constitutes the best plan for pharmacologic premedication prior to anesthesia. What is important is that each agent be

administered only if there is a clear and specific indication for its use. The most common indications for preoperative administration of medications are anxiolysis, analgesia, and gastric aspiration, surgical wound infection, and thromboembolic prophylaxis. None of these classes of medications should be administered on a purely "routine" basis. Each of these medications has a unique set of potentially dangerous side effects, including allergic reactions, drug–drug interactions, prolonged effects, and added cost. Hence, in the absence of clear indications, healthy patients undergoing elective operations should receive little or no pharmacologic premedication.

Anxiety is common in patients undergoing even minor surgery, and it tends to heighten as the surgical event approaches. It is difficult to discern which patients will be anxious prior to surgery by any other means but a direct interview. Treating preoperative anxiety not only improves patient satisfaction,[79] but may have more far-reaching effects, such as reduction of surgical stress response and lowering the incidence of PONV.[80] Although, the most commonly used agents used for this purpose are benzodiazepines, particularly midazolam, other agents, such as melatonin, are safe and efficacious.[81]

Preoperative analgesia may be considered when painful conditions, such as orthopedic fractures, are present. If opiates are chosen for this purpose, patients must be monitored for sedative and respiratory depressant side effects. Some studies even support the use of "preemptive analgesia" with agents such as ketorolac as a means to lower anesthetic requirements and their attendant side effects. Evaluation for the risk of nausea and vomiting was discussed above (see Postoperative Nausea and Vomiting). When this risk is identified, consideration should be given to single, or in select cases, multimodal, therapy to prevent this complication. Healthy patients occasionally will require thromboembolism prophylaxis in the perioperative period. This is most commonly accomplished with either low-dose or low-molecular-weight heparin preparations.

Postoperative Destination

The anesthetic plan must take into account the postoperative destination of the patient. Pre- and intraoperative planning must be flexible, so that safe and appropriate medical care is available if the ongoing needs of the patient change. For example, many airway procedures can be accomplished on an outpatient basis. However, there is a relatively high risk with this type of surgery that complications could require admission to, or even mechanical ventilation in, an intensive care unit. This sort of eventuality must be taken into account for two reasons. First, operations with a relatively high likelihood of admission or intensive care unit management (even in otherwise healthy patients) should not be scheduled in facilities that lack the means to provide this care. Second, patients and their families must be advised beforehand of this possibility. Patients and family members must be aware that intraoperative events can change the postoperative destination of the patient, even if the initial plan was for same-day discharge.

Patients have three ultimate postoperative destinations: home, a hospital "floor" or "ward" bed, or the intensive care unit. A stay in the postanesthesia care unit (PACU, or "recovery room") may precede any of these final destinations. Planning for the eventuality of any of these destinations must occur in both the pre- and intraoperative phases of an anesthetic. In the case of both the PACU and the intensive care unit, advance planning must be carried out so that a bed is available and the unit is appropriately staffed. Both patients and family members need to be made aware of the destination that was initially planned, and of any changes that may have been made based on intraoperative (or PACU events). Fortunately, many procedures that are planned on an outpatient basis and are free of complications entail very short PACU stays, or (as is increasingly common) bypass a recovery room altogether. This is generally safe, cost-effective, and well-received by patients, but necessitates simple, but crucial, advance planning. For example, it is mandatory that patients who have received sedating medications have safe transportation home, usually in the person of a caregiver who can also assist with medication, surgical dressing issues, and other forms of assistance.

Postoperative Pain

Postoperative pain resulting from surgical procedures performed in healthy patients ranges from none to severe and relatively long-lasting. As such, treatment of postoperative pain ranges from no treatment at one extreme (noninvasive endoscopic procedures) to invasive techniques, including epidural analgesia and indwelling nerve plexus catheters. This section provides a simple overview of available pain-control options in healthy patients, and readers are referred to Chap. 74 for a more in-depth review of this subject. It is the anesthesiologist's responsibility to couple analgesia with hypnosis in the intraoperative phase, and then continue some form of analgesia postoperatively, while minimizing additional drug effects such as sedation and respiratory depression. A key feature in the success of this plan is education, and physician–caregiver rapport in the preoperative phase. Although it is important for patients to wake up as pain free as possible, it is also critical that they be informed that they will likely experience some degree of postoperative pain. Realistic expectations regarding postoperative pain, as discussed further in Chap. 74, are a vital component in patient satisfaction and avoidance of complications related to pharmacologic control of pain.

As stated previously, healthy patients generally undergo short, simple surgical procedures. Occasionally, however, complicated operations are performed that result in severe postoperative pain. Thus, the entire array of pain-control modalities at the anesthesiologist's disposal must be available in this population. Despite controversy over its efficacy,[82] preemptive analgesia with agents such as acetaminophen and nonsteroidal antiinflammatory drugs (NSAIDs) must be considered. Use of these compounds is also typically the first line of therapy in patients having minor operations, such as carpal tunnel repair or vasectomy. These compounds are generally devoid of side effects, but patients must be cautioned regarding overdose with resultant damage to the liver and kidneys.

Opiates are indicated for moderate to severe pain, via either oral or intravenous routes of administration. Patient-controlled analgesia (PCA) represents a major advance in the use of opiates for postoperative analgesia, but success with the technique is dependent on proper planning and patient instruction. Grass published an excellent and

thorough review of this subject, covering its history, safety, efficacy, and current practice guidelines.[83] Major nerve conduction blockade (nerve blocks, plexus blocks) and epidural analgesia are occasionally necessary in healthy patients undergoing surgical procedures that will result in severe pain (e.g., orthopedic, intraabdominal, and pelvic procedures). Liu published an excellent practical review of indwelling catheters for postoperative pain relief.[84] Although highly successful, both techniques are associated with potentially serious complications and proper planning and consent entails disclosure of both aspects of these techniques. Finally, the issues of aging, opiate dependence, and abuse all have important implications for the successful planning and management of postoperative pain; Chap. 74 discusses these issues in detail.

MONITORING IN HEALTHY PATIENTS

The medical community, the anesthesia community, and to some extent patients assume that monitoring during anesthesia and surgery results in fewer preventable mishaps and improved outcomes. Fortunately, since its introduction into modern medicine, anesthesia is an increasingly safe proposition.[85] As Domino and others continue to point out, however, rare anesthesia mishaps continue to have catastrophic outcomes (death, major morbidity) that are very costly to society.[41] Every year, thousands of cases of death and serious morbidity are attributed solely to the provision of anesthesia.[86] In a large proportion of these cases, the cause of the morbidity or mortality is believed to be preventable.[87] Failure to prevent anesthetic catastrophes usually results from lapses in vigilance or simple human error. Anesthetic monitors are intended to aid in the maintenance of vigilance and to alert providers to the possibility of human error. Following is an overview of monitors commonly used in healthy patients and the rationale for their use in various clinical scenarios. For a more in-depth review of monitoring devices and their clinical applications and limitations, the reader is referred to Chaps. 29–34.

Despite the assumption that there is a correlation between monitoring and outcome, there is little in the way of scientific validation to support this assumption. In 1986, Eichhorn et al. suggested that intraoperative monitors may reduce adverse events and therefore improve outcomes.[88] From this body of work arose the ASA guidelines for intraoperative monitoring,[89] which have been amended (Table 5–13).

TABLE 5–13.

American Society of Anesthesiologists Standards for Basic Intraoperative Monitoring[a]

Standards

- Standard 1: Qualified anesthesia personnel shall be present in the room throughout the conduct of all general and regional anesthetics, and monitored anesthesia care
- Standard 2: Oxygenation, ventilation, circulation, and temperature shall be continually evaluated
  - Oxygenation
    - Oxygen concentration of inspired gas
    - Observation for the patient
    - Pulse oximetry
  - Ventilation
    - Auscultation
    - Observation of the patient
    - Observation of reservoir bag
    - End-tidal carbon dioxide analysis
  - Circulation
    - Continuous ECG display
    - Heart rate and blood pressure recorded every 5 min
    - Evaluation of circulation: auscultation of heart sounds, palpation of pulse, pulse plethysmography, pulse oximetry, intraarterial pressure tracing
  - Temperature
    - Core temperature and/or skin temperature

[a]The term *continuously* means prolonged without interruption, whereas *continually* means repeated regularly and frequently.[89]

The assumption that monitoring improves outcome, coupled with the zeal of anesthesia providers to gather information, can lead to practitioners erring on the side of more, rather than fewer, monitoring devices. This would be ideal if monitors were cheap, completely accurate, and completely safe. Most modern monitoring devices, however, are expensive and not always accurate. Some forms of monitoring have the potential to mislead anesthesia providers, while others are even capable of causing serious physical harm.[90,91] Therefore, in planning for an anesthetic, anesthesiologists must weigh the perceived advantages with the known potential for complications when choosing a monitoring strategy (Table 5–14).

Healthy patients having uncomplicated surgical procedures rarely need more than the ASA basic intraoperative monitors. Before considering machines that monitor the human body however, it is vital that anesthesiologists maintain basic physical examination skills. These skills can give vital information about patients quickly and reliably. For example, failure of the chest to rise combined with a bubbling sound emanating from the patient's throat, may indicate cuff failure or improper placement of an endotracheal tube. Tactile sensation of a bounding pulse in the presence of a low machine reading, may indicate a problem with mechanical blood pressure measurement. Discoloration of a patient's skin combined with a feeling of warmth could be an early indicator of malignant hyperthermia. Smelling a potent anesthetic vapor could be a sign of an airway leak or disconnect. Although it would be crude and unwise to rely solely on sense perception to assess patients, clinicians must maintain vital physical examination skills in addition to their knowledge and skills in use of mechanical monitoring devices. Analyses of anesthetic mishaps leading to serious morbidity and mortality[41] consistently reveal one common mechanism as a root cause for catastrophe: failure to deliver oxygen to vital organs. The most common cause of critical end-organ hypoxia is failure to ventilate the lungs, hence the ASA recommendation for continuous evaluation of oxygenation and ventilation, even in healthy patients. The goal of this monitoring is early recognition of ventilatory inadequacy, which can be rectified before end-organ damage ensues. Observation is still a vital skill in assessing tissue oxygenation, especially in the case of the awake patient. Signs of hypoxemia in an awake patient include decreased level of consciousness, loss of judgment, and disorientation, but these signs are not specific and occur in many other conditions. Cyanosis might be an indicator of hypoxemia, but it is late occurring and generally unreliable. Given the devastating consequences of arterial hypoxemia, however, this cause must be at the top of any differ-

TABLE 5–14.

Types of Anesthesia Monitors and Their Properties

Type of Monitor	What Is Measured	Invasiveness	Potential for Complications
Physical examination	Heart tones, breath sounds, pulse, color, etc.	Noninvasive	–
Pulse oximetry	Arterial oxygen saturation	Noninvasive	–
Arterial blood gas analysis	Ventilatory and acid–base status	Invasive	++
Sphygmomanometry, oscillometry	Blood pressure	Noninvasive	+
Arterial catheterization	Blood pressure	Invasive	++
Electrocardiography	Cardiac rhythm, integrity	Noninvasive	–
Capnography	Ventilatory, circulatory status	Non- to semi-invasive	–
EEG, bispectral index, entropy, others	Brain function, depth of anesthesia	Noninvasive	±
Temperature probes	Body temperature	Non- to semi-invasive	±
Central venous cannulation, pulmonary artery catheter	Volume status, cardiac function	Invasive	+++

ential diagnosis when these physical signs are encountered.

Measurement of Oxygenation

Three methods of assessing oxygen delivery are widely available: arterial blood gas analysis, pulse oximetry, and measurement of inspired oxygen concentration. The need for blood gas analysis in healthy surgical patients is relatively rare. This test is invasive (and therefore has potential complications), relatively expensive, and can only be performed intermittently. Its use in healthy patients should be considered when complex surgical procedures are being performed or when perioperative complications necessitate in-depth analysis of ventilation and acid–base status. Pulse oximetry is completely noninvasive, well accepted (despite being a continuous monitor), and is relatively inexpensive. Extensive reviews of the development, theory, and applications of pulse oximetry are available. Pulse oximetry and inspired oxygen analysis should be used in every patient undergoing general anesthesia. Pulse oximetry should be used in all patients anesthetized with sedating intravenous medications. What follows is a summary of pulse oximetry's technical aspects, perioperative uses, and limitations.

Pulse oximetry relies on two principles to continuously measure the degree of arterial blood oxygenation: differential light absorption of oxy- and deoxyhemoglobin, and pulsation of arterial blood. The pulse oximeter displays a number that corresponds to the arterial saturation obtained from an in vivo cooximeter. Also displayed on most units is a plethysmograph, or pulse waveform. Some advantages of pulse oximetry can also be viewed as limitations. First, the pulse oximeter is quite accurate when compared to in vivo oximetry, but only under ideal conditions and within a fixed range of arterial saturation. Artifacts that create less-than-ideal conditions include shivering, cold extremity, intravascular dyes, venous congestion, and electrocautery. In addition, the processor algorithms built into the device are unable to give meaningful output for oxygen saturations below 70%. Second, users must be familiar with limitations of the plethysmograph feature. It should not be assumed that the plethysmograph accurately reflects the magnitude of the arterial pulsation, and hence the adequacy of perfusion. This signal is variably (and sometimes highly) amplified to aid in the measurement of oxygen saturation.[92] Hence the plethysmograph magnitude should not be used to infer information about the adequacy of blood perfusion.

Hemodynamic Monitors

Hemodynamic monitors are those intended to assess the adequacy of circulatory function. All anesthetized patients must have at least intermittent blood pressure monitoring. For healthy patients having uncomplicated surgical procedures, intermittent cuff measurement is usually sufficient. Cuff measurement of blood pressure can be achieved via either sphygmomanometry or oscillometry. Both methods are accurate, noninvasive, and well tolerated. Clinicians using either of these methods must understand a few guidelines to insure accurate measurement. First, cuff size must be appropriate for the patient. Too large or too small a cuff size can under- or overestimate blood pressure, respectively. This is most common in obese patients, where cuff size is too small. Second, this method of blood pressure measurement is subject to motion artifact.

Direct intraarterial blood pressure monitoring involves insertion of a catheter into an artery followed by its connection to a pressure transduction system. Arterial lines are occasionally necessary in healthy patients because of procedural length or complexity. This technique is invasive and serious complications can result from its use. When correctly performed, this method provides continuous measurement of blood pressure that is very accurate. The data obtained from this measurement technique can even be used as an accurate measure of intravascular volume status.[93]

In patients who are intubated and mechanically ventilated, variation in the peak systolic pressure with ventilation has been used as a method to determine intravascular volume status.[94] This measurement, known as systolic pressure variation (SPV), has been compared to central venous pressure measurements, pulmonary artery occlusion pressure measurements, and transesophageal echo measurement of left ventricular volume, and found to be more accurate than other pressure measurements for determining adequacy of volume resuscitation.[94] Normal values of SPV are between 5 and 10 mm Hg, with high

values representing possible underresuscitation (hypovolemia) and low values meaning the patient may be overresuscitated.[94] This SPV has been described as a "dynamic variable of volume responsiveness."[94,95]

Clinicians must not forget basic physical examination skills that can be valuable when specifically assessing circulatory status. Palpation and auscultation are the two most useful of these skills. These tests can be immediately performed and require no mechanical devices. These methods are not sufficient to completely monitor the circulatory status in healthy patients. Regular use of these techniques, however, especially when baseline assessments were performed for comparison, can give anesthesia providers accurate and early information that can guide therapy or aid in selection of more complex assessment techniques. Palpation of a peripheral pulse can give valuable information about the circulatory status of the patient. Two properties of the pulse must be ascertained: magnitude and character. The pulse of a healthy patient at baseline should be strong and regular. Performing a baseline examination is mandatory so that later comparison can be made.

Auscultation is another physical examination skill with usefulness in the modern operating room. Auscultation is simple to perform, even on a continuous basis, and is an excellent qualitative measure of ventilation. Auscultation is most valuable to the clinician when a baseline examination is performed and used for later comparison. Baseline auscultation of heart and lungs should be performed in every anesthetized patient. As with palpation, both the quality and the magnitude of the sounds must be ascertained. Auscultation is never sufficient on its own to make definitive diagnoses or to guide therapy, but it can be performed easily, immediately, and without harm, and may guide the clinician in planning additional diagnostic steps. An example is development of a third heart sound combined with new pulmonary rales, raising suspicion of fluid overload and pulmonary edema.

The heart is not only a pump, but a vital end-organ that is susceptible to hypoxic insult. In addition, even healthy, anesthetized patients are susceptible to cardiac rhythm abnormalities that can compromise circulatory adequacy. Consequently, it is routine for anesthesiologists to monitor the integrity of the heart muscle and heart rhythm during anesthesia. This is accomplished mainly via the electrocardiogram (ECG) and, when possible, feedback from an awake patient (angina or anginal equivalent). ECG monitoring is considered a standard of care in modern anesthesia. ECG monitoring is completely noninvasive, relatively inexpensive, and can be assessed continuously. ECG data are crude representations of the heart's electrical activity, but critical information can be inferred from the trace regarding the integrity of the myocardium. Specific patterns of abnormality on ECG tracings can represent cardiac dysrhythmias, cardiac ischemia, and electrolyte imbalances that can compromise the integrity of the heart muscle and its function as a pump.

The most common ECG abnormality found in healthy anesthetized patients is dysrhythmias. Thus when using an ECG to monitor healthy patients, it is wise to monitor leads that are best suited for rhythm identification, such as lead II or V_1. Common causes of perioperative dysrhythmias are autonomic nervous system overactivity, ventilatory abnormalities such as hypoxemia and hypercarbia, and cardiac effects of anesthetic medications and adjuvants. Perioperative dysrhythmias in otherwise healthy patients are often well tolerated and self-limited. Some, such as severe bradycardia and junctional rhythms, can compromise circulatory status and require intervention. On occasion, the perioperative ECG will identify myocardial ischemia in patients who were previously thought to be healthy.

By definition, healthy patients are free of coronary artery disease. Use of perioperative ECG monitoring, however, will identify possible coronary ischemia in patients who were previously thought to be free of ischemic heart disease. The relationship between perioperative ECG evidence of coronary ischemia and the diagnosis of ischemic heart disease remains unclear. For ECG to function well as a monitor for myocardial ischemia, correct combinations of leads must be used. Highest sensitivity can be achieved when these combinations include lead V_5. Changes in ST segments and in T-wave configurations are the most universally accepted ECG findings representative of coronary ischemia, but the specificity of these findings is far from perfect.[96] Newer monitors use computer-assisted ST-segment analysis to assist in early detection of coronary ischemia. Most monitors allow printing or "freezing" of a short ECG trace to compare with later findings. When these are not performed, clinicians should closely observe a preinduction ECG tracing so that comparisons can be made later, if necessary.

Capnography

Measurement of respiratory carbon dioxide is useful and strongly encouraged in all anesthetized patients. The methodology most commonly used is end-tidal carbon dioxide measurement, or capnography, to measure the carbon dioxide concentration in respiratory gas. Portable colorimetric devices are also available for use at the bedside and in the emergency room, and are used to confirm proper placement of an endotracheal tube. Capnographic samples can be obtained from closed or open (e.g., near the nose of a patient who is spontaneously breathing room air) breathing circuits. Capnography gives clinicians vital information regarding the pattern and the magnitude of ventilation. Capnography gives useful information regarding cardiopulmonary function. To produce a normal capnogram, the patient must be producing CO_2 at the normal rate, blood must be returning it to the pulmonary circulation, and the lungs must be ventilated. Therefore, a continuous capnogram insures, on a breath-to-breath basis, that all of the following are functioning normally: metabolism, blood flow, and ventilation.

A sudden drop in end-tidal carbon dioxide might indicate pulmonary embolism.[97] Capnography is useful in confirming proper placement of endotracheal tubes, but it is not useful in ruling out endobronchial intubation. End-tidal carbon dioxide concentration can be monitored continuously, the machinery is relatively inexpensive and the technique noninvasive.

Mental Status and Depth of Anesthesia

The best monitor of cerebral function in a healthy patient who requires anesthesia is interaction with a conscious patient. This is the rationale for using

awake anesthetic techniques in certain settings where feedback regarding brain integrity is critical (carotid endarterectomy, prostatectomy with use of nonionic irrigants). In many surgical settings, however, awake anesthetic techniques are unsuitable. A concept that is intimately related to perioperative cerebral function is the ability of anesthesia providers to accurately assess the efficacy, or "depth," of anesthesia in unconscious patients. The ideal general anesthetic renders a patient unconscious and pain free, facilitates ideal surgical working conditions, is rapidly reversible at the conclusion of surgery, and has no lasting side effects. During anesthesia-induced unconsciousness, however, there is no completely reliable method of assessing whether a patient is aware and possibly perceiving intraoperative events. Anesthesia providers undergo rigorous training in pharmacology and physiology to correctly dose medications and interpret physiologic data so that they can provide assurance *on these grounds* that patients are adequately anesthetized. Unfortunately, correct drug dosing and "normal" physiologic values do not insure that all patients are unconscious and free from pain.

One method of monitoring brain function (and, presumably, consciousness) that has seen occasional intraoperative use is the EEG. This monitoring technique is cumbersome, expensive, and requires highly trained personnel to interpret the highly complex data generated. Currently, an unprocessed EEG is rare in intraoperative settings. A variation of the EEG that has gained much notoriety in both the medical community and with the lay media is bispectral index (BIS), or "entropy" monitoring. These devices use only select EEG leads and then filter and transform the signals into a single digitized value.[98] BIS or entropy values correlate inversely with depth of anesthesia.[98] Use of the device has been advocated for two reasons: its use reduces both the incidence of intraoperative awareness during general anesthesia and anesthetic drug costs.[99] Although intraoperative awareness is a real problem, the issue has been somewhat sensationalized by the public media, which has led to much public interest in BIS. The ability of BIS to eliminate awareness, however, remains controversial,[100] and some even argue that BIS could actually cause anesthesiologists to underdose their medications, leading to a higher incidence of awareness.[101] This issue remains unsettled and requires further investigation.

Temperature Monitoring

It is vital that temperature be monitored in some way in all anesthetized patients, especially when general anesthesia is chosen or when MH triggering agents are used. Multiple investigators have shown improved outcome with maintenance of normothermia during major operations.[102] Hypothermia slows metabolism, inhibits coagulation, can cause cardiovascular lability, and is very uncomfortable in awake patients. Hypothermia is easily and commonly achieved in the operating room, but the best treatment strategy is prevention. Several methods of temperature monitoring are available to anesthesia providers. The simplest and least-invasive method is use of a skin temperature probe. These probes are somewhat accurate but it must be kept in mind that skin temperature is not truly representative of core, or internal, temperature. In addition, skin probes are easily rendered inaccurate by ambient conditions, such as warming and cooling mattresses and forced air blowers. Several semi-invasive methods of temperature monitoring are available, including tympanic, nasopharyngeal, esophageal, and rectal. Although these methods are quite safe, accurate, and more reflective of core temperature, complications are possible (ruptured tympanic membrane, nosebleed, irretrievable probe wires). The most accurate monitors of core body temperature are also the most invasive. Temperature probes are present on the tips of pulmonary artery and urinary catheters, but these are generally reserved for major operations in medically ill patients.

CONCLUSION

Safety and efficacy are the primary determinants of a successful anesthetic. Safety in anesthesia is mainly achieved through the avoidance of complications. A main source of complications is patient comorbidity. Healthy patients, by definition, lack comorbidity, but may still experience anesthetic complications. The main goals of the anesthetic plan in healthy patients are insuring the absence of comorbidity and the identification of potential complicating factors. The primary method of accomplishing these goals is the careful performance of a preoperative history and physical examination, which is typically a joint effort between the surgeon and anesthesiologist. In most cases, the anesthetic portion of this evaluation can be performed on the same day as surgery. Once the evaluation of the healthy surgical patient is complete, the plan is formulated, taking into account the needs of both the patient and the surgeon. The patient must be fully informed of the nature of the operation and the type of anesthesia involved. Patient instructions and use of premedications are important steps that lead to safe and successful anesthesia. Finally, monitoring devices are believed to be a major contributor to avoidance of complications and overall patient safety. Generally, healthy patients only need basic ASA intraoperative monitoring, but on occasion, the extent of surgery may dictate a more invasive monitoring scheme.

SECTION B

Preoperative Evaluation of the Anesthesia Patient

CHAPTER 6

Appropriate and Effective Use of Consultants

Lee Goldman, MD, and
Thomas H. Lee, MD

As pressures to improve the quality, safety, and efficiency of healthcare intensify, perioperative consultation has evolved into an increasingly well-defined area of medicine, and hospital staffs are giving more thought on when and how to use them. Like most medical interventions, perioperative consultations are susceptible to the three basic types of medical errors:

1. Overuse—requesting consultations on patients who are unlikely to benefit from them leads to delays and needless expense.
2. Underuse—failing to request a consultation on a patient who might benefit from such an evaluation; this failure can contribute to the occurrence of preventable complications.
3. Misuse—unnecessarily endangering patients as a result of poor communication or advice.

Although the risk of such errors has always been present, the need to reduce their frequency has grown as a consequence of several trends. First, the proportion of patients who might benefit from consultations has grown as a result of the aging of the population and the rise in the prevalence of comorbid illnesses in patients who undergo or are considered for procedures. This trend toward increased risk in the patient population has been accompanied by surgical and anesthetic advances that encourage the performance of ambitious procedures in increasingly aged patients. Progress in the fields of anesthesiology and medicine has made these disciplines so sophisticated that the interfaces between them require special skills. Multiple specialists must often be involved if these complex patients are to receive optimal care.

Additional pressure for efficiency and coordination comes from the healthcare marketplace. Rising insurance premiums are causing employers and other healthcare purchasers to use every possible tactic to reward efficiency (and to punish inefficiency) among hospitals and physicians. One of these tactics is publication on the Internet and elsewhere of data on quality of care, including mortality and complication rates for surgical procedures, so that patients who are bearing an increasing portion of their costs can decide where they might get the highest quality care.

In response, hospitals have developed preadmission evaluation centers where patients can be seen and examined by anesthesiologists and consultants before admission for same-day procedures. The informal scramble to obtain immediate preoperative consultation for a patient with an unexpected problem is being replaced by the development of coordinated team care, with consultants who have a special interest in perioperative medicine and a commitment to provide on-demand consultations at these centers.[1–3] Several investigations have shown that such consultations can lead to the detection of important new diagnoses that may warrant preoperative interventions[2–5] or help in arranging followup care.[4]

However, the effectiveness of consultations provided by such services or by individual physicians is highly variable and is influenced by communication among the surgeon, anesthesiologist, and medical consultant.[6–11] In one study of 156 cases at a teaching hospital, consultants and the physi-

KEY POINTS

1. The increasing prevalence of high-risk patients undergoing complex surgical procedures and the increasing pressures for improved efficiency and quality have created an increased need for effective and timely perioperative medical consultation.
2. Anesthesiologists and surgeons have a duty to recognize when consultations are needed, to notify the patient of the planned consultation, and to inform the patient of important consultation findings.
3. The questions to be answered by the consultant should be stated clearly.
4. The consultant should limit initial recommendations to those of high priority in the perioperative period.
5. Direct communication between the primary physician and the consultant can help to avoid misunderstandings and to clarify management goals.
6. In addition to estimating perioperative risk and developing appropriate initial management strategies, the consultant should follow the patient through the postoperative period.
7. The consultant should respect the primary physician's relationship with the patient.

cians who requested the consultation disagreed on the reason for the consultation and the principal clinical issue in 14% of cases.[10] When communication among physicians is so tenuous, it is not surprising that rates of compliance with the recommendations of consultants are only 54–77%.[12–14]

In summary, the potential contribution by consultants has never been greater, but there are many opportunities for the perioperative consultation process to go awry. This chapter describes ways in which consultations may be used and misused by describing their role, performance, medicolegal issues, and factors associated with effectiveness.

ROLE OF THE CONSULTANT

One of the most common reasons for perioperative consultation is a request for "clearance" for surgery.[4] For medicolegal and clinical reasons, requesting physicians and the consultants should narrow the purpose of the consultation in such cases. "Clearance" implies a guarantee of a good outcome, which is impossible to provide. The provision of such a guarantee is considered ill-advised from a medicolegal perspective; in addition, the impact of consultations aimed at "clearing" patients usually is limited.[15]

Instead of providing "clearance," the consultant should provide an estimate of the risk of cardiac and noncardiac complications associated with the planned procedure for the patient (Table 6–1). For higher-risk patients, the consultant should identify strategies that might mitigate those risks and can help compare the risks associated with surgical versus medical therapy. Finally, the consultant can anticipate potential intra- and postoperative problems, and follow the patient postoperatively to help prevent, detect, and manage such complications.

TABLE 6–1.

Key Functions of the Consultant

- Estimation of cardiac and noncardiac risk of surgery
- Identification of management strategies that minimize risks
- Anticipation of complications that may occur during the perioperative period
- Postoperative followup to help prevent, detect, and manage complications
- Perioperative management of acute and chronic medical conditions
- Education—teaching and learning

In the management of acute or chronic medical conditions that often complicate perioperative care, consultants can play a role analogous to that of a primary care internist. Input from an internist may be required when the patient has an unstable medical problem (e.g., acute ischemic heart disease), an uncertain medical status (e.g., dyspnea of unknown cause), multiple chronic diseases (e.g., diabetes, hypertension, or alcohol abuse), or psychological distress. When the internist has been the primary care physician for that patient, familiarity with the past history and the baseline condition can enhance management of clinical and social issues.

Although the perioperative consultation process virtually always goes smoothly, the potential complexity of the consultant's role and relationship to the patient and the other physicians involved in the patient's care become painfully apparent. The consultant is a physician directly involved in the patient's care, and thus should perform thorough evaluations and gather primary data through a history and examination (as opposed to a review of the medical record). However, the primary physicians are the surgeon and the anesthesiologist. Thus, consultants should not be delegated responsibility for performing the definitive preoperative evaluation—and the primary physicians bear ultimate responsibility for the overall care.

On the other hand, the consultant should respect the relationships among the patient, surgeon, and anesthesiologist, and be appropriately circumspect in conversations with the patient. For example, a consultant might answer a patient's questions about diabetes mellitus but should not generally engage in lengthy discussions concerning whether the surgery should be performed or is likely to succeed. The consultant's obligations to the patient can almost always be met through the consultant's primary relationship with the other physicians.

Occasionally, however, these obligations come into conflict. A trilateral deliberative model has been proposed to describe the ethical duties of the primary physician and the consultant.[7] This model cautions that both the consultant and the primary physician should avoid seeking to "dominate" each other and should minimize expression to the patient of insignificant differences of judgment between them. Both consultants and primary physicians have an obligation to the patient to keep information confidential from each other if the patient so desires, as long as the information is not relevant to immediate healthcare concerns.

According to this model, consultants can have a direct discussion with the patient over a difference of opinion with the primary physician (e.g., regarding the issue of whether surgery be performed) to avoid serious harm to the patient or in the case of malpractice by the primary physician. Implicit in this model is the assumption that the consultant and the primary physician have attempted to resolve differences of opinion before either alarms the patient through such discussions.

Although consultants may be expert in their own specialties, they should recognize issues on which their expertise is less than that of the anesthesiologist or surgeon. For example, an internist's recommendations on the choice and route of anesthesia are not authoritative and may generate animosity within the healthcare team. Similarly, trivial recommendations (e.g., "avoid hypotension") are unlikely to improve care but remain distressingly common. In a series of medical consultations to surgeons at one teaching hospital, 122 (12%) of 1016 recommendations were judged to be "insulting."[12]

Just as consultants can learn from colleagues in anesthesia and surgery, they can play important roles as teachers. This educational role requires tact and sensitivity. Opinions should be expressed concisely and without condescension; references should be provided selectively. The description of a differential diagnosis may be helpful, but a long, intellectual discussion in the medical record is unlikely to be read.

LOGISTIC ISSUES IN THE PERFORMANCE OF A CONSULTATION

Timing of the Preoperative Evaluation

The increase in ambulatory and "same-day" inpatient surgery has been ac-

companied by the development at several institutions of "preadmitting test centers," where large numbers of patients undergo preoperative laboratory work and evaluations by anesthesiologists and other personnel. As the volume at such centers increases, the historical practice of searching for consultants as the need arises becomes untenable. Consequently, many hospitals have identified consultants who are onsite or nearby, available to perform general medical, cardiology, and other types of preoperative consultations on short notice. The availability of such consultations minimizes costly disruptions to the operating room schedule.

In the ideal situation, the surgeon who plans elective surgery for a patient should perform an evaluation that is sufficiently thorough to determine whether a consultation will be needed. If so, an elective outpatient consultation should be arranged well in advance of the surgical date, allowing the consultant time to obtain previous medical records, electrocardiograms (ECGs), and radiographs; perform additional tests (e.g., an exercise tolerance test); and make adjustments in the patient's medical regimens, such as the initiation of therapy for hypertension. Unfortunately, the need for such information or intervention often is detected during the surgeon's or anesthesiologist's evaluation only a few days or hours before an operation. For this reason, institutions with high surgical volumes need to develop mechanisms for providing consultations with an internist or cardiologist on a "walk-in" basis.

One approach that some organizations have used to identify patients who need consultation more reliably and in a more timely manner is to have the surgeon or anesthesiologist use a risk index to stratify patients according their likelihood of major cardiac complications.[16] In this approach, higher risk patients (e.g., class III or IV according to the Revised Cardiac Risk Index) are automatically referred for cardiology or other consultation. Such standardized approaches to use of perioperative consultations are consistent with a substantial emerging literature supporting the use of clinical guidelines or critical pathways for a variety of medical and surgical conditions.

Technologic advances both increase the need for these consultations and make evaluations of patients easier. Computerized ECG machines provide preliminary interpretations of the tracing, but the interpretative software generally is written to have a high sensitivity for detecting abnormalities. An unofficial reading of "poor R-wave progression; cannot exclude anterior myocardial infarction" often will force the evaluating anesthesiologist to request a cardiology consultation. However, electronic medical records often make old tracings and other data readily available, so that new findings can be readily differentiated from old abnormalities.

Even with the most effective systems for detecting patients who might benefit from preoperative consultations, the need for consultation may be recognized the evening before, or even the morning of, a scheduled procedure. Last-minute preoperative cardiology consultations are most commonly precipitated by a history of cardiovascular disease that might not have been fully evaluated previously or by an abnormality on the preoperative ECG. In one study of 166 last-minute consultations,[2] the cardiology consultant recommended an exercise test or echocardiogram in 21% of patients, sometimes leading to a delay in surgery. In 13% of patients, the cardiology consultants suggested an adjustment or change in medications. In 5 patients (3%), the consultant specifically suggested that surgery be delayed or cancelled because of the ECG finding of an unexpected previous myocardial infarction of uncertain age, marked ischemia, or advanced conduction system disease.

When consultations are requested at the last minute before surgery, consultants should resist the temptation to "punish" other physicians (and the patient) by forcing a postponement of the procedure. Because operating room time is among the most costly of hospital resources, the consultant should make every effort to see the patient before the scheduled procedure time. Afterward, the various members of the healthcare team should attempt to identify strategies for a more orderly consultative process.

When performed in a timely and effective manner, perioperative consultations can improve the efficiency of care. For example, in one study, the addition of an internist to a cardiothoracic surgery service at a tertiary care teaching center was associated with major reductions in postoperative lengths of stay and in the number of radiologic procedures and laboratory tests that were ordered.[17] Involvement of a diabetes consultation team reduces the length of stay for patients with diabetes.[18] In a randomized trial at a Veterans Affairs hospital, outpatient preoperative evaluation by an internist significantly reduced hospital length of stay.[19]

Unfortunately, consultants also have the ability to worsen efficiency. When consultants suggest additional tests, hospital length of stay may be prolonged.[20] Consequently, consultants should exercise restraint in suggesting additional tests and limit recommendations to those that are absolutely necessary during hospitalization. Elective tests may be postponed until after the patient has been discharged.

Postoperative Care

A rule used by many experienced consultants is "never go home before the patient is out of the operating room." Patients are often unstable in the immediate postoperative period, so consultants should be prepared to reevaluate patients shortly after their admission to the recovery room. For example, postoperative hypertension often occurs 30–60 minutes after the end of anesthesia, and ischemia on an initial ECG in the recovery room is a powerful predictor of major postoperative cardiac complications.[21] Thus, consultants and primary physicians should evaluate the patient's volume status and fluid orders so as to avoid marked hemodynamic changes, and should consider early performance of an ECG to detect asymptomatic ischemia.

The period of risk does not end with the immediate perioperative period. Mobilization of extravascular fluid, high sympathetic tone associated with pain, and hypercoagulable states may contribute to cardiovascular complications, such as acute myocardial infarction, 24–48 hours or more after surgery.[22] Other medical conditions also may worsen later in the hospitalization; for example, mild renal failure may be unmasked by perioperative fluid volume shifts. Thus, consultants should follow patients for at least 3–5 days after surgery, or until discharge, if the patient leaves sooner.

Formal medical comanagement incorporates the medical physician into

postoperative care as a codecision maker rather than as a consultant. This model can reduce the percentage of patients who have postoperative problems, while simultaneously being preferred over standard care by both nurses and surgeons.[23]

Some hospitals have instituted rapid-response teams to aid in the postoperative care of patients whose impending complications might otherwise not be addressed as promptly, completely, and expertly as desired. Data are inconclusive on the benefits of this model—one study showed striking benefits after this type of service was instituted compared with before,[24] whereas a randomized trial showed equal improvement in both the control and intervention groups compared with the historical, preintervention period.[25]

MEDICOLEGAL ISSUES

Consultations are often ordered mainly for "defensive medicine" purposes, but such consultations can lead to delays and increased resource use.[10] Several legal decisions have made clear that primary physicians have a duty to request consultations when clinical problems lie outside their expertise,[26] but there is no such duty to consult when the anesthesiologist or surgeon does not recognize any special problems. Nevertheless, judgments have been made against physicians when the patient's recovery does not progress and no consultation was sought, or when a physician undertook a procedure beyond his or her training when specialists were available. Furthermore, the primary physician has an obligation to inform the consultant of any subsequent developments that may be relevant to the consultant's expertise.[26,27]

The implication of these principles is that anesthesiologists and surgeons should have a low threshold for requesting consultation from internal medicine and subspecialty colleagues when patient outcomes are potentially influenced by acute or chronic medical conditions. Although anesthesiologists may be comfortable managing common problems such as hypertension or diabetes, cardiology consultations are appropriate for reviewing equivocal ECGs or evaluating a chest pain syndrome. Informal or "hallway" consultations, in which the internist or subspecialist does not examine the patient but may write a note, are inadequate.[28,29] These informal consultations sometimes can suffice if the question is brief and simple, but, especially in the era of managed care, physicians should resist the financial temptation to avoid formal consultation on difficult or complex cases.[30]

The consultant bears an important legal, ethical, and financial responsibility for formalizing and documenting the relationship with both the primary physician and the patient. Even though the request for a consultation is made by the anesthesiologist or surgeon, the primary physician should inform the patient and obtain the patient's consent because of legal and ethical considerations.[27] Legal decisions indicate that the patient may not be liable for the consultant's fees if the patient does not give such consent.[26,27] The request for a consultation and patient consent should be documented in writing;[28] under many payment systems, the consultant's fee may be denied if the request for consultation is not evident in the medical notes.

Despite the consultant's direct duties to the patient, the primary physician remains the individual who is responsible for all decisions regarding the patient's treatment. The consultant should write a full report to the primary physician because oral recommendations may not be recognized in any legal proceedings. In general, the consultants should not discuss findings directly with the patient unless the primary physician has given permission, particularly if the clinical decisions that flow from those findings have not been discussed yet. The primary physician is the individual with the duty to convey important information to the patient.[28]

FACTORS ASSOCIATED WITH THE EFFECTIVENESS OF CONSULTATIONS

Consultations often lead to new diagnoses and management decisions, including changes in medical therapy, triage to a new service, and delay or cancellations of surgery.[1–4] Nevertheless, in the perioperative setting, about half of consultants' recommendations are ignored.[14] Consultants sometimes make unimportant or ill-advised recommendations, do not convey the recommendations appropriately to the primary physicians, or have appropriate recommendations ignored by primary physicians.

Effective communication between the consultant and the primary physician who requests a consultation is gaining increasing attention as the pace of modern healthcare accelerates, and face-to-face contact among colleagues becomes less predictable. In one study, disagreement existed between the consultant and the primary physician on the issues of a consultation in 14% of internal medicine consultations at a teaching hospital.[10] At another teaching hospital, no specific question was asked in 24% of preoperative diabetes consultations, and consultants ignored the stated question in another 12%.[31] Primary physicians report that the impact of the consultation is diminished when breakdowns in communication occur.[10]

The best way to prevent such misunderstanding, of course, is direct oral communication between the consultant and primary physicians[32] (Table 6–2), both just after the initial consultation and in the days afterward. Nonetheless, face-to-face or telephone conversations between busy colleagues are often difficult to arrange, so written notes in the medical record are critical to communication—and for documentation. E-mail or faxed communications may be useful for coordination of care, but should not be relied upon for transmittal of critical or confidential information.

The consultant should continue to be involved in the patient's case after surgery when such involvement is appropriate. Several investigations have found that recommendations are more likely to be followed if consultants write periodic followup notes, repeat-

TABLE 6–2.

Factors Associated with Compliance with Consultant's Recommendations

- Direct contact between consultant and primary physician[32]
- Continued followup of patients[14,31,34]
- Limited number of recommendations[13,34]
- Identification of high-priority recommendations[13]
- Specification of drug dosage, route, and duration[33]

ing essential recommendations.[31,33,34] In one study, consultations that included more than one followup note had an effect on diagnosis in 92% of patients and an effect on treatment in 84% of patients.[33] When one or no followup note was written, effects on diagnosis were detected in just 74% of patients ($p < 0.001$), and effects on treatment were found in only 56% of patients ($p < 0.001$).

When consultants make a higher number of recommendations, compliance decreases[13,34] with any recommendation. In one series of 202 consultations, compliance was highest when 5 or fewer recommendations were made, regardless of the severity of the patient's illness.

The number of recommendations can usually be reduced by thoughtful prioritization and elimination of trivial suggestions. One study[12] found that 12% of recommendations made by a general medical consultation team were judged to be "insulting" by the reviewer, a surgical chief resident, and an additional 6% were considered nonessential. After the consultants at this teaching hospital were encouraged to use moderation in making recommendations, the mean number of recommendations per consultation decreased from 6.2 per patient to 3.8.

Clear identification of important recommendations in the written record leads to a greater rate of compliance. One study[32] found that labeling recommendations as "crucial" resulted in more than 90% compliance, even if they were part of a long list of suggestions. Clarifying the priority of recommendations is best accomplished by direct oral communication. Communication of urgent recommendations should not rely on written communication alone.

Another tactic for the consultant seeking to reduce the number of recommendations in the initial consultation note is to determine which issues can be deferred until after surgery. If the consultant continues to be engaged in the patient's care, evaluations and management of some issues can be conducted later without disrupting the surgical schedule. For example, because postponing surgery to improve control of hypertension in patients with a moderately increased diastolic blood pressure does not affect cardiac risk,[22] the consultant need not emphasize potential recommendations, such as screening for renovascular hypertension or pheochromocytoma, for moderate hypertension that is newly discovered before surgery.

The effectiveness of the consultation is likely to increase if the consultant makes important recommendations as specific and complete as possible. When suggesting a drug, the dose and duration should be provided so that a surgeon or anesthesiologist who may not be familiar with a drug can copy the recommendations directly into the order book. In one study,[33] for example, compliance decreased to 85% when only one was specified and to 64% when neither was listed ($p < 0.001$).

SUMMARY

The importance of the role of the consultant has increased because of increasing clinical risk among the patient population undergoing procedures, logistic changes that have accompanied the trend toward outpatient and same-day surgery, and intensifying pressures for efficiency and improvement in quality. Advances in anesthesia and internal medicine have helped create a special area of medicine for the consultants who function at their interface.

Primary physicians (surgeons and anesthesiologists) and consultants should be aware of the medicolegal issues in the consultative process and the impact of communication breakdowns on patient care. Primary physicians should recognize when consultations are needed, inform patients that a consultation will be requested, make the request in writing, and identify the specific issue to be addressed (Table 6–3).

The consultant has a duty to respond to the consultation request in a timely manner, to provide a written note detailing the evaluation, to respect the primary physician's relationship with the patient, and to transmit recommendations to the physician as clearly as possible.

With these considerations in mind, a list of "Ten Commandments for Effective Consultation"[35] can be directed at medical physicians who perform consultations (Table 6–4). These "commandments" recommend that consultants clarify the issue of the consultation, establish priorities, gather primary data via a history and physical examination (as opposed to just a review of the chart), and make concise, yet detailed, recommendations. Consultants should provide contingency plans so that their notes may provide guidance regardless of how a case develops, respect the primary physicians and their relationships with the patient, and directly communicate with the primary physicians. Finally, the consultants are urged to follow the patient for at least several days postoperatively.

TABLE 6–3.

Responsibilities of the Primary Physician

- Care of the patient
- Identification of problems beyond his or her expertise
- Obtaining the patient's consent to call a consultation
- Making the request for the consultation in writing
- Clearly identifying the issues for the consultant to address
- Conveying the results of the evaluation to the patient

TABLE 6–4.

Ten Commandments for Effective Consultations

1. Determine the question
2. Establish urgency
3. Look for yourself
4. Be as brief as appropriate
5. Be specific
6. Provide contingency plans
7. Honor thy turf
8. Teach...with tact
9. Talk is cheap...and effective
10. Follow up

Evaluation of the Patient with Cardiovascular Disease

Ronald P. Olson, MD

PREOPERATIVE ASSESSMENT

Preoperative evaluation has changed over the last few years. In an increasingly distant past, the attending anesthesiologist would interview the hospitalized patient and family a day or two before surgery. All resources of the medical systems were mobilized to ensure that all aspects of the patient's health were assessed and treated. Surgery was delayed until any cardiac condition was fully addressed. Now patients usually arrive on the morning of surgery, and anesthesia is administered by a practitioner who has not previously met the patient. Cardiac conditions may (or may not) have been stabilized by other physicians. Some surgical procedures are unlikely to cause any more stress than activities of daily living; other procedures are high risk, but the risk of postponing surgery to allow the anesthesiologist to interview the patient is higher. In essence, the paradigm of preoperative assessment is shifting from predicting risk to actively managing risk.[1] The issue is less whether to cancel surgery, and more whether indicated cardiac tests and management need to be done preoperatively under the supervision of the perioperative physician or postoperatively in a more elective fashion by primary care clinicians. Consequently, there is a need for a reassessment of what preoperative investigations and treatments are indicated preoperatively.[2] This chapter focuses on the patient presenting for noncardiac surgery. Many of the studies in this area have been done on patients having vascular or cardiac surgery, but as much as possible, evidence on other surgical populations is presented.

Evaluation of a patient's cardiac status is based first and foremost on a clinical examination. The general level of risk can usually be determined with questions, hands, and a stethoscope. Although detailed quantification of that risk may require investigations, it is important to remember that the history and physical examination may provide all the information needed for a given anesthesia plan. If further testing will not result in interventions or change the anesthesia plan, there is no need to require such testing preoperatively.

Benefits of Preoperative Assessment

Because of a sometimes fragmented healthcare system, the preoperative encounter may be one of the few times a careful assessment of a patient's cardiac status will occur. Conditions such as hypertension, chronic obstructive pulmonary disease (COPD), asthma, and diabetes may be identified and treated so that the patient's health will be improved for years to come. Some medications, such as antihypertensives, β-blockers, statins, and hypoglycemics, can be easily initiated with instructions for followup with primary care. To miss these opportunities to improve the patient's health is reprehensible.

Dangers of Testing in Low-Risk Populations

On the other hand, investigations and interventions should not be started by clinicians who cannot ensure followup, as doing so entails some risk. If enough tests are done, especially in a low-prevalence population, there inevitably are mild abnormalities. These are likely to be either false positives or to be true positives that have little bearing on the perioperative period. If surgery is delayed to follow up even just the true positives, the inconvenience and risks of delayed surgery

KEY POINTS

1. Although imbalance of oxygen supply and demand of the myocardium during perioperative stress continues to be a common mechanism of perioperative morbidity and mortality, an equally important cause is the rupture of a vulnerable plaque with subsequent thrombosis of a coronary artery. Maintenance of healthy endothelial function is vital to prevent this.
2. Perioperative risk assessment requires consideration of the functional status of the patient and the risk inherent in the surgical procedure, as well as the diseases of the patient and how optimal is the disease management.
3. The history and physical examination, along with limited indicated tests, are often adequate to determine the perioperative risk of a patient. Preoperative cardiac testing is generally not needed unless a patient has at least two of the following: chronic disease, need for high risk surgery, poor exercise tolerance. Perhaps surprisingly, preoperative cardiac testing is sometimes not needed in patients who have two or three of these conditions, but who have detailed documentation of optimal management. Further testing is unlikely to change management and these patients may proceed directly to surgery.
4. Preoperative cardiac testing is most useful in those patients who do not clearly fit into the low-risk or the fully optimized category. In these patients, further testing is usually needed to formulate an anesthesia plan.
5. In some of these intermediate-risk patients, risk can be managed by relatively simple interventions by the anesthesiologist. If these patients can be so optimized, testing may not be necessary.
6. A few small studies have shown that perioperative β-blockade has a dramatic reduction in long-term morbidity and mortality after surgery. Like any medication, however, there are some risks and it needs to be used selectively.
7. There are many interventions, such as control of diabetes, hypertension, and endothelial function, that can be well within the scope of an anesthesiologist's skill set. If anesthesiologists wish to consider themselves perioperative clinicians, they must be active in these well-established aspects of medicine.

might outweigh the minimal benefits of followup. Also, perioperative clinicians are unlikely to follow up on these abnormalities,[3] and thus to expose the patient to possible false reassurance and delayed diagnosis. The clinician may be left vulnerable to litigation if there is any remotely related adverse event. The perioperative period is too short and isolated for disease screening. Screening is better done by primary care, where follow up is done over time in the context of overall health, and the few true positives will be sifted out from the many false positives.

Each institution must balance how much intervention can be done without exposing the patient and institution to the dangers of inadequate followup. Generally, what can be done easily and safely should be done; other investigations or interventions that do not directly impact on the perioperative period should be deferred to primary care. The perioperative team and the primary care practitioners ideally should share information and resources.

Who Should Do the Preoperative Assessment?

One method of preoperative assessment is to refer any patient with potential cardiac risk to the cardiology service, and await "clearance" for surgery by that specialist. Unfortunately, cardiologists are not generally in the best position to balance the risk of surgery, risk of not proceeding with surgery, risks of various anesthesia techniques, and skills of a specific anesthesiologist. Thus it is inappropriate for a cardiologist, or any other clinician, to "clear" the patient for surgery. The decision whether it is appropriate for a specific patient to undergo a specific procedure with the given resources can only be done by the anesthesiologist responsible for that patient on the day of surgery. This chapter clarifies what information the anesthesiologist needs to make that final decision and to formulate the anesthesia plan.

Someone must first determine if the patient is at increased risk. If risk is low, surgery can proceed. On the other hand, if the risk is high, it will be necessary to ensure that everything has been done to reduce or manage that risk. If so, no further investigation is needed. It is the intermediate- or indeterminate-risk patients who require the most careful assessment to determine whether extra intervention is required. These assessments of increased risk may require consultation with cardiologists, but increasingly can be done by the anesthesia team, especially if the patient has had previous cardiac care.

PHYSIOLOGY OF PERIOPERATIVE CARDIAC MORBIDITY

Patients with cardiac disease are at increased risk for perioperative morbidity and mortality. The overall rate of perioperative myocardial infarction (MI) in these patients is approximately 5%.[4,5] Approximately 50% of patients with cardiac disease develop other complications perioperatively.[6] Vascular surgery patients are in a yet higher risk category by virtue of the disease which brings them to surgery. Even vascular patients with no risk factors for coronary artery disease (CAD) have a 5% incidence of perioperative cardiac complications (PCCs).[7] This chapter focuses primarily on the cardiac complications, but it is important to remember that these changes are also occurring elsewhere in organs such as the brain, kidneys, and lungs.

Several cardiac complications can occur perioperatively (Table 7–1). As most of these are either the cause or the result of ischemia,[8] all of which may ultimately lead to infarction,[9] the emphasis is on the causes of ischemia.

The traditional view of PCCs is one of a mismatch between oxygen supply and demand. Recently there is more appreciation of the mechanism of endothelial dysfunction, leading to rupture of a vulnerable plaque, followed by thrombosis. This chapter describes the physiology of perioperative morbidity as a result of myocardial ischemia resulting from these two mechanisms. The etiology is clearly multifactorial and defies simple classification, but this approach assists in developing different strategies needed to prevent and treat the different etiologies.[10]

Supply–Demand Mismatch

Some infarctions occur at a site of relatively high-grade stenosis that has formed gradually and with the development of collaterals. These tend to present with ST elevation and result in non–Q-wave infarctions. These are the sites where a supply–demand mismatch results in ischemia. Infarction probably occurs only after several hours of ischemia.[10] Reduction of the mismatch by reducing heart rate and increasing oxygen supply may relieve the ischemia. These sites are often amenable to coronary artery bypass grafting or percutaneous transluminal coronary angioplasty (PTCA) with stenting.

TABLE 7–1.

Perioperative Cardiac Complications

Sudden death

Diastolic heart failure
Arrhythmias

Angiography may not be the gold standard for detecting sites of critical stenosis. Angiography compares the lumen of a segment of artery with the lumen before and after that segment. But atherosclerosis is a systemic disease in which all of the arteries are affected to some degree; thus angiography cannot compare diseased with healthy segments, but compares severely diseased with mildly or moderately diseased. A severe stenosis in the middle of moderate stenosis will not show up as a critical lesion (Fig. 7–1). There is also evidence of a "Glagov" phenomenon of vascular remodeling where the plaque may increase in size, yet the lumen remains unchanged or even enlarges slightly.[11,12] Repeated small leaks from plaque fissures may cause the growth of plaques until they become unstable. Angiography is unlikely to measure these changes. Instead, intravascular ultrasound or cardiac MRI is needed.

Thrombosis from Endothelial Dysfunction

Other infarcts start with an abrupt occlusion of an often insignificant coronary stenosis because of plaque rupture at that site (Fig. 7–2). The sudden blockage of these less-critical stenoses may be more lethal because it is more difficult to reverse the pathology and there are no collateral arteries. These episodes result in ST depression on an electrocardiogram (ECG).

Ellis et al. assessed the preoperative angiograms of vascular patients experiencing a postoperative MI and com-

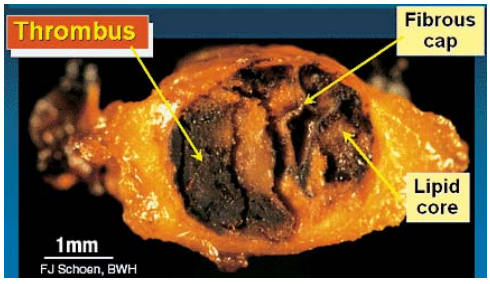

FIGURE 7–1. Plaque rupture with thrombosis. Available at: *http://images.medscape.com/pi/editorial/cmecircle/2004/3598/images/libby/slide005.gif*. Last accessed July 5, 2007. Illustration courtesy of Frederick J. Schoen, MD, PhD.

pared them with the findings in a matched group of nonoperative MIs; they did not find a high-grade stenosis (>70%) in any of the patients who had a PCC.[13] Cohen studied the coronary artery autopsies of 26 cases of fatal postoperative MIs. Plaque rupture was present in 12 cases and intracoronary thrombus was present in 9 cases. A thrombus occurred on a stenosis of >50% in only 31% of cases.[14] This is consistent with Dawood's earlier study of coronary artery autopsies, which showed evidence of plaque disruption in 55% of fatal perioperative MIs and in 40% of nonoperative MIs.[15] As described in Figure 7–2, part of the reason for occlusion occurring at so many noncritical lesions may be that the angiogram cannot detect that some of these are actually high-grade stenoses.

Endothelial dysfunction is a result of three broad groups of cardiovascular etiologies: hypercoagulability, inflammation, and sympathomimetic overdrive. These detrimental forces are controlled to some extent by endothelial protective factors (Fig. 7–3).

Hypercoagulability

Surgery induces a prothrombotic state that may be variable and measurable.[16] If this could be measured, it would be valuable to selectively treat high-risk patients with anticoagulants. Some patients are probably predisposed to hypercoagulability. Factor V Leiden is an example of this which has not turned out to be very significant perioperatively.[17]

Inflammation

Surgery initiates an inflammatory response, and current research on the utility of markers such as C-reactive protein (CRP) in prediction of myocardial infarction[18] are yet to be extended to the perioperative period. This topic is discussed further in sections below.

Sympathetic Stimulation

The obvious sympathetic response to the stress of surgery may be attenuated by neuraxial anesthesia[19] or β-blockers.[20] Reduction of anxiety is important to reduce all the above factors.

Protective Factors

A few short episodes of ischemia may induce preconditioning that results in less damage if later ischemia occurs. Zaugg et al. summarized these concepts.[21]

Nitric oxide induces endothelial stability. The anesthetic nitrous oxide does the opposite.

Postoperative Ischemia

Advances in anesthesia have resulted in the intraoperative period being a controlled and safe period. Most ischemia occurs in the immediate postoperative period during emergence from anesthesia, when catecholamines are surging,[22] rather than during anesthesia. Landesberg showed

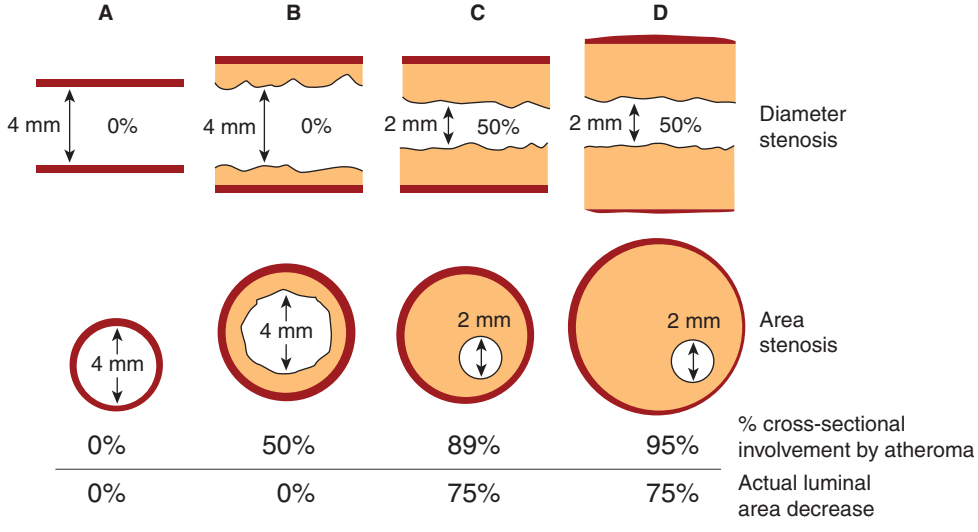

FIGURE 7–2. Angiographic versus pathologic views of stenosis. **Top row:** angiographic views; **bottom row:** pathologic views. **Column A:** normal artery; **column B:** artery with "moderate" atherosclerosis. Because of remodeling, angiography shows a normal lumen with enlargement of the vessel. A pathologic view of the same artery would see the same lumen, but 50% of the cross-sectional area would be occupied by plaque. **Column C:** more involved artery. Angiography shows that the lumen is 50% less in diameter than the adjacent "normal" (**B**) segment. Pathology shows the 2-mm lumen but a larger plaque and measures the stenosis as an 89% narrowing. **Column D:** same situation but with even more remodeling present. Angiography shows a 50% diameter narrowing even though the plaque is much larger than in column C, and still concludes that this is not severe disease. Because of the greater enlargement of the artery, the pathology now shows the stenosis as a 95% cross-sectional narrowing, even though the lumen size is actually the same as in column C. Reproduced with permission from Fishbein MC and Siegel RJ.[12]

that most ischemic events, and most ischemic events that result in infarction, occur immediately postoperatively (Fig. 7–4).[23] Badner, among others, has shown that postoperative MIs occur mostly in the first few days after an operation (Fig. 7–5), and are often asymptomatic.[5,22,24] Prolonged ischemia is more likely to result in infarct than is a shorter duration of ischemia. When the endothelium is damaged, acetylcholine causes muscarinic receptor-mediated vasoconstriction instead of endothelium-dependent vasodilatation.[21] Thus, prolonged ischemia may be the cause, as well as the result, of vasoconstriction and subsequent thrombus formation.[23]

Although much emphasis is placed on ischemia, postoperative stress may result in the anaerobic threshold of a patient being reached, leading to diastolic dysfunction, which may cause later morbidity even if no ischemia occurs.[25] Cardiac damage is a continuum, not a dichotomy of infarction or no infarction.[26] Even asymptomatic ischemia may predict long-term complications.[8] Asymptomatic plaque rupture may heal but leave the plaque more vulnerable to subsequent rupture.[27,28]

With these mechanisms in mind, we proceed to an analysis of risk for these events.

IDENTIFYING PERIOPERATIVE RISK

This section reviews the overall incidence of PCC in the set of patients with cardiovascular disease, as well as why it is important to identify higher-risk patients. After comparing the common risk indices that are used for identifying these patients, individual risk factors are discussed in greater detail. Finally, an updated scheme for determining which patients need further preoperative cardiac assessment is presented. The selection of preoperative tests is the topic of the last section.

Overall Perioperative Risk in Patients with Cardiovascular Disease

Cardiovascular complications may be the most common of all perioperative complications,[4] although one recent study found that gastrointestinal, pulmonary, renal, infectious, wound, and pain control complications were all more common in hospitalized patients.[29]

Risk of perioperative complications is very low (<1%) in patients with no evidence of cardiac disease.[30] A recent analysis of the 6 studies assessing the

incidence of major cardiac complications in patients at risk showed an overall rate of 3.9%.[182] Patients with peripheral vascular disease are a well-studied group because they are easily identifiable and have a high complication rate. Polderman's β-blocker study of a selected group of vascular patients with stress echocardiography wall motion abnormalities showed a 34% cardiac complication rate.[31] The Coronary Artery Surgery Study (CASS) showed an 8.5% complication rate in vascular surgery patients with medically managed coronary artery disease.[32]

An observational study of 67,548 patients undergoing total hip arthroplasty between 1987 and 2000 gives a more contemporary comparison of the difference between patients with and without vascular disease[33] (Fig. 7–6). This study shows that in both groups, the majority of complications occur during the first 20 postoperative days.

Mangano's β-blocker study showed how the risk from surgery may extend up to 2 years beyond the immediate perioperative period. This is likely because even asymptomatic infarct or ischemia may have long-term detrimental effects.[34]

Purpose of Identifying and Quantifying Risk in Individuals

It is somewhat useful to know what the overall risk of adverse events is for a given group of patients, but it is more critical to identify individual patients who are at risk and in whom optimization is possible.

Initial assessment places the patient into a low-risk, high-risk, or intermediate/indeterminate-risk category. The threshold for testing has traditionally been set somewhere in the intermediate- or indeterminate-risk category. However, this concept of a threshold for testing in the middle of a graduated risk scale is not always helpful. Certainly patients at low risk for PCC do not require special testing; but neither do high-risk patients who have documented optimization. In both these cases, surgery can usually proceed with no further investigation. It is important to use previous records and common sense to avoid tests that only duplicate previous investigations.

It is also clear that testing should be done if the individual is at high risk and not optimized. In this case, how-

ever, the patient should be sent to the consultant, who can choose the tests.

It is the intermediate- or indeterminate-risk patient who most needs further preoperative testing to quantify risk and guide optimization choices. The tests are needed not because the patient falls above a threshold for testing, but because the patient's place on the risk continuum and adequacy of optimization are unknown. This testing can often be done by the anesthesia team without cardiac consultation. The main questions to be answered are these: "Can the patient be made better?" and "Can the risk of PCC be reduced?" The main goal of preoperative assessment, then, is not just to identify perioperative risk, but to identify those patients who may benefit from some change in perioperative management. Table 7–2 lists the reasons for doing preoperative risk assessment.

Comparison of Risk Indices

Starting with Lee Goldman in 1977, a number of collections of risk factors have been proposed to determine which patients are high risk and require detailed cardiac investigations. The most commonly used index is the one set out by the American Heart Association and American College of Cardiology. The Revised Cardiac Index proposed and validated by Lee is probably the best studied.[35] Risk indices are cost-effective in vascular surgery.[36,37] They are derived from, and most appropriately applied to, populations.[26] Although they do not perform well in defining exact risks in individuals, they can place a patient in a general risk category.[38] Most divide patients into one of three risk groups: high, moderate, or low.

High Risk for PCC

This is a group of patients who have a greater than 5% risk of PCC. These patients warrant full precautions, such as postponement of surgery to allow optimization or special perioperative measures to control risk as well as careful assessment and acceptance of the risk-to-benefit ratio of proceeding to surgery. In the past, these patients were believed to require an automatic referral to cardiology. However, as described above, if the patient is already known to be optimized, further investigation is unnecessary.

Moderate or Indeterminate Risk for PCC

This group of patients are not clearly either high risk or low risk, and are the patients who often warrant further risk analysis. Increasingly, however, if these patients are stable, they may proceed to surgery with relatively simple risk reduction interventions such as the initiation of β-blockers.

Low Risk for PCC

These patients rarely require preoperative testing.[39] Tests that might be indicated in routine primary care should not be ordered unless full followup of results can be guaranteed.

Paul's study of 4 risk factors (history of diabetes, prior angina, previous myocardial infarction, and history of congestive heart failure) in 878 vascular surgery patients showed good correlation with coronary angiography[40] (Fig. 7–7).

Table 7–3 compares the contents of the most common risk indices. The next section discusses the specific risk factors that have been proposed for these and other assessments of perioperative risk.

Specific Risk Factors

The clinical history will uncover risk factors for PCCs. These risk factors are usually the same as the risk factors for cardiovascular disease in general.[41] Because they are part of the disease etiology, changing the risk factor (if possible) might reduce the perioperative risk. Thus identification of these factors provides initial guidance on perioperative optimization options. If these risk factors have already been minimized as much as possible, or if the perioperative assessment clinician can easily arrange for optimization, there may be no need to investigate further.

This section discusses the putative risk factors individually.

TABLE 7–2.

Reasons for Risk Assessment

Determine if the risk of proceeding to surgery is acceptable
Assist anesthesiologist in reducing and balancing risks
Assist surgeon in choosing procedure with best risk-to-benefit balance
Identify those cases that are inappropriate for ambulatory surgical sites
Identify conditions that may be improved
Identify needs for postoperative management (monitoring, admission, ICU)
Enable informed consent by the patient

Known Coronary Artery Disease

Before discussing the various risk factors for CAD, it is important to review how patients with known CAD should be evaluated. As recommended by American College of Cardiologists/American Heart Association (ACC/AHA) guidelines, any unstable CAD (major clinical predictor) needs to be addressed before surgery.[42] It has sometimes been assumed that the presence of known CAD automatically required a detailed cardiology consultation to "clear" the patients. But

[a]Vascular surgery, predictors of all-cause mortality.

[b]Although trending to association, was not a statistically significant independent predictor.

"clearing" a patient for surgery is a nebulous concept, implying some impossible guarantee against bad outcome. What is really needed is someone to judge whether the patient is optimized and to clarify the risks involved. Ideally, one would also have the assurance that the patient is stable. When is CAD considered stable? Certainly either lack of symptoms or optimization and stabilization of symptoms is an important part of this assessment. Left main vessel disease or three-vessel disease should be carefully assessed even if asymptomatic.

The time period of increased risk after infarction or invasive intervention has changed, and is discussed next.

Previous Myocardial Infarction A couple decades ago, a patient was considered at high risk for PCC for 6 months after an MI, and at some increased risk forever. Today, advances in treatment of acute coronary syndrome have improved the prognosis after MI. However, as shown by Van Belle's angiography study of 56 post-MI patients, plaques remain unstable and vulnerable to reocclusion for at least 4 weeks, even after thrombolysis.[43] Now the high-risk period is 6 weeks, with a period of relative risk from 6–12 weeks. In this relative-risk period, cardiac function is more important than time.

Recent Coronary Artery Bypass In 1997, the Coronary Artery Surgery Study showed that high-risk patients undergoing a variety of noncardiac operations faired better if they had coronary artery bypass (CABG) surgery than if they had not. Clinically stable patients who had undergone CABG within the last 5 or 6 years were relatively "protected" from myocardial infarction complicating noncardiac surgery and thus probably did not warrant routine preoperative stress testing.[32] McFalls' study in vascular patients suggests revascularization may not be necessary preoperatively.[44] Revascularization should be done if it would have been indicated irrespective of the planned surgery. Which procedure should be done first requires a case-by-case analysis. This topic and the McFalls' study are discussed in more detail in the section, Managing Risk: What Interventions?

Recent Percutaneous Transluminal Coronary Angioplasty Recommendations for surgery after PTCA have changed dramatically. In the 1990s, it appeared that PTCA performed a couple of weeks before an operation resulted in halving the rate of PCC.[45] However, with the advent of stenting during PTCA, things changed. In 2002, Kaluza studied 40 patients who underwent noncardiac surgery less than 6 weeks after PTCA with stents. Ticlopidine and aspirin were continued postoperatively. There were 8 deaths, all in patients who had operations less than 2 weeks after PTCA. Six deaths were from MI; 2 were from bleeding complications.[46]

Wilson retrospectively studied 207 patients who had undergone PTCA with stent placement followed by noncardiac operations in the following 2 months. Eight (3.9%) had PCC; 6 (3%) died. All 8 complications occurred in patients who had had an operation less than 6 weeks after PTCA. There were no PCC in patients who were operated on 7–9 weeks after PTCA. Patients had received ticlopidine or clopidogrel for 2–4 weeks after stent placement. No major clinical adverse outcomes were attributed to excessive bleeding.

Posner retrospectively studied 686 matched pairs of patients with CAD undergoing noncardiac operations—one set having undergone PTCA preoperatively, and one set who did not get revascularization of their CAD. These groups were compared with 2155 normal controls; 142 patients had had PTCA less than 90 days before surgery. There was no difference in PCC between these patients and matched patients with CAD who were not revascularized. Patients who had PTCA more than 90 days before the operation had a lower risk of PCC than did CAD patients who were not revascularized, although not as low as normal controls.[47]

On this basis, it is recommended that surgery be delayed until at least 6 weeks after PTCA, and preferably for 12 months after PTCA and stenting with a drug-eluting stent.[47a]

Hypertension

Hypertension is the leading cause of cardiac morbidity and strokes.[48] Even white-coat hypertension is associated with endothelial dysfunction[49] and increased risk of cardiac events.[50]

Evidence that hypertension actually results in increased perioperative morbidity is limited. A meta-analysis of 30 observational studies demonstrated an odds ratio of the association between hypertension and PCC of 1.35 (range: 1.17–1.56).[51] This difference is not clinically significant in the short-term. However, even if hypertension in and of itself is not a significant perioperative risk factor, the cardiac conditions which often accompany hypertension are. These include left ventricular hypertrophy (LVH),[52,53] renal failure, and stroke. Uncontrolled hypertension becomes an unoptimized risk factor that should be addressed preoperatively. Management of preoperative high blood pressure is discussed in the section Management of Hypertension.

Diabetes

Asymptomatic type 2 diabetics have the same risk of MI as do patients with previous MI.[54] Diabetes is considered a risk factor for perioperative cardiac complications by most sources,[42,45,55] although some studies have not shown it to be so.[56–59] Whether strict control of diabetes reduces risk is discussed in the section Medications: What to Start and What to Stop.

Smoking

Smoking is a clear risk factor for cardiac disease and poor wound healing. Smoking cessation is one of the most effective ways to reduce cardiovascular risk. The unsolved question is how long before surgery is cessation necessary in order for there to be some benefit. There is concern that the stress of withdrawal may add to perioperative catecholamine surge. The issue of preoperative cessation is discussed in Smoking Cessation below.

Hyperlipidemia

Hyperlipidemia is a major risk factor for CAD, and improving the lipid profile leads to a reduction in risk. It was initially assumed that because lipid profiles change so slowly, management of lipids was not a practical perioperative issue. However, treatment with statins is proving to have some fairly rapid benefits, although there is no study specifically in the perioperative setting. The benefit of statins is more than just improvement of hyperlipidemia. The perioperative benefits of statins are discussed in Medications: What to Start and What to Stop below.

Peripheral Vascular Disease

Of patients with peripheral vascular disease (PVD), 30% have CAD. The fact that many of these patients are unable to exercise puts them at in-

creased risk and also makes quantification of cardiac status difficult. This is a very significant, but unfortunately a minimally modifiable, risk factor.

Congestive Heart Failure/Cardiomegaly

Congestive heart failure is both a cause and a result of ischemia. Cardiomegaly is a risk factor for PCC.[52]

Renal Insufficiency

This was added to the list of intermediate clinical predictors of PCC by the last update of the ACC/AHA guidelines.[42] Lee's analysis showed increased risk with creatinine >2 mg/dL in the derivation cohort but not the validation cohort.[56]

Arrhythmias

Arrhythmias are a cause and an effect of ischemia. Generally arrhythmias in and of themselves will not precipitate problems unless the heart is already compromised. Therefore, they are of more concern if there is other evidence of cardiac disease.

Conditions that may occur in otherwise healthy persons which are of perioperative concern are Wolff-Parkinson-White (WPW) disease and prolonged QT syndrome. These conditions have a bearing on which drugs are selected to treat arrhythmias that might occur.

Valvular Lesions

An increase in the sensitivity of echocardiography a couple of decades ago resulted in a plethora of diagnoses of trivial regurgitation. Trivial regurgitation is just that; it is virtually never of consequence perioperatively, even for consideration of endocarditis prophylaxis. Mitral valve prolapse is also quite common, If asymptomatic, it is generally of no concern perioperatively, except in men older than 40 years of age, who will require prophylaxis against endocarditis.[60] Detection of any diastolic murmur requires further investigation.

Aortic stenosis is of very grave concern to the anesthesiologist, and the discovery of this condition is a primary objective of preoperative assessment. The history may give evidence of some recent change in exercise capacity if this lesion is becoming significant. However, where aortic stenosis is a possibility, the threshold for investigation of a heart murmur should be very low, as the rate of PCC can be very high.[61,62] With advance planning and careful technique this risk can be minimized.[63]

History of Cardiovascular Accident

History of stroke or transient ischemic attack was an independent correlate of PCC in both the derivation and the validation cohort of the Revised Cardiac Risk Index,[56] as well as in Boersma and Kertai's studies.[64,65]

Anemia

The general trend is toward greater tolerance of perioperative anemia. However, patients with CAD are an exception to this.[66] If this condition is identified far enough in advance of the operation, arrangements can be made for preoperative erythropoietin and iron, intraoperative isovolemic hemodilution, and special ICU maneuvers.[67] With advance preparations, transfusion can be avoided in many situations. In addition to disrupting the supply–demand balance, anemia is a marker for other comorbidities.

Age

Age greater than 70 years was an independent risk factor in some multivariate analyses,[64,68] but not in others.[56,65,69] Age in and of itself is probably not a significant risk factor if it is carefully separated from the associated comorbidities. If an MI does occur, however, mortality is higher.[68,70]

Markers of Inflammation

A recent analysis of more than 14,000 women in the Women's Health Initiative shows that increased CRP is predictive of adverse cardiovascular events.[71] Other studies also show it to be an independent risk factor, and a recent workshop by the Centers for Disease Control and Prevention and the American Heart Association concluded that the high sensitivity test for CRP is the recommended marker of inflammation in atherosclerotic disease.[72] Whether it can be used to guide perioperative management is yet to be determined.[18]

B-type natriuretic peptide is a marker of inflammation that is abnormal in advanced heart failure.[73] It has a high negative predictive value and might be useful to select out some high-risk patients who do not need echocardiograms to rule out ventricular dysfunction.[74]

Albumin

Low albumin is a marker of overall debilitation and acute-phase reactants, and thus serves as a very good prognostic test for PCC. Unfortunately, this test result does not offer much guidance in perioperative management, aside from possibly a long delay in surgery to allow improved nutrition.

Depression

A recent quantitative review suggests that depressive symptoms contribute a significant independent risk for the onset of coronary disease, a risk (odds ratio [OR] = 1.64) that is greater than the risk conferred by passive smoking (OR = 1.25) but less than the risk conferred by active smoking (OR = 2.5).[75] Patients with coronary heart disease who also display depressive symptoms have an increased risk of mortality.[76]

The Neurological Outcome Research Group conducted a prospective study of 555 CABG patients for 6 months and showed that, after adjustment for other risk factors, depression was associated with a 2- to 3-fold increase in risk of death. Patients who were depressed at the time of surgery, but not depressed at 6 months, did not have the same increased death rate.[77] This reminds us of the importance of treating depression discovered preoperatively. Again, cooperation with primary care or consultant specialists is critical.

Genetic Polymorphisms

Genetic testing is increasingly commonplace, and there is increasing interest in how this might be applied to perioperative risk stratification. Factor V Leiden is a good example of a common genetic polymorphism. However, with the possible exception of cardiac surgery, routine antithrombotic measures are sufficient to counteract the effects of this condition and routine preoperative testing for this is not recommended.[17]

Some studies show an association of specific genetic polymorphisms with atherosclerotic complications after CABG,[78–80] whereas others have not shown strong associations.[81] The Multicenter Study of Perioperative Ischemia Research Group showed that certain polymorphisms for platelet glycoprotein IIIa and the degree of platelet activation are related to levels of troponin after CABG, suggesting

that this platelet polymorphism contributes to perioperative myocardial injury.[82] Inflammatory response is also altered by genetic variability of key inflammatory genes.[83–86] Genetic variability in β-adrenergic responses may assist in determining who should receive perioperative β-blockers and who should not.[87–89]

Although not routinely indicated at this time, genetic testing is a significant frontier in perioperative medicine.

Carotid Stenosis

In addition to being a marker for cardiovascular disease, carotid stenosis may predispose a patient to perioperative stroke. A common dilemma is whether or not carotid surgery should precede other operations. The risk of serious stroke in patients undergoing a nonvascular operation is less than 1%. It is no higher in patients with bruits than in those without bruits.[90] The benefits of carotid surgery in patients with asymptomatic stenosis is small, and likely achievable only in certain centers.[91] In the case of coronary artery surgery, selective duplex ultrasound screening for carotid stenosis does have benefits,[92] but there is no evidence to support prophylactic carotid endarterectomy before general surgery.[93] Even in cardiac surgery patients, most strokes occur in patients without carotid stenosis.[92,94] The exception may be high risk patients—those with stenosis >90% and either a history of transient ischemic attacks (TIAs) or elevated creatinine. These patients warrant carotid surgery whether or not they are scheduled for other surgery.[95]

Surgical Procedure Risk

The planned surgical procedure defines the overall requirements for preoperative assessment. High-risk operations, such as an abdominal vascular operation, is almost guaranteed to include significant stress from events such as cross-clamping of the aorta. By definition, a vascular operation occurs in a patient with cardiovascular disease. At this level of surgical risk, it is imperative to know that cardiac function has been optimized.

At the other end of the spectrum, low-risk operations, such as cataract removal, entails risks not much different from activities of daily living. If the patient can walk to the surgical suite, the patient has probably demonstrated the cardiac capacity necessary to endure the stress of surgery. Schein's large study of 18,189 cataract surgery patients showed that foregoing preoperative testing did not result in any change in outcome. The critical element of this study, which is sometimes missed, is that all of these patients were assessed by their primary care practitioners, and any tests required for general health maintenance were done. This study supports the concept that a clinical examination is the irreplaceable foundation of preoperative assessment, and tests are secondary.

The ACC/AHA guidelines categorize surgical risk (Table 7–4). Kumar's study verifies the profound influence of the type of surgical procedure on perioperative risk.[69]

Functional Status

The remarkably simple tool of asking about the functional status of the patient provides good prediction of risk for PCC. It is a descriptor of how much the risk factors impact the patient, and is most useful as a screening tool to select out patients who are very unlikely to have PCCs. Reilly showed that patients who reported they could not climb 2 flights of stairs or walk 4 blocks had twice as many PCCs as those who reported they could.[96] Although patient self-description of exercise capacity correlates well with actual functional capacity,[97] the accuracy of this test can be improved by actually observing the stair climbing. Girish observed maximum stair climbing in 83 operation candidates. The overall rate of postoperative complications, including cardiac events, arrhythmias, reintubation, atelectasis, and pneumonia, was 25%. The rate in those who could not complete 1 flight of stairs was 89%. No patient able to climb 7 flights of stairs had a complication.[98] It is important that the patient be able to climb 2 flights of stairs without developing dyspnea, chest pain, or leg pain. This helps ensure that a poor anaerobic capacity does not coexist with a good aerobic capacity.[99] Biccard recently described this and other limitations of a stair-climbing test.[100]

Clinical Determination of Need for Specific Preoperative Cardiac Investigations

Increasingly, the options for testing have outstripped the resources for testing; as a result, it is important to be selective. Testing where it is not needed depletes resources needed elsewhere, and may delay surgery needlessly. Selective testing is cost-effective and safe.[36] Similar to other aspects of medicine, preoperative assessment of cardiac status should occur in two stages: through a clinical history that defines general risk, then through se-

TABLE 7–4.

Cardiac Risk[a] Stratification for Noncardiac Surgical Procedures

High	(Reported cardiac risk often greater than 5%) • Emergent major operations, particularly in the elderly • Aortic and other major vascular surgery • Peripheral vascular surgery • Anticipated prolonged surgical procedures associated with large fluid shifts and/or blood loss
Intermediate	(Reported cardiac risk generally less than 5%) • Carotid endarterectomy • Head and neck surgery • Intraperitoneal and intrathoracic surgery • Orthopedic surgery • Prostate surgery
Low[b]	(Reported cardiac risk generally less than 1%) • Endoscopic procedures • Superficial procedure • Cataract surgery • Breast surgery

[a]Combined incidence of cardiac death and nonfatal myocardial infarction.
[b]Do not generally require further preoperative cardiac testing.

lective tests that further define that risk.

The Bayesian theorem states that testing a group with a low prevalence of a given condition results in too many false positives for the information to be useful. The purpose of the clinical assessment is to select patients who have a roughly 5% or greater likelihood of PCCs,[101] and in whom further testing will yield a useful change of pretest to posttest probabilities. Applying tests to a lower prevalence (unselected) group is ineffective.

A rapid initial assessment of risk can be done by assessing three areas: (a) the number of clinical risk factors present; (b) the type of operation planned; and (c) the functional status of the patient.[45] This format is the foundation of the ACC/AHA guidelines, specifically the shortcut to determination of need for cardiac investigation.[42]

The ACC/AHA guidelines will soon be updated to reflect the increasingly common situation where management of risk does not necessarily need to be preceded by extensive investigation. A modified scheme foreshadowing this is presented below. This is not meant to be yet another competing scheme, but a simplification and refinement of existing schemes.

If the patient is not in an emergency situation or experiencing serious cardiac conditions such as unstable coronary syndromes, decompensated congestive heart failure (CHF), significant arrhythmias, and severe valvular disease (all major clinical predicators in the ACC/AHA guideline), then 3 factors will determine the need for preoperative cardiac investigations. Presence of 2 of these 3 factors generally warrants further cardiac investigations (Fig. 7–8).

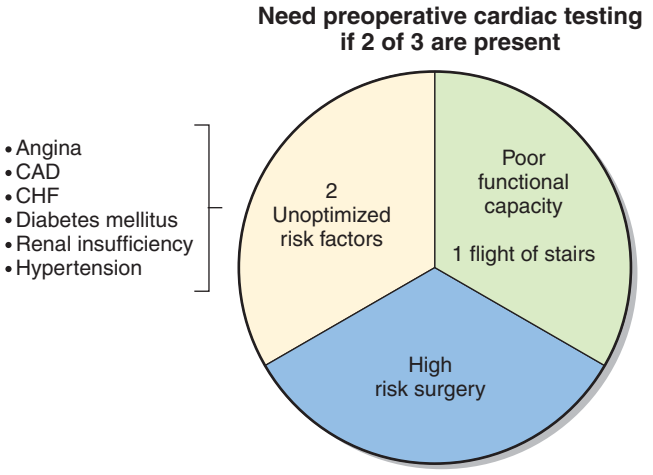

FIGURE 7–8. Clinical determination of need for preoperative cardiac investigation.

Functional Status

As described above, inability to do 1 flight of stairs is a predictor of increased perioperative risk.[96,98] Climbing 1 flight of stairs is equivalent to an aerobic capacity of 4 metabolic equivalents (METS) (Duke Activity Status Assessment)[97] and probably represents a capacity to endure postoperative stresses without ischemia.

Presence of Unoptimized Risk Factors

Unoptimized risk factors include the conditions categorized as intermediate clinical predictors in the ACC/AHA guidelines (angina pectoris, prior MI, CHF, diabetes, and renal insufficiency) that have not been assessed, managed, and deemed to be under optimal control by a qualified physician. This physician may be the primary care physician, a consultant, or the anesthesiologist. Also considered are other conditions, such as hypertensive urgencies and dyspnea.

Often one risk factor that is stable but not fully optimized (e.g., hyperlipidemia, hypertension, smoking) does not warrant further preoperative investigation. Two or more unoptimized risk factors do warrant the change of perioperative management.[65,102,103] This is consistent with Lee's algorithm and the American College of Physicians guidelines where the use of a scoring system results in no further testing unless more than 1 risk factor is present.[56,104]

Surgical Procedure

A planned operation in the high-risk category (Table 7–4) requires consideration of further quantification of risk if there is also poor functional status or presence of 2 unoptimized risk factors.

Moderate-risk procedures entail a less than 1% risk of PCC, even in patients with known cardiac disease.[32] Very-low-risk procedures such as cataract surgery and diagnostic arthroscopy entail no more risk than activities of daily living; they could be done even with disease that is not fully optimized. Disease management may be required, but could occur postoperatively.

It is important to remember that the patient is an active partner in the risk analysis. If a patient refuses invasive cardiac intervention, then medical optimization is likely all that will be done, regardless of what tests are considered.

PREOPERATIVE CARDIAC TESTS TO FURTHER QUANTIFY RISK

If the initial clinical assessment of risk factors shows that further quantification of risk will be useful, it is appropriate to proceed to other tests. These tests are usually good prognostic indicators of outcome, but are not parameters that directly cause risk. The information provided by these second-level tests may not lead to quick, direct modification of risk, as is the case for risk factors. These tests provide prognostic information, and are useful if the information will change the risk above or below some management threshold—for example if the patient is on the threshold for having the operation done at an ambulatory center, or it is not clear whether angina is stable or not. If the patient is already clearly on one side or the other of the threshold, there is no need to apply prognostic indicators. This is another application of the principle that tests are not useful if the pretest probability is very low because the number of false positives (with needless delay of surgery) will be high. Even angiography is imprecise in a low-risk population.[40]

Not all testing is useful. A common case example is a patient with known stable cardiac disease for whom it would be "nice" to have more information. A stress echocardiogram is arranged, and the result is indeterminate. The cardiologist, when faced with the possibility of serious cardiac disease, wants to be sure nothing is missed. This motivation may stem as much from the concern for litigation as from indications for good medical practice. Thus an angiogram is scheduled, and it shows a stenosis amenable to stenting. A stent is placed and clopidogrel started, which means that surgery should be delayed for up to 12 months.[47a] All this is done for cardiac disease that may have been less hazardous than the indication for operation. Delay of operation is inconvenient at least, probably unnecessary, and possibly dangerous. McFalls showed that there is no benefit in preoperative versus postoperative cardiac intervention in vascular surgery. If this is true for vascular surgery, it is likely even more true for lower-risk operations and lower-risk patients[44] (the shortcomings of this study are addressed in Preoperative Invasive Interventions: When Should CABG or PTCA Be Done Preoperatively? below).

It is sometimes best to keep a patient off the "cardiac train" of stress test, angiogram, angioplasty, and antiplatelet agent, because once a patient is onboard, the patient is unavailable for elective surgery until the end of the journey. Before purchasing the "ticket" of a stress test, the clinician and patient must be willing to go the full journey. The Dutch Echocardiographic Cardiac Risk Evaluation Applying Stress Echocardiography Group analyzed[45] patients with PCCs. They suggest that in intermediate-risk patients, the addition of perioperative β-blockers reduces the risk of PCCs to a level where dobutamine stress echocardiography would not change management.[64]

Invasive tests, such as angiography, or alternatives, such as intravascular ultrasonography, coronary artery calcium by electron-beam tomography,[105,106] cardiac CT,[107] or cardiac MRI[106] are not discussed. These specialized tests are not generally ordered or interpreted without a cardiology consultation.

Second-level tests, for purposes of discussion, are divided into resting cardiac tests, cardiac stress tests, and postoperative tests.

Resting Cardiac Tests

Electrocardiogram

An ECG is often done routinely. This test may be useful as a baseline in case of subsequent PCCs, but it is not useful for screening or for diagnostic purposes except in high-risk patients. This is because the specificity of abnormalities is too low. An ECG should not usually be done preoperatively in low-risk operations, unless it would have been done outside of the perioperative period. Having said that, either the presence of 2 risk factors for CAD or diabetes alone warrants having a baseline ECG even in low-risk operations. For baseline purposes, an ECG less than 6 months old is adequate if there have been no clinical changes.

If there is a change on the ECG, what does it mean perioperatively? Most studies show that preoperative ST-T–wave changes (ST segment elevation or depression or T-wave inversion) are not associated with worse outcomes.[56,108] However, this generalization does not apply to high-risk patients. In a study of exclusively vascular surgery patients, Landesberg showed that ECG changes of LVH and ST depression were predictive of PCCs.[52]

What about Q waves? Again, if the Q waves would have raised concerns outside of the operation, they should also be investigated before the operation. Liu's study of surgical patients age 70 years and older suggests ECG changes are not predictive of PCCs. But this study of 386 patients with abnormal ECGs, only 104 (27%) of whom had major Q waves, did not have an adequate sample size to draw firm conclusions.[108]

Ejection Fraction

Transthoracic (2D) echocardiography or radionucleotide ventriculography are used to measure ejection fraction. Left ventricular dysfunction is a predictor of future cardiovascular events and increased overall mortality.[109] Although helpful in monitoring heart failure and valvular disease, if there is concern about ischemia, it is preferable to select other tests.

Measurement of Heart-Rate Variability

A decrease in heart-rate variability predicts adverse cardiac outcomes.[110] A recent study of high-risk patients showed that a decreased low-frequency-to-high-frequency power ratio before induction of anesthesia predicted adverse cardiac events up to 2 years after the operation.[103] A small study by Laitio showed that fractal analysis of certain preoperative heart-variability parameters may be predictive of prolonged postoperative myocardial ischemia in emergency hip operation patients.[111]

With current analysis methods, the resting cardiac tests give supportive data only. Stress tests are usually needed to define risk or optimization.

Cardiac Stress Tests

Cardiac stress tests involve 2 components: a stressor and a test. These can be mixed in any way, but the most common combinations are treadmill ECG, dobutamine echocardiography, and adenosine radionuclide (Table 7–5).

Treadmill Exercise Testing

This is the simplest of the stress tests. Treadmill ECG testing is a good first-line test in those patients able to do the exercise.[45,112] It is not useful in patients unable to exercise, with ECG changes (left bundle-branch block, pacemaker, WPW, ST elevation at rest), or with a history of revascularization. It produces 30% false positives in women. In practice, if a patient is able to do treadmill

TABLE 7–5.

Matching of Stressor and Test in Cardiac Stress Test

		Test		
		ECG	Echocardiogram	Myocardial Perfusion
Stressor	Exercise treadmill	Common	Sometimes	
	Pharmaceutical stimulation (e.g., dobutamine)		Common	
	Vasodilation (e.g., dipyridamole)		Sometimes	Common

testing, the patient probably does not need further preoperative testing. If further testing is needed, a more accurate test, such as stress echocardiography, is generally preferred.

Older has shown that cardiorespiratory exercise testing for anaerobic threshold is useful for identifying high-risk patients who are unlikely to develop diastolic heart failure postoperatively, and therefore are unlikely to need postoperative ICU admissions.[25] Unfortunately, few institutions can logistically arrange these tests preoperatively.

Dobutamine Stress Echocardiography

This test has the advantage of requiring relatively little time to complete. It is a functional test in that it shows how cardiac function is affected by underlying pathology. Image quality is limited in obesity. Both Kertai's and Beattie's meta-analyses show that the receiver operating curve of dobutamine stress echocardiography is better than other tests.[113] Table 7–6 summarizes the other characteristics in Kertai's study.[114] Beattie's analysis, which included 68 studies of 10,049 patients, judged that stress echocardiography was superior to thallium imaging because the negative predictive value of stress echocardiography was superior. Because accuracy and availability vary between locations, each institution may have a different preferred test.[45]

A common dilemma is whether a dobutamine stress echocardiogram should be postponed in the case of a patient taking β-blockers. Weissman's study in dogs showed that dobutamine was less able to reproduce ischemia if esmolol was administered.[115] If the test is being done to assess whether β-blockade will reduce ischemia, then β-blockers should be stopped before the test. If, on the other hand, the purpose is to see if the β-blockade is providing protection from ischemia, the test should be done with β-blockers on board. If we are trying to minimize preoperative stress, stopping β-blockers may be counterproductive, even if it is informative.

Radionucleotide Imaging

This test may be more sensitive than others in this category as it will detect flow anomalies that do not yet cause wall-motion abnormalities; however, it is also less specific. Compared with echocardiography, its accuracy is less affected by obesity, but is altered by large breasts.

Cardiac MRI

This is a new test that can combine flow studies with wall-motion studies in remarkable resolution. It is useful for complex high-risk cases, but does not yet have a clear role in preoperative screening. Fuster and Kim published a recent review of this technology.[116]

Tests of Endothelial Dysfunction

As described above, endothelial dysfunction is one of the unifying mechanisms of PCCs. Several new tests for this are showing prognostic value for cardiovascular disease in general, and may prove to be useful in the perioperative period. One of these is brachial artery flow-mediated dilation. In this "stress test" of the vasculature, nitroglycerin dilation is the "stressor" and ultrasonic observation of the brachial artery is the test.[117]

Postoperative Tests

As most ischemia occurs postoperatively and is silent, it makes sense to monitor for it. Postoperative ECG changes suggesting ischemia may be predictive of postoperative morbidity and mortality even in low-risk patients.[118,119]

Postoperative troponin elevation indicates increased risk of cardiac events.[8,120] It is more sensitive than ECGs[5] or creatine kinase myocardial band (CK-MB),[119] and has become the gold standard for identifying postoperative ischemia. Le Manache studied the postoperative troponin levels of 1136 abdominal aortic aneurysm surgical patients, and found that a slightly elevated level was associated with delayed postoperative myocardial infarction. Discovery of elevated postoperative troponin may represent an opportunity to reduce asymptomatic ischemia.[10] Landesberg's study of major vascular surgery showed a similar correlation of troponin and CK-MB and overall mortality.[121]

TABLE 7–6.

Summary of Clinical Characteristics of Cardiac Tests

Type of Test	No. of Studies	No. of Patients	Mean Age (years)	Proportion of Men (%)	History of CAD (%)	Proportion of DM (%)	Sensitivity (%; 95% CI)	Specificity (%; 95% CI)
Radionuclide ventriculography	8	532	67.0	83	45	25	50 (32–69)	91 (87–96)
Ambulatory electrocardiography	8	893	68.0	72	55	32	52 (21–84)	70 (57–83)
Exercise electrocardiography	7	685	64.5	72	36	28	74 (60–88)	69 (60–78)
Dipyridamole stress echocardiography	4	850	66.8	78	28	33	74 (53–94)	86 (80–93)
Myocardial perfusion scintigraphy	23	3119	65.5	78	40	30	83 (77–89)	49 (41–57)
Dobutamine stress echocardiography	8	1877	67.3	76	37	16	85 (74–97)	70 (62–79)

CAD, coronary artery disease; CI, confidence interval; DM, diabetes mellitus.
Tests are sorted according to ascending sensitivities.
Kertai MD, Boersma E, Bax JJ, et al. A meta-analysis comparing the prognostic accuracy of six diagnostic tests for predicting perioperative cardiac risk in patients undergoing major vascular surgery. Heart 2003;89(11):1327–1334. Reproduced with permission from the BMJ Publishing Group.[113]

MANAGING RISK: WHAT INTERVENTIONS?

Anesthesiologists are well situated to practice perioperative medicine. Increasingly, this includes perioperative optimization of cardiac conditions. Although consultation and cooperation with cardiology specialists are needed for many aspects of this optimization, some interventions are well within the anesthesiologist's range of skills. This is because it is the anesthesiologist assigned to a case who best knows what information is needed or not needed in order to balance risks, obtain informed consent, and form an anesthesia plan. The anesthesiologist is in the best position to know when detailed investigations would not change any of these decisions, and thus would entail needless delay, expense, and risk.

This section focuses on preoperative and postoperative interventions. Intraoperative management is addressed in other chapters.

Many of the medical interventions for reducing perioperative risk are part of the secondary prevention of cardiac disease. While the perioperative team must limit itself largely to the management required in the perioperative period, this is an ideal time to institute or reinforce long-term cardiac care, especially the simple, proven interventions, such as control of hypertension and diabetes, along with the use of β-blockers and statins.

Preoperative Invasive Interventions: When Should CABG or PTCA Be Done Preoperatively?

Because of the known increase in PCCs in patients with cardiac disease, and because initial studies showed increased PCCs after MI, it has been deemed logical to postpone elective operations until the cardiac status is optimized.[122] This optimization has generally been either an operation or intensive medical management.

Glance, in a decision-tree model, found that proceeding directly to vascular surgery resulted in the poorest 5-year survival (77.4%) compared with 3 screening strategies: (a) screening all patients with a dipyridamole-thallium test (86.1% 5-year survival); (b) screening all patients with coronary angiography (87.9% 5-year survival); and (c) selective screening where high-risk patients underwent preoperative angiography, intermediate-risk patients were screened noninvasively, and low-risk patients proceeded directly to surgery without further testing (86.0% 5-year survival). While the 5-year survival rate was similar in all screening strategies, the cost ($/year of life saved) of selective screening was half that of either nonselective strategy. There was no difference in 30-day outcome between any of the 4 strategies.[36]

The Asymptomatic Cardiac Ischemia Pilot study randomized 558 patients who had coronary anatomy suitable for revascularization to 3 treatment strategies: (a) angina-guided drug therapy (n = 183); (b) angina plus ischemia-guided drug therapy (n = 183); and (c) revascularization by angioplasty or bypass surgery (n = 192). Two years after randomization, the total mortality was 6.6% in the angina-guided strategy, 4.4% in the ischemia-guided strategy, and 1.1% in the revascularization strategy.[123]

On the other hand, the following studies raise doubts about the need to revascularize before surgery in reasonably stable cardiac patients.

Mason did a decision analysis modeling comparing 3 perioperative strategies for vascular surgery in high-risk patients: (a) proceed directly to vascular surgery with close monitoring of cardiac status and aggressive treatment of myocardial ischemia; (b) perform coronary angiography followed by selective coronary revascularization, then proceed to vascular surgery except in patients with severe, inoperable CAD; and (c) perform coronary angiography followed by selective coronary revascularization, then proceed to vascular surgery in all patients, including those with inoperable CAD. In the best-case analysis of the 4 end points of nonfatal myocardial infarction, stroke, cost, and a successful vascular procedure, the first strategy of proceeding directly to vascular surgery with close monitoring of cardiac status led to better outcomes than either of the coronary angiography strategies.[124]

McFalls randomized 510 Veterans Administration patients undergoing abdominal aortic aneurysm repair to either coronary artery revascularization before surgery or no revascularization before surgery. Percutaneous coronary intervention was performed in 59%, and bypass surgery in 41%. There was no difference in MI in the first 30 days after surgery or in mortality at 2.7 years.[44] This study excluded patients with more than 50% stenosis of the left main coronary artery from randomization. Drug-eluting stents were not used. This widely quoted study needs to be repeated with these shortcomings addressed.

Godet's group analyzed a cohort of 1152 patients after abdominal aortic surgery in which 78 patients underwent percutaneous coronary intervention. A propensity score analysis was performed. The observed percentages of patients in the percutaneous coronary intervention group with severe postoperative coronary events (9.0% [95% confidence interval (CI), 4.4–17.4]) or death (5.1% [95% CI, 2.0–12.5]) were not significantly different than the expected percentages (8.2% and 6.9%, respectively).[125]

Coronary interventions should be performed as indicated by guidelines used in nonsurgical settings. Whether or not an operation should be delayed depends more on the urgency of the surgery than on the presence of CAD.

Management of Hypertension

In 1988, Stone et al. described the effect of a single preoperative dose of β-blocker on mild hypertensives.[126] The dramatic reduction in postoperative ischemia made it appear that treatment of hypertension was very important. Subsequent studies suggest the important aspect of this study was not the mild hypertension, but the β-blockers.

Hypertension as a risk factor for cardiovascular disease was discussed previously in Specific Risk Factors: Hypertension above. Management is usually elective, and an operation does not need to be delayed unless blood pressure is quite high. There are no evidence-based guidelines on the threshold of hypertension that warrant delay of surgery. The oft-quoted threshold for postponing surgery of 180/110 mm Hg is the result of a recommendation by Goldman and Caldera in their 1979 study which included 5 such patients, none of whom had any complications.[68] Rohgi did show an increased risk of cardiac complications in vascular surgery patients whose diastolic blood pressure was >110 despite taking 2 or more antihypertensive medications.[37]

The important aspect of management of severe hypertension (>180/110 mm Hg) is the search for end-

organ damage (cardiac ischemia, renal dysfunction, cerebral impairment). If there is any evidence of end-organ damage, the patient needs emergency care. In the absence of these, the condition is termed a hypertensive urgency, and the treatment goal is to gradually improve blood pressure control. Indeed, rapid reduction of blood pressure has added risks. If these patients are sent to the emergency department, they will be assessed with a clinical examination, ECG, and simple blood tests to rule out end-organ damage. If there is no such damage, they will be started on an oral antihypertensive and sent home. The anesthesiologist can often do this as well as the emergency department. There is probably no need to delay an operation if there is no end-organ damage and improvement in long-term management is underway.[51]

Blood pressure control must be continued through and beyond the perioperative period.[127] Hypertension is the classic condition that may present preoperatively and whose treatment will result in long-term health benefits. Modena has shown that treatment of hypertension results in improvement in endothelial function and reduction in cardiovascular events in 6 months.[128] The reasons for treating hypertension may not stem so much from perioperative benefits as from the clear lifelong benefits. Patient compliance is often suboptimal and perioperative attention to this condition by the anesthesiologist will assist greatly in long-term management. Compared to the potent drugs used daily for anesthesia, antihypertensives have great margins of safety. Anesthesiologists need to learn to write prescriptions for long-term hypertension management where needed. Primary care physicians can assume responsibility for titration of medication prescribed perioperatively.

Medications: What to Start and What to Stop

β-Blockers

Large studies have demonstrated the benefit of β-blockers after MIs and in heart failure.[129,130] There are small studies showing marked benefit from perioperative use. Mangano's prospective study of 1 week of perioperative β-blocker use showed dramatic results in morbidity and mortality extending to 2 years[131] (Fig. 7–9).

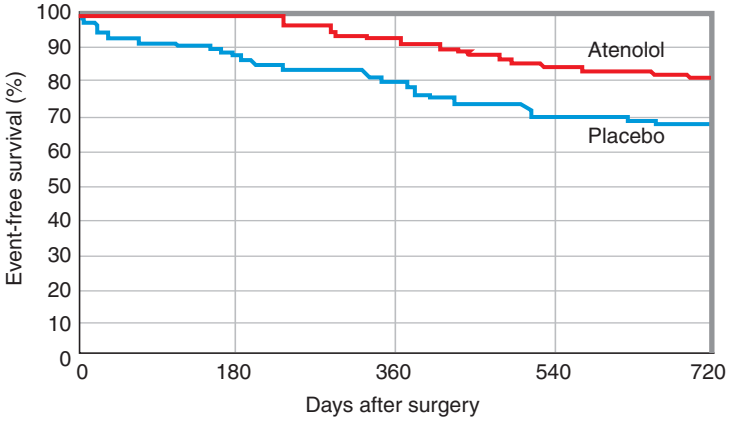

FIGURE 7–9. Event-free survival after surgery: atenolol versus placebo. Event-free survival in the 2 years after noncardiac surgery among 192 patients in the atenolol and placebo groups who survived to hospital discharge. The outcome measure combined the following events: myocardial infarction, unstable angina, the need for coronary artery bypass surgery, and congestive heart failure. The rate of event-free survival at 6 months (180 days) was 100% in the atenolol group and 88% in the placebo group (P <0.0001); at 1 year (360 days), the rates were 92% and 78%, respectively (P = 0.003); and at 2 years (720 days), 83% and 68% (P = 0.008). Mangano DT, Layug EL, Wallace A, Tateo I, The Multicenter Study of Perioperative Ischemia Research Group. Effect of atenolol on mortality and cardiovascular morbidity after noncardiac surgery. N Engl J Med 1996; 335(23):1713–1721. Copyright 1996, Massachusetts Medical Society. All rights reserved.[131]

Stevens estimates the number needed to treat (NNT) for prevention of 1 episode of intraoperative or postoperative ischemia with β-blockers to be 8.[132] The benefits of perioperative use are based on only 5 studies.[133,134] (Table 7–7). There were only 83 serious adverse events in all the studies.[132,135]

Polderman's study of high risk patients randomized 59 of them to an average of 30 days of preoperative bisoprolol, and 53 of them to standard care. In the first 30 postoperative days, there were 18 (34%) PCCs in the standard care group and 2 (3.4%) in the bisoprolol group. This very dramatic result was recently questioned.[135]

Although the mechanism of β-blockers is likely multifactorial, a probable major effect is reduction of postoperative asymptomatic ischemia and resultant long-term morbidity. Although this may not affect immediate PCC,[131,136] it reduces long-term PCC for up to 2 years[9] (see Physiology of Perioperative Cardiac Morbidity above). β-Blockers also reduce the likelihood of fibrillation with ischemia. Esmolol reduces anesthetic requirements.[137,138]

Who should get perioperative β-blockers is not well defined. There is recent evidence that low-risk patients do not benefit.[133] The Dutch Echocardiographic Cardiac Risk Evaluation Applying Stress Echocardiography Group's analysis of 45 patients with PCCs suggests that only patients with at least 1 risk factor benefit from addition of β-blockers. As all of the patients in this study were vascular patients, this equates to a threshold for treatment of 2 risk factors. Because there are side effects that might not be fully monitored after discharge, β-blockers should be reserved for cases when 2 of the risk factors are present and there are no contraindications.[139] An exception would be uncontrolled hypertension, which in and of itself may warrant initiation of β-blockers.

Asthma and COPD are not contraindications to initiation of cardioselective β-blockade unless the patient is having an acute attack.[140,141] Diabetics benefit from β-blockers,[142] although other cardiac medications may be preferable.[48,143]

Bradycardia is a relative contraindication. The ACC/AHA guidelines actually recommend titration of β-blockers to achieve a heart rate of 50–60 beats per minute.[42]

The β-blocker should not be one with intrinsic sympathomimetic activity. Atenolol,[131] bisoprolol,[31] and metoprolol[144] have proven beneficial in studies. Preliminary animal studies show that metoprolol does not interfere with preconditioning[145] but that atenolol and propranolol do.[146] Lanfear's study of the benefit of β-blockers after acute coronary syndromes shows that not all genotypes respond equally well.[89]

TABLE 7–7.

Summary of Perioperative β-Blocker Studies

Source, y	Study Population and Eligibility	β-Blocker Regimen	Target Heart Rate	Findings (Postoperative Ischemia/Other)	Number Needed to Treat	Adverse Events†	Comments
Mangano et al, 1996; Wallace et al, 1998	200 patients undergoing elective noncardiac surgery according to several clinical criteria (see Box 1)	Atenolol, 5–10 mg intravenously 30 min before and after surgery and 50–100 mg/d by mouth throughout the hospital stay (up to 7 days)	55–65/min (doses held if rate <55/min or systolic blood pressure <100 mm HG or if there was a defined adverse event)	No difference in in-hospital cardiac or mortality outcomes. All-cause mortality at 2 years: 9% vs 21% (P = .02); cardiac death at 2 years: 4% vs 12% (P = .03); post operative ischemia: 24% vs 39% (P = .03)	All-cause mortality at 2 years, 8.3; ischemia, 6.7	Intraoperative bradycardia more common with atenolol (38% vs 15%; P <.001) but no difference in need for treatment. No increase in third-degree heart block, hypotension, bronchospasm, or congestive heart failure	Included patients taking β-blockers long-term, most of whom (19% vs 8%) were in the β-blocker group
Poldermans et al, 1999	112 patients with positive test results on dobutamine echocardiography and undergoing elective abdominal aortic or infrainguinal arterial reconstruction	Bisoprolol, 5–10 mg/d by mouth begun an average of 37 days preoperatively and continued for 30 days postoperatively	Intravenous metoprolol to target heart rate if patient not taking by mouth perioperatively: doses held if heart rate <50/min or systolic blood pressure <100 mmHg	Reduced incidence of perioperative cardiac death and nonfatal MI. Cardiac death: 3.4% vs 17% (P = .02); nonfatal MI: 0% vs 17% (P <.001)	Cardiac death or nonfatal MI, 3.2	No exacerbation of peripheral vascular disease	Excluded patients taking β-blockers long-term
Raby et al, 1999	26 patients with preoperative ischemia by Holter monitor and undergoing aortic aneurysm repair, infrainguinal endarterectomy	Esmolol, intravenous for 48 hours postoperatively	Titrate to heart rate 20% below ischemic threshold but no less than 60/min	Postoperative myocardial ischemia: 33% vs 73% (P <.05)	2.5	No patient had β-blocker therapy suspended because of unacceptable adverse events	Physicians prescribe postoperative β-blockers more often in control groups (82% vs 13%; P <.05)

(continued)

TABLE 7–7.

Summary of Perioperative β-Blocker Studies (continued)

Source, y	Study Population and Eligibility	β-Blocker Regimen	Target Heart Rate	Findings (Postoperative Ischemia/Other)	Number Needed to Treat	Adverse Events†	Comments
Stone et al, 1988	128 untreated hypertensive (systolic blood pressure, 160–200 mm Hg; diastolic, 90–100 mm Hg) patients undergoing elective surgery	Labetalol, atenolol, oxprenolol; patients randomized to control, labetalol (100 mg by mouth), atenolol (50 mg by mouth), or oxprenolol (20 mg by mouth) given before induction of anesthesia	None described	Postoperative MI: 2/89 (2%) vs 11/39 (28%) untreated ($P < .001$)	3.8	21 patients taking β-blockers had bradycardia and half required atropine; no bradycardia in control patients	Patients had similar baseline characteristics, but these were not statistically compared. No description of surgeries performed
Urban et al, 2000	120 patients undergoing elective knee arthroplasty according to the criteria of Mangano et al	Esmolol intravenously within 1 hour after surgery; change to metoprolol the morning of the first postoperative day	<80/min (esmolol); <80/min for 48 hours postoperatively and then continue dose until discharge (metoprolol)	Postoperative ischemia: 6% vs 15% (NS); postoperative MI: 2% vs 6% (NS)	Not calculated	None noted	Included patients with long-term β-blocker use (30% in each treatment arm)

MI indicated myocardial infarction; NS, not significant.
†All comparisons are presented as β-blocker vs control.

There are no studies comparing the different timing of perioperative β-blocker usage. Generally, the rule of thumb is the sooner the better, so as to allow titration to maximum effect without side effects. It is very important that β-blockers not be discontinued postoperatively.[147,148] Chronic β-blocker use does not seem to provide the same benefit as acute perioperative use.[148]

Perioperative β-blockers have perhaps not turned out to be quite as wonderful as initially believed, but are clearly beneficial. Like all medications, there is a risk-to-benefit ratio that requires some selectivity.

Statins

Inhibitors of the 3-hydroxy-3-methylglutaryl coenzyme A (statins) may reduce perioperative mortality partly through the improvement of lipid profile, but also through the stabilization of coronary plaques, improvement in endothelial function, and antiinflammatory effects (pleomorphic effects). The Heart Protection Study has shown that even at-risk patients with normal low-density lipoprotein (LDL) benefit from simvastatin.[149] Poldermans' group did a case analysis of 160 vascular surgery patients who died in hospital postoperatively. They were each matched to 2 controls who had similar surgery in the same time period. Statin therapy was significantly less common in cases than in controls (8% vs. 25%; $P = 0.001$).[150]

Pan undertook a study of 1663 patients undergoing primary CABG surgery with cardiopulmonary bypass. Patients were classified into a group receiving statin therapy at the time of operation (n = 943) and a group who were not receiving statin therapy (n = 720). Multivariate logistic regression analysis demonstrated that preoperative statin therapy was independently associated with a reduction in all-cause mortality. There was, however, no reduced risk of postoperative MI, cardiac arrhythmias, stroke, or renal dysfunction. An independently associated reduction in the composite end point of 30-day all-cause mortality and stroke (7.1% vs. 4.6%; $P = 0.05$) was found only when the cohort was matched for propensity (presence of CAD or risk factors for CAD).

Lindenhauer retrospectively studied 780,591 patients who underwent a variety of noncardiac surgical procedures, of which fewer than 10% were vascular cases. Of the studied patients, 77,082 received lipid-lowering agents, which included statins in 70,145 (91%) of these patients. Using propensity-matched groups and conditional logistic regression, they showed that treated patients had a risk of mortality with an adjusted odds ratio of 0.62 (95% CI, 0.58–0.67). The lowest quintile of risk did not benefit from lipid-lowering therapy.[151]

Durazzo randomized 100 patients to receive either 20 mg atorvastatin or placebo at least 2 weeks before vascular surgery, and continuing for 45 days. The occurrence of a 6-month composite of PCCs was analyzed in a double-blind fashion. During the 6-month followup, primary end points occurred in 17 patients—4 in the atorvastatin group and 13 in the placebo group. The Kaplan-Meier graph shown in Figure 7–10 displays event-free survival after vascular surgery.

The Anglo-Scandinavian Cardiac Outcomes Trial–Lipid-Lowering Arm (ASCOT-LLA)[152] showed significant reduction in adverse cardiac end points at the first analysis 1 month after randomization. Statins may improve endothelial function in as little as 3 days.[153] Given the proven risk reduction even in asymptomatic nonsurgical patients,[149] there is enthusiasm that statins will prove equal to β-blockers as a simple, safe, and effective intervention to reduce PCCs. The benefits of statins and β-blockers are probably additive in high-risk patients.[154]

Angiotensin-Converting Enzyme Inhibitors/Angiotensin Receptor Blockers

β-Blockers and diuretics have been recommended as first-line treatment for hypertension, but evidence is building that other classes of medication are at least as efficacious. The Anglo-Scandinavian Cardiac Outcomes Trial–Blood Pressure Lowering Arm (ASCOT-BPLA) showed that an antihypertensive regimen based on a calcium channel blocker (CCB) and an angiotensin-converting enzyme inhibitor (ACEI) results in less-adverse cardiovascular end points than a regimen based on atenolol and a diuretic.[143,155] The effects cannot all be attributed to blood pressure reduction alone.[143]

A angiotensin receptor blockers (ARBs) decrease cardiac end points in patents with normal cholesterol by 35% in 3 years.[156] Losartan was shown to produce superior reduction in adverse cardiac end points when compared to atenolol, even though blood pressure reduction was similar.[155]

Whether or not ACEIs or ARBs should be discontinued preoperatively is unclear. A recent retrospective study of 267 hypertensives by Comfere supports the clinical suspicion that moderate hypotension during anesthesia is more common if ACEIs and ARBs are not stopped, but that it is usually easily

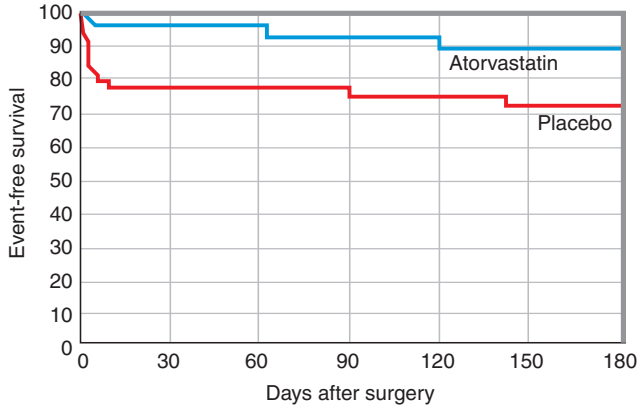

FIGURE 7–10. Event-free survival after vascular surgery—with and without statin. Event-free survival in the 6 months after vascular surgery, according to study group. Outcome measures included death from cardiac causes, nonfatal acute myocardial infarction, ischemic stroke, and unstable angina. Rate of event-free survival at 6 months (180 days) was 91.4% in the atorvastatin group and 73.5% in the placebo group ($P = .018$). Reprinted from Durazzo A, Machado F, Ikeoka D, Caramelli B. Reduction in cardiovascular events after vascular surgery with atorvastatin: a randomized trial. J Vasc Surg 2004;39:967–976, with permission from Society for Vascular Surgery.[183]

managed.[157] That study did not show an increase in the incidence of severe hypotension, although other studies have.[158,159] Angiotensin is important for reversal of hypotension in volume-depleted states, especially during general or epidural anesthesia.[160] It may be advisable to stop ACEIs and ARBs the night before an operation where the risk of volume depletion is high.[158]

Calcium Channel Blockers

Even normotensive patients with CAD benefit from calcium channel blockers.[161] This reduction was similar to enalapril, but was not compared to β-blockers. A meta-analysis by Wijeysundera and Beattie showed that calcium channel blockers, mostly diltiazem, significantly reduced PCCs[162] (Fig. 7–11).

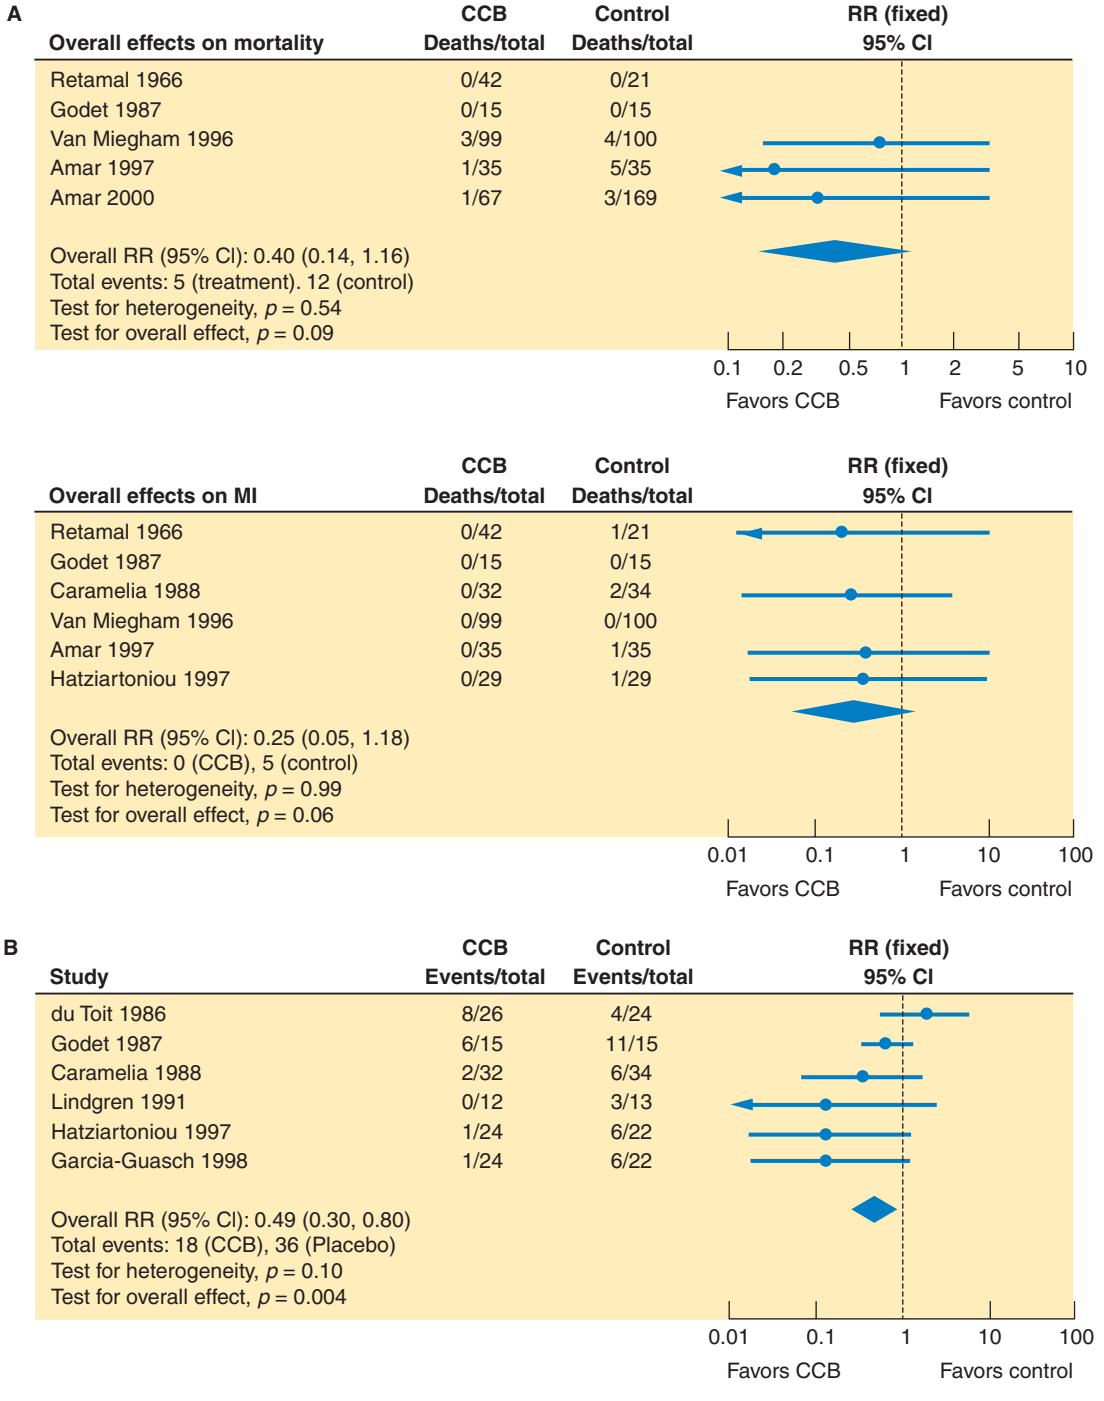

FIGURE 7–11. Effect of calcium channel blockers on mortality and myocardial infarction. **A:** Effect of calcium channel blockers (CCBs) on mortality (*above*) and myocardial infarction (MI) (*below*), with a combined analysis of these results. *Circles* represent point estimates. The area of a circle correlates with its contribution towards the weighted summary estimate. Horizontal lines denote 95% confidence intervals (CI), some of which extend beyond the limits of the scale. The diamonds represent overall summary estimates. **B:** Effect of CCBs on myocardial ischemia, with a combined analysis of these results. *Circles* represent point estimates. The area of a circle correlates with its contribution towards the weighted summary estimate. Horizontal lines denote 95% confidence intervals, some of which extend beyond the limits of the scale. The *diamonds* represent overall summary estimate. RR, relative risk. Reproduced with permission from Wijeysundera D, and Beattie S.[162]

Diuretics

Whether or not to discontinue diuretics should be determined on a case-by-case basis. The benefit of holding them is a reduction in the dehydration induced by preoperative fluid restrictions. Sometimes intravenous access is made more difficult with diuresis. The danger of holding diuretics is the potential loss of control in patients with heart failure or hypertension.

Clonidine

Clonidine is an old drug with several beneficial perioperative effects. A recent meta-analysis by Nishina showed reduction of preoperative ischemia with the use of clonidine without an increase in bradycardia[163] (Fig. 7–12). Most of these studies are of CABG patients. Wijeysundera's meta-analysis of various types of surgery showed benefit in cardiac and vascular surgery, but not in nonvascular surgery.[164] A recent prospective trial by Wallace that included nonvascular surgery did show positive benefits[165] (Fig. 7–13).

Oliver showed that the absolute risk of cardiac death among vascular surgery patients randomized to placebo was 4%, and mivazerol reduced this to 1.3%, an absolute risk reduction of 2.7%. However, the number needed to treat is 37. Mivazerol is not currently available in the United States. Clonidine may be a good alternative for those patients for whom β-blockers are not indicated.[132]

Nitroglycerin

Dodd's small prospective study did not show any benefit to preoperative nitroglycerin.[166] Sear's small case control study suggested slightly increased risk.[136] There are no randomized studies of postoperative benefit of preoperative nitroglycerin.

Antiplatelet and Anticoagulant Agents

Balancing aspirin's cardioprotective effects in the procoagulant milieu of perioperative stress, against the increased risk of surgical bleeding must be done on a case-by-case basis. Generally, aspirin should be stopped 5 days before an operation and clopidogrel should be stopped 7 days before an operation. In vascular surgery cases, aspirin is generally continued throughout the perioperative period. In some cases, continuation of both aspirin and clopidogrel may be the best balance of risks. Tuman showed that aspirin use did not increase the need for transfusion in redo CABG,[167] and Anekstein showed that femur fracture repair on patients taking aspirin resulted in the transfusion of an average of 0.5 more units of blood.[168] This is a small increase in risk compared to the benefit.

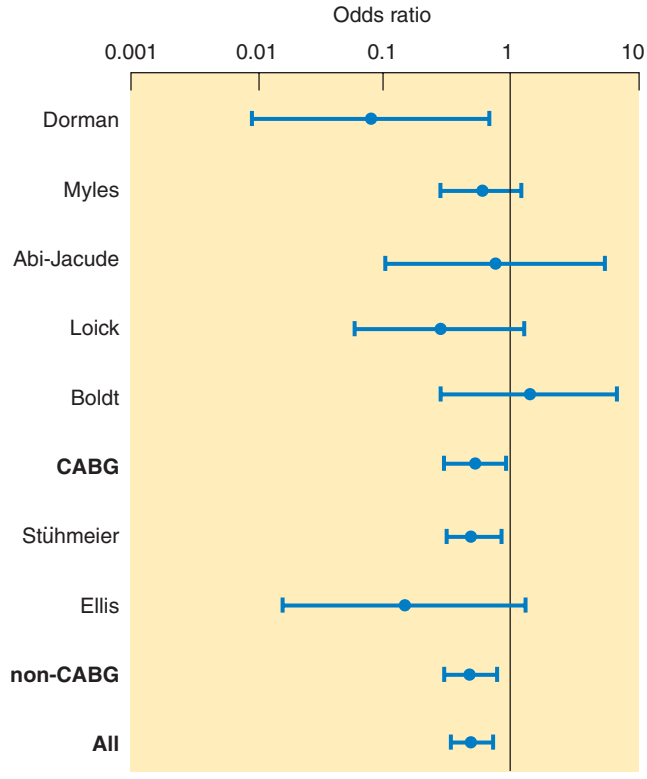

FIGURE 7–12. Pooled odds of myocardial ischemia in patients receiving perioperative clonidine. The subgroup analysis is based on surgery. The odds ratios are plotted on the X-axis on a logarithmic scale. *Solid circles* indicate the odds ratio of each study and *horizontal lines* show the 95% confidence interval of each study. CABG, coronary artery bypass grafting. Reproduced with permission from Nishina K, Mikawa K, Uesugi T, et al.[163]

Patients on anticoagulants because of valvular heart disease and prosthetic valves likewise require a balancing of the risk of bleeding from continued anticoagulation versus the increased risk of thromboembolism resulting from a cessation of therapy. For patients with a bileaflet mechanical valve and no other risk factors, war-

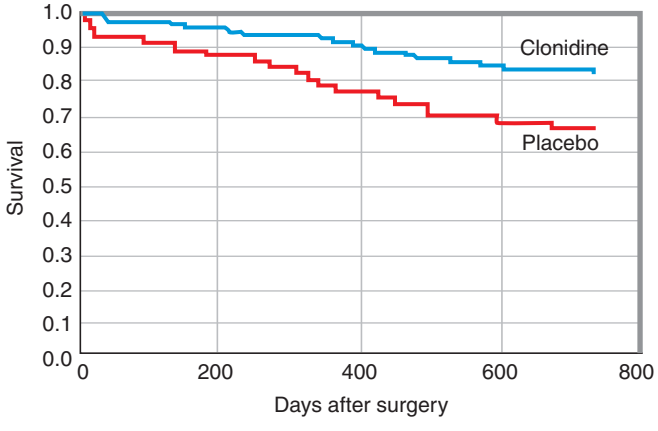

FIGURE 7–13. Postoperative survival—clonidine versus placebo. Survival for clonidine-treated versus placebo-treated patients. Survival curves for 2 years after surgery for patients treated with clonidine (n = 125) and placebo (n = 65). Clonidine reduced the incidence of death ($P = 0.01$ by long-rank test and $P = 0.01$ by Wilcoxon test). Reproduced with permission from Wallace AW, Galindez D, Salahieh A, et al.[165]

farin should be discontinued 2–3 days before the procedure so that the international normalized ratio (INR) is less than 1.5 at the time of operation, and restarted within 24 hours of the procedure.[169,170] Because the evidence defining the perioperative management of anticoagulation in this patient population is so sparse, the specifics of cessation or bridging with heparin of a patient with any of the risk factors in Table 7–8 must be individualized.[171] A rough guideline is that a patient with 2 risk factors should have therapeutic doses of intravenous heparin started when the INR has been allowed to fall below 2.0 (typically 48 hours before surgery). Heparin should be adjusted to maintain the activated partial thromboplastin time at 55–70 seconds, stopped 4–6 hours before the procedure, restarted as early after the operation as possible, and continued until the INR is therapeutic on warfarin.[170] Although there are some concerns over the use of low-molecular-weight heparin for bridging,[172] especially in patients with mechanical valves,[173] this is an attractive option.

Glucose Control/Insulin

Metformin has traditionally been stopped up to 1 week preoperatively because of fear of metabolic acidosis and renal insult. A recent Cochrane analysis revealed no cases of fatal or nonfatal lactic acidosis in 35,619 patient-years of metformin use.[174] Metformin is proving to be valuable in improving endothelial function.[175] Stopping it preoperatively may turn out to be a counterproductive measure.

Ideally, no patient should proceed to an elective operation without stable glucose control. Although there is strong evidence that perioperative hyperglycemia increases risk of surgical wound infections in cardiac surgery, and fairly good evidence that hyperglycemia increases overall risk of CAD,[176] evidence that tight perioperative glucose control changes perioperative outcome is elusive.[177]

Van den Berghe's study on intensive insulin therapy in the intensive care unit showed that a history of diabetes or hyperglycemia at the time of admission did not affect measures of morbidity.[178]

Antibiotics

Clinicians should refer to established guidelines for the use of preoperative antibiotics to prevent surgical infections[179] and to prevent endocarditis.[180] Effective prophylaxis against surgical infections requires that the antibiotic be administered within the hour before incision. Antibiotics for endocarditis prophylaxis are often overused, and should be given only when indicated.

TABLE 7–8.

Risk Factors for Thrombotic Complications

Atrial fibrillation
Previous thromboembolism
Hypercoagulable state
Older-generation mechanical valves (e.g., Bjork-Shiley)
Left ventricular ejection fraction <30%
More than 1 mechanical valve
Any mitral valve replacement

Smoking Cessation

Smoking is one of the strongest modifiable risk factors for cardiovascular disease. Whether the stress of smoking cessation outweighs the short-term benefits of preoperative cessation is unclear. Warner showed that it took more than 6 months to see a benefit from preoperative smoking cessation. There was actually an increase in pulmonary complications during the first 2 months.[181] Moller studied 120 joint replacement patients who were randomized to either a 6-week preoperative smoking cessation program that included weekly meetings and free nicotine replacement medication or to standard care. The overall complication rate was 18% in the smoking intervention group and 52% in controls ($P = 0.0003$). Wound-related complication rate was 5% in the intervention group and 31% in the controls ($P = 0.001$). There were no cardiovascular complications in the intervention group and 10% in the controls ($P = 0.08$).

It is likely that smoking cessation programs would pay for themselves in the savings from reduced postoperative complications, to say nothing of the long-term benefits of smoking cessation.

There are a number of risk-reducing interventions that can be implemented preoperatively in a relatively easy fashion. If anesthesiologists are serious about being perioperative physicians, participation in these well-established practices of medicine will be important.

CONCLUSION

The perioperative plan can often be made on the basis of good interviewing and examination skills. Specialized tests should only be applied as needed to refine management decisions. Perioperative management now entails more than just identifying high-risk patients and referring them back to other specialists. It is possible for the anesthesiologist to actually reduce perioperative risk through relatively simple medical interventions. The extent and timing of interventions can be tailored to each patient according to specific perioperative risks. Anesthesiologists are well positioned to efficiently reduce perioperative risk and institute simple forms of secondary disease management.

CHAPTER 8

Evaluation of the Patient with a Difficult Airway

James C. Phero, DMD,
Andranik Ovassapian, MD,
and William E. Hurford, MD

SCOPE OF THE PROBLEM AND INCIDENCE

A difficult airway may present as difficulty with ventilation, difficulty with rigid laryngoscopic tracheal intubation, or both. The American Society of Anesthesiologists' (ASA) *Practice Guidelines for Management of the Difficult Airway* has defined difficult ventilation as a circumstance where "it is not possible for the unassisted anesthesiologist to prevent or reverse signs of inadequate ventilation during positive pressure ventilation."[1]

Difficult rigid laryngoscopy is defined as a situation in which "it is not possible to visualize any portion of the vocal cords with conventional laryngoscopy." A difficult intubation is defined as a circumstance in which "the proper insertion of an endotracheal tube using conventional laryngoscopy requires more than three attempts, or greater than 10 minutes."[1]

The incidence of difficult intubation by rigid laryngoscopy varies from 0.5–13.6% in published studies.[2–8] Discrepancies in the reported incidence of difficult intubation are to be expected. Most reports are retrospective studies and apply different definitions of what constitutes a difficult intubation. The incidence of failed intubation in the general surgical population has been reported as one in every 2230 patients.[4] The incidence of failed intubation in the parturient population has been reported as 1 in 283–750 patients.[4,8] This represents a 3- to 10-fold increase compared with the incidence in nonparturient patients. The precise frequency of difficult mask ventilation is unknown, but an Australian study indicated that 15% of difficult intubations were also associated with difficult mask ventilation.[9]

Thirty to 40% of all anesthetic deaths have been attributed to inability to manage a difficult airway.[10] The ability to predict with precision difficulty with ventilation and intubation would help minimize disasters related to airway management. Unfortunately, the positive identification of all difficult airways is not possible at present. The coexistence of difficult ventilation is even more difficult to predict accurately.

Difficult airway management results from anatomic extremes or diseases affecting the airway. These factors may prevent a good mask fit or adequate positioning of a laryngeal mask airway (LMA), interfere with positioning of the head and neck, limit the opening of the mouth, and narrow or distort the airway. Inability to ventilate the lungs or intubate the trachea may of course also result from poor technique and/or lack of technical skills.

GRADING THE DIFFICULTY OF TRACHEAL INTUBATION

Cormack and Lehane developed a classification for the view obtained at laryngoscopy.[11] This classification uses four grades as follows: grade I—a full view of glottis; grade II—only the posterior commissure is visible; grade III—only the tip of the epiglottis is visible; grade IV—no glottic structures are visible (Fig. 8–1). Use of the original Cormack and Lehane scoring system led Yentis and Lee to develop a modified Cormack and Lehane scoring system in which grade II (only part of the glottis visible) was divided into IIa (part of the cords are visible) and IIb (only the arytenoids or the very posterior origin of the cords are visible) (Fig. 8–2).[12] In this system, grade IIb denotes a laryngoscopic view that is relatively common and often associated with difficulty passing a tracheal tube. This system is now frequently used for recording the ease or difficulty in laryngoscopic view in the anesthetic record and in studies of tracheal intubation.

The Intubation Difficulty Scale (IDS) is another tool used in airway research that can be a useful indicator of total intubation difficulty in a prior intubation.[13,14] The IDS is a quantitative measure of the total intubation difficulty encountered during a chosen

KEY POINTS

1. A patient with a history of difficult intubation should be treated as having a difficult airway, even though physical appearance and physical examination may be unremarkable.
2. A patient with anatomic variations indicative of possible difficult intubation should receive a careful history and physical examination to define the scope of the potential airway problem.
3. Possible or potentially difficult intubation may be predicted by the Mallampati test, evidence of receding mandible, limited mouth opening as a result of tissue or TMJ restriction, enlarged teeth, high arched palate, narrow small mouth, or restricted cervical spine movement.
4. All tests to predict difficulty with airway management are associated with a high incidence of false-positive and false-negative results and have low predictive value. To minimize airway-related complications, it may be necessary to accept a high incidence of false-positive predictions by the various tests and treat any patient identified as having a possible difficult intubation accordingly.
5. Unexpected failed ventilation and intubation may result from a supraglottic mass or lingual tonsillar hyperplasia that may not be identified by external examination.
6. In pediatrics, infection-related airway compromise and congenital airway malformations are the major airway management problems.
7. In adults, stridor at rest indicates a serious degree of obstruction with a cross-sectional opening less than 4 mm.
8. Upper airway endoscopy with a rigid laryngoscope or fiberoptic bronchoscope is useful in defining anatomic challenges in patients with upper airway pathology before induction of general anesthesia.
9. If in doubt about the ability to ventilate or intubate, the airway is best secured while the patient is awake and breathing spontaneously.

FIGURE 8–1. Laryngoscopic views obtained per Cormack and Lehane.

procedure or sequence of procedures and is calculated after the fact. The score is based on 7 parameters known to be associated with difficult intubation. The 7 parameters are number of supplementary attempts, number of supplementary operators, number and type of alternative techniques used, laryngoscopic grade, subjective lifting force, the use of external laryngeal manipulation, and mobility or position of the vocal cords. The scoring of each individual parameter represents a divergence from ideal, and the total score represents the sum divergence from a zero difficulty, ideal intubation.

Patients with difficult tracheal intubation can be categorized into 3 groups (Box 8–1). The first group consists of patients in whom tracheal intubation is known or expected to be difficult. The second group includes patients with external anatomic features indicative of probable airway difficulties. The third group includes patients who present no external anatomic evidence or history of a difficult airway, but nonetheless prove to be difficult.

EVALUATION OF THE POTENTIALLY DIFFICULT AIRWAY

These patients have anatomic variations that may interfere with rigid laryngoscopy and tracheal intubation. The failure to identify these patients correctly may lead to an improper anesthetic induction plan and an unexpected failed intubation. If ventilation proves impossible, a life-threatening emergency situation is created.

To identify patients with potentially difficult to manage airways, a careful history regarding patient breathing, sleep position, and voice quality is taken. During physical examination, the patient should be viewed from a frontal and profile view to assess mandibular size. Thyromental distance is measured, and neck rotation, flexion, and extension mobility are evaluated and graded. The neck is palpated for identification of the cricothyroid membrane. Additionally, one should check for temporomandibular joint (TMJ) problems, mouth opening, loose or protruding teeth, degree of overbite, size of the tongue, visibility of faucial structures, and patency of the nares.

A number of predictive tests have been described that detect potentially difficult intubation (Box 8–2). These clinical examinations are straightforward and can be done at the bedside. Although useful in airway evaluation, all these tests are associated with relatively high rates of false-positive and false-negative predictions (Box 8–3).

Anatomic Considerations

In the early development of rigid laryngoscopy, certain anatomic features were recognized as contributing to the difficulty of intubation.[15] These features included a recessed mandible, limited extension of the head and neck, limited mouth opening, and mandibular depth.

Five physical features were evaluated prospectively by Wilson et al. in an attempt to identify potentially difficult intubations (Table 8–1).[6] Each risk factor was given three possible scores (0, 1, or 2). A total score of greater than 2 predicted a 75% chance of difficult intubation, but with a significant incidence of false-positive results. Changing the prediction criteria to a score of greater than 4 reduced the number of false-positive results, but also increased the incidence of false-negative predictions. In this study of 778 patients, 1.5% of rigid laryngoscopies were found to be difficult.

Atlantooccipital Mobility

Adequate cervical mobility and mouth opening are essential for alignment of the oral, pharyngeal, and laryngeal axes required for visualization of the glottis during rigid laryngoscopy.[15,16] Decreased neck mobility also limits maneuvers that can be used to keep the airway open, thereby predisposing to difficult mask ventilation.

Bedside evaluation of atlantooccipital extension is performed by having the patient sit straight and extending the head while maintaining the cervical spine in a neutral position.[16] The greater the atlantooccipital distance in the neutral position, the greater the possible degree of head extension. A reduction of atlantooccipital extension by one-third or more will contribute to the difficulty of intubation.[16] If the posterior tubercle of the atlas is in

Original Cormack and Lehane system	1 Full view of the glottis	2 Partial view of the glottis or arytenoids		3 Only epiglottis visible	4 Neither glottis nor epiglottis visible
View at laryngoscopy					
Modified system	1 As for original Cormack and Lehane above	2a Partial view of the glottis	2b Arytenoids or posterior part of the vocal cords only just visible	3 As for original Cormack and Lehane above	4 As for original Cormack and Lehane above

BOX 8–1.

Categories of Difficult Airway

- Known or expected difficult airway
  - History of difficult or failed intubation
  - History of difficult or failed mask ventilation
  - Conditions associated with difficult airway
    - Acquired
    - Congenital
- Potentially difficult airway
  - Limited neck extension
  - Limited mouth opening
  - Receding mandible
  - Mallampati class 3
  - Short thyromental distance
- Unexpected difficult airway
  - Unknown supraepiglottic mass
    - Hyperplasia of lingual tonsils
    - Supraepiglottic cyst or tumor
  - Missed evidence of difficult airway
    - Poor preoperative evaluation
    - Ignoring presence of evidence

contact with the occiput in the neutral position, attempts to extend the head result in anterior bowing of the cervical spine and forward displacement of the larynx.[17] Limitations in head extension may occur secondary to anatomic variations of the atlantooccipital gap in otherwise healthy people or secondary to pathologic conditions such as rheumatoid arthritis.

Mouth Opening

In addition to head and neck extension, other anatomic factors may interfere with the line of vision from mouth opening to vocal cords and exposure of the glottic opening. The hinge movement of the mandible controls mouth opening. A horizontal gliding movement allows for subluxation of the mandible, which allows additional anterior displacement of the tongue during rigid laryngoscopy. A mouth opening (distance between mandibular and maxillary central incisors) limited to 3.5 cm or less tends to make intubation more difficult. Temporomandibular joint dysfunction, congenital fusion of the joints, trauma, tissue contracture around the mouth, and trismus may limit mouth opening. Trismus secondary to pain associated with infection usually relaxes under general anesthesia, but this cannot be assured if the infection has been long-standing or involves the pterygoid space.

Protruding maxillary anterior teeth may interfere with laryngoscope placement and passage of the endotracheal tube during intubation. During rigid laryngoscopy, the tongue is displaced into the mandibular space, opening the line of vision from mouth to the larynx. A small mandibular space may fail to adequately accommodate tongue displacement, thus interfering with visualization of the larynx.

BOX 8–2.

Tests Applied to Predict Difficult Intubation

- External anatomic features
  - Head and neck movement (atlantooccipital joint)
  - Jaw movement (temporomandibular joint)
    - Mouth opening
    - Subluxation of mandible
  - Receding mandible
  - Protruding maxillary incisors
  - Obesity
  - Thyromental distance
  - Sternomental distance
- Visualization of the oropharyngeal structures
- Anterior tilt of larynx
- Radiographic assessment

BOX 8–3.

Shortcomings of Tests Predicting Difficult Intubation

- High incidence of false-positive results
- High incidence of false-negative results
- Do not address lower airway problems
- Do not address mask ventilation difficulties
- Miss lingual tonsil as cause of failed intubation

Thyromental Distance

Patil et al. reported that rigid laryngoscopy may be impossible in adults if the thyromental distance is less than 6.0 cm (3 finger breadths).[18] Alignment is more difficult in the patient with a receding mandible where the thyromental distance is short, as the laryngeal axis must form a more acute angle with the pharyngeal axis. The thyromental distance is measured between the bony point of the mentum of the mandible and the thyroid notch with the head fully extended. Maximum extension of the head ensures reproducibility of measurements.

TABLE 8–1.

Five Risk Factors of Difficult Intubation

Risk factor	Level of Risk
Weight	
<90 kg	0
90–110 kg	1
>110 kg	2
Head and neck movement	
>90°	0
~90°	1
<90°	2
Jaw movement	
Interincisor gap (IG) measured with mouth fully open	
Subluxation (SLux) (maximal forward protrusion of the lower incisors beyond the upper incisors)	
IG >5 cm or SLux >0	0
IG <5 cm or SLux =0	1
IG <5 cm or SLux <0	2
Receding mandible	
Normal	0
Moderate	1
Severe	2
Protruding maxillary anterior teeth	
Normal	0
Moderate	1
Severe	2

From Wilson ME, Spiegelhalter D, Robertson JA, et al. Predicting difficult intubation. Br J Anaesth 1988;61:211. The Board of Management and Trustees of the British Journal of Anesthesia. Reproduced by permission of Oxford University Press/British Journal of Anesthesia.

Sternomental Distance

The sternomental distance is measured with the head fully extended and the mouth closed. This measurement is reported to be more sensitive and specific in predicting difficult rigid laryngoscopy than the Mallampati test, thyromental distance, mouth opening, and mandibular subluxation measurements.[5] The predictive value of sternomental distance regarding difficult intubation has not been studied by other investigators.

Visibility of Oropharyngeal Structures

Predicting probability of laryngoscopy difficulty by physical evaluation was reported by Skolimowski et al. in 1975, when describing a micrognathic patient who could not be intubated: "The an-

teroposterior dimension of the pharynx was markedly reduced by a large tongue reaching far posteriorly. It was not possible to examine the lower pharynx by means of a laryngoscope mirror because the tongue was situated too far posteriorly to be pulled forward."[19]

Mallampati described the examination signs and related them to intubation difficulty. He correlated the degree of visibility of the oropharyngeal structures with the difficulty of rigid laryngoscopy.[20] In this study, a sitting patient was asked to open his or her mouth as wide as possible and maximally protrude the tongue. The visibility of the faucial pillars, soft palate, and uvula was noted. The airway was classified into three categories: class I—soft palate, fauces, uvula, and pillars are visualized; class II—soft palate, fauces, and pillars are visualized, but the uvula is masked by the base of the tongue; and class III—only the soft palate can be visualized. In class III, visualization of the glottis with rigid laryngoscopy is expected to be difficult.[20] Samsoon and Young extended the oropharyngeal exposures to include a fourth class.[4] This four-category system is in common use and classified as follows: class I—soft palate, fauces, uvula, and pillars are visualized; class II—soft palate, fauces, uvula are seen; class III—only the soft palate and base of the uvula are observed; class IV—the soft palate is not visible (Fig. 8–3). A further modification of the Mallampati visualization scoring included a class zero view.[21,22] Class zero is defined as the ability to see any part of the epiglottis upon mouth opening and tongue protrusion. Ezri et al. evaluated 764 patients and reported that 1.18% of patients had a class zero airway.[23] A class zero airway was noted to be an excellent predictor of uncomplicated laryngoscopy.

In a retrospective study of 13 patients with failed intubations, Samsoon and Young found that in 12 of the patients there was a good correlation between the degree of difficulty of tracheal intubation and the visibility of the oropharyngeal structures.[4] Rocke et al. reported the association between Mallampati class and difficulty of intubation to be significant ($p < 0.001$), but only 6.6% of class IV airway cases were associated with difficult tracheal intubation, and all could be intubated.[8] Using the concept of relative risk they calculated the probability of difficult intubation. The presence of class III airway was associated with a relative risk of 7.58 times greater than class I, and airway class IV had a relative risk of 11.2 times greater than class I. Oates et al. compared Mallampati's classification with that of Wilson's 5 risk factors.[24] The predictive value of both tests was found to be similar, but both tests had a high incidence of false-positive and false-negative predictors. Interobserver variability was less with Wilson's scoring system. Other investigators have found Mallampati's classification too subjective and the class III classification not useful as a predictor of difficult intubation when used alone.[25–27]

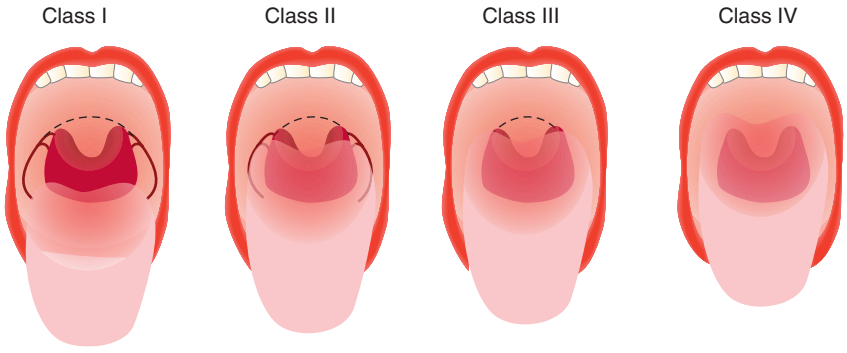

FIGURE 8–3. Classification of pharyngeal structures as proposed by Mallampati and Samsoon. Note: class III—soft palate visible; class IV—soft palate not visible.

Phonation during tongue protrusion increases the specificity of the Mallampati test, thus improving its correlation with difficult intubation, but also increases the number of false-negative results.[26] Tham reported that phonation created a marked improvement in view.[28] Evaluation of the airway in the supine position produced a small but nonsignificant worsening of the view. Lewis et al. recommended that the visibility of oropharyngeal tissues be conducted with the patient in the sitting position, with the head in full extension, the tongue out, and during phonation.[29]

In a retrospective review of failed intubations by Samsoon and Young, 7 of 1980 obstetric patients could not be intubated (incidence of 1:280) and 6 of 13,380 surgical patients could not be intubated (incidence of 1:2230).[4] All patients had a class IV airway except one class II patient who had tracheal stenosis. These authors felt that preanesthetic assessment using the Mallampati classification had merit. Lee et al. used the Cormack and Lehane grading system in their systematic meta-analysis review of the accuracy of Mallampati tests to predict the difficult airway.[30] In their review of 42 studies involving 34,513 patients, they found that both versions of the Mallampati test had good accuracy for predicting difficult laryngoscopy. The modified Mallampati score had good accuracy, but the original Mallampati had poor accuracy in predicting difficult tracheal intubation. Both versions of Mallampati score were poor at identifying difficult mask ventilation. The authors concluded that to be useful the Mallampati test must be part of a comprehensive evaluation that also includes assessment of dentition, thyromental distance, and neck extension, as recommended by the American Society of Anesthesiologists Task Force on the management of the difficult airway.[1]

In summary, the Mallampati test has been broadly applied, even though its predictive value for difficult intubation is low. As a result, some essential factors, such as suppleness and mobility of the neck or dentition status, may be minimized. No test is perfect, but this should not discourage practitioners from seeking a more reliable test or combination of tests.[31]

Anteriorly Tilted Larynx

Roberts et al. measured the degree of anterior tilt of the thyroid cartilage relative to the horizontal and demonstrated a relationship between degree of the thyroid cartilage tilt and the difficulty of laryngeal exposure using a Macintosh laryngoscope.[32] Laryngeal tilt can be directly measured using a bubble inclinometer. When the tilt of the anterior surface of the thyroid cartilage is greater than 40°, rigid laryngoscopy was predicted to be difficult. The sensitivity of this test was reported to be 70%, with a specificity of 95% and a positive predictive value of 80%.

Anterior laryngeal tilt is reduced by depression of the thyroid cartilage but is increased by cricoid pressure.

Radiographic Assessment

Lateral radiographs of the head and neck and the measurement of distances between bony landmarks have been used to identify predictive factors for difficult rigid laryngoscopy.[33] Reduction in the distance between the occiput and the spinous process of C1 (atlantooccipital distance), and to the C1-C2 interspinous gap, has been correlated with the degree of difficulty in intubation. Reduction of the atlantooccipital gap may be found in some otherwise normal cases. Any limitation of cervical extension may interfere with rigid laryngoscopy and glottic exposure. Radiographic assessment is not considered cost effective for routine airway evaluation.

Multiple Factors

Combining several tests for the prediction of difficult laryngoscopy and tracheal intubation improves the accuracy of the assessment. The simplified airway risk index (SARI) was developed to preoperatively evaluate airway status using multiple factors: mouth opening measurement, thyromental distance, ability to protrude the mandible, Mallampati class, head mobility, and body weight.[34] Calculation of the SARI in 136 patients revealed good interobserver agreement in assessing the Mallampati classification, mouth opening, and mandible protrusion, whereas measurement of thyromental distance and neck mobility did not have good interobserver agreement.[35]

Multiple factors often play roles in both difficulty with intubation and difficulty with mask ventilation. In a prospective study of 1502 patients, difficult mask ventilation was reported in 5%, with one occurrence of impossible ventilation.[36] Difficulty with mask ventilation was anticipated by the anesthesiologist in only 17% of the cases in which difficulty occurred. Using multivariate analysis, 5 criteria were recognized as independent factors for difficult mask ventilation: age older than 55 years, body mass index (BMI) >26 kg/m^2, presence of a beard, lack of teeth, and a history of snoring. The presence of two factors suggested a high likelihood of difficult mask ventilation.

Bellhouse and Dore reported that combining factors (e.g., limited atlantooccipital extension, chin protrusion, and tongue size) increases the sensitivity of predicting a difficult intubation.[16] Frerk reported that combining two tests, Mallampati and thyromental distance, improved the specificity of the prediction to 97.8% but did not improve sensitivity, which remained at 81.2%.[37] A meta-analysis performed by Shiga et al. of preanesthetic airway evaluation test performance on 50,760 patients in 35 studies demonstrated a 5.8% overall incidence of difficult intubation.[38] Each test in their analysis, including the Mallampati classification, thyromental distance, sternomental distance, mouth opening, and the Wilson risk score,[39] possessed only poor to moderate sensitivity and moderate to fair specificity. The most useful evaluations were found to be combinations of the Mallampati classification and thyromental distance. These authors concluded that the clinical value of airway evaluation tests for predicting difficult intubation remains limited.

A stepwise approach to decision making in the evaluation of the airway is the airway approach algorithm.[40] This algorithm is based on 5 clinical questions: Is airway control necessary? Is there potential for difficult laryngoscopy? Can supralaryngeal ventilation be used? Is there an aspiration risk? Will the patient tolerate an apneic period? Answers to these basic questions can help guide the practitioner in potential use of the ASA difficult airway algorithm.

EVALUATION OF THE COMPLEX AIRWAY

Patients with a history of difficult ventilation or intubation and patients with anatomic or abnormal conditions associated with a complex airway fall into the category of known difficult airway.[41] The causes of the expected difficult airway may be grouped into congenital or acquired conditions, and be further classified on the basis of the location of involvement or disease.

Increased frequency of ventilation, chest retractions, increased use of accessory muscles, stridor, voice weakness, or hoarseness, alone or in combination, may indicate a potential airway problem (Table 8–2). Stridor is a particularly important sign, and may provide evidence of the site and severity of airway obstruction related to severe glossopharyngeal, glottic, and/or upper tracheal occlusion. Stridor during inspiration generally indicates obstruction at or above the larynx. Expiratory stridor is most often associated with intrathoracic or subglottic obstructions. Obstruction associated with the larynx or glottic region may produce biphasic stridor, although either inspiratory or expiratory sounds may predominate. In the adult, stridor at rest indicates a serious degree of obstruction with a cross-sectional airway opening of less than 4 mm or an irregularly narrowed airway several centimeters in length.

Obesity

Airway assessment of the obese patient should be performed with the patient in both the sitting and supine positions. Respiratory function and airway patency can be significantly altered by this change in position.[42] A large neck circumference is associated with obstructive sleep apnea (OSA) in obese patients. In evaluating 123 patients with thick necks for OSA, Katz et

TABLE 8–2.

History Findings That Suggest Difficult Airway Management

Finding	Implication
Dry cough	Possible tracheobronchial compression
Easy bleeding	Epistaxis risk
Gastroesophageal reflux	Aspiration risk
Long-standing diabetes mellitus	Limited cervical mobility
Loud snoring	Prone to soft-tissue obstruction
Major trauma	Unstable neck, limiting safe mobility
Radiation to neck	Fibrosis, immobility
Recent temporal craniotomy	Limited mandibular motility
Smoking	Salivation, cough, laryngospasm
Undigested food returning to mouth	Aspiration risk from pharyngeal pouch

al. found that the sleep apnea–hypopnea index (AHI) correlated with external neck circumference, BMI, and the internal circumference of the distal pharynx.[43] Men more commonly have sleep-disordered breathing than women and the sleep-disordered breathing tends to be more severe.[44] In an evaluation of 3942 OSA patients, the frequency and severity of OSA in the sleep clinic population was found to be greater in men than women, with unknown factors other than neck circumference, age, and BMI contributing to the gender differences.[45] In a prospective study of 100 morbidly obese patients (BMI >40 kg/m^2), preoperative measurements of height, weight, neck circumference, width of mouth opening, sternomental distance, thyromental distance, and Mallampati score were recorded.[46] The view during direct laryngoscopy was graded, and the number of attempts at tracheal intubation was recorded. Neither absolute obesity nor BMI was associated with intubation difficulties. Large neck circumference and high Mallampati score were the only predictors of potential intubation problems.

In the supine position, changes in chest compliance and vital capacity may interfere with adequate spontaneous ventilation. The incidence of hiatal hernia, gastric pH of 2.5 or lower, and reduced functional residual capacity found in obese patients places these patients at increased risk for the consequences of aspiration of gastric contents.[47,48] To minimize the risk of aspiration, a rapid sequence induction is commonly performed in obese patients.

There is consensus that airway management is more difficult in the morbidly obese patients. Opinions differ, however, on the difficulty of endotracheal intubation. Wilson and coworkers regarded obesity as a weak predictor of difficult intubation.[6] Buckley et al. reported a 13% rate of difficult intubation using a rapid sequence technique in the obese patient.[48] Rocke et al. excluded obesity as a risk factor in intubation.[8] Bond et al. found no correlation between BMI and difficulty of laryngoscopy.[47] Juvin et al. compared difficulty in tracheal intubation in obese to lean patients using the IDS and patient vital signs. A Mallampati score of III to IV was the only independent risk factor for difficult intubation in obese patients. Difficult tracheal intubation was more frequent in obese (15.5%) than lean (2.2%) patients. The use of the IDS score demonstrated that tracheal intubation, not laryngoscopy, was more difficult in obese than lean patients.

Body weight may not be as critical as the location of excess weight. Massive weight in the lower abdomen and hip area may be less important than when the weight is in the upper body area. A short, thick, immobile neck caused by cervical spine fat pads will interfere with rigid laryngoscopy. Furthermore, the redundancy of soft-tissue structures inside the oropharyngeal and supralaryngeal area may also make visualization of the laryngeal structures difficult.

Mask ventilation may prove difficult in the obese patient. When high positive pressure is required to ventilate the patient, the chance of inflating the stomach is increased. Rapid oxygen desaturation during apnea, secondary to reduced functional residual capacity, limits available intubation time. In the case of a cannot intubate–cannot ventilate situation, access to the neck for transtracheal jet ventilation or establishing a surgical airway (e.g., emergency tracheostomy or cricothyroidotomy) will also be more complex.

Pregnancy

The incidence of failed intubation is predicted as 1 in 300 patients undergoing cesarean section.[4] Airway-related problems account for one-third of all anesthetic related maternal mortality.[49] During pregnancy, mucosal vascular engorgement, laryngeal edema, immobility of the floor of the mouth related to tongue engorgement, enlarged breasts, and general weight gain contribute to difficult intubation.[49–51]

Airway anatomy may become distorted during prolonged labor or toxemia, leading to edematous soft-tissue encroachment of the upper airway.[50,51] Nasal intubation in these patients should be avoided, as the mucous membranes become increasingly engorged and friable during late pregnancy. Similar to the obese patient, the obstetric patient should be considered to have a full stomach and at increased risk for gastric aspiration.

The physical changes created by pregnancy may lead to marked alteration in cardiovascular and respiratory function when the patient changes from a sitting to a supine position. Furthermore, in cases of fetal distress or maternal hemorrhage, the emergency nature of the circumstances compounds airway management problems.

Rheumatoid Arthritis

The airway management of these patients should be based on an understanding of the pathologic changes affecting the airway. In patients with advanced rheumatoid arthritis and spondylosis, airway management may be extremely difficult. Rheumatoid arthritis may involve any joint of the body, including the cervical spine, temporomandibular joint, and cricoarytenoid joint. A change in voice, the presence of dysphagia, dysarthria, stridor, or a sense of fullness in the oropharynx may indicate laryngeal involvement. A careful fiberoptic examination of the larynx and glottic structures may be informative when such signs and symptoms are present. An edematous larynx with hyperemic arytenoids and/or mucosa with swollen aryepiglottic folds and false cords may be observed. Changes in phonation may be associated with decreased mobility of the vocal cords. In the case of a narrowed glottic opening, endotracheal intubation frequently requires a smaller sized endotracheal tube. Temporomandibular joint ankylosis may prevent orotracheal intubation because of limited mouth opening.

Physical examination of the patient with rheumatoid arthritis should include flexion, extension, and rotation of the head with palpation of the larynx and trachea for evidence of deviation and/or limitation. A history of neck pain radiating to the occiput may be associated with decreased neck mobility. Upper-extremity radiculopathy suggests cervical spine arthritis. Progressive cervical spondylosis associated with rheumatoid arthritis leads to severe flexion deformity of the cervical spine, which complicates airway management.[52] Synovial destruction and vertebral erosion, along with ligamentous changes, lead to instability of the cervical spine.[53] Instability of the atlas and odontoid or of subaxial vertebral alignments may lead to subluxation of the cervical spine and cord compression. Cervical spine flexion and extension radiographs may be required for evaluation of instability and potential spinal cord compression. While chin lift and jaw thrust are commonly used to improve mask ven-

tilation and oxygenation, these maneuvers may increase the possibility of spinal cord compression and damage.[54] If a head and neck stabilizing device is used by the patient, it generally should be left in place to prevent unintended movement of the cervical spine.[55] Chest wall distortion in patients with rheumatoid arthritis may produce a major decrease in total lung volume and vital capacity. Pulmonary function tests may be helpful in determining a patient's ventilatory status in some cases.

Congenital Disease

Anomalies of the cardiovascular, nervous, musculocutaneous, or excretory systems may produce abnormalities of the head, neck, or upper airway. Rosenberg and Rosenberg have tabulated the syndromes most often accompanied by aberrations of the upper airway.[41] These include Crouzon, Goldenhar, Pierre Robin, and Treacher Collins syndromes, which are known for their grossly abnormal head and neck anatomy. Patients with congenital malformations associated with micrognathia, retrognathia, and macroglossia have a smaller oropharyngeal cross section and are prone to soft-tissue upper-airway obstruction.[56,57] Children with craniocarpotarsal dysplasia have severe microstomia that becomes more inadequate as they grow older and develop teeth. These children often require repeated anesthetics for correction of their musculoskeletal and soft-tissue deformities and can pose a significant problem for the anesthesiologist.

The most significant vascular malformations related to airway compromise are vascular rings, usually of aortic arch origin, encircling the trachea. Tracheomalacia, congenital tracheal stenosis, shortened trachea, and bronchogenic cysts can contribute to difficult airway management (Fig. 8–4).[58] Wells et al. reported that a significant percentage of infants with congenital malformation syndromes associated with cardiovascular anomalies and skeletal dysplasia have a shortened trachea.[59] These infants may benefit from fiberoptic evaluation of endotracheal tube position to avoid unrecognized bronchial intubation.

Congenital malformation syndromes also may be associated with varying degrees of acute, progressive, or chronic airway obstruction. Congenital tumors or cysts may invade or obstruct the airway. Preoperative assessment should include determination of the site of the tumor and the extent of obstruction or distortion of the airway.

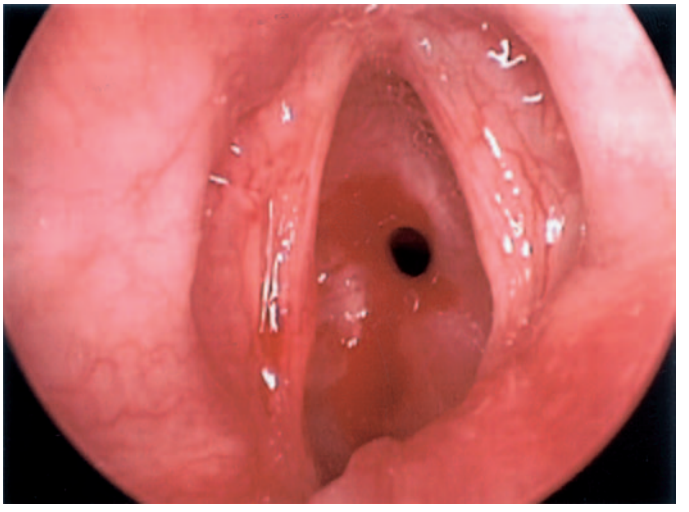

FIGURE 8–4. Tracheal stenosis. (Photo courtesy of Dr. Dana M. Thompson, Department of Otolaryngology, UC College of Medicine, Cincinnati, Ohio.)

Airway Infection

Inflammation and edema can distort the anatomy, fix the tissues, and compress the airway, interfering with ventilation and intubation.[60,61] Airway compromise by infection poses a major airway management problem in patients younger than 10 years old. Of 90 deaths resulting from upper airway obstruction in children, 36 were related to airway infections.[62] Advanced or fulminant peritonsillar or retropharyngeal abscesses and acute epiglottitis can produce rapid deterioration of the airway in young children. Evaluation of lateral neck radiographs to determine the extent of the prevertebral involvement and narrowing of the oropharynx may be beneficial in the preanesthetic examination of the patient with peritonsillar infection. Fungal epiglottitis can initially be difficult to diagnosis because of no spike in the patient's temperature (Fig. 8–5). In older children and adults, retropharyngeal or intraoral abscesses and Ludwig angina are more common.[63] Patients with advanced Ludwig angina have a greatly decreased oropharyngeal space because of edema in the floor of the mouth and tongue. They breathe with their mouths open, tongues protruded, and lean forward in a sitting position. Inflammation of the pharyngeal soft tissue may severely reduce oropharyngeal patency and interfere with rigid laryngoscopy.

Trauma

Trauma to the head and neck may produce major acute or chronic anatomic changes. These changes may affect airway accessibility, making

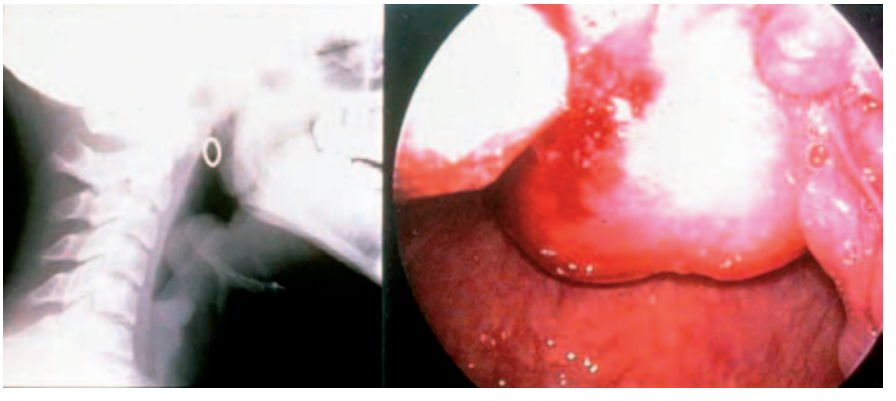

FIGURE 8–5. **Left:** Epiglottis lateral radiograph. **Right:** Afebrile fungal epiglottitis. (Photo courtesy of Dr. Dana M. Thompson, Department of Otolaryngology, UC College of Medicine, Cincinnati, Ohio.)

tracheal intubation or mask ventilation difficult. Blunt or penetrating trauma to the larynx, trachea, hyoid structure, and facial bones can result in a complex, difficult-to-manage airway.[64,65] Subcutaneous emphysema, hoarseness, stridor, and tracheal deviation are warning signs of airway injury. Such patients should be observed closely as progression of the condition may lead to airway obstruction. With direct trauma, the larynx may be crushed, the cricoid or other tracheal cartilages may be fractured, and the larynx or trachea may be severed. Tracheostomy below the injury site often is required.

The trauma patient should be examined for cervical spine injuries, because movement of the neck during intubation may lead to irreversible paralysis. Maintaining cervical collar placement or applying axial traction may minimize spinal cord injury during intubation.[66] Mouth opening may be limited in the patient with facial trauma. Improvement in the ability to open the patient's mouth after induction of anesthesia and paralysis cannot be guaranteed.

Blunt cervical trauma or internal jugular vein cannulation resulting in a retropharyngeal hematoma may produce tracheal compression and airway obstruction. Symptoms include neck pain, dysphagia, dyspnea, and hoarseness. Clinical signs include superior mediastinal obstruction and bruising on the neck appearing within 48 hours and spreading to the chest wall. Diagnosis is aided by a lateral radiograph of the neck to determine if there is a widening of the prevertebral space.[67] Although most retropharyngeal hematomas occur within hours of the precipitating incident, airway obstruction has been reported 2–5 days from onset of initial symptoms.[68]

Tissue destruction and scarring caused by surgery, chemotherapy, or radiotherapy may result in severe limitation of neck mobility and mouth opening, which limits direct rigid laryngoscopy. Airway management may be seriously impaired by tracheal scarring, webs, or granulomas related to previous intubation, tracheostomy, or airway surgery.

Tumors

Mouth opening and proper positioning of the head and neck for rigid laryngoscopy can be limited by tumors, surgical scars, or radiation fibrosis of head and neck tissues (Table 8–3).[2,53] Supraepiglottic masses may severely limit mobility of the epiglottis and cause complete airway obstruction after induction of anesthesia. Routine maneuvers, such as jaw thrust and head positioning, may not resolve the situation, because the supraglottic mass can prevent displacement of the epiglottis away from the posterior pharyngeal wall.[69,70]

The presence of cancerous goiters is also a concern. Difficult tracheal intubation was reported in 17 (5.3%) of 320 patients undergoing thyroidectomy.[71] Multivariate analysis suggested that the presence of a cancerous goiter and Cormack and Lehane grade III or IV laryngoscopic view were independently associated with difficult intubation. Large goiters were not specifically associated with increased difficulty with intubation.

Radiologic studies are indicated in the presence of trauma or tumors in or near the airway.[72] Lateral cervical spine films, computed tomography

TABLE 8–3.

Physical Findings That Suggest Difficut Airway Management

Finding	Implication
Obesity	Easily obstructed airway, aspiration risk, diminished chest wall compliance, difficult laryngoscopy because of macroglossia and immobile head
Pregnancy	All the problems associated with obesity, especially aspiration risk; large breasts impair laryngoscope insertion; swollen mucosa bleed easily
Ascites	Aspiration risk, diminished chest wall compliance
Whiskers, flat nasal bridge, large face	Difficult mask seal
Mouth opens less than 40 mm	Glottic exposure blocked by maxillary teeth
Cervicooccipital extension limited to an angle at the hyoid less that 160°	Difficult to align mouth and pharynx for glottic exposure
Short, thick, muscular neck	Prone to soft tissue obstruction, difficult to extend neck for intubation or mask ventilation
Thyromental distance less than 60 mm, receding chin	Difficult to mobilize tongue for glottic exposure, glottis too anterior to visualize
Maxillary gap from missing incisors with other teeth present to the right	Laryngoscope fits into gap while adjacent teeth, lip, or gums block view of glottis and passage of tracheal tube
Edentulous with atrophic mandible	Small face and furrowed cheeks impair mask fit, tongue and soft palate block exhalation
Prominent or protruding maxillary incisors	Teeth block view of glottis
Advanced caries, loose teeth, caps, bridges	Dentition can be damaged or aspirated, rough edges can tear tube cuff
Stridor, retractions	Risk or insurmountable airway obstruction
Hoarseness	Chance of vocal cord dysfunction or airway masses
"Underwater" voice	Vallecular or epiglottic cysts
Nasogastric tube in situ	Difficult to seal mask
Poorly visualized soft palate and fauces in upright patient with mouth fully open (Mallampati sign)	Difficult to expose glottis with rigid laryngoscopy
Large goiter or immobile tumor displacing trachea	Difficult to expose glottis, airway obstruction, or tracheal collapse
Tracheostomy scar	Possible tracheal stenosis

(CT), or magnetic resonance imaging (MRI) may be used to assess the degree of airway compression and the involvement of associated structures. Topical anesthesia, sedation, and fiberoptic laryngoscopy may prove beneficial in airway inspection.[55]

Airway Stents

Patients with malignant and benign tracheal and endobronchial disorders such as Wegner disease and relapsing polychondritis may receive rigid Teflon or silastic airway stents to treat airway malacia and stenosis (Figs. 8–6 and 8–7).[73,74] Conditions treated by stent placement include tracheomalacia, posttracheostomy stricture/rupture, postpneumonectomy bronchopleural fistula, stricture related to lobectomy, tuberculosis, traumatic injury, or compression secondary to achalasia, multinodular goiter, aortic aneurysm, and brachiocephalic artery aneurysm. Preoperative evaluation requires communication with the otolaryngologist to verify the underlying diagnosis, position of the stent, and the best method of airway management. Presence of a stent may complicate or prevent traditional endotracheal intubation. Laryngeal mask airways, however, can often be used to manage the airways of such patients.

Intrathoracic Lesions

Intrathoracic lesions can compromise airway integrity through compression of the tracheobronchial tree or by invasion of the trachea or bronchi. Mediastinal lesions leading to life-threatening airway obstructions may be found in neonates, infants, children, or adults.[61,75–78] Congenital tumors or tumors arising in early infancy include hemangiomas, lymphangiomas, cystic hygromas, teratomas, dermoids, rhabdomyosarcomas, neurofibromas, neuromas, and thymic hyperplasia. Adults with mediastinal masses, commonly lymphomas and thymic tumors, appear to be less at risk for perioperative complications than are children.[79,80]

By nature of their anatomical location, these lesions may produce compression of the heart, compression of the large vessels, primarily the vena cava, and compression of the trachea and main bronchi. Anterior mediastinal tumors that are undiagnosed or underestimated as to degree of airway obstruction may completely block the airway on induction of anesthesia and induced muscle relaxation.[76,81] Evaluation focuses on an estimate of the presence and degree of obstruction of the tracheobronchial tree and the possibility of avoiding general anesthesia if possible.

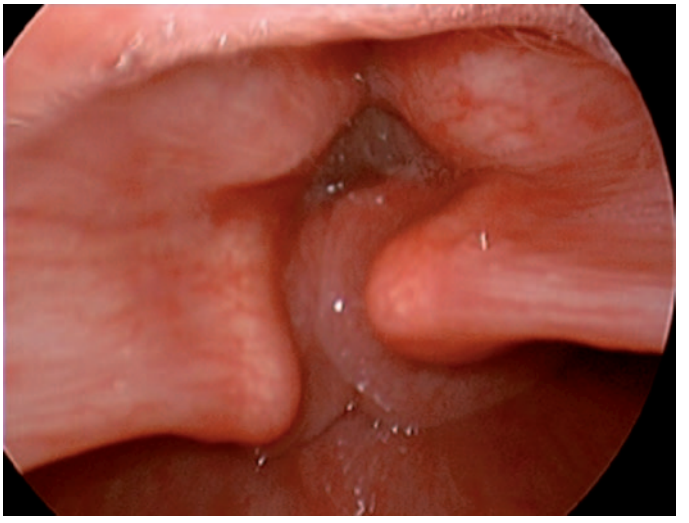

FIGURE 8–6. Relapsing polychondritis. (Photo courtesy of Dr. Dana M. Thompson, Department of Otolaryngology, UC College of Medicine, Cincinnati, Ohio.)

Evaluation to assess the patency of the airway at the tracheal and the bronchial level is necessary to formulate an anesthetic plan. By history, symptoms of airway obstruction including dyspnea at rest, on exertion, and in different positions require additional workup. The presence of stridor, wheezing, rhonchi, and diminished breath sounds should be reviewed with the patient in different positions. Careful analysis of chest radiographs, CT, and MRI studies may prove essential for planning airway control in the patient with a mediastinal mass. Chest radiographs in the posteroanterior position allow measurement of the tracheal diameter at the level of the clav-

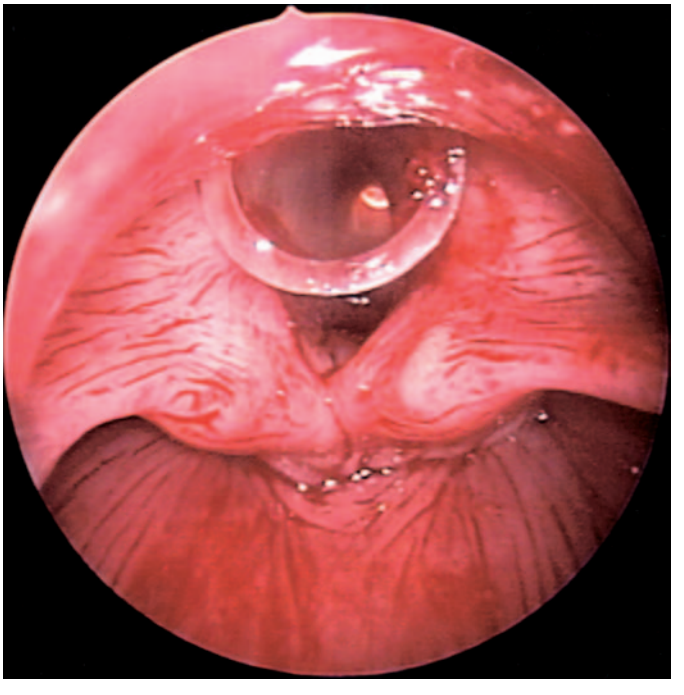

FIGURE 8–7. Suprastomal stent for management of tracheal compromise caused by subglottic and glottic stenosis. (Photo courtesy of Dr. Dana M. Thompson, Department of Otolaryngology, UC College of Medicine, Cincinnati, Ohio.)

icles.[82] A lateral chest view shows the degree of compression of the trachea in an anteroposterior position. A CT scan of the chest permits accurate measurements of airway diameters and indicates the exact level and extent of compression of the tracheobronchial tree.

Pericardial effusion on preoperative CT scan was the only variable associated with intraoperative complications in a review of 98 patients with mediastinal mass.[79] In this population, postoperative respiratory complications were related to tracheal compression of greater than 50% on a preoperative CT scan and a finding of mixed restrictive and obstruction disease on pulmonary function testing. A review of 29 pediatric patients with mediastinal masses who were undergoing general anesthesia concluded that CT evidence of superior vena compression along with symptoms and signs of superior vena cava syndrome (SVCS) were associated with potential development of life-threatening situations.[80] In this review, SVCS was the only nonrespiratory sign or symptom that was associated with increased anesthetic risk. All 4 children with SVCS developed acute airway compromise with general anesthesia.

Pulmonary flow volume loop studies performed in the upright and supine positions may sometimes assist in defining the severity of position-related airway compromise. Maximal inspiratory and expiratory flow volume curves may help to quantify the degree of impairment and differentiate extrathoracic from intrathoracic obstruction.[61,76] In an evaluation of 37 patients with anterior mediastinal masses by Hnatiuk et al., however, the incidence of perioperative surgical complications was found to be low. The results of upright and supine spirometry did not always alter the anesthetic technique and normal spirometry results did not exclude the occurrence perioperative complications.[83] In a review of 77 mediastinal mass patients who underwent pulmonary function tests prior to general anesthesia, airway collapse did not occur in any patient.[79] This patient population included 10 cases with a peak expiratory flow rate (PEFR) that was less than 50% of the predicted rate and 6 cases with a PEFR that was 40% or less of the predicted rate. A PEFR of 40% or less of predicted, however, was associated with a more than 10-fold increase in the risk of postoperative respiratory complications.

In general, patients with mediastinal masses are considered at high risk for perioperative complications if they have cardiorespiratory signs and symptoms, tracheal compression >50%, pericardial effusion on CT scan, or combined obstructive and restrictive patterns on pulmonary function testing.[79] General anesthesia and the use of neuromuscular blocking agents may reduce lung volume, relax bronchial smooth muscle leading to greater compressibility of the airway from the overlying mass, and reduce the transmural pressure gradient across the airway that helps maintain airway diameter.[76] A conservative management strategy may be necessary in such patients as mask ventilation may not be possible. Tracheostomy may not relieve airway obstruction, because the obstruction may occur at or below the level of the carina. Some clinicians have advocated femoral vessel cannulation in high-risk patients so that cardiopulmonary bypass can immediately be initiated in a crisis.[81]

UNEXPECTED DIFFICULT AIRWAY

Both the ASA difficult airway algorithm[1] and the British Difficult Airway Society *Guidelines for Management of the Unanticipated Difficult Intubation*[84] conclude that even the experienced anesthesiologist's airway evaluation will not predict the difficult airway. In evaluation of 24 cases of unanticipated difficult airway, both personnel and system failures were noted that could have been reduced by combining several preanesthesia airway evaluation checks.[85]

In several reported cases, a supraepiglottic mass contributed to an unexpected failed intubation.[69,70] Difficult mask and LMA ventilation, combined with an inability to intubate, is common in these patients and can result in anesthetic morbidity and mortality.[69] Hyperplasia of the lingual tonsils, a lingual thyroid, and epiglottic cysts are commonly missed conditions that can contribute to failure to ventilate and/or intubate, because patients with these finding often have no obvious physical findings indicative of a problem. In clinical studies of the difficult airway, lack of information regarding the epiglottis or lingual tonsils complicates interpretation of tests used to predict the probability of difficult intubation.

RECOMMENDATIONS

A patient with a history of difficult intubation or with conditions associated with difficult airway management should be approached with organized primary and secondary plans for airway management. Often awake intubation, especially if a history of difficult mask intubation is present, is the optimal approach. Patients with physical findings suggestive of a high possibility of difficult intubation may benefit from an awake intubation or the maintenance of spontaneous ventilation during induction of anesthesia. The patient who unexpectedly presents with a difficult or failed intubation history is at most risk because the anesthesiologist may not be prepared.

The hidden cause of a difficult airway (e.g., an asymptomatic supraepiglottic cyst) may not be detectable without direct or indirect laryngoscopy. Physicians involved with airway management should be aware of the weaknesses of various tests used to predict difficult airway management and must be prepared to manage an unexpected difficult airway. The American Society of Anesthesiologists' difficult airway algorithm suggests limiting attempts at intubation to avoid trauma. It encourages changing to other techniques to establish ventilation and oxygenation. In a prospective study of 11,257 intubations, this predefined algorithm was effective in solving most problems.[86] Impossible ventilation never occurred during the 18-month study; 100 cases (0.9%) of unexpected difficult intubation were recorded. A preanesthetic diagnosis of difficult intubation remains a task of recognizing subtle signs, with a tendency for the experienced practitioner to err on the side of a conservative diagnosis because of the difficulty associated with managing an unexpected airway problem.

CHAPTER 9

Evaluation of the Patient with Pulmonary Disease

Philip G. Boysen, MD, MBA

Pulmonary disease results in ventilatory defects that can be characterized as either restrictive or obstructive in nature.[1] Restrictive ventilatory defects (RVDs), although less common and less amenable to reversal, often coexist with and complicate obstructive ventilatory defects (OVDs). Typified by chronic obstructive pulmonary disease (COPD), OVDs are a major source of morbidity and mortality.[2] Irrespective of the type of ventilatory defect, the surgical patient with preexisting pulmonary disease experiences additional risk of postoperative respiratory complications in the immediate postoperative period. Thus, preanesthetic identification and treatment of reversible ventilatory defects, most often those associated with COPD, are essential to improving outcome.[3,4] Knowledge of the typical clinical presentations of the various types of ventilatory defects allows rational development of preoperative, intraoperative, and postoperative management techniques to improve physiologic function. Familiarity with the objective tests used to define limitations of pulmonary function is essential to rational management of the surgical patient with pulmonary disease. Advances in monitoring have made possible continued sophisticated evaluation of lung function intraoperatively.[5]

PULMONARY FUNCTION TESTS

The decision regarding the need for pulmonary function tests is based on the history and physical examination of the patient with pulmonary defects. Spirometric tests are the most used and useful pulmonary function tests.[6] Spirometry helps distinguish RVDs from OVDs, and irreversible from reversible disease processes.

Simple in concept, spirometry often is difficult for the patient with chronic pulmonary disease to perform.[7] Much effort is required to meet testing standards and achieve quality results. Forced exhalation of lung gas from total lung capacity (TLC) to residual volume (RV) is measured as a function of time.[8] Graphic depiction of this maneuver reveals several measurable and derivable parameters (Fig. 9–1). They include, but are not limited to, forced vital capacity (FVC), forced expiratory volume at 1 second (FEV_1), FEV_1/FVC ratio, and midflow rate (i.e., forced expiratory flow from 25% to 75% of vital capacity [$FEF_{25–75\%}$] and forced expiratory flow at 50% of vital capacity [$FEF_{50\%}$]).[9]

An alternative way of representing the FVC maneuver is to plot the change in exhaled and inhaled gas flow in relation to attainable lung volumes.[10] By coupling an inspiratory maneuver from RV back to TLC following forced exhalation beginning at TLC to RV, a *flow–volume loop* is derived. Data similar to those obtained from spirometry are measured using flow–volume loops. They include FVC, FEV_1, peak expiratory flow rate (PEFR), $FEF_{25–75\%}$, and $FEF_{50\%}$ (Fig. 9–2). This technique is a sensitive means of detecting early chronic obstructive lung disease be-

KEY POINTS

1. Ventilatory defects can be restrictive or obstructive in nature, with mixed defects often making diagnosis problematic.
2. Patients with chronic obstructive pulmonary disease usually do not show reduction in forced vital capacity (FVC) until late in the course of the disease.
3. The hallmark of chronic airflow obstruction is a decreased ratio of forced expiratory volume in 1 second (FEV_1) to FVC.
4. Flow–volume loops can differentiate among extrathoracic, intrathoracic, and fixed obstructions.
5. Asthma and chronic bronchitis lead to changes in the bronchial lumen wall such as hypertrophy and bronchospasm.
6. Emphysema is characterized by destruction of lung parenchyma and loss of surface area for gas transfer.
7. Chronic bronchitis is characterized by proliferative hypertrophy of bronchial glands and smooth muscle.
8. In asthma, the balance between (1) cyclic adenosine monophosphate–mediated bronchial relaxation and cyclic guanosine monophosphate–mediated bronchoconstriction and (2) sympathetic nervous system–mediated bronchial relaxation and parasympathetic nervous system bronchoconstriction is affected by antigens/IgE and mediators from mast cell contents (e.g., slow-releasing substance of anaphylaxis, eosinophilic chemotactic factor-A, bradykinin, and histamine).
9. Lung volume in chronic bronchitis is near normal, except during acute exacerbation. In emphysema, usually total lung capacity is increased, with increased functional residual capacity and increased residual volume.
10. Bronchodilator therapy may improve airflow obstruction and gas exchange (e.g., β-agonists, methylxanthines, ipratropium bromide, corticosteroids, and, for patients in remission, cromolyn sodium).
11. The carbon dioxide dissociation curve is linear and the gas is readily diffusible; hence, the ability to eliminate carbon dioxide is well preserved until ventilation–perfusion abnormalities and bronchospasm are severe.
12. Physiologic changes in pulmonary function, seen particularly during abdominal and thoracic surgery, include (1) diaphragmatic dysfunction, (2) decreased forced residual capacity, (3) decreased total lung capacity, (4) decreased tidal volume, (5) increased respiratory rate, and (6) increased alveolar-to-arterial oxygen tension gradient.
13. For the patient about to undergo thoracotomy and lung resection, analysis of the total contribution of each lung to overall function or split lung function studies is necessary (e.g., ventilation–perfusion lung scanning). Predicted postoperative FEV_1 must exceed 800 mL for the patient to survive pneumonectomy.

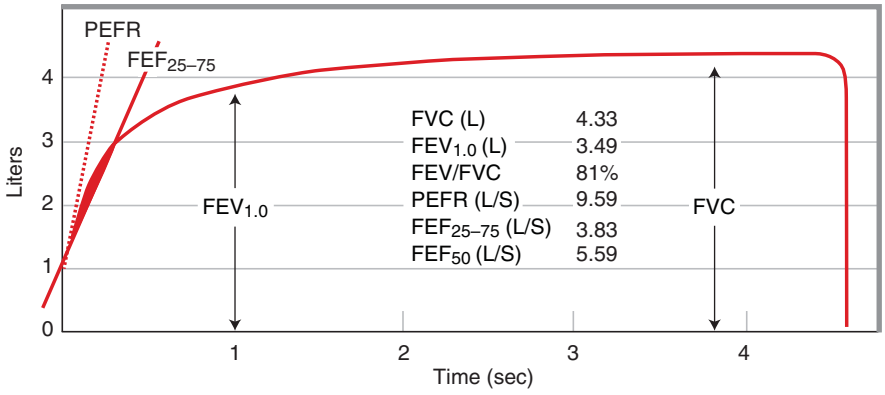

FIGURE 9–1. Spirogram plots volume versus time during a forced exhalation. Several attempts are made to achieve the best effort. The forced vital capacity (FVC), forced expiratory volume at 1 second (FEV_1), FEV/FVC ratio, peak expiratory flow rate (PEFR), forced expiratory flow between 25% and 75% of vital capacity ($FEF_{25–75\%}$), and forced expiratory flow at 50% of vital capacity ($FEF_{50\%}$) then are calculated. Spirometry is repeated after bronchodilator therapy.

cause the final decrement in flow (i.e., at low lung volume) is independent of effort, and decreased flows are evident before changes in FEV_1 or FEV_1/FVC are obvious.

An advantage of flow–volume loops over standard spirometry is their ability to differentiate the anatomic location of flow obstructions. Because both exhalation and inhalation are depicted by flow–volume loops, intrathoracic distal airway obstruction can be differentiated from extrathoracic upper airway obstruction by analyzing flow–volume loops.[11] Extrathoracic obstruction at the level of the upper airway, larynx, or trachea is of particular interest to the anesthesiologist. Abnormalities of anatomy in these regions often result in fixed but limited airflow through an obstructing lesion (Fig. 9–3). When the obstruction is extrathoracic, changes on the flow–volume loop are most obvious during inhalation. The clinical correlate is inspiratory stridor. Conversely, when the lesion is intrathoracic, exhalation is affected and the clinical correlate is wheezing. Fixed obstruction in the upper airway affects the entire loop.

Coupled with history and physical examination, data from spirometry and flow–volume loops form the basis of clinical judgments. Specific test result patterns characterize and differentiate OVDs and RVDs. Reduction of FVC with preservation of FEV_1 and FEV_1/FVC is characteristic of either extrinsic (e.g., paralyzed diaphragm, obesity, kyphoscoliosis) or intrinsic (e.g., interstitial fibrosis) RVDs. In contrast, patients with OVDs usually do not show a reduction in FVC until late in the natural history of the disease, long after reductions of FEV_1 and FEV_1/FVC ratio are present.

Evidence of reversibility is always sought with spirometric and flow–volume loop test results. Patients with surgically correctable extrathoracic or intrathoracic airway obstructions can be appropriately managed based on knowledge of flow–volume loops. Because patients with asthma and chronic bronchitis will show immediate improvement in test results after bronchodilator therapy,[12,13] documented improvement in exhaled midflow rates ($FEF_{25–75\%}$ and $FEF_{50\%}$) is valuable preanesthetic information in patients with OVDs. Thus, preanesthetic attention should be focused on patients with reversible pathology because of the benefit they derive from preoperative therapy to maximize pulmonary function.

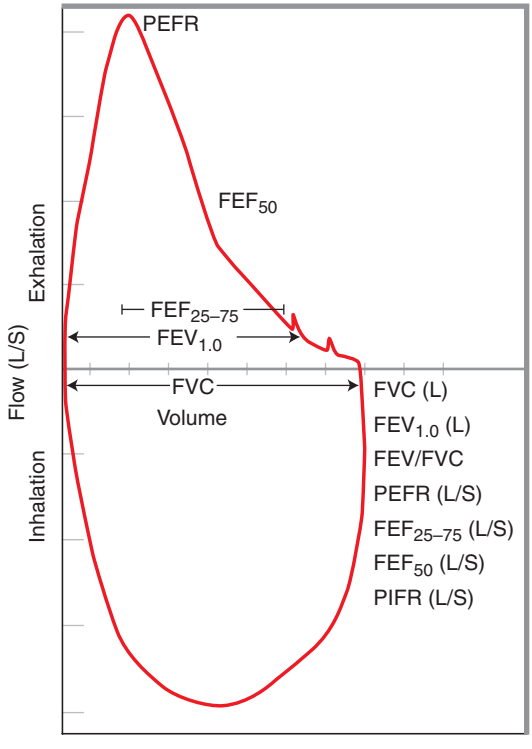

FIGURE 9–2. Same forced exhalation as shown in Fig. 9–1 represented on a flow versus volume graph. A deep inspiration closes the loop. Forced expiratory volume at 1 second (FEV_1), forced vital capacity (FVC), peak expiratory flow rate (PEFR), forced expiratory flow between 25% and 75% of vital capacity ($FEF_{25–75\%}$), and forced expiratory flow at 50% of vital capacity ($FEF_{50\%}$) also can be obtained. Note the concave shape of the last half of the exhalation curve, suggesting early airflow obstruction in small airways despite apparently normal FEV_1 and FVC.

RESTRICTIVE VENTILATORY DEFECTS

RVDs exist when ventilation is impaired by mechanical forces that restrict alveolar ventilation (Fig. 9–4). Inspiratory and expiratory resistive forces are increased. RVDs are either intrinsic or extrinsic in nature. Primary disease of alveoli and supporting tissues, constrictive diseases of the pleura and chest wall, and neural disorders that alter ventilatory mechanics constitute the spectrum of RVDs.

Patients with RVDs present with tachypnea and dyspnea, features also

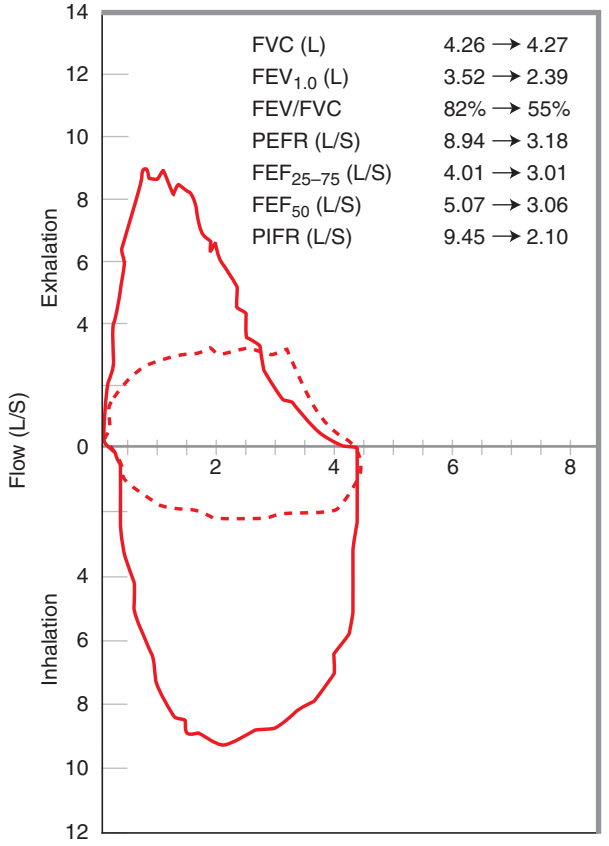

FIGURE 9–3. Normal flow–volume loop (*solid line*) superimposed on a box-shaped loop (*dashed line*) characteristic of fixed upper airway obstruction. Major limitations in peak flow and midflow are recorded.

commonly present in postoperative patients experiencing pain. The chest radiograph reveals interstitial patterns and concentric decreases in lung volumes. Arterial hypoxemia may be present at rest in severe cases and may be exacerbated by exercise. Chronic hypoxemia can result in altered pulmonary arterial pressures superimposed on any preexisting vascular involvement, placing these individuals at high risk for right heart failure over time.

Pulmonary function tests reveal parallel and proportional decreases in FVC and FEV_1 that result in near-normal or greater than normal values for FEV_1/FVC. This is in contradistinction to OVDs, in which factors that obstruct alveolar gas flow exist even when ventilatory mechanics are normal and pulmonary function tests reveal decreases in FEV_1 out of proportion to decreases in FVC. When RVDs and OVDs coexist, mixed ventilatory defects are present. These may have spirometric patterns that combine features of both types of ventilatory defects. Although isolated RVDs usually are progressive and irreversible, palliative measures (e.g., antibiotics or bronchodilator or steroid therapies) are directed at the reversible components of mixed conditions.

Intrinsic RVDs exist when alveolar membranes are thickened and present a barrier to gas diffusion (e.g., in patients with pneumonia, bronchiolitis obliterans, pulmonary alveolar proteinosis, or pulmonary fibrosis). Extrinsic RVDs exist when alveolar volume is reduced because of either specific mass compression of alveoli (e.g., blood, effusion, tumor) or generalized reduction of thoracic compliance with secondary diminution of ventilated alveoli (e.g., scoliosis, muscular dystrophy, neuromuscular diseases, obesity). Sarcoidosis initially is restrictive in nature but can develop obstructive characteristics. Adult respiratory distress syndrome is an example of a potentially reversible RVD that has a 50% mortality rate. It often presents in the perioperative period in patients with a history of severe trauma, sepsis, pancreatitis, or failure of multiple organ systems.[14]

RVDs are important for two reasons. First, they present a diagnostic and management challenge, especially with coexisting OVDs. Second, they serve as a model for the reversible restrictive changes that follow anesthesia and surgery, especially intrathoracic and upper abdominal surgery. Pain, residual neuromuscular blockade, thoracic or abdominal wound dressings, and neuromuscular dysfunction of the diaphragm and chest wall can result in RVDs that are a source of significant postoperative respiratory complications if not adequately treated but are reversible if adequately and systematically treated. It is this second point that must be emphasized with respect to either RVDs or OVDs: anesthesia and surgery superimpose mechanical restrictions upon preexisting ventilatory defects that are largely restrictive in nature. Acute restrictive ventilatory physiology is observed during laparoscopic procedures with gas insufflation of the abdomen.

OBSTRUCTIVE VENTILATORY DEFECTS

OVDs are pathologic conditions in which increased airflow resistance results from airflow obstruction during the respiratory cycle. OVDs are either acute or chronic. Whether acute or chronic, airflow obstruction is intraluminal, extraluminal, or mixed. Because OVDs are more common than RVDs and are more amenable to reversal than are RVDs, a more detailed discussion of their pathology is warranted.

OVDs include obstructing airway tumors, foreign bodies, anatomic problems such as vocal cord paralysis or tracheobronchomalacia, and the COPDs of emphysema, chronic bronchitis, and asthma. Among OVDs, entities included under the rubric of COPD are the most common. Although distinct patterns exist, acute and chronic OVDs all are characterized by airflow resistance during exhalation caused by decreased airway diameters. These may be caused by glottic or subglottic obstructing airway masses, accumulation of inadequately cleared mucus secretions, local inflammation, smooth muscle hypertrophy, and bronchiolar and alveolar structural weaknesses. The patient with COPD, unlike the patient with upper airway or pharyngeal level obstruction, usually has no problem

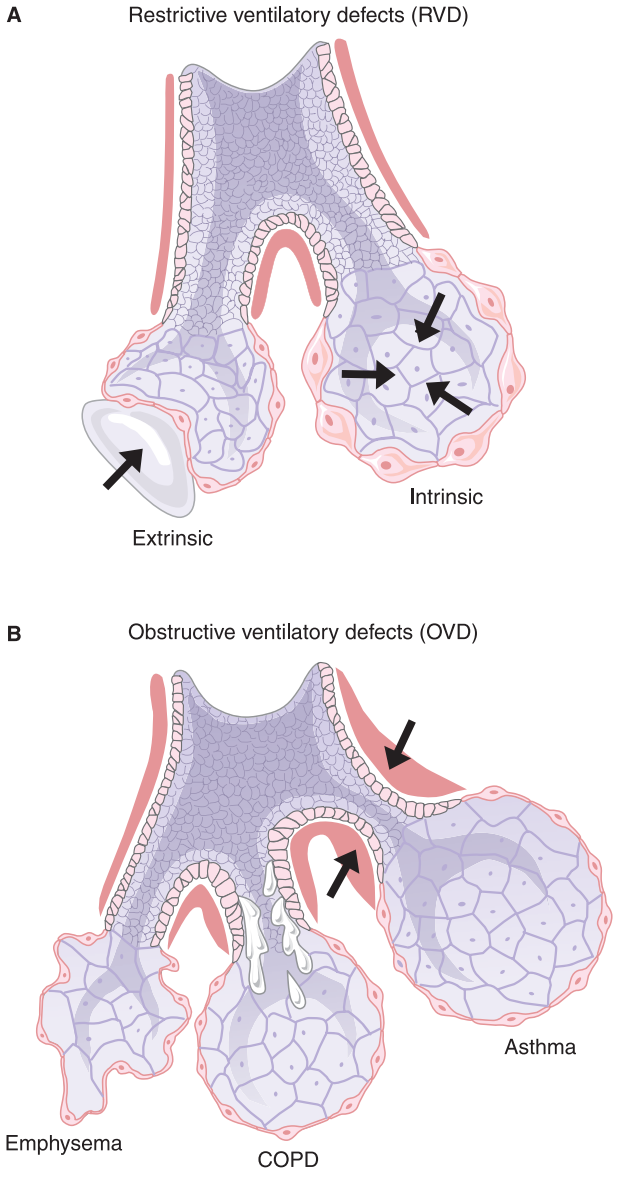

FIGURE 9–4. **A.** Restrictive ventilatory defects (RVD). **B.** Obstructive ventilatory defects (OVD).

during inspiration. Inspiratory resistive forces do not contribute to additional respiratory work during ventilation. Expiratory resistive forces, however, are significant because of air trapping behind obstructed small airways. Pulmonary function test results for COPD are discussed in Pulmonary Function and Chronic Obstructive Pulmonary Disease below.

CHRONIC OBSTRUCTIVE PULMONARY DISEASES

As a category of OVD, COPD includes emphysema, chronic bronchitis, and chronic asthma.[15] Each of these pathophysiologic states is accompanied by typical clinical presentation, history, physical examination, and changes in pulmonary function test results. Although asthma is characterized by episodic alteration of bronchial smooth muscle tone with normal pulmonary function and a complete absence of symptoms during remission, it is best considered a chronic disorder. Asthma patients usually function in a compromised state because of increased smooth muscle tone and experience symptomatic exacerbations that cause acute worsening of their pulmonary function test results. Because these patients are at increased risk when anesthetized for surgical procedures, they are included under the classification of COPD.

COPD is marked by intraluminal and extraluminal airflow obstruction resulting in air trapping. Intraluminal small airway changes may be caused by altered ciliary function, increased mucus production by goblet cells, and ineffective clearance of secretions from the airway. Aspiration of liquid contents from the pharynx or stomach and chronic inflammatory conditions also may increase airway secretions. Specific airway wall changes include hypertrophy and hyperreactivity of bronchial smooth muscle, conditions especially evident in patients with asthma and chronic bronchitis. Also, edema and inflammation of the airway walls decrease lumen diameters and cause airflow obstruction during exhalation.

Extraluminal airway changes associated with airflow obstruction include loss of lung parenchyma and concomitant structural support, external compression of the airway by lymph nodes or tumors, and peribronchial and perivascular edema impinging on the airway wall. Any of these changes, alone or in combination, may be present in patients with COPD.

Specific examples of COPD include emphysema, chronic bronchitis and asthma.

Emphysema

Emphysema often is referred to as type A COPD.[16] Although many patients present with symptoms that indicate a diagnosis of pure emphysema, some show a clinical and physiologic picture consistent with chronic bronchitis, and some show a mixed clinical picture.

Emphysema is characterized by destruction of lung parenchyma and loss of effective surface area for gas exchange caused by loss of radial traction within the thin, filamentous alveoli where gas exchange occurs. Descriptively referred to as *pink puffers* because of their acyanotic appearance and tendency to exhale through pursed lips to provide end-expiratory pressure, patients with emphysema can have relatively advanced disease with preservation of arterial oxygen tension. In addition, they usually do not retain carbon dioxide, so increases in alveolar and arterial carbon dioxide tensions usually are not evident in blood gas analyses until very late in the disease course.

Spirometry in emphysematous patients is characterized by a decrease in FEV_1/FVC, the hallmark of chronic air flow obstruction, and diminished air-

flow at all lung volumes.[16] Because of the tendency toward hyperinflation and gas trapping, an increase in the ratio of RV to TLC may be evident and reflected in specific changes in the chest radiograph.[17] These changes include low, flat diaphragms and extremely hyperlucent lung fields, consistent with both gas trapping and the loss of lung parenchyma. Because of these changes, the heart usually appears small on the chest radiograph, and evidence of decreased pulmonary vasculature with destruction of alveolar septae is seen.

Most patients with emphysema do not suffer repeated episodes of respiratory failure, have scant or insignificant sputum production, and tend not to manifest signs of right heart failure and cor pulmonale.

Chronic Bronchitis

Chronic bronchitis sometimes is referred to as type B COPD. It is characterized by anatomic changes that include proliferation and hypertrophy of the bronchial goblet cells and hyperreactivity of the bronchial smooth musculature. Because of changes in goblet cell structure and function, mucus secretion is increased. Copious secretions tend to inspissate and occlude the airways. A chronic, usually productive, cough is characteristic. Secretions often are purulent because of gram-positive and gram-negative bacteria colonization.

Unlike emphysematous patients, patients with chronic bronchitis have marked tendency toward decreased arterial oxygen tension and desaturation early in their disease course. In addition, alveolar and arterial carbon dioxide tensions tend to be increased, so hypoxia and hypercapnia are characteristic of chronic bronchitis. Because of arterial oxygen desaturation and cardiopulmonary dysfunction, patients may appear cyanotic, plethoric, and bloated, giving rise to the descriptive term *blue bloaters,* in contradistinction to the emphysematous *pink puffers.*

As in emphysema, resting pulmonary function is characterized by a decrease in FEV_1/FVC. Nonetheless, lung volumes usually are near-normal unless there is an exacerbation of infection and bronchospasm, in which case there is a tendency toward hyperinflation and gas trapping.[16] Both of these changes are observable on the chest radiograph and with measurement of lung volumes. Successful treatment of acute episodes usually results in return to baseline lung volumes.

The course of chronic bronchitis is characterized by multiple episodes of respiratory compromise or overt failure. Acute and episodic bronchospasm, increased mucus secretions, and a purulent productive cough accompanied by fever herald an exacerbation of disease.[18] During these episodes, hypoxia and hypercapnia may worsen. Acutely ill patients usually do not do well if tracheal intubation and mechanical ventilation are necessary. For this reason, therapy concentrates on pharmacologic management and low-flow oxygen therapy to preserve oxygen delivery during an acute episode.

These patients often have increased pulmonary vascular resistance, most likely caused by the changes in arterial oxygen saturation. As the disease progresses, right-sided work of the heart increases, predisposing patients to right-heart failure and cor pulmonale. This is manifested by increased hepatojugular reflux and peripheral edema.

Asthma

Asthma, which is common in young patients, is characterized by long periods of remission punctuated by exacerbations.[19] During remission, the patient usually is asymptomatic with measured pulmonary function data that are normal or near normal. During exacerbations, when airflow obstruction and bronchial smooth muscle constriction occur, changes in FEV_1/FVC are noted. Secretions may increase and occlude the airway, further compromising exhaled gas flow.[20] These secretions often are thick and tenacious, but sterile. When they occlude the airway the secretions are referred to as *Curschmann spirals.* Examination of these secretions may reveal hypereosinophilia, a finding consistent with the observation that an allergic process can either initiate or complicate episodes of asthmatic airflow obstruction.

The mechanisms for changes in the airway and in bronchial smooth muscle function are not fully elucidated. A series of intracellular events modulate smooth muscle function through the production of cyclic adenosine monophosphate (cAMP) or cyclic guanosine monophosphate (cGMP). These two compounds have opposite effects, such that an increase in cAMP results in relaxation of bronchial smooth muscle, whereas an increase in cGMP results in constriction of bronchial smooth muscle. This balance is further modulated by reaction to specific antigens, which is initiated when immunoglobulin E (IgE) is released in the presence of antigenemia and fixes itself to plasma cells in the bronchial smooth muscle in the wall of the airway. Once this occurs, mediators are released from granules in the mast cell. Some of these mediators include histamine, slow-releasing substance of anaphylaxis (SRSA), eosinophilic chemotactic factor-A (ECF-A), and bradykinins. All of these compounds increase the tone of bronchial smooth muscle and cause local edema, thereby causing airway obstruction and bronchospasm.

The autonomic nervous system also plays a role in control of bronchial smooth muscle tone. A balance between the sympathetic and parasympathetic nervous systems results in differential alteration of the caliber of the airways: stimulation of the sympathetic nervous system causes bronchial relaxation or bronchodilation, whereas parasympathetic stimulation causes bronchoconstriction or increased bronchomotor tone. The latter mechanism is particularly instrumental in patients who tend to have bronchospasm triggered by emotional stress, nonallergic irritants, inhalation of cold air, or exercise. For this reason, a therapeutic approach has been advised that includes stimulation of the sympathetic nervous system using sympathomimetic agents and/or blockade of the parasympathetic nervous system using parasympatholytic drugs.

Because activation of the parasympathetic system tends to be vagally mediated, parasympatholysis should be used in the patient about to undergo general anesthesia with an endotracheal tube because manipulation and intubation of the upper airway may cause bronchospasm. In addition to bronchodilation therapy, administration of systemic corticosteroids often is indicated. Use of corticosteroid therapy has been shown not to interfere with wound healing or to increase the incidence of postoperative infections.[21]

PULMONARY FUNCTION AND COPD

Early in the course of emphysema or chronic bronchitis, FVC usually is nor-

mal. Nonetheless, both conditions are diagnosed by history, physical examination, and a measurable decrease in FEV_1/FVC, as noted previously. Because of airflow obstruction, the maximal voluntary ventilation also decreases.

Lung volume measurements are near normal in the patient with chronic bronchitis unless measurements are taken during an acute exacerbation of the disease.[22] In the emphysematous patient, TLC usually is increased, but functional residual capacity (FRC) and RV are markedly increased. Thus, RV/TLC or FRC/TLC, which are evidence of hyperinflation and increased gas trapping, are useful measures of disease status in emphysema.

The diffusing capacity for carbon monoxide usually is normal or near normal for the patient with chronic bronchitis[18,23] because the anatomic changes occur in bronchial smooth muscle and not in lung parenchyma.[4] Nevertheless, because the emphysematous patient has loss of effective surface area for gas exchange, a decrease in diffusing capacity for carbon monoxide is present.

When either disease is progressive, additional changes may mimic the other condition. For example, the patient with chronic bronchitis may manifest changes in lung volumes and diffusing capacity similar to those in the patient with emphysema. Conversely, the severely affected emphysematous patient may become so compromised and hyperinflated that his or her vital capacity is restricted because of lung volume changes. When this occurs, marked prolongation of FEV_1 and a decrease in FVC are consistent with the severe hyperinflation associated with marked COPD.

The patient with asthma also tends to have specific pulmonary function abnormalities, especially during exacerbations. In addition to the decrease in FEV_1/FVC, airflow decreases throughout the range of vital capacity. Tests used to describe these changes include the maximal midexpiratory flow rate (MMEFR), maximal midflow rate (MMFR), and $FEF_{50\%}$. In addition, during acute attacks of bronchospasm, RV/TLC and FRC/TLC may increase.[24]

The diffusing capacity of lung for carbon monoxide (DLCO) may be abnormal and varies depending on how it is measured. Many investigators have suggested correcting the DLCO for the lung for the inhaled gas volume when the single-breath measurement technique is used.[25] This measurement, the ratio of diffusing capacity for the lung (DL), divided by the alveolar gas volume (VA) is designated as the DL/VA.[26] This measurement usually is normal, especially during disease remission.

The patient with asthma may have a significant response to bronchodilators when spirometry is repeated. In the untreated asthmatic patient. administration of a nebulized bronchodilator (e.g., isoproterenol or other β-agonist) has been suggested to result in an improvement in airflow and, if the obstruction relieved is severe enough, an increase in the vital capacity. The degree of improvement in airflow is debatable, but in general a 20–25% increase in either FEV_1 or FVC is considered a significant response to the bronchodilator, consistent with a diagnosis of asthma.

Like the patient with asthma, the patient with chronic bronchitis tends to respond immediately to a nebulized bronchodilator. In this case, anatomic changes in the airway but also some degree of bronchospasm may occur. However, rarely does the patient with chronic bronchitis manifest a 25% improvement in spirometric function. A change in the range from 5–10% is consistent with the clinical diagnosis of chronic bronchitis.[12]

It should be reemphasized that spirometric testing is useful only in demonstrating physiologic abnormalities or the degree of impairment. As an example, a patient with chronic bronchitis is diagnosed by history and physical examination. If this patient produces sputum 2 months out of the year for 2 years in a row and has the stigmata and history of wheezing, cyanosis, and so on, the diagnosis is confirmed.[16]

The patient's response to bronchodilators has been used as a technique to determine who may benefit from a preoperative regimen of bronchopulmonary toilet that usually includes bronchodilators. This response, when seen in a patient with a consistent history and physical examination, indicates the need for preoperative therapy. Both the intraoperative and postoperative courses improve with pharmacologically sustained improvement in airflows. It is becoming more apparent that such treatment not only can decrease morbidity but also mortality, particularly after upper abdominal surgery.

GAS EXCHANGE ABNORMALITIES

Gas exchange abnormalities occur whenever pulmonary mechanics change. Bronchospasm, in particular, affects pulmonary mechanics, with dramatic effects on gas flow and blood distribution. The end result of bronchospasm is mismatching of ventilation and perfusion. During bronchospasm, blood flow patterns change to maintain matching between regions of ventilation and perfusion. Although compensatory to some degree, the resulting low ventilation-perfusion ($\dot{V}/\dot{Q}$) state characteristic of chronic bronchitis and acute asthma results in arterial oxygen desaturation and hypoxemia.

These abnormalities have been elegantly demonstrated in studies using six gas techniques to demonstrate regions of low $\dot{V}/\dot{Q}$ and their improvement following administration of bronchodilators. Bronchodilator therapy not only improves airflow obstruction and lung mechanics but also gas exchange and related perfusion abnormalities. Indeed, a transient decrease in arterial oxygen saturation is sometimes noted after administration of a bronchodilator. This presumably is caused by an effect on vascular smooth muscle that is more immediate than the subsequent effect on bronchial smooth muscle that results in airway dilation and improved gas exchange. The fall in the arterial oxygen tension usually is transient, not clinically significant, and followed by an immediate rise as bronchial smooth muscle tone decreases. Bronchial provocation tests also have been used to demonstrate the dynamic nature of $\dot{V}/\dot{Q}$ matching.[27,28]

In most patients with acute bronchospasm, carbon dioxide elimination is normal, but hypoxemia may be severe. Unlike the oxyhemoglobin dissociation curve, the carbon dioxide dissociation curve is linear, a reflection of carbon dioxide's higher diffusibility compared with oxygen. As a result, carbon dioxide elimination is relatively well preserved until $\dot{V}/\dot{Q}$ abnormalities and bronchospasm are severe. When arterial carbon dioxide tension begins to rise, however, the acutely ill asthmatic patient has reached the point of impending respiratory failure.

Chronic carbon dioxide retention, as seen in the patient with chronic bronchitis, usually is observed as the dis-

ease progresses and occurs so slowly that a compensated respiratory acidosis is noted on arterial blood gas analysis. The reason for this rise in carbon dioxide tension is not well defined but probably is caused by the increased work of breathing that occurs late in the course of the disease.[29] At some point, the ability to maintain normal carbon dioxide tension apparently is overwhelmed by a significant increase in respiratory muscle work such that a new baseline must be established, and a new steady state then evolves.

BRONCHODILATOR THERAPY

Bronchodilator therapy is efficacious in patients with bronchospasm and increased intraluminal secretions. The sympathetic and parasympathetic nervous systems regulate bronchomotor tone, and humoral factors and inflammation play a role in airway obstruction. Thus, therapeutic approaches using sympathomimetic and parasympatholytic agents continue to evolve alongside approaches that prevent mediator release or decrease inflammation. Combined therapy with drugs that influence each component also can help achieve the desired therapeutic results.

The primary sympathomimetic therapeutic strategy is to stimulate intracellular cAMP production. Therapy usually starts with an inhaled β_2-agonist bronchodilator. These sympathomimetic agents are designed to act at β_2-receptor sites that modulate changes in smooth muscle tone. Drugs that are relatively free of α_1 and β_1 side effects, such as tachycardia and increased blood pressure, are particularly useful. Albuterol, metaproterenol, and orciprenaline are the sympathomimetic agents of choice.

The second sympathomimetic approach is to increase availability of cAMP by administration of methylxanthines. This therapeutic effect is mediated by inhibition of the phosphodiesterase enzyme that breaks down cAMP. Whereas other sympathomimetics are delivered by a metered-dose aerosol inhaler, methylxanthines are given either intravenously or orally. Aminophylline (85% theophylline) is the agent of choice.

Together or alone, β-agonists (by stimulating cAMP production) and methylxanthines (by inhibiting cAMP breakdown) achieve the same effect.

Parasympatholytic drugs, such as atropine and its analogues, help alleviate bronchospasm by blocking the effects of acetylcholine on bronchial smooth muscles. In an attempt to avoid atropine's often troublesome side effects, the atropine analogue ipratropium bromide has been introduced as an adjunct to bronchodilator therapy. Like β-agonists, it is given by metered-dose inhaler. To date it appears remarkably free of adverse side effects. Once adequate sympathomimetic and parasympatholytic therapy is achieved, cardioselective β-blocker therapy can be administered safely if indicated.[30]

Cromolyn sodium and corticosteroids are useful in preventing bronchospasm in the asthmatic patient in remission, but they are of limited use during acute episodes. Cromolyn sodium stabilizes mast cell granules and prevents release of mediators, but it has no role in treatment of acute bronchospasm. Inhaled corticosteroids are relatively nonabsorbable, whereas oral and parenteral steroids have a wide variety of effects, including suppression of inflammation. These drugs can be used during the consolidation therapy phase of acute asthma and for long-term therapy for severe COPD. Beclomethasone dipropionate and triamcinolone acetonide are examples of these drugs.

When devising an anesthetic plan for the patient with asthma or chronic bronchitis, it is important to consider that although volatile anesthetics alter upper airway function and reflexes to varying degrees,[31] all volatile agents are bronchodilators.[32]

PREOPERATIVE EVALUATION

A thorough history and physical examination, including assessment of functional capability at rest and with activity, serve as the basis for obtaining further diagnostic tests as part of the preoperative evaluation.[33] The type of surgical procedure the patient is to undergo also is considered before preoperative tests are ordered.

If a patient is suspected of having compromised pulmonary function, it is reasonable and cost effective to measure baseline spirometry—both before and after administration of a nebulized bronchodilator—and maximal voluntary ventilation. Arterial blood gas analysis provides a baseline assessment of gas exchange and identifies the patient who is chronically hypoxemic or hypercapnic.

Additional studies, such as measurement of lung volumes and diffusing capacity, further define abnormal physiology and are helpful for the patient being assessed for thoracotomy.[34,35]

For the patient about to undergo an abdominal surgical procedure, no evidence indicates that additional testing is helpful. Also controversial is whether to extend testing to patients who are elderly or obese or who smoke. Tisi[36] recommends an approach to preoperative pulmonary function testing (Box 9–1). The predictive value of various pulmonary function tests was extensively reviewed by Zibrak et al.[37]

It is important to recognize the physiologic abnormalities that are superimposed on baseline pulmonary function in the immediate postoperative period, particularly after abdominal or thoracic surgery.[38] Because of a combination of factors, including pain-related splinting and non–pain-related abnormal diaphragmatic function,[39,40] there is a loss of lung volume (FRC and TLC), an increase in respiratory rate, a decrease in tidal volume, and a widening of the alveolar-to-arterial oxygen tension gradient in the postsurgical patient. The latter change is caused by the fall in lung volume (often referred to as *microatelectasis*) and manifests as right-to-left shunting in the lung.

In essence, the abnormalities in pulmonary function are characteristic of a transient, superimposed, restrictive physiologic process that is most evident on the first postoperative day (Fig. 9–5). Recovery of 80% of preoperative function usually is evident by the third

BOX 9–1.

Candidates for Preoperative Evaluation of Pulmonary Function

- Patients having thoracic surgery
- Patients having upper abdominal surgery
- Patients with history of heavy smoking and cough
- Obese patients
- Elderly patients (age >70 years)
- Patients with documented pulmonary disease

Data from Tisi GN. Pulmonary physiology in clinical medicine. Baltimore: Williams & Wilkins, 1980.

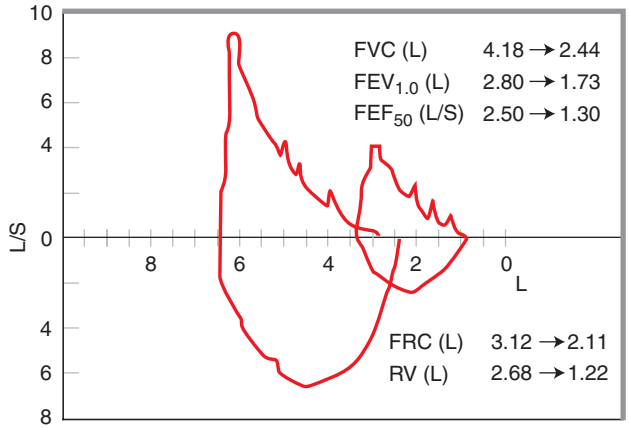

FIGURE 9–5. Flow–volume loops measured before cholecystectomy (*left*) and on the first postoperative day after coaching and pain medication (*right*). The shift to the right indicates a fall in lung volumes. The smaller, but similarly shaped, loop indicates a restrictive process.

day after surgery. An underlying chronic change in physiology—either restriction or airway obstruction—may combine with acute changes, resulting in the patient's inability to sustain spontaneous ventilation. Intraoperative and postoperative monitoring, combined with preoperative assessment, are essential to assist recovery during this crucial time.

Unfortunately, no pulmonary function test specifically relates to postoperative outcome or the occurrence of postoperative pulmonary complications. In addition, assigning a specific value for each test or reduction in function that defines risk is difficult; however, some guidelines are useful (Box 9–2).

If a patient fails to meet any of these parameters, the risk of postoperative pulmonary complications is increased. How to respond to these abnormalities depends on the type of surgery being considered. For the patient about to undergo an abdominal procedure, adequate attention should be focused on a regimen of preoperative therapy. This regimen should include administration of a nebulized β_2-agonist for bronchodilation, an oral theophylline preparation, and antibiotic therapy if the patient has a productive cough and purulent sputum. Consideration should be given to the addition of nebulized atropine or an atropine analogue to achieve parasympatholysis and thus facilitate anesthetic induction, especially if there is clinical evidence of reactive bronchospasm.[41]

The patient about to undergo thoracotomy and lung resection who fails to meet these criteria is at considerable risk.[42–45] If a pneumonectomy is required, the remaining lung tissue may be inadequate to sustain life. Severe hypoxemia and cor pulmonale leading to imminent death may result.[46] An analysis of the total contribution of each lung to overall function, or *split-lung function studies,* is necessary. This has been accomplished by bronchospirometry,[47] the lateral position test,[48–51] balloon occlusion studies,[52–54] $\dot{V}/\dot{Q}$ lung scanning,[55–58] and photon emissive tomography.[59]

Bronchospirometry, an early method of measuring split-lung function, is the most direct technique.[47] An awake patient is prepared with topical anesthetics, and then a double-lumen tube is passed into the patient's airway. Because the distal portion of the tube allows endobronchial intubation, inflation of appropriately positioned cuffs allows collection of exhaled gas from each lung. Flow resistance through these orifices is markedly increased, but exhaled volume can be measured and the total FVC appropriately partitioned into right versus left components.

The hemodynamic correlate of the ventilatory measurement achieved by bronchospirometry is temporary unilateral balloon occlusion of the pulmonary artery of the lung about to be resected. Interruption of flow to that lung causes a temporary pneumonectomy, with subsequent shift of ventilation away from the occluded lung. A rise in the proximal pulmonary arterial pressure or a decrease in oxygen tension or saturation indicates a lessened likelihood of survival with one lung remaining. If the arterial oxygen tension falls < 45 mm Hg during occlusion or mean pulmonary artery pressure rises > 30 mm Hg, the occurrence of cor pulmonale after pneumonectomy is likely.[54]

The results of these studies are combined with those found during low levels of exercise. For general exercise tolerance studies, the usefulness of various protocols has yielded conflicting results.[17,60–66] If low levels of exercise cause arterial oxygen saturation to fall > 2% from resting baseline, the prognosis is serious.[67] Exercise testing is increasingly available,[65] and postoperative testing is consistent with routine pulmonary function testing combined with split function testing.[68]

Less invasive methods of achieving similar information are available, including the lateral position test and $\dot{V}/\dot{Q}$ lung scanning. The latter test is widely available. Lung scanning data can be combined with preoperative pulmonary function data to predict postoperative level of function. The less expensive perfusion scan can be used alone with technetium or iodine isotopes,[69] but radioactive xenon provides information for both ventilation and perfusion with one study.[56] The total number of counts over both lungs is obtained, and each lung is scanned separately through a split function crystal and collimator.

Ventilation and perfusion are reported as the percent of overall function in each lung relative to the total number of radioactive counts taken over a specified period. Predictive formulas usually involve FEV_1 as follows[58]:

$$\text{Predicted postoperative } FEV_1 = \text{preoperative } FEV_1 \times \%\ \text{perfusion nonoperative lung.}$$

BOX 9–2.

Pulmonary Function Criteria Indicating Increased Risk of Postoperative Complications from Respiratory Failure:

- Forced vital capacity (FVC) <50% of predicted
- Forced expiratory volume at 1 second (FEV_1) <50% of predicted or <2.0 L
- Maximal voluntary ventilation (MVV) <50% of predicted or <50 L/min
- Diffusing capacity of lung for carbon monoxide (DLCO) <50% of predicted
- Residual volume/total lung capacity (RV/TLC) >50%

Data from Tisi GN. Pulmonary physiology in clinical medicine. Baltimore: Williams & Wilkins, 1980.

The predicted postoperative FEV_1 must be >800 m: for the patient to survive pneumonectomy after curative surgical resection. Calculations are made for pneumonectomy in all patients because removal of the entire lung may be necessary once the opened chest is examined during surgery. In the event that less resection is adequate, postoperative function also can be predicted using anatomic information. For example, right upper lobectomy involves removal of three of the 10 bronchopulmonary segments on the right side. Therefore:

$$\text{Predicted postoperative } FEV_1 = \text{preoperative } FEV_1 \times \% \text{ perfusion nonoperative lung} + 0.7 \times \% \text{ perfusion operative lung.}$$

Using this approach to physiologic assessment to predict postoperative pulmonary function in combination with use of newer anesthetic agents and improved monitoring, lung resection surgery can be offered to older and more compromised patients.[70,71]

POSTOPERATIVE MANAGEMENT

As with cardiac morbidity and mortality, pulmonary morbidity and mortality may be more influenced by postoperative management than intraoperative management.

Recovery of lung volume and thus lung function is the goal of postoperative therapy. Inspiratory maneuvers designed to increase FRC include active regimens, such as incentive spirometry, deep-breathing exercises, or passive lung inflation by intermittent positive-pressure breathing. If FRC increases as a result of these measures, lung mechanics and gas exchange are improved. This improvement is manifested as increased tidal ventilation, decreased respiratory rate, and improved arterial oxygen saturation and oxygen tension. The ability to cough adequately and to clear accumulated secretions further decreases the risk of developing postoperative pulmonary complications.

Although adequate management of postoperative pain is an integral part of postoperative therapy, it will not totally reverse the abnormalities induced by surgery. Furthermore, narcotic therapy—intravenous or otherwise—may unmask a tendency to retain carbon dioxide in patients with COPD. Especially after thoracotomy, pain relief, postoperative breathing maneuvers, and inhalational therapy can be important to recovery of function. Following lobectomy, the remaining 70% or so of lung tissue on the operative side may be edematous as a result of manipulation. Maneuvers that help reexpand the lung are important to normal gas exchange. They may be more readily accomplished in the presence of adequate pain control, such as local anesthetic administration via a thoracic-level epidural catheter. Evidence indicates that this same technique can improve diaphragmatic function, independent of pain control, in a manner not achieved when narcotics are administered instead of local anesthetics.[72]

CONCLUSION

Preoperative assessment of the patient with pulmonary compromise is based on sound physiologic principles. Knowledge of chronic pulmonary disease and pathophysiologic alterations in pulmonary function is integral to preanesthetic evaluation. Changes in function intraoperatively and postoperatively depend on the site of surgical incision, duration of operation, and underlying pulmonary function. An adequately designed regimen for anesthetic management is used to maximize pulmonary function during the preoperative, intraoperative, and postoperative periods. Judicious use of epidural analgesia postoperatively can have a salutary effect on recovery of pulmonary function.

CHAPTER 10

Evaluation of the Patient with Neuropsychiatric Disease

John Morris, MD, and
Dell Burkey, MD

PREEXISTING NEUROLOGIC DISEASE

Patients with preexisting neurologic disease present challenges for the anesthesiologist, both as a consequence of their pathology and as a result of concurrent management of their neurologic disease. Anesthesiologists can expect to have more frequent encounters with these patients as the general population ages.[1] Although longevity is not a neurologic disease, the incidence of most common neurologic diseases increases markedly with age. The "cognitive reserve," a qualitative measure of the brain's ability to restore normal cognitive function after anesthesia, may also be reduced in the aged, independent of a formally diagnosed disease process.[2] Happily, the management of patients with neurologic diseases is well reviewed.[3,4]

Multiple Sclerosis

Multiple sclerosis (MS) consists of a constellation of symptoms caused by demyelination of the white matter of the central nervous system. These symptoms exacerbate and remit, are generally focal, and progress over time. MS affects women twice as frequently as men, and patients are generally young to middle age and more often white. Although smoking is a risk factor, the cause of MS is unknown. A body of evidence supports the theory that MS is an autoimmune disease triggered by environmental exposures in genetically susceptible individuals. Because the symptoms of MS can affect nearly every organ system, the anesthetic management of such patients depends far more on their individual condition than on the diagnosis of MS.[5,6]

MS patients are often particularly anxious that the perioperative period will lead to an exacerbation of their condition. Although there is anecdotal evidence that stress and surgery increase MS symptoms, there is no research evidence that general anesthesia leads to a relapse.[7] However, postoperative infection with associated fever might.[8]

The situation regarding regional or local anesthesia is less clear. Local anesthetics, whether given intravenously, locally, or neuraxially, may transiently worsen or unmask previously undiagnosed MS symptoms.[9] Although epidural anesthesia and analgesia have been used safely in obstetric patients with MS, there are case reports of the worsening of symptoms.[10–15] As such, although not specifically contraindicated, neuraxial anesthesia using local anesthetics should be used with caution in these patients.

Preoperative evaluation of the MS patient must include a history of steroid intake to screen for adrenal suppression and as an index of disease severity. Patients may also have a restrictive lung disease secondary to muscular impairment. Patients taking baclofen at home may suffer from withdrawal perioperatively, which can cause seizures and hallucinations.

There are a number of other perioperative issues that are particularly important to the MS patient. Hyperthermia must be scrupulously avoided in these patients, as increased temperature has been shown to worsen MS symptoms;[16] in fact, in the late 19th century, hot baths were used as a diagnostic test for multiple sclerosis. Platelet aggregation is increased in patients with MS for unknown reasons. Finally, patients with MS are at increased risk for postoperative urinary retention.[17]

Myasthenia Gravis

Myasthenia gravis is an autoimmune disease in which antibodies attack the postsynaptic acetylcholine receptors at the neuromuscular junction, causing varying degrees of weakness and fatigability. Symptoms usually begin with the ocular muscles, progressing to other bulbar muscles, and then the proximal skeletal muscles. Muscle function is worse at the end of the day or after exertion. Epidemiologically, the disease is bimodal, relatively more common in women younger than 30 years of age and men older than 50 years of age.[18] Patients may present for thymectomy outside of these age distributions, however.

Patients with myasthenia gravis represent a significant challenge to the anesthesiologist. Both their disease process and the medications used to treat it cause difficulties in anesthetic

KEY POINTS

1. As the population ages, surgical patients with neuropsychiatric diseases will become more common. Older patients, even in the absence of diagnosed disease, may have a reduced "cognitive reserve."
2. Multiple sclerosis patients can safely undergo both general and conduction anesthesia. However, anesthesiologists should scrupulously avoid hyperthermia and prevent postoperative pain.
3. Patients with myasthenia gravis may benefit from an anesthetic technique that does not use muscle relaxants or volatile agents, such as a propofol-remifentanil total intravenous anesthetic.
4. Although it has traditionally been held that perioperative neuropathies resulted from preventable failures of patient positioning, particularly in courts of law, more recent data indicate that these injuries are multifactorial and not necessarily preventable.
5. The risk of autonomic hyperreflexia in chronic spinal cord injury patients mandates adequate anesthesia even for procedures below the level of injury.
6. Although there is concern that general anesthesia represents a risk factor for the development of Alzheimer's disease or a worsening of its symptoms, research is inconclusive. Furthermore, no conclusive advantage of regional over general anesthesia has been demonstrated.
7. Depression is a significant risk factor for postoperative complications, and therefore its presence should be screened for in any preoperative evaluation.

management. Classically, these patients are inordinately weak after anesthesia, are resistant to succinylcholine, and are sensitive to the nondepolarizing muscle relaxants.[19–22] As a result, despite the availability of practice recommendations for these patients, their perioperative management may require the consultation of a neurologist.[23] A neurology consultation may provide a quantitative assessment of the patient's baseline impairment, as well as a strategy for maintaining their home medication regimen through the perioperative period, during which the patient may be unable to take oral medications.

Because patients with myasthenia gravis are at heightened risk for perioperative respiratory difficulties, the preoperative assessment should focus on identifying factors that contribute to postoperative respiratory compromise. Although pulmonary function tests may provide quantitative assessment of ventilatory mechanics, a history of bulbar symptoms may be more informative. Patients with difficult swallowing or speaking, weakness in flexion of the neck or movement of the face are at particularly high risk for postoperative respiratory compromise. The presence of steroids in the patient's medication regimen indicates higher-risk patients, and elective operations should be postponed if possible in patients requiring steroids. Intravenous immunoglobulin (IVIg) or plasma exchange may be used in emergent cases. If pyridostigmine is needed, the IV dose is $^1/_{30}$ the oral dose. Patients should take their usual dose on the morning of surgery, but this practice may result in prolongation of the action of mivacurium or succinylcholine.[3] Preoperatively patients should be evaluated for coexisting diseases. Diseases associated with myasthenia gravis include diabetes, thyroid disorders, systemic lupus erythematosus (SLE), and rheumatoid arthritis.

Choice of anesthetic may have a dramatic effect on the patient's postoperative course. All volatile anesthetics negatively impact neuromuscular function, as do nondepolarizing muscle relaxants. Although both have been used safely in these patients, it seems wiser to avoid these agents when possible.[19,20] Case reports have suggested various combinations of total intravenous anesthesia (TIVA), including remifentanil and propofol, in these patients.[23–25] In the authors' experience, intravenous anesthesia without the use of muscle relaxants results in superior wakefulness and a lack of postoperative respiratory compromise in patients undergoing thymectomy. If nondepolarizing agents must be used, $^1/_5$ of the usual dosage is recommended, with avoidance of long-acting agents. Reversal with an anticholinesterase postoperatively may trigger a cholinergic crisis. Similarly, ester local anesthetics should be avoided, and amides, at lower doses, used instead for regional anesthesia. Other agents that can result in weakness in myasthenics include β-blockers, aminoglycosides, and procainamide. In cases of inadequate reversal of neuromuscular blockade, 3,4-diaminopyridine may be effective.[26]

In summary, it may be safest to avoid muscle relaxants whenever possible in these patients. The need for postoperative ventilation in these patients may be predicted by an increased length of disease, preoperative respiratory symptoms, pyridostigmine dosage greater than 750 mg/d, and vital capacity < 40 mL/kg.[27] In obstetric practice, myasthenic mothers have not been shown to have a higher incidence of cesarean section or other complications than normal mothers. The acetylcholine receptor antibodies do cross the placenta, however, and neonatal weakness is possible.[28]

Neuropathy

Perioperative nerve injuries account for one-third of all anesthesia malpractice claims in the United States, with a third of these nerve injuries involving the ulnar nerve.[29–31] Patients presenting for an operation from the ICU are at increased risk of weakness and neuropathy, particularly patients with sepsis or multiorgan dysfunction syndrome.[32]

Peripheral nerve injuries may occur as a result of myriad mechanisms; however, the most common etiologies are likely prolonged compression, stretch, trauma, and ischemia. There are a number of comorbidities and medications that predispose to nerve injury (Tables 10–1 and 10–2).[33] These injuries are rare in children, three times more common in males, and more common in cardiac surgery. The incidence of ulnar neuropathy has ranged from a high of 1.5–24% of patients undergoing cardiac surgery to 0.040.5% in noncardiac surgery.[34–38] Risk factors for ulnar nerve injuries include male gender, prolonged hospitalization, and extremes of body habitus.[33,39] Patients often do not report neuropathy until more than 48 hours after surgery, leading to the hypothesis that prolonged supine position combined with preexisting defects may be the deciding factor in neuropathy.[33] Although it has traditionally been held that perioperative neuropathies result from preventable failures of patient positioning, particularly in courts of law, more recent data indicate that these injures are multifactorial and not necessarily preventable.[31,40]

The American Society of Anesthesiologists (ASA) has published recommendations for the reduction in risk of perioperative neuropathies (Table 10–3).[41] These recommendations include arm abduction less than or equal to 90°, avoidance of pressure on the ulnar groove, use of padded arm boards, and elbow padding that *might* reduce the risk.

Parkinson Disease

Parkinson disease is the second most common neurodegenerative disease, affecting more than 3% of persons older than the age of 65 years.[42,43] If one includes parkinsonism, the constellation of extrapyramidal symptoms of which one cause is Parkinson dis-

TABLE 10–3.

American Society of Anesthesiologists Consensus Practice Advisory for Preventing Perioperative Peripheral Neuropathies

Preoperative assessment
- When judged appropriate, it is helpful to ascertain that patients can comfortably tolerate the anticipated operative position.

Upper-extremity positioning
- Arm abduction should be limited to 90° in supine patients; patients who are positioned prone may comfortably tolerate arm abduction greater than 90°.
- Arms should be positioned to decrease pressure on the postcondylar groove of the humerus (ulnar groove). When arms are tucked at the side, a neutral forearm position is recommended. When arms are abducted on armboards, either supination or a neutral forearm position is acceptable.
- Prolonged pressure on the radial nerve in the spiral groove of the humerus should be avoided.
- Extension of the elbow beyond a comfortable range may stretch the median nerve.

Lower-extremity positioning
- Lithotomy positions that stretch the hamstring muscle group beyond a comfortable range may stretch the sciatic nerve.
- Prolonged pressure on the peroneal nerve at the fibular head should be avoided.
- Neither extension nor flexion of the hip increases the risk of femoral neuropathy.

Protective padding
- Padded armboards may decrease the risk of upper-extremity neuropathy.
- The use of chest rolls in laterally positioned patients may decrease the risk of upper-extremity neuropathies.
- Padding at the elbow and at the fibular head may decrease the risk of upper- and lower-extremity neuropathies, respectively.

Equipment
- Properly functioning automated blood pressure cuffs on the upper arms do not affect the risk of upper-extremity neuropathies.
- Shoulder braces in steep head-down positions may increase the risk of brachial plexus neuropathies.

Postoperative assessment
- A simple postoperative assessment of extremity nerve function may lead to early recognition of peripheral neuropathies.

Documentation
- Charting specific positioning actions during the care of patients may result in improvements of care by (a) helping practitioners focus attention on relevant aspects of patient positioning; and (b) providing information that continuous improvement processes can lead to refinements in patient care.

Modified with permission from ASA Task Force.[41]

ease, the incidence is even higher. More than half of persons aged 85 years or older have parkinsonian symptoms.[44] The cause of Parkinson disease is unknown, but it involves neuronal destruction in the substantia nigra, locus ceruleus, and other brain centers. Parkinson disease is a disorder of the extrapyramidal system caused by an imbalance between the inhibitory actions of dopamine and the excitatory actions of acetylcholine. The characteristic signs of Parkinson disease are bradykinesia, festinating gait, tremor, rigidity, and postural instability. The coexistence of dementia with Parkinson disease doubles the mortality rate.[45] Smoking is protective for Parkinson disease.[46] One of the more severe causes of parkinsonism, multisystem atrophy (of which Shy-Drager syndrome is a variant), consists of a progressive neurologic disease characterized by parkinsonism, autonomic dysfunction, impaired cerebellar function, and mild cognitive impairment.[42] The autonomic dysfunction in these patients results in difficult-to-treat orthostatic hypotension. The mainstay of treatment for Parkinson disease is levodopa, a prodrug converted to dopamine in the brain. Dopamine agonists or type B monoamine oxidase inhibitors (MAOIs) may also be used.

General anesthesia represents an added degree of risk in Parkinson disease patients.[47] Parkinson disease patients have a baseline degree of respiratory impairment caused by dysfunctional control of the airway and ventilatory muscles, resulting in an obstructive pattern.[48–50] In fact, respiratory complications (i.e., aspiration) represent the most common cause of death in these patients.[51] Parkinson disease patients may also be at increased risk of laryngospasm secondary to this upper airway dysfunction.[52] Withdrawal of Parkinson disease medications in the perioperative period can cause a clinically significant worsening of the respiratory symptoms.[53] The short half-life of levodopa (1–3 hours) and its lack of parenteral formulation create a risk of symptom exacerbation during long procedures. Its administration intraoperatively by nasogastric tube might be a solution.[54]

Regional anesthesia may offer significant advantages in patients with Parkinson disease by allowing an earlier return to PO intake, eliminating the

use of neuromuscular blocking drugs and the risks of general anesthesia.[47,55] The addition of systemic opiates for postoperative analgesia to patients who are already on a number of sedating medications may make management difficult. This may contribute to the fact that Parkinson disease patients have an 8-fold increase in the risk of postoperative delirium.[56]

Polypharmacy in Parkinson disease patients may also contribute to their higher incidence of orthostatic hypotension.[57] This hypotension is exacerbated by the direct vasodilatory effects of dopamine agonists or tricyclic antidepressants, agents often used in this population.

There are reported problems with the use of most anesthetic agents and medications in Parkinson disease patients. Parkinson symptoms were triggered in a patient by general anesthesia who went on to develop the disease.[58] Propofol has triggered dyskinetic movements in these patients.[59] Levodopa should be avoided with halothane because of the theoretical risk created by halothane's action of sensitizing the heart to catecholamines. Succinylcholine has been used safely in Parkinson disease patients.[60] There are no reports, yet, of nondepolarizing muscle relaxants worsening Parkinson disease symptoms. Alfentanil has been linked to an acute dystonic reaction in a Parkinson disease patient.[61] Morphine has been reported to reduce dyskinesia at low doses and to induce akinesia at higher doses.[62] The concomitant use of meperidine and selegiline, a selective monoamine oxidase (MAO) type B inhibitor, has resulted in agitation, muscle rigidity, sweating, and hyperpyrexia, and its use is not recommended with these agents.[63] Ketorolac has been used safely in patients taking MAOIs.[64] Phenothiazines, butyrophenones, and metoclopramide should be used with caution, if at all, in the management of Parkinson patients secondary to their antidopaminergic effects.

In summary, the patient's home regimen should be administered immediately preoperatively and resumed as soon as possible postoperatively. The anesthesiologist must be aware of potential interactions with anesthetic agents. Patients should be carefully screened for comorbidities, including dysautonomia, respiratory, and cardiovascular problems. Baseline cognition should be established prior to surgery.

Seizure Disorder

Patients presenting for surgery with a history of seizure may be categorized as having either chronic seizures with a known diagnosis or a new-onset seizure. Patients with new seizures require evaluation to determine the cause of the seizure, preferably prior to the induction of anesthesia. Apart from epilepsy, seizures may be caused by fever, trauma, medication ingestion or withdrawal, toxins, metabolic derangements, and neurologic and infectious disorders, among other things. Anesthetic management is influenced more by the cause of the seizure than the presence of the seizure itself.

Seizure disorders are relatively common, with a prevalence in the general population estimated as high as 1%.[4] Two million Americans have epilepsy, and it has a bimodal distribution with increased incidence below the age of 15 and above the age of 65.[65] Seizures may be partial, affecting only part of the brain, or generalized, spreading from a foci to cover the entire brain. Complex seizures involve a change in consciousness; simple seizures do not. Absence seizures are similar to complex seizures in that they involve a change in consciousness but are more often of short duration, have different electroencephalogram (EEG) findings, have a rapid onset and recovery, and may be initiated by hyperventilation.[65]

Different agents are used to treat the different types of seizures, and each agent has unique concerns in the perioperative period. In general, most anticonvulsants induce the P450 enzyme system and cause resistance to neuromuscular blockers. This resistance is extended to agents, such as cisatracurium, that do not rely on the liver for metabolism. Valproic acid may interfere with hemostasis by reducing fibrinogen, von Willebrand factor, as well as platelet count and function. Preoperative coagulation profiles should be obtained from patients taking this medication.[66]

Anesthetic agents have both pro- and anticonvulsant properties. Propofol, thiopental, benzodiazepines, and potent agents (with the exception of enflurane) all increase the seizure threshold, whereas methohexital, alfentanil, and remifentanil all reduce it. In refractory cases of status epilepticus anesthesia may be induced, preferably without the use of muscle relaxants.[67]

Perioperative plans for patients with seizures must include maintenance of the patient's home anticonvulsant therapy. This will often require conversion to intravenous agents, such as phenobarbital and phenytoin.

Spinal Cord Disorder

Surgery on the spinal column is most commonly performed on the cervical and lumbar regions. These operations are generally for pain and carry a mortality rate of less than 1%.[68–70] The chance of postoperative nerve injury ranges from 0.2–0.6%.[69] The risks of these operations are dependent largely on the patient's comorbidities, the duration of the surgery, and the surgical complexity. The syndrome of inappropriate antidiuretic hormone secretion may develop in up to 5% of spinal surgery patients, more commonly in patients with large blood loss and undergoing spinal fusion.[71]

Patients with spinal injury or who are undergoing a spinal operation that results in immobility have a 42% incidence of deep venous thrombosis (DVT), an incidence similar to that of stroke patients.[72] Low-dose unfractionated subcutaneous heparin is only slightly more effective (70% risk reduction) than elastic stockings (60%) or intermittent pneumatic compression devices (66%) in preventing DVT in neurosurgical patients.[73] These mechanical agents are not recommended as sole prophylaxis in acute stroke or spinal injury patients, however. Acute stroke or spinal injury patients should receive low-molecular-weight heparin prophylaxis despite the possibility of increased CNS bleeding.[73,74]

Patients with prior spinal injuries presenting for surgery may have altered physiologic responses to anesthesia and surgical stimuli. The sympathetic response to intubation is blunted in acute and chronic quadriplegics but not in paraplegics.[75] The risk of autonomic hyperreflexia mandates adequate anesthesia even for procedures below the level of injury.

CARDIOVASCULAR DISEASE

Dementia

Dementia of the Alzheimer type effects approximately 4 million Americans, making it the most common cause of dementia, with that number expected to triple by 2050.[76–78] The incidence

increases markedly with age, with half of those older than age 85 years affected and 1 in 10 of those older than age 65 years. Life expectancy after a new diagnosis is 8 years.[76] Risk factors for Alzheimer disease include family history, age greater than 65 years, female gender, poor education, and a history of seizures, head injury, myocardial infarction, or hypothyroidism.[77] Furthermore, the presence of the allele apolipoprotein E e4 on chromosome 19 has been definitively associated with Alzheimer disease.[78] The pathologic changes in Alzheimer disease focus on the cortex and limbic system.[79] Although concern has been raised that general anesthesia represents a risk factor for the development of Alzheimer disease or a worsening of its symptoms, research is inconclusive,[80–83] and no conclusive advantage of regional over general anesthesia has been demonstrated.[84–87]

The onset of Alzheimer disease is insidious, and the patient may be misdiagnosed as depressed. Defects in recent memory are the first sign of the disease, and executive functions and planning are lost early.[88] The differential diagnosis for Alzheimer disease is myriad, but Alzheimer disease and multiinfarct (vascular) dementia account for the vast majority of cases seen in clinical practice.

Treatment of Alzheimer disease is aimed at improving the quality of life. Acetylcholinesterase inhibitors such as rivastigmine, donepezil, and galantamine, are the mainstays of treatment.

Alzheimer disease patients are at increased risk during anesthesia and surgery. Although a recent review reported that "no specific complications have been reported of anesthesia for patients with Alzheimer disease," patients with preoperative cognitive impairments have a higher overall mortality rate than those who do not have such impairments on a general surgical service.[88,89] Alzheimer disease patients receiving antipsychotics are at increased risk for aspiration, whereas those taking only benzodiazepines are not.[90] In patients with advanced Alzheimer disease, the swallowing reflex is impaired secondary to dysfunction of the basal ganglia.[91]

Postoperative delirium may be either hypo- or hyperactive.[92] Preoperative cognitive defects, depression, longer operative time, and impaired vision suggest risk factors for postoperative confusion.[93] Demonstrated risk factors for postoperative delirium include prior delirium, age greater than 70 years, preexisting cognitive impairment, substance abuse, and abnormal laboratories.[4,94,95] Increased postoperative pain correlates with postoperative confusion, and the addition of analgesics to the anesthetic reduces the incidence of confusion.[96,97] Elderly patients with postoperative confusion have increased levels of cortisol and interleukin (IL)-6.[98] A proportion of postoperative confusion in the elderly may simply be unmasked dementia.[99]

Stroke and Transient Ischemic Attack

Surgery and anesthesia represent a period of increased risk for stroke.[100–101] The perioperative period often is the setting of abrupt changes in blood pressure, cardiac output, coagulability, and oxygen delivery. The risk of perioperative stroke in a general surgical population is reported to be between 0.02% and 0.7%.[100,102–105] Most of these strokes occur postoperatively, on average 7 days after the surgery.[103] It is rare for a stroke to occur intraoperatively, but this risk increases dramatically in vascular surgery (0.8–3.0%), head and neck surgery (4.8%), and cardiac surgery (3–5%).[104,106,107] Previous stroke doubles the risk of perioperative stroke.[104,108] The largest study available (173 patients) reported an even higher rate of recurrent stroke perioperatively of 2.9%.[109] The incidence of vertebrobasilar stroke may be as high as 6.0% in high-risk patients.[110] In patients with a history of symptomatic vertebrobasilar stenosis or occlusion, confirmed by vascular imaging, who underwent surgical procedures with general anesthesia, 3 of 50 operations resulted in stroke. Each of the patients with a postoperative stroke had an episode of hypotension (systolic blood pressure <100 torr) for longer than 10 minutes during the surgery. Transient neurologic symptoms (transient ischemic attacks) may also increase the risk of perioperative stroke, but neither asymptomatic carotid stenosis nor asymptomatic bruits increase risk.[111–114] Other risks for cerebrovascular events include increasing age, atrial fibrillation, recent myocardial infarction, hypotension, dehydration, and emergency surgery.[104,115–117] The highest risk operations are cardiac, carotid, and aortoiliac.[103,117] The hypercoagulable state occurring after surgery may be the most important factor in these primarily thrombotic events.

There is no clinical evidence available for deciding how long to delay surgery after a stroke. Recommendations have ranged from 3 weeks to 2 years. Current recommendations are 2–3 weeks' delay after acute stroke for general surgery and 2–3 months' for elective cases.[4]

Anesthetic choice may effect the risk of stroke by effecting coagulability; however, no anesthetic type has been shown to be superior for the prevention of stroke. Propofol and epidural anesthesia may reduce the hypercoagulable state,[118,119] but these results are far from conclusive.[120] In general, clinical management should seek to maintain or increase oxygen delivery to at-risk tissue, reduce the oxygen demands of at-risk tissue, or interrupt the apoptotic signaling cascade. It has been conclusively demonstrated that hypotension results in a decrease in cerebral blood flow in hypertensive patients with acute ischemic stroke, and further treatment of postoperative hypertension may worsen outcome.[121,122] This must be balanced against a possible worsening of brain edema and increased risk for hemorrhage. The management of intracerebral hemorrhage and intracranial hypertension is beyond the scope of this chapter but has been well-reviewed elsewhere.[100,123] Even mild hyperthermia is associated with worsened outcome. On the other hand, mild hypothermia may be beneficial.[124] Models of global ischemia have demonstrated worse outcomes with hyperglycemia, and treatment of hyperglycemia is currently recommended. Propofol, as compared to a volatile technique, may limit infarct size.[125] Methods that have been studied but not found to be of benefit include hemodilution to a hematocrit of 30%, deep hypothermia, hyperoxia, and hyperventilation.[126] Techniques for which there no conclusive benefit has been demonstrated but that might be of use include barbiturate therapy, isoflurane (as compared to other volatile anesthetics), ketamine, etomidate, nimodipine, and magnesium.[125] Possible future agents include nonsteroidal antiinflammatory drugs (NSAIDs), chelation agents, antibodies to the *N*-methyl-D-aspartate (NMDA) receptor, and lazaroids.[127–130] Lidocaine infusions show

promise in cardiac surgical patients, through a postulated interruption of the ischemic cascade, in reducing postoperative cognitive defects.[131,132] It is likely that all general anesthetics except nitrous oxide (which increases cerebral metabolism) reduce infarct size as compared to being awake.[133,134]

Stroke patients should be carefully evaluated to determine functional status, particularly in terms of their ability to ambulate and communicate. Strokes that result in a degree of immobility increase the patient's risk for DVT, with reported incidence as high as 42%.[72] Dysfunction of the bulbar muscles may increase aspiration risk after extubation. While the evidence of this is inconclusive, it seems prudent to manage all patients at risk for cerebral ischemia in a manner that minimizes cerebral oxygen demand and maximizes delivery.

PSYCHIATRIC DISORDERS

A perhaps surprisingly high percentage of patients presenting for surgery are taking psychotropic medications or carry a psychiatric diagnosis.[135] Of patients presenting for elective surgery, 35% report the current use of antidepressants and 34% report the use of benzodiazepines.[136] Benzodiazepines are the most frequently prescribed psychotropic drugs in the elderly, a population particularly susceptible to their effects.[137]

Schizophrenia

The perioperative management of patients with schizophrenia is challenging not only because of the disease process and the medications used to treat it, but because these patients often also have undiagnosed or undertreated comorbidities.[138] Patients with schizophrenia are at increased risk for diabetes and cardiopulmonary diseases, and should be screened for both.[139,140] This increased rate of comorbidities is likely secondary to the disease itself, side effects of chronic antipsychotic treatment and the relatively higher incidence of obesity and smoking among schizophrenics.[141–143] These comorbidities, in turn, may explain the higher postoperative mortality rates observed in schizophrenics.[144]

Patients taking antipsychotic drugs are at increased risk from sudden death as a result of torsade de pointes and have a markedly higher rate of postural hypotension and tachycardia.[145] A relative insensitivity to pain has been reported in schizophrenics, which may lead to a delay in diagnosis of postoperative complications.[146] Discontinuing home antipsychotic medications prior to surgery is not recommended, as patients whose medications were withheld for 72 hours preoperatively had a markedly higher incidence of confusion but no differences in incidence of hypotension.[147] An additional risk of antipsychotic medications is an increased incidence of intraoperative hypothermia, without an increased incidence of postoperative shivering.[148]

Anesthetic choice may impact postoperative confusion in patients suffering from psychosis, neurosis, or anxiety disorders. Ketamine is safe for use in these patients, with no increased risk of postoperative hallucinations.[149,150] In fact, total intravenous anesthetic techniques that include ketamine may decrease the incidence of postoperative confusion.

While antipsychotic agents may cause neuroleptic malignant syndrome, which is clinically similar to malignant hyperthermia, there is no evidence that patients with this side effect to antipsychotics should receive nontriggering anesthetics. Patients taking long-term antipsychotics have an increased incidence of postoperative ileus, and epidurals are effective at reducing the rate of postoperative ileus in these patients.[151]

Depression

Depression is a significant risk factor for postoperative complications, and therefore its presence should be screened for in any preoperative evaluation. In a prospective cohort of 648 Veterans Administration patients presenting for cardiac valve surgery, an incidence of preoperative depression was found to be 29.2%. Their 6-month mortality was nearly twice that of nondepressed patients. Depressed patients were more likely to be younger, have worse heart function, and present emergently for surgery. And in multivariate analysis, depression remained a significant predictor of death.[152]

Antidepressants should be continued perioperatively, as withholding antidepressants for 72 hours prior to surgery results in a higher incidence of postoperative confusion and depression.[153] Depressed patients who abuse alcohol have a 33% higher incidence of confusion postoperatively than depressed patients who do not.[154] Postoperative confusion in this group was coincident with increased plasma levels of cortisol.

Anesthetic choice has not been shown to impact outcome for depressed patients significantly. Low-dose ketamine is a safe, and possibly beneficial, addition to anesthetic regimens for depressed patients.[155]

Management of postoperative pain may be more challenging in depressed patients. These patients report higher postoperative pain scores but, paradoxically, do not differ from controls in response to a standardized stimulus.[156]

Electroconvulsive Therapy

The perioperative management of patients for electroconvulsive therapy (ECT) must encompass the physiologic effects of ECT, the interaction of the anesthetic agents with the duration and intensity of the seizure, and the patient's comorbidities and concomitant psychotropic medications. Ideally, the anesthetic should be of short duration to match the procedure duration; be free of the need for intense postprocedure monitoring; and if not increase seizure duration or intensity, then at least not decrease it.

Anesthesia for ECT is one of the most common anesthetic procedures performed in the United States each year.[157] Indications for ECT are wide ranging and include severe major depression, schizophrenia, anorexia, and catatonia. Patients presenting for ECT may not be active participants in their healthcare and may also be taking potent antipsychotic drugs that may impact their anesthetic management.

The application of electrical current to the brain results in both a generalized motor seizure and a significant autonomic discharge. A brief initial parasympathetic discharge resulting in bradycardia is generally followed by a vigorous sympathetic outflow with increased heart rate and blood pressure.[158,159] The increases in cardiac output and myocardial oxygen consumption may be significant. Adverse events associated with ECT have included myocardial infarction, stroke, and blindness.[160–162] Additionally, the convulsions induced by ECT have resulted in fractures and dislocations in inadequately anesthetized subjects.[163,164]

TABLE 10–4.

Anesthetic and Cardiovascular Drugs and Their Effects on the Duration of ECT-Induced Seizure Activity (Relative to Methohexital or Saline)

Drug	Increased	No Change	Decreased
Anesthetic drugs	Etomidate, alfentanil, remifentanil	Methohexital	Thiopental, thiamylal, lorazepam, ketamine, fentanyl, propofol, midazolam
Cardiovascular drugs	Aminophylline, caffeine	Clonidine, esmolol, labetalol, nifedipine, dexmedetomidine, nicardipine, nitroglycerin, trimethaphan, nitroprusside	Diltiazem, lidocaine, labetalol, esmolol

Reproduced with permission from Ding Z, and White PF.[166]

As patients experiencing seizure duration of less than 15 seconds or greater than 120 seconds have suboptimal responses to ECT, and because many common anesthetics increase the seizure threshold, much debate has centered around the choice of anesthetic agent and dose.[165] Because methohexital (0.5–1.0 mg/kg) has a limited effect on duration of seizure duration, is short acting, and is relatively free of postprocedure side effects, its use is touted as the "gold standard" (Table 10–4.)[166] Etomidate is useful in patients with brief seizure durations despite maximal electrical stimulus, as it may increase seizure duration. This, however, comes at the price of increased post-ECT confusion, emesis, and an increased autonomic response.[83,167,168]

Seizure activity may also be impacted by ventilatory management.[177] As elevated CO_2 increases the seizure threshold, more effective ventilation during ECT, as may be achieved by a laryngeal mask airway, improves seizure duration.[169]

SUMMARY

Patients who present for surgery with neuropsychiatric diseases represent a host of challenges for the consultant anesthesiologist. Careful assessment of baseline function, screening for comorbidities, and a catalogue of the patient's current home medications are prerequisites for successful anesthetic management. In general, changes to the patient's home regimens should be minimized so as to make the perioperative period as much of a "nonevent" as possible. Newer, shorter-acting anesthetic agents allow safer, more patient-centered management regimens.

CHAPTER 11

Evaluation of the Patient with Neuromuscular or Skeletal Disease

Philip D. Bailey, Jr., DO, and Joseph R. Tobin, MD

Perioperative management of patients with neuromuscular disorders is challenging because of the low incidence, diverse etiology, coexisting diseases, and variable responses to anesthetics that often are present. Paramount to developing a safe anesthetic plan is the ability of the anesthesia provider to assess the extent and rate of the disease's progression. Despite distinct etiologies, all neuromuscular disorders may adversely affect the respiratory and cardiovascular systems. Unfortunately, the extent of peripheral muscle involvement does not always correlate with the extent of cardiovascular and respiratory system involvement. Indeed, during an acute illness, anesthesia, or surgery, the patient with a neuromuscular disorder may have his or her reserve easily overwhelmed, resulting in unanticipated complications, especially when the extent of the underlying neuromuscular disorder is underestimated.

This chapter focuses on the perioperative evaluation of patients with neuromuscular and skeletal diseases, emphasizing the respiratory and cardiovascular systems while highlighting important anesthetic issues. Individual neuromuscular disorders are grouped anatomically in an attempt to delineate specific anesthetic issues and to help predict possible anesthetic complications.

PREOPERATIVE ASSESSMENT

Respiratory System

The major cause of death in patients with neuromuscular disorders is respiratory insufficiency.[1] Respiratory involvement often varies considerably among various neuromuscular disorders, and the extent of general muscle weakness does not necessarily correlate with the severity of respiratory muscle involvement.[2] In fact, patients with peripheral neuropathy tend to experience less frequent and less severe respiratory involvement compared to individuals with myopathy, myelopathy, and neuromuscular junction disease.[3] Significant respiratory muscle involvement may occur early (e.g., Guillain-Barré syndrome) in the course of the disease or late (e.g., myasthenia gravis), and it may be progressive, reversible, or intermittent. Impaired upper airway function and cranial nerve involvement often result in airflow obstruction and recurrent aspiration. Symptoms of airway involvement may be present preoperatively, following administration of se-

KEY POINTS

1. The major cause of death in patients with neuromuscular disorders is respiratory insufficiency. Respiratory involvement often varies considerably among the various neuromuscular disorders, and the extent of general muscle weakness does not necessarily correlate with the severity of respiratory muscle involvement.
2. Cardiovascular involvement in patients with neuromuscular disorders may manifest as myocardial failure in patients with myopathic disorders and as autonomic dysfunction in patients with neuropathic disorders. Clinical signs of autonomic dysfunction include orthostatic hypotension, resting tachycardia, paralytic ileus, anhidrosis, and constricted pupils. The presence of these clinical signs may indicate profound hemodynamic instability that may manifest during the perioperative period, requiring invasive monitoring to manage the patient's volume status and ventricular contractility.
3. In patients with neuromuscular disorders, the severity of skeletal muscle involvement does not necessarily correlate with the severity of cardiac involvement.
4. Children with asymptomatic, undiagnosed muscular dystrophy are at significant risk for serious, life-threatening anesthetic complications. Specifically, these patients may develop intractable hyperkalemic cardiac arrest after receiving succinylcholine intravenously.
5. Spinal anesthesia has been associated with exacerbation of multiple sclerosis, although the mechanism is unclear. Speculation is that demyelinated areas of the spinal cord are more sensitive to the effects of the local anesthetic, causing a relative neurotoxicity.
6. Numerous anesthetics have been implicated in exacerbating an acute attack of porphyria and should be avoided. Propofol, ketamine, local anesthetics, muscle relaxants, nitrous oxide, isoflurane, and opioids are considered safe.
7. Myasthenic crisis is a rapid deterioration of neuromuscular and respiratory function that may occur at any time perioperatively as a result of infection, stress, or an overdose with anticholinesterase drugs (cholinergic crisis).
8. Patients with myasthenia gravis and myasthenic syndrome are exquisitely sensitive to the effects of nondepolarizing muscle relaxants.
9. Succinylcholine should be avoided in patients with muscular dystrophies. In light of the abnormal muscle membrane, succinylcholine administration may further damage the muscle membrane and cause the release of intracellular contents.
10. Succinylcholine produces an exaggerated contracture, and its use should be avoided in patients with myotonias. The myotonic response produced by succinylcholine may be so severe that ventilation and tracheal intubation are difficult and may be impossible.
11. Rheumatoid arthritis, osteoarthritis, and ankylosing spondylitis all share possible cervical spine disease and may make airway management difficult.
12. Some musculoskeletal disorders are associated with an abnormal heat dissipation mechanism such that central temperature monitoring is important.
13. Many etiologies of high creatine kinase concentrations or rhabdomyolysis may be associated with malignant hyperthermia susceptibility.

dation or induction agents, or develop early after anesthetic administration, requiring persistent airway control.

Inspiratory muscle disease is frequently observed as a change in respiratory pattern, alternating work between fatiguing muscles and accessory muscles and increasing the respiratory rate to allow more efficient use of weakened muscles early in the course of the disease.[4] In addition, inspiratory time and the ratio of dead space to tidal volume are increased, resulting in decreased ventilatory efficiency, increasing the risk of respiratory embarrassment. More advanced inspiratory muscle disease is characterized by hypoventilation, atelectasis, and hypoxemia. When muscle strength is <30% of normal, hypercapnia develops.[5] Ventilatory responses to hypercapnia and hypoxia usually are impaired, especially in the presence of motor neuron and demyelinating disorders.[6] Although central ventilatory drive usually remains intact, it may be diminished in some patients with certain neuromuscular disorders (e.g., myotonic dystrophy). Indeed, respiratory drive may reflexively diminish in order to protect against respiratory muscle fatigue, injury, and failure. Chronic hypoventilation or hypoxemia may result in pulmonary hypertension, further complicating cardiopulmonary function.

The ability to cough and clear secretions is impaired in patients who have expiratory muscle dysfunction, and reductions in forced expiratory capacity after abdominal and thoracic procedures may be exacerbated. When cough is impaired, atelectasis may develop and secretions are retained, predisposing patients to bacterial contamination and pneumonia.

Preoperative evaluation should focus on history, physical examination, and diagnostic studies. Breathlessness on exertion is common; however, many patients who have advanced disease cannot generate sufficient exertion to offer this complaint. Orthopnea is a prominent symptom of diaphragmatic weakness because the abdominal contents limit diaphragmatic movement when a patient is in the supine position. Snoring, morning headaches, and daytime somnolence are indicative of sleep-related breathing disorders that are commonly present in patients with neuromuscular disease. In addition, liquids tend to be harder to swallow than solids in patients who have pharyngeal muscle weakness, and patients often report a perioperative history of aspiration or chest infection after procedures. A history of use of nocturnal respiratory assist devices (continuous positive airway pressure or bilevel positive airway pressure) predicts an increased propensity to postanesthesia airway or respiratory problems and may require advanced monitoring (ICU or similar site) for postoperative respiratory/airway complications.

Important findings indicative of ventilatory muscle weakness, such as frequent changes in respiratory pattern, tachypnea, use of accessory muscles, and ventilatory muscle incoordination, may be observed during relaxed breathing and auscultation.[7] In addition, paradoxical motion of the abdomen during inspiratory efforts suggests profound weakness of the diaphragm; this is best observed when a patient is supine.

Preoperative laboratory evaluation should focus on the patient's oxygenation and ventilation. Radiographic examination of the chest is useful to exclude pulmonary abnormalities but is not very helpful for diagnosing muscle weakness. Arterial blood gas analysis helps identify patients with hypercapnia and hypoxia. Restrictive patterns typically are demonstrated by classic pulmonary function testing. However, vital capacity is not significantly affected until respiratory muscle strength is 50% below normal. Diaphragmatic weakness is suggested when a >25% decrease in vital capacity is observed between upright and supine positions.[8] Total lung capacity decreases in patients with inspiratory muscle weakness whereas residual volume increases. Flow–volume loop studies commonly reveal truncation of peak inspiratory and expiratory flow rates, a delay reaching peak expiratory flow rate, and an abrupt decrease in end-expiratory flow rate. Upper airway muscle weakness results in oscillations of forced inspiratory or expiratory flow as well as plateauing of the inspiratory flow curve.[9] Inspiratory pressure generated by maximal effort against a closed airway can be used to measure the strength of respiratory muscles. Clinically significant ventilatory failure becomes more likely when maximum inspiratory pressure generated is <30 cm H_2O.[10]

Cardiovascular System

Cardiovascular involvement in patients with neuromuscular disorders may manifest as myocardial failure in patients with myopathies or as autonomic dysfunction in patients with neuropathic disorders. Patients are at risk for left ventricular thrombi, systemic emboli, pulmonary hypertension, and right ventricular failure. Also, because most patients with neuromuscular disorders are relatively immobile, deep venous thromboses and pulmonary emboli are a concern.

Paradoxically, cardiomyopathy can range from subclinical in individuals with advanced neuromuscular disease to severe in patients with mild neuromuscular disorders, such as mildly affected female carriers of Duchenne muscular dystrophy[11] or patients with Friedreich ataxia. Factors influencing the severity of Duchenne muscular dystrophy cardiomyopathy are multifactorial and may not be predicted by the extent of Xp21 (dystrophin) gene deletion.[12]

Heart rate, inotropic state, venous tone, and systemic vascular resistance are regulated by the autonomic nervous system. The most sensitive indicator of autonomic cardiac involvement is loss of beat-to-beat variability.[13] Resting tachycardia and postural hypotension often are observed when autonomic dysfunction is present and has been associated with intraoperative hemodynamic instability. Clinical signs of autonomic dysfunction include orthostatic hypotension, resting tachycardia, paralytic ileus, anhidrosis, and constricted pupils.

The presence of these clinical signs suggests profound hemodynamic instability that may manifest in the perioperative period and require invasive monitoring to manage volume status. Recently transesophageal echocardiography has been used more commonly to monitor cardiovascular performance and diastolic ventricular volume.

Cardiomyopathy typically is difficult to assess by auscultation in the early stages. Persistent tachycardia usually is the earliest manifestation of cardiomyopathy. Although determination of creatine phosphokinase level is used to detect active systemic myopathy, it may not detect myocardial dystrophy. Both atrial natriuretic peptide and norepinephrine concentrations are useful for detecting and monitoring heart failure. Atrial natriuretic peptide concentrations typically increase in patients with muscular dystrophy once left ventricular ejection fraction is <25%.[14]

The electrocardiogram (ECG) is a very reliable test for evaluating suspected cardiac involvement in patients with neuromuscular disorders. Characteristics include tall right precordial R and Q waves in leads I, aVL, V_5, and V_6.[15] Fibrous replacement of the myocardium is thought to be responsible for the Q wave often observed on the ECG. Unfortunately, the prognostic value of the ECG is not very good because of very little correlation among the clinical course, ECG alterations, and the level of cardiac enzymes.[16] Chest radiograph may be helpful to determine heart size; however, echocardiography is preferred to determine the size of the cardiac chambers, valvular involvement, and regional wall-motion abnormalities. In addition, serial measurements of fractional shortening and left ventricular ejection fraction are useful to monitor progression of cardiomyopathy and response to therapy.[17]

Anesthetic Considerations

In patients with neuromuscular disorders, the severity of disease tends to correlate well with the incidence of perioperative complications. Postoperative respiratory failure can occur, especially in patients with severe restrictive lung disease. The presence of cardiomyopathy can lead to arrhythmias, blood pressure lability, and increased sensitivity to the depressant effects of anesthetics. The risk of aspiration is increased in patients who have a diminished, or absent, gag reflex. Positioning injuries may occur as a result of contractures, skeletal deformity, and lack of subcutaneous adipose tissue. Also, adverse reactions with anesthetics, particularly succinylcholine-induced hyperkalemia, are well documented in patients with neuromuscular disorders.[18–20] The anesthetic concerns for patients with neuromuscular disease are summarized in Table 11–1.

Of concern are reports of children with asymptomatic, undiagnosed muscular dystrophy who are at significant risk for serious, life-threatening, anesthetic complications. Specifically, these patients may develop intractable cardiac arrest after receiving succinylcholine intravenously (IV) or after intramuscular injection, with or without the use of halogenated agents.[21,22] In this situation, hyperkalemia, acidosis, and myoglobinuria are common clinical findings. A number of these patients have been found to have abnormal or absent dystrophin, usually indicating myopathy, more specifically Duchenne muscular dystrophy. As a result, the United States Food and Drug Administration has determined that succinylcholine should be used in children and adolescent patients only for emergency tracheal intubation or in cases where immediate securing of the airway is necessary.

PERIOPERATIVE ASSESSMENT OF SPECIFIC NEUROMUSCULAR DISEASES

Myelopathy

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS) is a degenerative disease involving the corticospinal tract and anterior horn cells. Loss of motor function is progressive, with development of asymmetric weakness of the limbs (lower motor neurons are affected first), spasticity, and muscle atrophy. Death usually occurs within 3–5 years of diagnosis, although approximately 10% of patients may live more than 10 years.[23] The etiology of ALS is unknown, but possible causes include viral or prion infection, glutamate excitotoxicity, free radical stress, autoimmune response, and heavy metal exposures.[24]

Involvement of the bulbar region typically manifests as respiratory and pharyngeal muscular insufficiency. Pulmonary function tests reveal a decrease in vital capacity, maximal voluntary ventilation, and diminished expiratory muscle function.[25] Ventilatory support will be necessary as the disease progresses because respiratory failure eventually develops in all patients. Indeed, the cause of death in most patients with ALS, as is in most patients with neuromuscular disorders, is respiratory failure. Autonomic dysfunction may be present in patients with ALS, as evidenced by resting tachycardia, orthostatic hypotension, and increased concentrations of catecholamines.

The antiglutamate drug riluzole is the only drug approved specifically for treatment of ALS. Riluzole has been demonstrated to prolong survival and delay the need for tracheostomy.[26] Anticholinergic agents usually are administered to decrease secretions and facilitate swallowing, whereas dantrolene sodium and benzodiazepines are commonly administered to relieve muscle cramps and spasticity. However, these agents may exacerbate respiratory and skeletal muscle weakness. Anticholinesterase therapy may transiently improve muscle function and therefore is sometimes administered to these patients.

Ventilatory and upper airway muscle impairment significantly affects anesthetic management. Aspiration is an ongoing risk, and the need for postoperative ventilatory support is high because the already decreased respiratory reserve is reduced even further postoperatively. In ALS patients, the response to muscle relaxants, either depolarizing or nondepolarizing, is altered and may be compounded by perioperative administration of anticholinesterase medication. As with other patients with muscle denervation and muscle wasting, ALS patients are susceptible to succinylcholine-induced hyperkalemia and cardiovascular arrest.[27] Therefore, whenever possible, depolarizing and long-acting nondepolarizing muscle relaxants should be avoided. Autonomic dysfunction may produce exaggerated decreases in cardiovascular function in response to anesthesia. No evidence indicates that any one specific anesthetic drug or anesthetic technique is best for patients with ALS. Neuraxial anesthesia has been safely used in patients and can be considered.[28,29] Concern has been raised regarding neuraxial anesthesia and acute or subacute worsening of symptoms postoperatively, but no scientific evidence has been forthcoming.

Multiple Sclerosis

Multiple sclerosis is a chronic disease of the central nervous system (CNS) that is characterized by a demyelinating process of the brain and spinal cord with unpredictable intervals of exacerbations and remissions. The cause of the disease is multifactorial, involving immunologic-mediated events occurring in susceptible individuals. Initially, a virus or other agent triggers an inflammatory response that initiates an autoimmune response to myelin. Plaques in the white matter of the CNS are the fundamental lesions. The ability of the CNS to repair itself during the early phases of the disease accounts for the relapsing nature of the disease. Unfortunately, there is no curative treatment.

TABLE 11–1.

Anesthetic Considerations in Patients with Neuromuscular Disorders

Disease	Response to Succinylcholine	Response to Nondepolarizing Muscle Relaxants	Other Anesthetic Considerations
Myelopathy			
Amyotrophic lateral sclerosis (ALS)	Hyperkalemia, contracture	Increased sensitivity	Impaired ventilation Aspiration risk Epidural anesthetics have been used successfully
Multiple sclerosis	Hyperkalemia in severe disease	Decreased sensitivity	Avoid stress and hyperthermia Spinal anesthesia may exacerbate disease and cause neurotoxicity Epidural anesthetics have been used successfully
Peripheral Neuropathy			
Guillain-Barré syndrome	Hyperkalemia	Increased/decreased sensitivity depending on phase of disease	Autonomic instability Aspiration risk Postoperative respiratory failure
Porphyrias	Normal response	Normal response	Avoid barbiturates, etomidate Propofol, ketamine, local anesthetics, opioids, nitrous oxide, isoflurane considered safe
Neuromuscular Junction Disease			
Myasthenia gravis	Decreased sensitivity	Increased sensitivity	Avoid muscle relaxants Postoperative respiratory failure
Myasthenic syndrome	Increased sensitivity	Increased sensitivity	Avoid muscle relaxants
Myopathy			
Dystrophinopathies	Increased sensitivity, hyperkalemic response	Increased sensitivity	Succinylcholine contraindicated Regional anesthesia safe Avoid inhalational agents if possible Postoperative respiratory failure Delayed recovery of muscle strength
Myotonias	Induced myotonia	Increased sensitivity if major muscle wasting is present	Avoid factors known to induce perioperative myotonia (cold, succinylcholine, hypothermia, anticholinesterase drugs) Monitor for cardiac dysrhythmias
Periodic Paralyses			
Hyperkalemic	Hyperkalemic response	Increased sensitivity	Avoid factors known to induce myotonia Avoid potassium supplementation Avoid carbohydrate depletion Monitor for dysrhythmias Monitor serum potassium levels Regional anesthetics best avoided
Hypokalemic	Alters serum potassium level	Increased sensitivity	Avoid hypothermia Avoid carbohydrage loading Monitor serum potassium levels Monitor for dysrhythmias Regional anesthetics best avoided

Published in and adapted from Longnecker DE, Tinker JH, Morgan GE, eds. Principles and Practice of Anesthesiology. 2nd ed. St. Louis, Mosby, 1998. Copyright Elsevier.

The symptoms of multiple sclerosis depend on the site(s) of demyelination. The most common presenting symptoms are sensory losses and ocular disturbances. Limb weakness and paresthesias may occur as a result of demyelination of motor neurons and sensory pathways. The lower extremities are affected more than the upper extremities. Brainstem involvement may produce cranial nerve deficits and abnormal ventilatory drive. Hypotension may reflect the presence of autonomic nervous system involvement. Bowel and bladder irregularities are frequent complaints. The course of multiple sclerosis is characterized by exacerbation of symptoms at unpredictable intervals over a prolonged period. Eventually, residual symptoms persist and lead to progressive disability. However,

10–20% of patients have a relatively benign course and trivial disability.[30] Interestingly, pregnancy is associated with an improvement in symptoms, but relapse occurs postpartum.[31]

The diagnosis is based primarily on clinical signs and symptoms. Laboratory confirmation of the diagnosis may be made by analysis of the cerebrospinal fluid (CSF) and magnetic resonance imaging (MRI). The CSF typically reveals increased concentrations of albumin and IgG. MRI can detect CNS and spinal cord involvement and can be used as a measure to determine the effectiveness of various treatment modalities.[32,33]

Therapeutic modalities are directed at modulating the immunologic and inflammatory responses that damage myelin. Corticosteroids and interferon are used most commonly. Glatiramer is a polypeptide mixture that mimics the structure of myelin and serves as a distraction for autoantibodies. Mitoxantrone can be used to treat aggressive disease; however, it is cardiotoxic. Dantrolene, baclofen, and benzodiazepines can be used to treat spasticity. Carbamazepine can be used to treat painful dysesthesias, seizures, and paroxysmal symptoms. Antidepressants and anticholinergic drugs can be given for depression and urinary incontinence, respectively. Avoidance of emotional stress, fatigue, and hyperthermia is essential. Indeed, a 0.5°C increase in temperature can block impulse conduction in demyelinated fibers, resulting in an exacerbation or relapse.[34]

Surgery may be required more frequently in patients with multiple sclerosis because of orthopedic, urologic, and neurologic issues. Unfortunately, the effects of surgery and anesthesia on the course of this disease are controversial. Both regional and general anesthesia have been reported to exacerbate multiple sclerosis. However, factors other than anesthesia, such as emotional stress and hyperpyrexia, may increase the risk of an exacerbation as well.[35,36] The patient should be adequately informed that, despite a well-managed anesthetic, a relapse might occur perioperatively. Patients with multiple sclerosis should undergo a comprehensive, well-documented neurologic examination aimed at identifying any existing deficits. After surgery, the neurologic examination should be repeated in order to correlate preoperative and postoperative findings.

Spinal anesthesia has been associated with exacerbation of multiple sclerosis, although the mechanism is unclear.[35] Speculation is that lesions may cause the breakdown of the blood–brain barrier, and, in demyelinated areas of the spinal cord, the CNS is more sensitive to the effects of the local anesthetic, causing a relative neurotoxicity. Indeed, higher concentrations of local anesthetics are more likely to cause a relapse than are lower concentrations of local anesthetics. Interestingly, epidural analgesia has been used safely and does not appear to increase the incidence of disease relapse.[31,36] General anesthetics do not appear to have any significant intrinsic adverse effect.

Consideration must be given to the potential interactions of anesthetics with medications patients may be taking for their disease. Patients receiving corticosteroids may require stress doses in the perioperative period. Immunosuppressants may produce subclinical cardiac dysfunction. Anticonvulsants produce resistance to nondepolarizing muscle relaxants,[37–39] whereas baclofen may increase the sensitivity to nondepolarizing agents. Patients with significant muscle atrophy theoretically have an increased risk of a hyperkalemic response to succinylcholine, so its use should be avoided. The hypotensive effects of volatile anesthetics may be exaggerated by autonomic dysfunction, so patients with severe disease may require invasive monitoring. Respiratory dysfunction, when present, increases the likelihood of the need for postoperative mechanical ventilation.

Peripheral Neuropathy

Guillain-Barré Syndrome

Guillain-Barré syndrome, the most common cause of acute flaccid paralysis, is an autoimmune inflammatory polyneuropathy of motor, sensory, autonomic, and cranial nerves. The syndrome is triggered by an immune response to either a viral or bacterial infection that produces antibodies to an antigen of the infectious agent. The antigen mimics an epitope of the Schwann cell, and affected axons undergo lymphocytic infiltration and demyelination. A respiratory or gastrointestinal infection 3–4 weeks earlier usually precedes the onset of this disorder. Usually, the disease evolves over the course of 3–4 weeks, with complete recovery eventually occurring in >80% of patients. Unfortunately, 3% of patients will experience a relapse, and 5% are permanently disabled.[40]

The clinical course is characterized by an ascending, symmetric muscle weakness of the lower extremities that develops over several days, followed by gradual recovery. Paresthesias often precede weakness and paralysis. Difficulty swallowing and impaired ventilation may occur if bulbar and respiratory muscles are involved. Respiratory insufficiency often is characterized by decreased forced exhalation and impaired cough.[41] Rapid shallow breathing indicates inspiratory muscle weakness and usually develops later in the disease. Vital capacity should be measured frequently. When vital capacity is <15–20 mL/kg, mechanical ventilation often is required.[42] In addition, tracheostomy may be required for management of ventilatory failure and for bulbar muscle weakness even after ventilatory function returns to normal. Autonomic dysfunction may be severe, especially in patients experiencing respiratory failure and quadriparesis. Blood pressure lability, tachycardia, and cardiac conduction abnormalities may be present. Physical stimulation may precipitate hypertension, tachycardia, and cardiac dysrhythmias.[43]

Management is primarily supportive and directed at intensive respiratory care and treatment of autonomic dysfunction. Plasmapheresis and IV immunoglobulin may hasten recovery and mat alleviate the harmful effects of the immune response. Corticosteroids and immunosuppressive therapy have not been demonstrated to be effective.[19]

Anesthetic management of the patient with Guillain-Barré syndrome often is dictated by the severity of respiratory and autonomic nervous system dysfunction. Compensatory cardiovascular responses may be absent. Hypotension secondary to hypovolemia, positional changes, and positive-pressure ventilation is possible. Severe autonomic dysfunction may produce exaggerated responses in heart rate and blood pressure; thus, invasive monitors may be necessary and direct acting vasopressors and antihypertensives must be readily available.

Succinylcholine should be avoided because it can precipitate hyperkalemic arrest.[44] Interestingly, this risk may persist for some time after recovery from the disease. Depending on the phase of

the disease, the sensitivity of patients to nondepolarizing muscle relaxants may vary from extreme sensitivity to resistance.[45] Mechanical ventilation should be anticipated postoperatively. Profound sensory disturbance may be present, and patients will need adequate pain control. Although the use of regional anesthesia is limited, the use of epidural opioids has been reported and appears beneficial to patients experiencing intense sensory disturbance.[46] Systemic opioid use must be judicious and closely monitored because these patients may be more sensitive to respiratory weakness or depression secondary to their underlying disease.

Familial Dysautonomia (Riley-Day Syndrome)

Familial dysautonomia is an inherited disease thought to be caused by a deficiency of dopamine-hydroxylase with a subsequent decrease in the level of norepinephrine. Patients with this disorder exhibit impaired temperature regulation, denervation supersensitivity, insensitivity to pain, vasomotor instability, and copious pulmonary secretions.

Riley-Day syndrome has numerous anesthetic implications, including excess secretions, pneumonia, decreased responsiveness to hypoxia and hypercarbia, labile blood pressure, intravascular volume depletion, postural hypotension, decreased gag reflex, corneal abrasions, and emetic crisis. Preparation of the patient for surgery includes achieving adequate pulmonary function and correcting fluid and electrolyte imbalance. Opioids should be used sparingly because pain, hypercapnic, and hypoxic responses are blunted. Because of a risk for aspiration, a nonparticulate antacid can be given. Invasive monitoring may be necessary, and vasopressors should be titrated carefully using direct acting agents as needed.[47] Profound bradycardia and hemodynamic collapse may occur, and the anesthesiologist should be prepared for hemodynamic support and resuscitation.

Porphyrias

Porphyrias are a group of inherited disorders of heme synthesis that result in overproduction and accumulation of porphyrin compounds because of a specific enzyme deficiency in the production of heme. Porphyrias are classified as acute (inducible) or nonacute (noninducible) based on clinical presentation. Several reviews contain more detailed discussions of porphyrias.[48,49]

Acute porphyria may affect the CNS and peripheral nervous system via direct neuronal damage, axonal degeneration, and demyelination. Generally, clinical manifestations of acute attacks occur after puberty. Severe abdominal pain, nausea and vomiting, autonomic dysfunction, mental status changes, electrolyte abnormalities, and peripheral neuropathy ranging from paresis to flaccid quadriplegia characterize acute attacks. Death may occur from respiratory muscle paralysis. The cause of neurologic involvement is unknown but may be related to metabolites of heme intermediates or result from deficiency of the heme pigment in the nerve cell. Factors known to precipitate acute porphyric crisis include fasting, dehydration, infection, emotional stress, excessive ethanol intake, and administration of certain drugs.[50] Nonacute porphyrias are not associated with neurologic disorders or acute crisis.

Because the porphyrias are rare disorders, experience with the clinical use of many drugs, particularly anesthetics, is limited. Pharmacologic therapy of acute attacks is aimed at decreasing the activity of aminolevulinic acid synthetase, the rate-limiting step in heme production. Hematin and heme arginate are potent suppressors of aminolevulinic acid synthetase and markedly decrease the pain associated with acute crisis within 48 hours.[51,52] Hydration and correction of electrolyte imbalance, glucose infusion to prevent starvation, and propranolol to control autonomic dysfunction and aminolevulinic acid suppression are several mainstays of treatment. Avoidance of precipitating factors is the foundation of therapy in the latent period.

Commonly used anesthetics rarely precipitate an acute attack during latent porphyria.[53] Numerous anesthetics have been implicated to exacerbate an acute attack of porphyria and should be avoided. Propofol, ketamine, local anesthetics, muscle relaxants, nitrous oxide, isoflurane, and opioids are considered safe (Table 11–2). Drugs that induce cytochrome enzyme production may trigger a crisis and should be avoided (e.g., barbiturates, ethyl alcohol, etomidate, nonbarbiturate sedatives, hydantoin anticonvulsants, hydralazaine and glucocorticoids).[50] Although regional anesthetic techniques have been described in porphyria, most experts advise against them because of a risk for exacerbating preexisting neuropathy, which could create confusion if neurologic signs develop postoperatively.[54] Perioperative glucose infusion should be administered. Careful positioning is necessary to protect fragile blisters and skin during surgery.

TABLE 11–2.

Safe Anesthetic Drugs in the Presence of Acute Porphyria

Inhaled Anesthetics
Nitrous oxide: safe
Isoflurane: probably safe
Desflurane: probably safe
Sevoflurane: probably safe
Intravenous Anesthetics
Propofol: safe
Ketamine: probably safe
Analgesics
Morphine: safe
Fentanyl: safe
Sufentanil: safe
Acetaminophen: safe
Neuromuscular Blocking Agents
Succinylcholine: safe
Pancuronium: safe
Cisatracurium: probably safe
Vecuronium: probably safe
Rocuronium: probably safe
Mivacurium: probably safe
Anticholinesterases and Anticholinergics
Neostigmine: safe
Atropine: safe
Glycopyrrolate: safe
Local Anesthetics
Lidocaine: safe
Bupivacaine: safe
Tetracaine: safe
Mepivacaine: safe
Ropivacaine: probably safe
Anxiolytics
Midazolam: probably safe
Antiemetics
Droperidol: safe
Metoclopramide: probably safe
Ondansetron: probably safe

Charcot-Marie-Tooth Disease

Charcot-Marie-Tooth disease is the most frequent inherited peripheral neuropathy. Typically, the defect is restricted to the lower third of the legs, causing foot deformities and peroneal muscle atrophy; however, the disease

may slowly progress and affect other areas. Patients typically have stocking-glove sensory loss. Sensory deficits usually are milder than are the motor disturbances.[55] Pregnancy has been associated with exacerbations.[56] Despite long-term disability, life expectancy is not decreased, and treatment usually is supportive.

The effects of nondepolarizing neuromuscular blocking agents appear to be predictable. Although succinylcholine has been used without untoward consequences, it seems prudent to avoid using this neuromuscular blocker based on theoretical concerns about hyperkalemia and cardiac arrest.[57] Respiratory insufficiency, vocal cord paresis, and cardiac conduction disturbances have been described.[58–60]

Neuromuscular Junction

Myasthenia Gravis

Myasthenia gravis is an autoimmune disorder involving the neuromuscular junction. Antibodies develop and are directed against postsynaptic acetylcholine receptors and other muscle membrane proteins.[61,62] The thymus is abnormal in 90% of patients with this disorder (i.e., thymic hyperplasia, thymoma, or thymic atrophy).[63,64] Autoimmune disorders such as thyroiditis and systemic lupus erythematosus are common in patients with myasthenia gravis.

The hallmark of this disorder is skeletal muscle weakness that is aggravated by exercise and improves with rest. Exacerbations and remissions are common. Any skeletal muscle may be affected, but the most common clinical presentation is ocular muscle weakness. Bulbar involvement may cause difficulty swallowing and respiratory insufficiency. When peripheral muscle groups are involved, ambulation may be difficult. Interestingly, the first manifestation of myasthenia gravis may occur when a patient is administered drugs that stabilize the muscle membrane, such as magnesium sulfate or local anesthetics. Myasthenic crisis occurs in approximately 20% of patients during the course of the disease and usually is precipitated by pulmonary infections.[64]

The diagnosis of myasthenia gravis is suggested by complaints of muscle weakness, particularly ocular and bulbar muscles. In addition to clinical history, the edrophonium tests (or challenge), electromyography, and detection of circulating antiacetylcholine receptor antibodies may confirm the diagnosis. Surprisingly, the extent of the disease is not proportional to the receptor antibody titer.

Treatment aims to improve function by increasing the amount of acetylcholine available at the neuromuscular junction. Cholinesterase inhibitors effectively increase the concentration of acetylcholine available at the neuromuscular junction. Because of its long duration of action, pyridostigmine is the drug of choice. Consistent control of myasthenia gravis with cholinesterase inhibitors may be a challenge. Underdosing results in worsening of the disease, and overdosing may cause cholinergic crisis. Circulating acetylcholine receptor antibodies are reduced by plasmapheresis, immunosuppressants, and corticosteroids. Thymectomy is controversial, but improvement occurs in the majority of patients with myasthenia gravis, especially if performed early in the course of the disease.[65]

Myasthenic crisis is a rapid deterioration of neuromuscular and respiratory function that may occur at any time perioperatively as a result of infection, stress, or an overdose with anticholinesterase drugs (cholinergic crisis). Cholinergic crisis typically presents with respiratory and bulbar muscle weakness, excessive salivation, miosis, bradycardia, and abdominal cramps. The diagnosis usually is made after a small dose of edrophonium is administered and worsening of these symptoms is observed. Control of a cholinergic crisis is achieved with supportive measures and administration of atropine or glycopyrrolate.

Preoperative preparation includes assessment of pulmonary function and optimization of medical therapy. Preoperative plasmapheresis has been shown to decrease ICU stay and the need for mechanical ventilation after thymectomy.[66] Risk factors that have been identified to predict postoperative respiratory failure after transsternal thymectomy are disease duration >6 years, history of chronic respiratory disease, pyridostigmine dose >750 mg/d, and preoperative vital capacity <2.9 L.[66] Transcervical thymectomy carries a lower incidence of prolonged postoperative mechanical ventilation than does transsternal thymectomy.[67] Whether anticholinesterase medication should be continued up to and including the day of surgery is controversial.[68]

Volatile anesthetics can be used as the sole anesthetic to provide analgesia, amnesia, and muscle relaxation.[69] Muscle relaxants should generally be avoided in most patients with myasthenia gravis. Anticholinesterase therapy should antagonize nondepolarizing muscle relaxants in theory, but in practice patients with myasthenia gravis may be up to 100 times more sensitive to nondepolarizing relaxants than are normal patients.[70] Increased sensitivity remains in patients who are asymptomatic. The need for careful titration of nondepolarizing neuromuscular blockers via monitoring with a peripheral nerve stimulator in all patients with a history of myasthenia gravis is confirmed by these findings. Also, anticholinesterase therapy prolongs the response to succinylcholine by impairing plasma cholinesterase activity. Phase II block may be seen after administration of low doses of succinylcholine.[71] The decrease in the number of acetylcholine receptors also resists the action of succinylcholine.

Adjuvant drugs such as aminoglycoside antibiotics, magnesium, corticosteroids, loop diuretics, lithium salts, quinidine, and procainamide may exacerbate muscle weakness in myasthenic patients. Central respiratory depression is common in myasthenic patients, and the respiratory depressant effects of opioids and benzodiazepines may be enhanced.[72]

Epidural analgesia and anesthesia has been described in myasthenic patients.[73,74] However, caution is necessary because the muscle relaxation induced by regional anesthesia may accentuate the weakness of myasthenia. Amide local anesthetics are theoretically a better choice than are the ester local anesthetics because cholinesterase activity does not affect amide anesthetic metabolism (see Chapter 44 for a discussion of the local anesthetic structures). Pregnancy has an unpredictable affect on myasthenia, and exacerbations should be anticipated.

Myasthenic Syndrome (Eaton-Lambert Syndrome)

Myasthenic syndrome (Eaton-Lambert syndrome) is an acquired autoimmune disorder of the neuromuscular junction, often associated with carcinomas, in which release of acetylcholine from the nerve terminal is impaired despite normal production and processing of acetylcholine by the nerve cell. Onset of this disorder, when present, often

precedes discovery of the malignancy by several years. Antibodies are produced against calcium channels, specific to tumor cells, but unfortunately cross-reactivity with calcium channels at the neuromuscular junction results in a decreased release of acetylcholine. Proximal extremity weakness is common, with the bulbar musculature less likely to be involved. In contrast to myasthenia gravis, muscle weakness is not consistently reversed by anticholinesterase administration, and exercise tends to improve muscle function (Table 11–3). Diagnosis may be made with electromyography or antibody assay. 3-4-Diaminopyridine is commonly administered and increases the presynaptic release of acetylcholine. Treatment of an underlying neoplasm, if present, usually improves symptoms. Immunosuppression, plasmapheresis, and immunoglobulin may be effective.[75]

Anesthetic management should focus on interactions with muscle relaxants. Patients with myasthenic syndrome are hypersensitive to the effect of depolarizing and nondepolarizing muscle relaxants. Doses should be reduced and titrated to effect with a peripheral nerve stimulator. Administration of 3-4-diaminopyridine should be continued perioperatively.[76]

TABLE 11–3.

Myasthenia Gravis and Myasthenic Syndrome

Myasthenia Gravis	Myasthenic Syndrome
Extraocular, bulbar, facial muscle weakness	Proximal limb (arms › legs) weakness
Fatigue with exercise	Improved strength with exercise
Female › male	Male › female
Thymoma	Carcinoma (small cell of the lung)
Resistant to succinylcholine	Sensitive to succinylcholine
Sensitive to nondepolarizing muscle relaxants	Sensitive to nondepolarizing muscle relaxants
Good response to anticholinesterases	Poor response to anticholinesterases

Myopathies and Channelopathies

Muscular Dystrophies

Muscular dystrophies are disorders associated with abnormalities of the muscle membrane, resulting in variable, and progressive, loss of skeletal muscle function (Table 11–4). Dystrophin is a major component of the muscle cell cytoskeleton, which provides structural support to the muscle membrane in normal muscle. Lack of dystrophin results in membrane instability and permeability, eventually leading to intracellular calcium accumulation, cell necrosis, and replacement of degenerated muscle by fibrous and adipose tissue.[77] In addition to skeletal muscle dysfunction, cardiac and smooth muscle are affected. Indeed, in many types of muscular dystrophy, cardiac muscle involvement may be more significant than skeletal muscle involvement.

Duchenne muscular dystrophy is the most common muscular dystrophy (1:3,500 male births) and has the most severe clinical course.[78] This disorder is a recessive, sex-linked genetic abnormality that is clinically evident in males, although female carriers may manifest subclinical abnormalities. Duchenne muscular dystrophy is characterized by painless skeletal muscle degeneration and atrophy. Muscle degeneration and weakness usually manifest in early childhood (age 2–5 years). Severe limitation in movement with development of contractures and kyphoscoliosis confine the child to a wheelchair by early adolescence. Marked increases of serum creatine kinase levels are present. Death commonly results from congestive heart failure or pneumonia. Although aggressive therapy for cardiopulmonary dysfunction has improved survival, afflicted individuals rarely survive beyond the third decade of life.[79,80]

As the patient ages and the disease progresses, cardiac muscle involvement typically is reflected by a progressive loss of R-wave amplitude in the lateral precordial leads of the ECG. Cardiomyopathy, ventricular dysrhythmias, and mitral regurgitation may develop as cardiac muscle is progressively lost and fibrous tissue replaces myocardial and conducting tissue. Treatment options include administration of angiotensin-converting enzyme inhibitors and β-adrenergic blockers to slow the deterioration of cardiac function.[80] Pulmonary function testing reveals a restrictive pulmonary disease pattern. Ineffective cough, resulting from diminished respiratory muscle strength, causes retention of secretions, pneumonia, and oftentimes death.[81] Many patients and families choose a tracheostomy and assisted ventilation, which may add years of life, but repetitive pulmonary infection contributes to a shortened life span.[82] Intestinal tract hypomotility develops as a result of smooth muscle involvement. Supplemental feedings may slow the process of cachexia, but the disease continues.

Although the cause of Duchenne muscular dystrophy is known, specific genetic therapy is elusive. Therapy is supportive and focuses on improving cardiopulmonary function and better nutrition.

Becker muscular dystrophy is similar to Duchenne muscular dystrophy; however, it has a later onset in life and slower clinical progression. Typically, patients remain ambulatory past the age of 16 years, and cardiac failure caused by occult cardiomyopathy may be the presenting symptom.[83] Any male with a persistent elevation in serum creatine kinase concentration

  - Hypokalemic periodic paralysis
  - Myotonia congenita
  - Myotonic dystrophy
  - Paramyotonia congenita
  - Proximal myotonic dystrophy
  - Recessive myotonia

should be evaluated for Becker muscular dystrophy.

Emery-Dreifuss X-linked muscular dystrophy is characterized by humeropectoral muscle weakness and contractures of the spine, elbows, and ankles. The autosomal dominant type of this disorder is caused by a defect in the protein lamin, whereas the recessive form is caused by a defect in the protein emerin. Clinical manifestations of skeletal muscle weakness usually are mild, but cardiac conduction defects may manifest as sudden death. Patients with this disorder are candidates for implantable defibrillating pacemakers.[84]

Limb-girdle muscular dystrophy patients have weakness of the muscles of the shoulder and pelvic girdles. Most forms of this disorder are inherited in an autosomal recessive fashion, although autosomal dominant defects have been discovered. A defect in the sarcoglycan protein is the usual etiology of this abnormality.[85] Cardiomyopathy and cardiac conduction defects may occur.

Fascioscapulohumeral muscular dystrophy is a disease with diverse clinical manifestations that is inherited in an autosomal dominant fashion. Facial, scapulohumeral, anterior tibial, and pelvic-girdle muscle weakness are common. Cardiac conduction defects as well as deafness and retinal vascular disease may occur.

Oculopharyngeal muscular dystrophy primarily manifests with ptosis and dysphagia late in adulthood. Commonly, weakness of the head and neck develop in addition to dysphagia that is present from pharyngeal muscle weakness and esophageal dysmotility.

Merosin-deficient muscular dystrophy, Fukuyama muscular dystrophy, Walker-Warburg syndrome, Ulrich disease, muscle–eye–brain disease, nemaline myopathy, myotubular myopathy, and rigid spine muscular dystrophy are a group of muscular dystrophies that comprise congenital muscular dystrophy.[85,86] Congenital muscular dystrophies are characterized by early onset of muscle weakness, feeding difficulties, respiratory dysfunction, and mental retardation.

Perioperative complications from anesthesia in patients with muscular dystrophies usually result from the effects of anesthetic drugs on myocardial and skeletal muscle. Preexisting myocardial dysfunction makes the patient with muscular dystrophy susceptible to the myocardial depressant effects of anesthetics. The abnormal muscle cell membrane predisposes patients with muscular dystrophy to hyperkalemia and rhabdomyolysis when subjected to volatile anesthetics alone or in combination with succinylcholine, as numerous case reports support. In light of the abnormal muscle membrane, succinylcholine administration may further damage the muscle membrane and cause the release of intracellular contents. Therefore, succinylcholine should be avoided in patients with muscular dystrophies. It has been speculated that volatile anesthetics cause the release of calcium from the sarcoplasmic reticulum and may elicit damage to the muscle cell membrane and cause rhabdomyolysis. Interestingly, sevoflurane appears to be a less potent stimulus for release of calcium from the sarcoplasmic reticulum than are other volatile agents.[87]

Nondepolarizing muscle relaxants may have a prolonged duration of action in patients with muscular dystrophy, although the response to mivacurium appears to be normal.[88] Therefore, close monitoring of neuromuscular function is indicated. Although unpredictable, some patients with muscular dystrophies may be susceptible to developing malignant hyperthermia (MH). Without regard to specific etiology, patients who have chronically increased creatine phosphokinase levels may have a 40–45% risk of being MH susceptible.[89] Therefore, careful consideration of anesthetic plan may be to avoid all MH-triggering agents until a patient has been evaluated by the caffeine–halothane contracture test on a muscle biopsy specimen.

Delayed gastric emptying and impaired swallowing increases the risk of perioperative aspiration. Postoperatively, patients with muscular dystrophies must be closely monitored for evidence of pulmonary dysfunction and retained secretions. Vigorous pulmonary toilet and mechanical ventilation are frequently required. Regardless of the need for postoperative mechanical ventilation, these patients should be placed in an advanced monitoring unit (ICU) for appropriate analgesic therapy and respiratory monitoring.

Myotonias

The myotonias are a diverse group of hereditary skeletal muscle disorders with a common clinical sign: myotonia (Table 11–1). Myotonia is the persistent contracture and delayed relaxation of skeletal muscle after cessation of voluntary contraction or stimulation of the muscle. One of the typical signs of myotonic dystrophy is the inability to relax the handgrip. Progressive muscle wasting, ptosis, and facial muscle weakness also are common in patients with myotonic dystrophy. Interestingly, in other myotonic syndromes, the most common finding is stiffness that improves with exercise. However, paramyotonia (cold-induced myotonia) is an exception, wherein exercise exacerbates symptoms. Recently, genetic defects in sodium, chloride, and calcium ion channels in the muscle membrane have been identified as the abnormalities responsible for myotonia. Therefore, drugs such as mexiletine, procainamide, tocainide, and quinine may relax myotonic contractures by altering ion channel activity and skeletal muscle membrane excitability.

The most common of the myotonic disorders is myotonic dystrophy (Steinert disease), although proximal myotonic myopathy, myotonic dystrophy type II, and proximal myotonic dystrophy are other myotonic diseases. Myotonic dystrophy is inherited in an autosomal dominant pattern, and symptoms typically appear in the second or third decade of life. A defect on chromosome 19 produces a decrease in protein kinase that causes degeneration of the sarcoplasmic reticulum.[90] This myotonic dystrophy is the only myotonic disorder to exhibit extramuscular manifestations. Cataracts, premature balding, diabetes mellitus, thyroid dysfunction, adrenal insufficiency, gonadal dysfunction, and cardiac conduction defects are common. Cardiac involvement does not correlate with the severity of skeletal muscle involvement.[91] There is a progressive deterioration of the conduction system resulting in atrioventricular conduction delay. First-degree atrioventricular block, bundle branch block, and widening of the QRS complex are common. Cardiomyopathy, cardiac failure, and sudden death may occur, and the incidences of septal defects, mitral valve prolapse, and valvular disease are increased.

Recurrent pulmonary infections and aspiration may result when bulbar musculature is affected. Pulmonary

function testing demonstrates a restrictive lung disease pattern, mild arterial hypoxemia, and diminished ventilatory responses to hypercapnia and hypoxia. Gastric atony may develop as a result of alterations in smooth muscle function. Exacerbations of myotonic dystrophy often occur during pregnancy as a result of increased concentrations of progesterone. Congestive heart failure is common during pregnancy, and cesarean delivery is indicated because of uterine smooth muscle involvement. Labor typically is prolonged, and the incidence of postpartum hemorrhage is increased. Infants may have congenital myotonic dystrophy, which typically is characterized by hypotonia, respiratory insufficiency, and feeding difficulties.

Therapy for myotonic dystrophy is focused on treating coexisting diseases and cardiac dysrhythmias. Drugs that alter sodium channel function have been the most effective for managing myotonia (e.g., mexiletine). Avoiding factors known to precipitate myotonia is important.

Anesthetic considerations for patients with myotonic dystrophy include the presence of coexisting diseases, abnormal responses to drugs, and avoiding factors that are associated with the development of perioperative myotonia. Perioperative myotonia has been precipitated by drugs (propofol and succinylcholine), physical factors (hypothermia), electrocautery, and surgical manipulation. Potassium administration will worsen clinical myotonia. Succinylcholine produces an exaggerated contracture, and its use should be avoided. The myotonic response produced by succinylcholine may be so severe that ventilation and tracheal intubation are difficult and may be impossible. The typical presentation of succinylcholine-induced myotonic contracture includes jaw, abdominal, and chest rigidity. Perioperative myotonia may be difficult to differentiate from MH. Recent evidence does not support an association between myotonic dystrophy and MH.[92] Nondepolarizing muscle relaxants and peripheral nerve blocks do not abolish myotonic contractures. Induction agents, volatile anesthetics, opioids (systemic and neuraxial), and sedatives may cause profound respiratory depression. Increased sensitivity to nondepolarizing muscle relaxants may occur, especially when there is muscle wasting. Prudence dictates the use of short-acting muscle relaxants when necessary, with careful monitoring of the response. Peripheral nerve stimulation may cause myotonia or be misinterpreted as sustained tetanus even though significant neuromuscular blockade exists. Reversal of neuromuscular blockade may induce myotonia.

Although no specific anesthetic technique has been determined to be superior for patients with myotonic dystrophy, close monitoring of cardiac and pulmonary function is critical to ensure an optimal perioperative outcome. Mechanical ventilation should be used until muscle strength and function return to baseline.[93] Regional anesthesia has been successfully performed in patients with myotonic dystrophy.[94]

Familial Periodic Paralysis

Periodic paralyses are skeletal muscle channelopathies, which include hyperkalemic and hypokalemic periodic paralysis, paramyotonia congenita, and potassium aggravated myotonia.[95–97] Periodic paralyses are characterized by acute reversible episodes of muscle weakness or paralysis of the extremities with sparing of the respiratory muscles. Although these disorders are classified by changes in serum potassium concentrations during an acute episode, these changes are relative to the baseline potassium concentration and are not always abnormally increased or decreased (Table 11–5).

Hyperkalemic periodic paralysis is inherited in an autosomal dominant fashion. The dominant trait has been discovered as a mutation in the sodium ion channel on chromosome 17.[90] As a consequence of this dysfunction, when the resting membrane potential becomes slightly more positive, the myofiber can more easily reach threshold and the muscle becomes hyperexcitable, which clinically manifests as myotonia.[98] When the membrane potential becomes even more positive, the myofiber cannot fire an action potential because of the loss of a sufficient membrane potential, and the result is paralysis.[98] Normokalemic periodic paralysis is rare and most likely is a variant of hyperkalemic paralysis in which the potassium concentration does not change during attacks.[99]

Attacks usually begin during childhood and vary in frequency from several times per week to once in a lifetime. These episodes of myotonia and paralysis may last several hours after exposure to a trigger. Triggering events include eating potassium-rich foods, IV infusion of potassium, fasting, cold exposure, and rest after strenuous exercise. Thiazide diuretics and a low-potassium diet are the mainstays of preventive treatment. Glucose and insulin infusion and IV calcium administration can be used to manage acute attacks.

Hypokalemic periodic paralysis is inherited in an autosomal dominant pattern. The dominant trait produces a defect in the calcium ion channel on chromosome 1.[100] The dihydropyridine receptor is a voltage-gated ion channel that is responsible for attacks, but the mechanism by which this defect results in attacks of paralysis is under investigation.

Attacks usually begin during childhood and vary in frequency. In contrast to the hyperkalemic form, attacks last longer—from hours to days. Also, cardiac arrhythmias are more common, myotonia is absent, and permanent muscle weakness eventually develops by the fifth decade of life. Paralysis is commonly triggered by ingestion of carbohydrates, strenuous exercise, glucose and insulin infusion, IV calcium, and exposure to cold. Paralysis often is incomplete, affecting

TABLE 11–5.

Clinical Features of Hypokalemic and Hyperkalemic Familial Periodic Paralysis

Hyperkalemic
Potassium concentration >5.5 mEq/L (or normal) during crisis
Precipitating events
Potassium infusion
Hypothermia
Rest after strenuous exercise
Metabolic acidosis
Duration of paralysis
Minutes to hours
Hypokalemic
Potassium concentration <3 mEq/L during crisis
Precipitating events
High glucose intake
Strenuous exercise
Stress
Hypothermia
Glucose-insulin infusion
Pregnancy
Duration of paralysis
Hours to days

the limbs and trunk but sparing the diaphragm. Treatment involves the administration of potassium, acetazolamide, and dichlorphenamide.

Maintenance of normal potassium concentrations and avoidance of events that precipitate weakness are the primary goals of the perioperative management of patients with hyperkalemic and hypokalemic periodic paralysis. Electrolyte abnormalities should be addressed and corrected as best as possible prior to surgery. Patients may be sensitive to nondepolarizing muscle relaxants; therefore, short-acting relaxants should be administered when necessary. The response should be monitored with a peripheral nerve stimulator. Reversal should be avoided because of concern that reversal agents may precipitate myotonia. However, adequate muscle strength must be assured prior to extubation.[101] Succinylcholine should be avoided because it alters serum potassium concentrations and therefore may precipitate an attack. Reductions in serum potassium from metabolic changes or medications should be avoided because this situation may initiate an episode of paralysis. Perioperative potassium values should be monitored serially. The ECG should be continuously monitored for evidence of arrhythmia, and normothermia and normocapnia should be maintained. Volatile anesthetics have been administered without complication. Regional anesthesia has been used successfully, although there is concern that regional techniques can create confusion if neurologic signs develop postoperatively.[102] MH has been associated with periodic paralyses.[103]

Skeletal Muscle Diseases

Central Core Disease

Central core disease is a hereditary, nonprogressive congenital myopathy that typically is characterized by lower extremity muscle weakness. Increased lumbar lordosis, kyphoscoliosis, and hip dislocations may occur. Histologically, type I muscle fibers display amorphous central areas (cores). The underlying defect is thought to be associated with the ryanodine receptor gene, similar to MH.[104] Of great concern when anesthetizing patients with central core disease is MH susceptibility.[105,106] MH precautions should be taken and nontriggering anesthetics used when anesthetizing patients with central core disease (see Chapter 89 for a thorough discussion of malignant hyperthermia).

Glycogen Storage Diseases

Glycogen storage diseases are inherited disorders characterized by a deficiency of enzymes involved in glucose metabolism. An enzyme deficiency results in a lack or excess of precursors and end-products of glycogen formation and breakdown. Type II (Pompe disease) glycogen storage disease is notable for the buildup of glycogen in smooth, skeletal, and cardiac muscle. Cardiac involvement typically leads to congestive heart failure. Anesthetic experience is limited.[107,108] Skeletal muscle involvement predisposes patients to upper airway obstruction secondary to glycogen infiltration of the tongue. Aspiration is common secondary to neurologic involvement and subsequent impairment of cough, gag, and swallowing mechanisms. Volatile anesthetics may precipitate cardiovascular embarrassment. Administration of succinylcholine to these patients may not be prudent because theoretically it could result in myoglobinuria and perhaps hyperkalemia with subsequent cardiac arrest. Hypoglycemia and acidosis may develop perioperatively, and patients should be hydrated and receive exogenous glucose. Hepatic dysfunction usually is present, so judicious administration of drugs hepatically metabolized should be taken into consideration. Regional anesthesia has been performed in patients with glycogen storage disorders.[109] Patients with type V (McArdle disease) glycogen storage disease are prone to developing myoglobinuria and rhabdomyolysis. Automated blood pressure readings should be performed cautiously, and tourniquets should be avoided to prevent muscle damage.[110]

Mitochondrial Myopathies

Mitochondrial myopathies are a group of disorders that affect oxidative phosphorylation, resulting in impaired adenosine triphosphate production. These disorders have many manifestations, including CNS and muscle pathology. Exercise intolerance, fatigue, muscle pain, progressive weakness, and cardiomyopathy may be present. Respiratory depression is common after administration of general anesthesia. There does not appear to be an association with MH with most mitochondrial disorders.[111–114] However, avoidance of succinylcholine seems prudent because of the potential for hyperkalemia.

Kearns-Sayre syndrome and mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes (MELAS) syndrome are distinct mitochondrial disorders. The anesthetic concerns are similar to the general concerns previously stated, with the following additional concerns. Kearns-Sayre syndrome is associated with heart block due to involvement of the cardiac conduction system. General anesthesia should be used with caution because it may increase the risk of myocardial depression and cardiac conduction defects.[115] MELAS syndrome is characterized by stroke-like episodes, seizures, dementia, recurrent headaches, vomiting, and lactic acidosis. There is suspicion that MH susceptibility may be increased.[116] Myocardial depression may occur with administration of volatile anesthetics, so they therefore should be used with caution.

PERIOPERATIVE ASSESSMENT OF MUSCULOSKELETAL CONDITIONS

Patients with musculoskeletal disease may present varied challenges to the anesthesiologist. A number of more common musculoskeletal conditions are included here for consideration in the evaluation of a patient for anesthesia.

Osteoarthritis

Osteoarthritis (OA) is a prevalent condition with advancing age.[117] Multiple joints are affected, most commonly weight-bearing joints. Patients with OA may require joint replacement surgery or other intricate orthopedic procedures. In patients with OA, the cervical spine may have a reduced range of motion, and the lumbar spine may be affected with osteal growths such that performing regional anesthesia may be difficult. Determination of what the surgical approach required for patient positioning is important. Whether regional anesthesia will be used intraoperatively or only for postoperative analgesia must be considered. How soon the patient is expected to become ambulatory and require full sensation and motor capabilities may dictate whether long-acting regional anesthetics or techniques can be used.

A careful list of recent nonsteroidal antiinflammatory drug (NSAID) use should be obtained. With many of the newer, more powerful, and long-lasting NSAIDs, there is concern for possible hematoma formation following regional or neuraxial anesthesia. Most practitioners are willing to perform peripheral blocks in patients who are receiving moderate doses of NSAIDs, provided there is no history of excessive bleeding; however, high-dose NSAID use or a history of bleeding should trigger a note of caution.

OA results in moderate to severe disability that may be relieved by surgical approaches. Of significant concern to the anesthesiologist is cervical spine disease with reduced range of motion and implications of difficulty in visualizing or securing the airway. Neurologic manifestations may occur from development of spinal stenosis at any spinal level. Chronic, subacute, and acute symptoms may be present, and acute neurologic symptoms may require emergency operation. This may require rapid sequence intubation, which may become complicated if the airway is not easily visualized.

Treatment of OA includes salicylates, NSAIDs, local heat, and surgical procedures to ameliorate painful symptoms. There is no effective therapy for slowing the pathogenesis of the disease. Selective cyclooxygenase-2 inhibitors were found to be effective in patients in patients with OA, and their side effect profile initially was thought to be advantageous compared with other nonselective NSAIDs. However, some of these drugs were withdrawn from the market when cardiovascular events associated with use of cyclooxygenase-2 agents were discovered. A careful history of medication use is necessary before considering neuraxial blockade.

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is an autoimmune disease that attacks numerous joints throughout the body and has some special considerations for the anesthesiologist. Patients with RA may have complications primarily from their disease or secondarily from treatment of the disease, including use of glucocorticoids, NSAIDs, as well as immunosuppressive drugs.

Patients with advanced stages of RA may have temporomandibular ankylosis that makes direct laryngoscopy for endotracheal intubation very challenging, if not impossible. Fiberoptic intubation may be required, or tracheostomy may be necessary. The cervical spine may be involved, including laxity of the C1–2 ligament causing instability of the cervical spine. Subluxation of the atlantoaxial joint and instability can progress to spinal cord compression. Long tract signs, including bowel and bladder dysfunction, may occur, and sudden death has occurred from spinal cord laceration by the odontoid process. Recognizing early signs of serious cervical spine instability is critical in planning the approach to the airway. Awake or fiberoptic intubation may be necessary to permit neurologic examination immediately following placement of an endotracheal tube (see Chapters 8 and 35 regarding airway evaluation and management). Patients with RA often have involvement of multiple digits and may suffer from compression fractures of the vertebral bodies secondary to glucocorticoid use. These presentations in this illness may make anesthesia particularly challenging.

RA afflicts peripheral joints, most often symmetrically. As the disease advances, patients may have severe limitations in movement because of inflammatory contractions, pain with motion, or bone joint fusions due to long-standing inflammation. These patients may present for multiarticular surgical procedures or other surgical procedures secondary to complications of RA.

Cricoarytenoid joint involvement may occur in RA. This condition may make the glottis more rigid and require insertion of a smaller-diameter endotracheal tube. Joints that are fixed in adduction may be life-threatening and require tracheostomy in order to establish a stable airway.

RA is a systemic disease with pulmonary and cardiac manifestations. Restrictive lung disease occurs from multiple complications. Pulmonary interstitial fibrosis, pulmonary effusions, and parenchymal rheumatoid nodules may lead to crepitations. With advanced disease, ventilation and oxygenation may require attention to small-volume, positive-pressure ventilation during surgery and supplemental oxygen use preoperatively and postoperatively. Consideration for assisted ventilation postoperatively should be discussed with the patient.

RA can be associated with pericardial effusion and pericarditis. Tamponade is rare but well described. Conduction disturbances and valvular dysfunction occurs in advanced stages of RA. Preoperative echocardiographic evaluation and a 12-lead ECG are indicated based upon symptomatology or length of duration of the disease.

Treatment of RA includes use of NSAIDs, glucocorticoids, gold salts, penicillin, and immunosuppressive (cytotoxic) drugs.[118,119] These drugs have multiple serious side effects. Glucocorticoids cause hypertension, cataracts, skin and muscle atrophy, and osteopenia, which may result in vertebral compression fractures. Immunosuppressive therapy may predispose to infections and can be cardiotoxic. NSAIDs and aspirin will result in thrombasthenia or other coagulation disorders, which must be considered prior to performance of regional neuraxial blockade. Peripheral neural blockade may have less risk of hemorrhagic complications, but the rare complications do not deter some anesthesiologists from careful use of peripheral neural blockade after thorough preoperative assessment of alternatives.

Ankylosing Spondylitis

Ankylosing spondylitis is an inflammatory disease of the spine and paraspinal tissue.[120] Ankylosing spondylitis typically affects young men and may become disabling due to chronic pain in less than a decade. Back pain with or without peripheral arthritis occurs. Ankylosis of the hip and sacroiliac joints may occur, and the cervical spine may also be involved. Cauda equina syndrome may occur with devastating consequences.

Anesthetic considerations are similar to those for patients with RA. Cervical fusion (ankylosis) or atlantoaxial subluxation may occur. Cardiopulmonary complications include restrictive pulmonary fibrosis, and possibly cardiac conduction abnormalities and aortic insufficiency.

Pharmacologic therapy includes NSAIDs and glucocorticoids. Side effect profiles of each of these classes are as discussed previously. Neuroaxial blockade may be contraindicated based upon coagulation status and recent use of NSAIDs.

Cerebral Palsy

Cerebral palsy (CP) is considered a static encephalopathy. It is included in the discussion of musculoskeletal diseases

because of the number of symptoms secondary to loss of upper motor neuron control. Patients have imbalances of flexor/extensor muscle activity resulting in significant contractures. These conditions may make the patient's airway difficult to approach, and the neck may have a reduced range of motion or fixed abnormal position. The usual extremity positions may not be obtainable because of contractures, and IV access may be difficult. Because patients with CP live into adulthood, the anesthesiologist must be aware that multiple procedures for CP are meant to reduce the patient's burden of care by allowing him or her to obtain a more neutral or balanced position. Procedures including osteotomies, botulinum toxin and phenol injections, and other major procedures often are necessary. Patients with CP are one of a group of patients presenting for neuromuscular scoliosis repair. Kyphoscoliosis can be a particularly challenging orthopedic problem requiring extensive instrumentation of the spine posteriorly and sometimes release of multiple ligaments anteriorly. The two-phased approach may be performed in one procedure or may be separated by a number of days or weeks (see Chapter 64 for a discussion of spinal surgery).

Anesthesia considerations include providing a stable airway, appropriate invasive monitoring for anticipated major blood loss, IV access for resuscitative fluid administration, and possible postoperative assisted ventilation. Patients may be limited to nonverbal communication skills, thereby making pain management challenging. Patients with CP may have a seizure disorder from brain injury at birth or traumatic or anoxic brain injury later in life. Anesthesia clinicians should be familiar with the many antiepileptic drugs currently prescribed. If therapeutic monitoring methods are available, optimal serum concentrations should be achieved preoperatively.

Osteoporosis

Osteoporosis is a generic diagnostic term describing loss of bone mass from one of several disease states. Osteoporosis occurs with advancing age and affects women more frequently than men. Decreased bone density may result in pathologic fractures and kyphosis. Although a systemic disorder, axial spine involvement usually is responsible for acute manifestations, and this is the problem that often presents the most difficulty for the anesthesia practitioner.

Osteoporotic fractures and kyphosis may significantly complicate regional anesthetic neuroaxial procedures. Acute fractures may be severely painful and, in rare circumstances, may result in neurologic compromise necessitating urgent operation. Patients may be unable to assume a sitting or supine position comfortably. With increasing kyphosis, a restrictive lung disease pattern appears. Airway management should include plans to ameliorate the patient's pain, use thorough preoxygenation, and institute assisted ventilation for neurodecompressive procedures with prone position. Postoperative respiratory insufficiency should be monitored secondary to underlying respiratory concerns and the moderate-to-heavy opioid requirement for postoperative analgesia.

Most patients with osteoporosis may have an idiopathic etiology. These patients have normal laboratory values for calcium, phosphorus, and alkaline phosphatase. Patients with abnormal laboratory values should be evaluated for coexisting diseases such as hyperparathyroidism or malignancy (hypercalcemia). Paget disease usually is accompanied by a high alkaline phosphatase.

Osteogenesis Imperfecta

Osteogenesis imperfecta (OI) is an inherited disorder of connective tissue that usually manifests in one of two presentations: osteogenesis imperfecta congenita or osteogenesis imperfecta tarda.[121] Newborns and children suffer multiple fractures in the congenital form, whereas the onset of fractures occurs in later childhood, adolescence and adulthood in the tarda form. In addition to musculoskeletal presentations, these patients may suffer otosclerosis and progressive hearing loss, dental hypoplasia, ligamentous laxity, cardiac valvular insufficiency, and easy bruisability.

Evaluation of a patient with OI includes attention to dental deformities preexisting at the time of anesthesia and echocardiographic evaluation if a murmur is present. Airway management usually is not complicated; however, patient positioning for comfort may be challenging. Regional anesthesia is a reasonable option as in healthy patients, but tourniquet use should be avoided to reduce risk of fracture.

When surgeons may not have the benefit of tourniquet use for a specific procedure, greater than expected blood loss should be anticipated. Although bleeding tendency in patients with OI has been described, this finding does not absolutely contraindicate regional anesthesia.

Patients with OI and many patients with musculoskeletal dysplasias tend to become febrile in the operating room. Ectodermal dysplasia or lack of vasorelaxation may prevent mechanisms of heat loss usually encountered in the operating room or during anesthesia. Special attention should be directed to temperature monitoring and control, even for short procedures. With recent attention to prevention of heat loss during anesthesia, patients often are protected from hypothermia. However, in patients with OI, moderate-to-severe generalized hyperthermia may occur, and this may be confused with MH. Patients with OI do not have an increased susceptibility for MH.

Scleroderma

Scleroderma (progressive systemic sclerosis [PSS]) is a disorder of connective tissue with destruction of small arterioles, leading to fibrosis of the skin and internal organs. It is not specifically a musculoskeletal disease. PSS causes swollen and stiff fingers and Raynaud phenomenon. Pain of the digits and knee joints is common, and a polyarthritis resembling RA may occur. Limited mobility secondary to diffuse fibrosis (scleroderma) becomes a feature that may make patient positioning for surgery difficult.

Visceral involvement in scleroderma includes esophageal (dysphagia and gastroesophageal reflux), gastric atony and dilation, intestinal (abdominal pain), pulmonary fibrosis, and cardiac involvement, including varying degrees of heart block, cardiomyopathy, and pericarditis, which may result in tamponade.[122]

Preoperative evaluation includes a comprehensive history of symptoms related to the airway, pulmonary, and cardiac systems. Airway management may require a rapid sequence or an awake technique. Cardiopulmonary evaluation depends on duration of the disease and symptoms of disability or signs on physical examination. Cardiac rhythm and performance should be thoroughly evaluated prior to elective anesthesia and operation.

When a patient with PSS presents for emergent surgery, a 12-lead ECG, and possibly echocardiography, should be considered. Electrolytes should be measured. Causes of death in PSS include cardiovascular etiologies and renal failure. Subclinical renal failure (increased blood urea nitrogen and creatinine, hyperkalemia, and hyperphosphatemia) is a relative contraindication to succinylcholine use. Patients may experience amnesia from lack of absorption of nutrients, and microangiopathic hemolytic anemia.

Postoperative care should include cardiovascular monitoring, serial electrolytes evaluation, and supplemental oxygen to address the combined effects of pulmonary involvement and opioid use for postoperative analgesia.

Carpel Tunnel Syndrome

Carpal tunnel syndrome is an entrapment neuropathy that may be idiopathic or secondary to a number of illnesses, including RA, tenosynovitis, and amyloidoses, and may occur secondary to edema during pregnancy. The surgical approach to entrapment is decompression by release of the transverse ligaments or removal of a space-occupying lesion compressing the nerve.

The anesthetic approach may include general anesthesia, upper extremity regional blockade, or local IV anesthesia (Bier block). These procedures usually are performed in an ambulatory surgical suite, and the anesthesia plan should anticipate the need for rapid recovery. Some surgeons will want to perform a sensorimotor examination immediately postoperatively to establish that no surgical complication occurred, but most are comfortable with regional anesthetic techniques for this procedure.

Achondroplasia

Achondroplasia is one etiology of dwarfism. A defect in endochondral ossification appears to lead to short tubular bones. Children often are identified at birth by their phenotypic presentation. Relative macrocephaly and hypoplastic midfacial features are common.

The two most concerning issues with achondroplasia are a relative stenotic foramen magnum, which may result in obstructive hydrocephalus, and atlantoaxial instability. These problems may cause acute neurologic presentation of increased intracranial pressure or spinal cord compression, respectively. These problems may present early in infancy and require emergent decompression.

As these children grow, they develop increasing lordosis and require spinal fixation/stabilization.[123] Multiple procedures may be necessary.

Anesthetic implications in patients with achondroplasia include anticipating a difficult seal of a face mask because of midfacial hypoplasia. Tracheal intubation is generally not difficult; however, care should be taken not to hyperextend the neck for visualization of the vocal cords so as to avoid cervical spinal cord injury. No additional side effects are associated with use of succinylcholine, and there is no association of achondroplasia with susceptibility to MH.

Patients with achondroplasia may have an inability to disseminate heat effectively. Special attention to central temperature monitoring and management should be anticipated. These patients may have an excessive thermal response to anticholinergic agents.

Polymyositis/ Dermatomyositis

Polymyositis and dermatomyositis are diseases that involve skeletal muscle, connective tissue, and the skin.[124] The etiology is unknown, but autoimmune phenomena are suspected. Usually slow progressive weakness occurring over months to years affects proximal extremity muscle groups, followed by neck involvement. Pharyngeal and laryngeal muscles also may be involved.

Cardiac involvement may include rhythm disturbances, myocardial necrosis, or inflammation. Pulmonary fibrosis or interstitial pneumonitis may be seen. Treatment of the illness consists of corticosteroids and immunosuppressive drugs. The consequences of these treatments should be considered in the preoperative evaluation (e.g., stress doses of corticosteroids may be indicated for major invasive procedures, and meticulous attention to sterile technique is required to prevent risk of infection following vascular access, etc.).

Anesthetic implications of these diseases are primarily of pharyngeal muscle activity and the risk for aspiration. No known anesthetic-associated exacerbation of cardiac involvement has been reported. Patients do not routinely experience respiratory weakness following anesthesia or use of neuromuscular blocking agents.

RHABDOMYOLYSIS

Rhabdomyolysis is a condition associated with many inherited disorders,[125] toxin and drug exposure,[126,127] ischemia, crushing, and burn injury.[128] Exercise-induced rhabdomyolysis can occur secondary to inborn errors or secondary to exercise-induced bioenergetic failure at the cellular level. Perioperative rhabdomyolysis has been associated with positioning, cardiopulmonary bypass, an excessive response to succinylcholine, and as a prominent symptom of MH syndrome[129] (see Chapter 89 for details regarding malignant hyperthermia).

A preoperative history of rhabdomyolysis should alert the anesthesiologist to the possibility of inborn genetic errors (carnitine palmitoyltransferase deficiency [not related to MH]) and susceptibility to MH. Exercise-induced rhabdomyolysis patients and patients with chronic hypercreatine kinasemia (hyperCKemia) are considered subgroups at high risk for MH susceptibility.[89,130,131] When in doubt regarding the possibility of susceptibility to MH, the MH hotline consultants are available 24 hours per day (1-800-MH-HYPER) in the United States and Canada (see Chapter 89).

Malignant Hyperthermia

MH is related to very specific muscle disorders as referred (hyperCKemia and exercise-induced rhabdomyolysis). MH is covered extensively in Chapter 89.

SUMMARY

Patients with neuromuscular or skeletal disease present special problems for anesthetic care. Issues range from physical problems such as airway access or patient positioning to biochemical problems such as abnormal thermal regulation. Cardiovascular or respiratory abnormalities accompany several of these diseases and further complicate perioperative anesthetic care. Susceptibility to serious anesthetic-related complications, such as rhabdomyolysis or MH, may occur in some patients. Thorough preoperative evaluation, knowledge of the underlying disease, and careful anesthetic plan-

ning and management are required to achieve the goals of safe and uneventful anesthetic care.

CHAPTER 12

Evaluation of the Patient with Endocrine Disease or Diabetes Mellitus

A.D. John, MD and
F.E. Sieber, MD

Although often not obvious as a physical deformity, a disturbance in endocrine function may increase the complexity of anesthesia care and the risks to the patient. The anesthesiologist must be attuned to the issues of endocrine abnormalities to ensure that the patient is treated preoperatively. This chapter focuses on the proper preoperative treatment of patients with specific endocrine abnormalities, with an emphasis on decreasing anesthetic-related complications.

THYROID

Physiology

The synthesis and release of thyroid hormones occurs as a result of the complex interaction between the hypothalamic–pituitary axis, the thyroid gland, and the thyroid hormones. The hypothalamus controls the release of thyrotropin-releasing hormone (TRH), which is secreted by the hypothalamic neurons and delivered to adenohypophysis via the hypophyseal portal system. Within the pituitary gland, TRH may stimulate the secretion of thyroid-stimulating hormone (TSH), which acts at the thyroid gland. A negative feedback loop is present between the pituitary and the thyroid gland, in which increased levels of thyroid hormone inhibit the secretion of TSH from the pituitary gland. Thyroid hormone levels are the primary determinants of TSH secretion, and increased thyroid hormone levels can override TRH-mediated hypothalamic influences.[1,2]

Thyroid hormones play several important roles—they function as important regulators of metabolism and development, and have effects on many different organs. Thyroid hormones stimulate calorigenesis and metabolism by increasing metabolic rate and oxygen consumption. In addition to regulating cellular respiration these hormones cause an increase in body protein turnover and adipocyte lipolysis. Thyroid hormones are necessary for skeletal maturation in the fetus, and for brain development during infancy, as demonstrated by the effects of thyroid hormone depletion in cretinism. Thus thyroid hormones affect multiple processes, including cellular metabolism; the cardiovascular system; bone formation and development with implications related to osteoporosis; and the neuronal system with regards to development, maturation, and maintenance, with implications of neuropsychiatry and dementia in adults. Thyroid hormones exert their effects by binding to nuclear receptors within cells, thereby affecting the synthesis and release of proteins and messengers regulating intracellular processes.[3,4]

The thyroid gland, using a sodium iodide symporter, takes absorbed iodide into the gland and sequentially synthesizes the thyroid hormones triiodothyronine (T_3) and thyroxine (T_4). Selenocysteine deiodinases found in tissues such as the liver, kidney, thyroid, pituitary, CNS, cardiac and skeletal muscle, placenta, as well as the skin, act on thyroxine to convert it to triiodothyronine, reverse T_3 (rT_3) with almost no physiologic activity, and also to inactive T_3 and T_4.[1–3] The thyroid gland secretes approximately 80–100 μg/d of T_4 with a serum half-life of 6–7 days. Approximately 20% of T_3 is also synthesized and released by the thyroid gland. The remaining T_3 is formed mostly in the liver and kidney by peripheral conversion of T_4 by selenodeiodinases. Once released into the bloodstream T_4 and T_3

KEY POINTS

1. Thyroid disorders are the second most common endocrine disease after diabetes. The range of presentation is vast, ranging from subclinical hyperthyroidism to life-threatening thyroid storm, and from subclinical hypothyroidism to myxedema coma with high mortality if not appropriately treated.
2. The current thyroid-stimulating hormone (TSH) assays, along with the free thyroxine (FT_4) level, will often lead to the correct diagnosis of the thyroid disorder. Although the signs and symptoms of hypo- and hyperthyroidism are quite distinct, with aging, the clinical picture may not be quite as clear. A high level of suspicion, the appropriate use of tests, and clarity in appropriately differentiating coexisting conditions will lead to increased patient safety.
3. Patients with mild hypo- and hyperthyroidism may safely undergo elective surgery if proper care is exercised; but, patients with thyroid storm or myxedema coma may have significant morbidity with elective surgery.
4. Hypercalcemia places a patient at increased risk for hypovolemia and cardiac dysrhythmias. Hypocalcemia may present with decreased myocardial contractibility, tetany, cardiac dysrhythmias, and altered response to muscle relaxants leading to increased perioperative patient risk. Prompt recognition and successful treatment can be lifesaving.
5. The complex interplay between the thyroid, adrenal, and pituitary glands must be considered in anesthetizing patients for surgery. Appropriate corticosteroid replacement will often result in a smooth and stable perioperative course.
6. The major goal in preoperative preparation of the patient with pheochromocytoma is to decrease cardiovascular morbidity and mortality resulting from excess catecholamine secretion. However, the optimal drug for preoperative preparation of the patient with pheochromocytoma is controversial.
7. Cranial diabetes insipidus (decreased vasopressin secretion) may have effects on both intravascular volume and electrolytes. Patients with acromegaly have a higher incidence of airway difficulty, as well as diabetes, hypertension, and cardiomegaly.
8. Diabetes has been strictly defined by the American Diabetes Association. Multiple studies demonstrate the beneficial effects of tight glucose control and consensus conferences have defined in-hospital goals, but where intraoperative glucose levels should be remains to be determined.

are tightly protein bound, with T_3 and T_4 being primarily bound to thyroid-binding globulin. Other binding proteins include albumin, which binds more than transthyretin, with only a very small amount being bound to lipoproteins. T_4 is more tightly bound than T_3, which accounts for the longer half-life of T_4—1 week—when compared to the less-than-1-day half-life of T_3. A larger amount of T_3 (0.4%) in comparison with T_4 (0.04%), circulates in the free form. It is the free form that is active and drives the patient's metabolic state. With stress, the levels of T_3 increase. Once carrier proteins transport T_4 and T_3 into the cell, cellular nuclear receptors have a much greater affinity for T_3 than T_4, leading to increased protein synthesis and cellular metabolic activity.[3,4] This makes T_3 much more potent than T_4.

Thyroid-Function Tests

To assess thyroid disease, it is important to combine the clinical picture with the laboratory tests of thyroid function. The principal tests currently used include TSH, serum T_4, serum T_3, resin triiodothyronine uptake (RT_3U), free thyroxine index (FT_4I), serum thyroglobulin, rT_3, and radioactive iodine uptake (RAIU). Currently, the third-generation TSH measurements with a functional sensitivity of 0.02 μU/mL or less are all that are required to assess primary thyroid disease, covering the range from overt hypothyroidism to overt hyperthyroidism, with sufficient specificity and sensitivity. Table 12–1 gives the reference ranges for normal values. Even though free thyroxine (FT_4) and free triiodothyronine (FT_3) assays tend to avoid the variation caused by thyroid-binding globulin fluctuations as seen with hormones, estrogens, and pregnancy, they may still be affected by artifact and coexisting conditions, such as severe illness, heparin therapy, medications, and severe disturbances in binding proteins.[5–7] These circumstances are more likely to occur with an ill hospitalized population requiring surgery than with an outpatient ambulatory clinic. The TSH and free T_4 can be used to assess for common conditions (Table 12–2).

With aging, there is an increase in baseline TSH normal values. For those younger than 50 years of age, the median TSH value is 1.49 μU/mL. After 50 years of age, it increases to 1.60 μU/mL. After 70 years of age, it increases to 1.98 μU/mL, and after 80 years of age it is 2.08 μU/mL in a population without thyroid disease.[5,8] Whether it is necessary to adjust the current reference range with respect to age is being debated.[9,10]

Other Tests to Assess Thyroid Function

RT_3U does not measure T_3; rather, it is a measure of the thyroid-hormone-binding-to-plasma-protein ratio. It actually measures the percentage of FT_4 not bound to protein. The FT_4I corrects T_4 for abnormalities caused by protein binding and is calculated by multiplying the T_4 by the RT_3U and dividing the result by 100. rT_3 measures the inactive metabolite of T_4 and may be useful in states of nonthyroidal illness. Serum thyroglobulin may be elevated in thyroid cancer and may be useful in differentiating thyrotoxicosis secondary to exogenous administration from thyroid gland dysfunction. RAIU measures thyroid uptake of iodine. This test is helpful in differentiating various entities: iodine deficiency and Graves disease have uniform increased uptake, whereas a single focus indicates a hyperfunctioning nodule, and multiple foci indicate multiple nodules.

Hyperthyroidism

Hyperthyroidism has a wide clinical spectrum that ranges from subclinical hyperthyroidism to mild hyperthyroidism to fulminant life-threatening crisis with thyroid storm. Laboratory values consistent with hyperthyroidism are a low TSH (< 0.05 μU/mL) and a high FT_4 (> 1.8 ng/dL). Occasionally the FT_4 may be in the normal range, but the FT_3 may be elevated (> 596 pg/dL).[5] In subclinical hyperthyroidism the TSH is low but both FT_4 and FT_3 are within the normal range. An elevated TSH with an elevated FT_4 may be suggestive of a TSH-secreting pituitary tumor.[5,6]

Table 12–3 lists the signs and symptoms of hyperthyroidism. Heat intolerance and weight loss despite increased food intake are 2 symptoms closely associated with hyperthyroidism.[10] Common causes of hyperthyroidism include Graves disease, toxic multinodular goiter, autonomously functioning thyroid nodule, thyroiditis (subacute, lymphocytic, or postpartum), exogenous thyroid hormone ingestion, and iodine induced.[6] Less common causes include follicular carcinoma of the thyroid, TSH-secreting pituitary tumor, human chorionic gonadotropin (hCG)-mediated trophoblastic disease, and struma ovarii.[6] Goiter is present in Graves disease and thyrotoxicosis, but may or may not be present in a patient with hyperthyroidism. If a patient has exophthalmos, care must be exercised in protecting the eyes during anesthesia

TABLE 12–1.

Reference Values for Thyroid Function Tests at Johns Hopkins Medical Institutions

Thyroid Function Test	Reference Range
Thyroid-stimulating hormone	0.5–4.5 m U/L
Thyroxine unbound (FT_4)	0.7–1.6 ng/dL
Triiodothyronine unbound (FT_3)	230–420 pg/dL

TABLE 12–2.

Assessment of Thyroid Function with TSH and FT_4

Condition	TSH	Free T_4
Hyperthyroidism	Decreased	Increased
Primary hyperthyroidism	Increased	Decreased
Secondary hypothyroidism	Decreased or normal	Decreased
Sick euthyroid		
Mild	Normal to low	Normal
Severe	Decreased	Normal to low
Pregnancy	Normal (may be low in 1st trimester)	Normal; Increased total T_4; Increased T_3

TABLE 12–3.

Symptoms and Signs of Hyperthyroidism

Symptoms	Signs
Nervousness	Thyroid enlargement
Increased sweating	Tachycardia
Heat intolerance	Atrial fibrillation
Palpitations	Hyperkinesis
Dyspnea	Eye signs
Fatigue and weakness	
Weight loss or gain	
Increased appetite	
Hyperdefecation	

with ointment (lubrication) and protective goggles. In the elderly (older than age 70 years), hyperthyroidism may be difficult to recognize because the hyperkinetic picture is often absent.[12] Also in the elderly, apathy, tachycardia, weight loss, anorexia, and atrial fibrillation are more frequent, whereas in patients younger than age 50 years, heat intolerance, increased appetite, sweating, tremor, hyperreflexia, goiter, and polydipsia are more prevalent.[13,14]

Hyperthyroidism affects many systems, including the cardiovascular, respiratory, and neuromuscular systems. McDevitt et al.[15] demonstrated the role of the thyroid gland in regulating the resting heart rate. Hyperthyroidism caused an increased heart rate when compared with healthy individuals. Hyperthyroidism is associated with an increase in heart rate, stroke volume, cardiac output, pulse pressure, and ectopy, including premature ventricular contractions and atrial fibrillation. Forfar et al.[16] showed a relationship between lone atrial fibrillation in the elderly and hyperthyroidism. In the elderly hyperthyroid patient, there is also an increase in the incidence of congestive heart failure. With increased chronotropy and decreased lusitropy, a third heart sound may be present. Both increased jugular venous pressure and peripheral edema may occur, even in the absence of heart failure. In hyperthyroidism, cardiovascular events as a result of embolic phenomena or myocardial disease may result in death.[4,17,18] The hypermetabolism caused by hyperthyroidism results in increased CO_2 production and, as a consequence, an increase in minute ventilation. Unfortunately, weakness of the respiratory muscles can occur, resulting in reductions in vital capacity and compliance and, ultimately, respiratory collapse. Myopathy is present in more than 50% of patients with hyperthyroidism with electromyograph (EMG) abnormalities present in more than 90% of hyperthyroid patients.[19] Graves disease may be associated with myasthenia gravis, and an association between hyperthyroidism and familial hypocalcemia periodic paralysis has been noted in Asian men.

Treatment of hyperthyroidism[6,18,20] usually consists of antithyroid medications, chiefly the thionamides (propylthiouracil or methimazole). Propylthiouracil is given at a dose of 75–100 mg 3 times a day and methimazole is given at a dose of 10–20 mg once a day. These medications are given for weeks to months and then thyroid function tests are used to ensure that a euthyroid state is being achieved. Radioactive iodine may be used for recurrent hyperthyroidism or persistent hyperthyroidism. Surgical treatment with thyroidectomy should be done only after a euthyroid state has been achieved with medication.

Subclinical Hyperthyroidism

Subclinical hyperthyroidism is characterized by a low TSH and normal FT_4 and FT_3. The prevalence of subclinical hyperthyroidism is approximately 2% and it is more common in the elderly, women, and African Americans.[21] Subclinical hyperthyroidism commonly occurs with multinodular goiter, hyperfunctioning solitary thyroid nodule, and thyroxine overreplacement. It is also associated with an increased risk of atrial arrhythmias in patients older than age 60 years, decreased bone mineral density in postmenopausal women,[6] and an increased risk of mood and affective disorders. There is possibly an increased risk of dementia in patients with antithyroid peroxidase antibodies.[22] The consensus panel's recommendation is to observe and monitor patients with partial suppression of TSH but to treat patients who have complete suppression of TSH (<0.1 mU/L).[21]

Thyroid Storm

At the other end of the spectrum from subclinical hyperthyroidism is thyroid storm. Thyroid storm is an acute life-threatening form of hyperthyroidism with a significant mortality rate of $>20\%$.[23,24] The diagnosis of thyroid storm is a clinical one, because serum levels of thyroid hormones are about the same as encountered in hyperthyroidism. Four clinical features are required for the diagnosis of thyroid storm:[23,24] (a) Temperature elevation with diaphoresis. Temperatures above 106°F have been reported. (b) A marked tachycardia that is disproportionate to the temperature elevation. This may manifest as sinus tachycardia, atrial fibrillation, or other supraventricular or ventricular tachycardia. (c) Cerebral dysfunction, which may range from agitation, restlessness, and emotional lability to confusion, psychosis, seizures, and coma. (d) Gastrointestinal disturbance ranging from nausea, vomiting, and diarrhea to intestinal obstruction or acute abdomen. The presence of jaundice is a poor prognostic sign.[23,24] The precipitating event varies and may include (most commonly) infection; surgery; treatment with radioactive iodine, or the administration of iodinated contrast dyes; cessation of antithyroid medication; amiodarone; exogenous administration of thyroid hormone; diabetic ketoacidosis; hypoglycemia; congestive heart failure; pulmonary embolism, cerebrovascular accident (CVA); bowel infarction; any acute trauma; toxemia of pregnancy, parturition, and the postpartum state; dental extraction; and even vigorous palpation of the thyroid.[23,24]

Treatment

The approach to treatment of thyroid storm is 4-fold[20,23–25]:

1. Decrease production and secretion of thyroid hormone.
2. Block the peripheral effects of thyroid hormones.
3. Maintain supportive care. Aggressive treatment of fever, temperature elevation, acid–base abnormalities, along with respiratory and cardiovascular support.
4. Determine the underlying cause.

Chapter 69 provides a more detailed discussion.

Preoperative

Ideally, the patient is euthyroid prior to any surgical procedure, because of the high risk of precipitating a cata-

strophic thyroid storm. Airway compromise by goiters may be present with laryngeal nerve compression, tracheal deviation or displacement, or even erosion of tracheal cartilage by large goiters. A CT scan or MRI of the neck may provide useful information. Because the use of thyroid medications and the testing takes a period of weeks to months, 1–2 months of treatment with antithyroid medication and a recent TSH and FT_4 may be optimal to indicate levels of effectiveness of treatment prior to an elective operation. In patients requiring emergency surgery, a combination of antithyroid medication, propranolol, and sodium iodide might be effective. The regimen includes propylthiouracil at a dose of 600–1000 mg orally in conjunction with intravenous propranolol to control heart rate; followed in 2–3 hours by an iodine solution to prevent the release of thyroid hormone.[24] Corticosteroids should also be administered, both to prevent the release and conversion of thyroid hormones and to avoid the possibility of coexisting adrenal suppression.[25,26] Heightened awareness must be maintained to quickly detect the manifestations of thyroid storm in patients who are thus prepared for emergency surgery.

Hypothyroidism

Hypothyroidism[5,6] is characterized by a hypometabolic state with generalized slowing of physical processes with fatigue, lethargy, diminished reflexes and slowing of intellectual processes. Hypothyroidism encompasses a vast clinical spectrum, ranging from subclinical hypothyroidism to classical hypothyroidism to fulminant life-threatening myxedema coma. Table 12–4 lists the signs and symptoms of hypothyroidism. Laboratory values characteristic of hypothyroidism are a high TSH (>10 mU/L) and a low FT_4 (<5 pmol/L). Secondary hypothyroidism characterized by both a low TSH (<0.4 mU/L) and a low FT_4 (<9 pmol/L) is a result of pituitary or hypothalamic dysfunction and is quite rare. The primary causes of hypothyroidism are autoimmune lymphocytic thyroiditis which may be either atrophic or of the Hashimoto's variety. This is diagnosed with a positive thyroid peroxidase antibody level. Hypothyroidism may occur after thyroidectomy or after radioactive iodine therapy. In many parts of the world, iodine deficiency is a major cause of hypothyroidism. Hypothyroidism is inducible by a variety of drugs including iodine, thionamides, lithium, amiodarone, interferon, iron, cholestyramine, and Carafate. Infiltrative diseases, such as sarcoid, amyloid, and hemochromatosis, may be associated with hypothyroidism. A transient hypothyroidism or sick euthyroid state may be seen in the postpartum period or after trauma, burns, and infections.[5,6]

TABLE 12–4.

Symptoms and Signs of Hypothyroidism

Symptoms	Signs
Cold intolerance	Weight gain (or loss)
Dyspnea	Bradycardia
Anorexia	Diastolic hypertension
Constipation	Cardiac rub or soft heart tones caused by pericardial effusion
Decreased libido	Ileus
Menorrhagia, amenorrhea	Galactorrhea
Oligoria	Urinary retention
Arthralgias	Loss of brow and scalp hair
Myalgia, muscle stiffness and cramps	Yellow (carotinemic) skin
Dryness	Psychosis
Fatigue	Coma
Depression	Carpal tunnel syndrome
Irritability	
Impaired concentration and memory	
Paresthesia	
Pallor	

Hypothyroid patients[3,4] show decreased heart rates, sinus bradycardia, atrioventricular blocks, and QT prolongation. Pathologically, there is myofibril swelling, loss of striation, and lipid accumulation in the heart. A widened heart shadow is often caused by pericardial effusion. There is a decrease in myocardial contractility, with a prolongation of diastolic relaxation[27] resulting in decreased myocardial work efficiency.[28] Patients with hypothyroidism and heart failure often have underlying cardiac disease.[4] Hyperlipidemia, diastolic hypertension, and increased cardiac risk factors are offset by the decreased metabolic demand and the negative inotropic and chronotropic state of hypothyroidism. The rapid correction of hypothyroidism may precipitate myocardial ischemia.[4]

The pulmonary system may be affected by myxedematous infiltration of the respiratory muscles, and depression of the respiratory responses to hypoxia and CO_2 may occur.[29] Wilson and Bedell[30] showed that myxedema decreases maximal breathing capacity and lung diffusion capacity. Enlargement of the tongue and changes in the voice may occur with severe hypothyroid myopathy. Even in the absence of muscle symptoms, serum creatine phosphokinase (CPK) may be elevated.[31] Other abnormalities noted with hypothyroidism include increased bleeding, hyponatremia, hypoglycemia, and hypothermia from a decreased basal metabolic rate.

Subclinical Hypothyroidism

Subclinical hypothyroidism in women older than 50 years of age has a prevalence of almost 20%, whereas the overall prevalence in the population is between 4% and 10%.[21] Subclinical hypothyroidism is defined by an elevated TSH (>4.5 mU/L) and normal FT_4 and FT_3. The consensus panel recommends that the level of thyroid peroxidase antibody also be measured. If it is positive, the risk per year of progressing to overt hypothyroidism is almost doubled. There is also an increased risk for other autoimmune diseases such as type 1 diabetes mellitus and adrenal insufficiency. For TSH >10 mU/L, the consensus panel recommends treatment to decrease the TSH in patients with subclinical hypothyroidism.

Treatment

In treating hypothyroidism, thyroxine is the preferred agent.[31] Because of its

long half-life (approximately 1 week), once-daily dosing is all that is required. Replacement dosing should begin gradually with a starting dose of 12.5–25 μg/d with the possibility that a small dose of 50 μg/d may be all that is necessary for replacement.[6]

Myxedema Coma

Myxedema coma[23,33] represents an extreme form of hypothyroidism often in elderly female patients with known hypothyroidism and carries with it a significant mortality rate of >20%. The three essential components to establish a diagnosis are[1] (a) altered mental status, which may range from disorientation, lethargy, and confusion to frank coma;[2] (b) abnormal thermoregulation with temperatures lower than 95°F as a result of impaired hypothalamic temperature regulation (note that pseudo normalization caused by infection may mask the low temperatures);[3] and (c) a precipitating illness or event such as a pulmonary or urinary tract infection. Other causes include cold exposure, stroke, trauma, congestive heart failure (CHF), GI bleeding, and medications such as amiodarone, anesthetics, and narcotics. Laboratory examination may reveal markedly elevated TSH with low FT_4 and FT_3, but with concomitant severe illness, glucocorticoid therapy, and pressors, such as dopamine, this clinical scenario may not be observed.[23,33]

Treatment of myxedema coma is based on thyroid hormone replacement and supportive care. The optimal method to replace thyroid hormones in myxedema coma is the subject of controversy and debate.[23,33] A common approach is to administer 300–500 μg of T_4 as an IV bolus and continue with 50–100 μg of IV T_4 until the patient is able to take oral medications. Supportive care is necessary to address the issues of hypoventilation, hypothermia, hyponatremia, hypoglycemia, hypotension, and sepsis. Hypoventilation may result from CO_2 narcosis or coma, and may be exacerbated by myopathy and an underlining pulmonic process. This may require mechanical ventilation and correction of arterial blood gas abnormalities. Hypothermia will correct with thyroid replacement, but is best initially treated by warming the room and using regular blankets. Warming blankets and aggressive correction may lead to vasodilatation and subsequent cardiovascular collapse. Hyponatremia if below 120 mg/dL may need correction with saline solutions, but this must be done gradually so as to avoid central pontine myelinolysis. Correct half the deficit over 24 hours and then reassess. Hypoglycemia may indicate adrenal suppression and should be treated with stress-dose steroids. Hypotension should be carefully addressed because of depressed myocardial contractility and the potential for cardiovascular dysfunction from aggressive resuscitation.[23,33]

Preoperative

An euthyroid state is desirable prior to elective surgery. For emergent surgery, the possibility of precipitating myxedema coma must be borne in mind, as well as the possibility of precipitating myocardial ischemia with overly aggressive thyroid replacement of a hypothyroid patient.[3,23,24]

CALCIUM DISORDERS ASSOCIATED WITH PARATHYROID DISEASE

Physiology

Within the circulation, calcium is distributed among a protein-bound, complex, and a free or ionized states.[1,2,34] The physiologically most important component is ionized calcium. Ideally, it is the direct measurement of ionized calcium that should be obtained in circumstances wherein measurement of serum calcium is clinically relevant. Alterations in serum proteins will affect the proportion of bound calcium. Thus, when interpreting total serum calcium levels, a convenient guide is to adjust the serum total calcium level by 0.8 mg/dL for each 1 g by which the serum albumin level is above or below 4.0 g/dL. If the serum albumin concentration is increased, the serum total calcium concentration should be adjusted downward, and vice versa if albumin concentration is decreased. In addition, acidosis may provoke hypercalcemia by decreasing calcium binding.

Total serum calcium levels are regulated within a range of 9–10.5 mg/dL. Three hormones interact to provide calcium homeostasis: parathyroid hormone, calcitonin, and vitamin D. Parathyroid hormone is secreted from the parathyroid gland and raises serum calcium levels while promoting bone resorption. In the kidney, parathyroid hormone increases the renal absorption of calcium, while increasing the excretion of phosphate, bicarbonate, potassium, sodium, and some amino acids. Vitamin D and its active metabolites, 25-hydroxycholecalciferol and 1,25-dihydroxycholecalciferol, increase intestinal Ca^{2+} absorption. Calcitonin is secreted by the thyroid gland in response to hypercalcemia. Calcitonin inhibits bone resorption and promotes renal excretion of phosphate, sodium, and potassium. In humans, calcitonin is of little physiologic importance. Several feedback mechanisms serve to regulate the levels of these hormones. Of importance, parathyroid hormone release is increased by hypocalcemia, whereas vitamin D inhibits parathyroid hormone secretion by increasing serum calcium. Hypermagnesemia may inhibit parathyroid hormone release, although severe hypomagnesemia causes paradoxical hypocalcemia resulting from inhibition of parathyroid hormone secretion and end-organ response.[1,2,34]

Hypercalcemia

Table 12–5 lists the clinical manifestations of hypercalcemia.[34–36] Patients usually are asymptomatic with calcium levels up to 12 mg/dL. At levels between 12 and 14 mg/dL, symptoms may vary. In this latter circumstance, the clinical manifestations of hypercalcemia should serve as a guide for the need and speed of treatment. Severe hypercalcemia (serum calcium level >14 mg/dL) may be life-threatening and requires immediate treatment, regardless of symptomatology. The majority of patients presenting with severe hypercalcemia develop this as a complication of malignancy.

Hypercalcemia secondary to parathyroid disease is a common condition. With the advent of routine chemical screening, there has been a marked increase in the incidence of diagnosed hyperparathyroidism, with approximately 50,000 new cases of primary hyperparathyroidism each year in the United States. Of these patients, 25–50% are asymptomatic with calcium levels less than 11 mg/dL. The disease primarily affects elderly women. The most common cause of primary hyperparathyroidism is a parathyroid adenoma (80–90%), followed by parathyroid hyperplasia (15%). Parathyroid carcinoma is uncommon. Secondary hyperparathyroidism usu-

ally is not associated with hypercalcemia. In patients with renal failure with secondary hyperparathyroidism, however, hypercalcemia may occur after correction of the renal failure (tertiary hyperparathyroidism). Hyperparathyroidism also may occur as a manifestation of multiple endocrine neoplasia type II (MEN II), which includes pheochromocytoma, hyperparathyroidism, and medullary thyroid carcinoma.

Hyperparathyroidism in pregnant women deserves special mention. Maternal hypercalcemia may have profound effects on the fetus and newborn, leading to neonatal hypocalcemia or tetany. The literature suggests that maternal hyperparathyroidism is associated with increased fetal morbidity and mortality rates. Because the primary treatment for symptomatic hyperparathyroidism is surgery, it is not unusual for the anesthesiologist to care for a pregnant woman undergoing parathyroidectomy.

Hypercalcemia has profound effects on cardiac function, with diverse clinical manifestations. The primary risk in anesthetizing patients with hypercalcemia is cardiac dysrhythmias. Hypercalcemia decreases the refractory period and increases ventricular excitability. These effects may depend on Ca^{2+} level. In addition, QT interval changes are an unreliable indicator of hypercalcemia. Bradyarrhythmias, bundle-branch blocks, and complete heart block are well-documented complications of acute hypercalcemia. Digitalis should be administered with caution because these patients may show increased sensitivity to the drug. Hypercalcemia also increases vascular tone, so the blood pressure often gives an inaccurate assessment of the severity of dehydration and volume contraction that is present.

Treatment

When confronted with an elevated calcium value the first test to order is a repeat calcium.[37–39] Laboratory abnormalities in a patient with hyperparathyroidism usually include hypercalcemia, hypophosphatemia, hypercalciuria, elevations of serum uric acid, and chloride with a decreased serum bicarbonate. The diagnosis of hyperparathyroidism is best supported by an increased parathyroid hormone level associated with hypercalcemia.

The basic goals of therapy for hypercalcemia include correction of dehydration, enhancing renal calcium excretion, inhibiting bone resorption, and managing the underlying disorder. Saline hydration and furosemide rapidly decrease the serum calcium level by 2–3 mg/dL by correcting the underlying fluid deficit and increasing renal calcium clearance. A commonly used regimen is to administer 3–4 L of isotonic saline daily along with a diuretic if signs of fluid overload become apparent. The diuretic agents of choice are the loop diuretics because they inhibit calcium reabsorption in the ascending loop of Henle. Complications of this therapy include hypokalemia, hypomagnesemia, and congestive heart failure.

General measures such as the use of hydration and diuretics do not affect the excessive mobilization of calcium from bone. In patients with an initial serum calcium concentration >15 mg/dL, and in patients with serum calcium concentrations >12 mg/dL after aggressive hydration measures, specific therapy to inhibit osteoclast-mediated bone resorption should be instituted. Several agents are useful in this regard, including bisphosphonates, plicamycin, calcitonin, gallium nitrate, phosphate, and glucocorticoids.[39,40] Bisphosphonates bind to hydroxyapatite in bone and inhibit the dissolution of crystals. Etidronate and pamidronate are the bisphosphonates available in the United States. These agents are given as slow IV infusions with decreases in serum calcium concentrations occurring within 2 days of the initial dose. Plicamycin, which acts directly on bone to block calcium resorption, has a faster onset of action. Its effects occur in 6–12 hours, and the dosage is 25 μg/kg administered intravenously over 4–6 hours. Use of plicamycin is effective for all types of hypercalcemia associated with increased bone resorption. Contraindications to the use of plicamycin include thrombocytopenia, coagulopathy, and overt renal or hepatic dysfunction. Among the drugs used in managing hypercalcemia, calcitonin has the most rapid onset of action. The dosage of synthetic salmon calcitonin is 4 IU/kg every 12 hours, subcutaneously. Calcitonin lasts 6–12 hours, with onset of action

in 1–2 hours. Calcitonin is a relatively weak agent, and it is unlikely that the serum calcium level will normalize with the use of calcitonin alone. To enhance its effectiveness, a combination of calcitonin and steroids have been administered, although whether glucocorticoids enhance the action of calcitonin is controversial.[34] Gallium nitrate is administered as a continuous infusion for 5 days. Its effects are slow, taking approximately 5 days for the normalization of serum calcium. In addition, nephrotoxicity is a major side effect of this drug. Although in certain circumstances glucocorticoids can be effective calcium-lowering agents, patients with primary hyperparathyroidism do not respond to this treatment. Intravenous phosphates have a rapid onset of action in managing hypercalcemia, although they are associated with risks of hypotension, pulmonary edema, hypocalcemia, and metastatic calcification and are contraindicated in renal failure. Intravenous phosphate is given in a dose of 1500 mg phosphorus over 6–8 hours. Indomethacin, which is used for prostaglandin-associated hypercalcemia, also has a slow onset of action.

Preoperative

When managing hypercalcemia preoperatively, reversible complications, such as dehydration, mental obtundation, and electrolyte disorders, should be corrected. Patients with calcium levels less than or equal to 12 mg/dL require no intervention (except possibly preoperative hydration), although the cause of the hypercalcemia should be sought. Management of more severe hypercalcemia may include pharmacologic intervention or hydration with diuresis.

Hypocalcemia

Hypocalcemia[37–39] associated with parathyroid hormone resistance is most commonly caused by hypomagnesemia, whereas decreases in parathyroid hormone are most commonly caused by surgical ablation. There are several other causes of decreased parathyroid hormone levels, such as DiGeorge syndrome in children, but these are far less common.

Table 12–6 lists the signs and symptoms of hypocalcemia. The cardinal sign of hypocalcemia is tetany. On laboratory examination, the electrocardiograph may exhibit a prolonged QT interval,

which indicates a predisposition to ventricular dysrhythmias. Primary hypoparathyroidism often is associated with hypocalcemia, hyperphosphatemia, and depressed levels of parathyroid hormone. In assessing the severity of hypocalcemia, decreased serum albumin levels might not be associated with symptoms if the ionized Ca^{2+} level is normal. Alkalosis also may predispose patients to hypocalcemia. Magnesium level should be determined for all patients with hypocalcemia, especially in cases of alcohol abuse, malabsorption, or poor nutrition. Hypomagnesemia induces hypocalcemia by one of several mechanisms, including a reduction of parathyroid hormone secretion, a resistance to the humeral actions of parathyroid hormone, and a direct parathyroid hormone-independent hypocalcemic effect.[35]

Preoperative

Clinical signs of hypocalcemia should be controlled before surgical procedures are performed. Hypocalcemia is managed chronically with dietary calcium and vitamin D supplementation. For emergency management of hypocalcemia, 10–20 mL of IV 10% calcium gluconate or calcium chloride is given over 10 minutes followed by infusion of 0.5–2 mg Ca^{2+}/kg/h with monitoring of Ca^{2+} levels. Magnesium levels can be restored acutely by administering 1–2 g of 10% magnesium solution IV.

The major anesthetic risks of hypocalcemia are cardiac dysrhythmias, decreased contractility, development of tetany (especially with hyperventilation), and altered response to muscle relaxants. Such patients may be resistant to digitalis.[36]

ADRENAL DISORDERS

Physiology

Adrenal corticosteroid secretion is controlled via a negative feedback loop with the hypothalamic–pituitary axis.[2,41] Corticotropin-releasing factor from the hypothalamus stimulates the release of corticotropin from the pituitary gland, which, in turn, stimulates the release of adrenal corticosteroids. Within the negative feedback loop, elevated corticosteroid levels depress the corticotropin secretion. In addition to the influences of corticosteroids and corticotropin-releasing factor, corticotropin release is modulated by stress and diurnal variation. Peak secretion occurs in the morning, with an evening nadir. Random plasma cortisol levels are of marginal benefit in diagnosing the integrity of the adrenal–pituitary axis, and various stimulation and suppression tests are used. In particular, assessment of adrenal-cortical reserve often is done with the corticotropin-stimulation test.

Glucocorticoids have several functions. Steroids increase hepatic gluconeogenesis and decrease fatty acid, nucleic acid, and protein synthesis. They also suppress the inflammatory reaction and inhibit vitamin D by reducing calcium absorption from the gut. Steroids antagonize the effects of antidiuretic hormone (ADH) and enhance catecholamine vasoconstriction. High doses of glucocorticoids can exhibit a mineralocorticoid effect, causing sodium and water retention with potassium loss.

Aldosterone is secreted by the adrenal cortex in response to hyperkalemia and is inhibited by increases in plasma volume. Aldosterone secretion is controlled by the renin–angiotensin system and circulating levels of corti-

	Exophthalmos

cotropin. Aldosterone works in the distal convoluted tubules of the kidney to promote sodium retention and potassium excretion. It is the major regulator of extracellular fluid volume and potassium balance.

After surgery, plasma cortisol increases 5–10 times by 6 hours postoperatively, with peak levels decreasing by 24 hours postoperatively, unless the stress continues. Epidural anesthesia delays the cortisol stress response, although it does not prevent it.[42]

Disorders of the adrenal gland present clinically as 1 of 3 problems: Cushing syndrome (excess secretion of corticosteroids), Conn syndrome (excess secretion of aldosterone), or Addison disease (corticosteroid insufficiency).

Cushing Syndrome

Prolonged exposure to excess glucocorticoids-cortisol results in the manifestation of Cushing syndrome (Table 12–7). Although the classic features of Cushing syndrome—round or "moon" facies, supraclavicular fat pad or "buffalo hump," purple striae, and proximal muscle weakness—may often be seen in a minority of patients, nonspecific features—such as obesity, hypertension, glucose intolerance, osteoporosis, osteopenia/fractures, emotional lability, depression, anxiety, easy bruisability, and thick skin—may be attributable to other causes or diseases.[43,44] The most common cause of Cushing syndrome tends to be exposure to exogenous glucocorticoids such as topical or inhaled corticosteroids.[44] The most common endogenous cause of Cushing syndrome (≈70%) is Cushing disease—the secretion by pituitary tumors of corticotropin (adrenocorticotropic hormone [ACTH]); approximately 15% is caused by ACTH-independent cortisol secretion by adrenal tumors and 15% is caused by ACTH producing tumors elsewhere.[43] A high level of suspicion should be maintained, especially in patients who are atypical or difficult to control, as many diseases may have similar symptoms.

If there is clinical suspicion that a patient is at risk for Cushing syndrome, then any 1 of 4 tests may be employed to diagnose Cushing syndrome and if nonconfirmatory, more than 1 test may be used. These tests include[1] an elevated urinary free cortisol level on three 24-hour urine samples;[2] a serum cortisol >50 nmol/L on dexamethasone suppression testing;[3] an examination of midnight plasma cortisol—if awake, >207 nmol/L, and if asleep, >50 nmol/L;[4] and an elevated late-night salivary cortisol. If one of these tests is positive, then the diagnosis of Cushing syndrome can be made.[44] Once the diagnosis is made, the next step is to localize the cause. The first step is to measure plasma corticotropin. If the level of plasma corticotropin is <1.1 pmol/L on 2 or more occasions, this is corticotropin-independent Cushing syndrome, which should be followed up with CT imaging of the adrenal glands. The presence of an adrenal lesion may indicate adenoma, carcinoma, or corticotropin-independent macronodular hyperplasia. The absence of a lesion in the adrenals tends to favor exogenous glucocorticoids. If the plasma corticotropin level is >3.3 pmol/L, this is corticotropin-dependent Cushing syndrome, which should be followed up with a pituitary MRI along with a positive response to corticotropin-releasing hormone and suppression with high-dose dexamethasone, after which the diagnosis of Cushing disease can be made. If the MRI is negative, this should be followed up by bilateral inferior petrosal sinus sampling. A positive corticotropin gradient indicates Cushing disease. The absence of a corticotropin gradient should be followed up with CT and MRI of the thorax and abdomen, along with somatostatin scintigraphy to localize the ectopic source of corticotropin.[44]

Therapy for Cushing syndrome consists of removal of the source of glucocorticoid, usually surgically. Ketoconazole and metapyrone are enzyme inhibitors of cortisol synthesis. Mitotane is an adrenolytic that can be used to lower cortisol.[44] Pituitary radiotherapy may also be used. Patients who undergo adrenal-sparing surgery require replacement with hydrocortisone until the hypothalamic–pituitary–adrenal axis recovers, and those who undergo bilateral adrenalectomy require both glucocorticoid and mineralocorticoid replacement.[43] Temporary adrenal supplementation considers the type of surgical or medical stress. For instance, minor procedures, such as herniorrhaphy or colonoscopy, would be supplemented with 25 mg of hydrocortisone or 5 mg of methylprednisolone IV for the procedure only, whereas a moderate procedure, such as open cholecystectomy or hemicolectomy, would be supplemented with 50–75 mg of hydrocortisone or 10–15 mg of methylprednisolone IV on the day of the procedure, followed by a 1–2-day taper to the usual dose. Severe stress or procedure, such as cardiac surgery, liver resection, and Whipple surgery, would be supplemented with hydrocortisone 100–150 mg or methylprednisolone 25–30 mg

Nausea, vomiting	Calcification of the pinnae	Fasting or reactive hypoglycemia (infrequent in adults)
Unspecified gastrointestinal complaints	Vitiligo	Hypercalcemia
Abdominal pain	Hyperthermia or hypothermia	
Diarrhea	Loss of axiliary hair in women	
Muscle pain		
Salt craving		
Orthostatic hypotension, dizziness, or syncope		
Lethargy, disorientation		

IV followed by a rapid taper to the usual dose over 1–2 days.[45]

Conn Syndrome

Primary hyperaldosteronism (Conn syndrome)[46–48] is characterized by diastolic hypertension, hypokalemic alkalosis, inability to concentrate urine, and skeletal muscle weakness. A normal serum K^+ level in a hypertensive patient will rule out this syndrome unless the patient is on a sodium-restricted diet or taking spironolactone. The preoperative preparation is aimed at improving fluid and electrolyte balance. Spironolactone is given in a dosage of 25–100 mg every 8 hours for at least 1 week preoperatively with concurrent potassium replacement.[39]

Adrenal Insufficiency

Adrenocortical insufficiency[49] can be classified as primary (adrenal gland destruction) or secondary (hypothalamic–pituitary axis dysfunction). Primary adrenal insufficiency usually is iatrogenic, resulting from bilateral adrenalectomy, inadequate steroid administration, or unilateral adrenalectomy for a hyperfunctioning adrenal tumor. A patient with primary adrenal insufficiency presenting as Addison disease usually exhibits hypoaldosteronism. Table 12–8 lists the signs and symptoms of Addison disease. In patients with secondary adrenal insufficiency related to suppressed hypothalamic–pituitary axis, aldosterone secretion remains intact, and hyperkalemia does not occur. An additional syndrome of isolated hypoaldosteronism occurs as a result of renin deficiency in patients with normal cortisol secretion but unexplained hyperkalemia. Patients with suspected adrenal insufficiency should undergo systemic examination to assess function before surgery. Associated laboratory findings include decreased plasma cortisol levels and impaired corticotropin stimulation. Additional provocation testing of the pituitary–adrenal axis might include using metyrapone stimulation or insulin-induced hypoglycemia. In addition to adequate steroid coverage, volume status replacement, electrolyte management, and correction of hypotension should occur preoperatively.

When adrenal insufficiency develops acutely, the symptoms can be severe and dramatic (Table 12–9). This may occur in a trauma or intensive care setting in patients with previously unsuspected inadequate adrenal reserve.[45] The dosage of glucocorticoids given depends on the urgency and severity of the clinical situation. Mineralocorticoid properties must be provided if primary adrenal insufficiency exists. Fluid support with 5% dextrose and normal saline should be instituted immediately to replace volume deficits and provide glucose.

PHEOCHROMOCYTOMA

Pheochromocytomas are chromaffin cell tumors and are members of the family of amino precursor uptake and decarboxylation (APUD) tumors. Massive amounts of catecholamines are released by these tumors, causing their characteristic signs and symptoms. They are rare, occurring in 0.5% of all hypertensive patients.[50] Although usually located unilaterally near the adrenal gland, pheochromocytomas may be found in various locations, including urinary bladder and bilaterally in the chest and abdomen. The extraadrenal pheochromocytomas are called paragangliomas. From 2–3% of these growths constitute neck or thoracic masses. Most tumors occur in adults. Children with pheochromocytomas have fewer malignant tumors but tend to have a greater incidence of bilaterality, extraadrenal location, and associated multiple endocrine neoplasias.

Diagnosis

Pheochromocytomas may be either sporadic or hereditary. Most tumors are sporadic and classic teaching has been that 10% of all tumors are hereditary. Pheochromocytoma can be a manifestation of the hereditary disorders of MEN IIA, IIB, neurofibromatosis (NF) type 1, familial paraganglioma syndrome, and von Hippel-Lindau (vHL) disease. A group of susceptibility genes

has been identified including protooncogene RET (associated with MEN type II), the tumor-suppressor gene VHL (associated with von Hippel-Lindau disease), and succinate dehydrogenase subunits D and B (which predispose carriers to pheochromocytomas and glomus tumors) (Table 12–10). Identification of mutations in these susceptibility genes has been found in 24% of suspected sporadic tumors, suggesting that heredity syndromes may play a greater role in pheochromocytoma occurrence than previously appreciated.[51] Current recommendations suggest that genetic testing should be considered in patients initially presenting with pheochromocytoma prior to age 50 years.[52] Genetic testing has demonstrated that pheochromocytomas presenting after age 50 years are almost always sporadic.[52]

Diagnosis depends on a high index of suspicion and observing for clinical signs and symptoms of this tumor. Signs and symptoms of pheochromocytoma should be sought in hypertensive individuals, and workup performed in those patients displaying characteristic signs and symptoms (Table 12–11). The diagnostic algorithm includes[1,2] documentation of increased catecholamine breakdown products in plasma, and tumor localization by appropriate imaging techniques, including CT, magnetic resonance imaging (MRI), I-metaiodobenzylguanidine scintigraphy, or positron emission tomography (PET) scanning. The first step in diagnosis is biochemical verification of the presence of pheochromocytoma. A multicenter cohort study of 858 patients with suspected pheochromocytoma compared the diagnostic ability of plasma free metanephrines, plasma catecholamines, urinary catecholamines, urinary total and fractionated metanephrines, and urinary vanillylmandelic acid.[53] Plasma free metanephrines were the best test to confirm or exclude the tumor. The sensitivity of plasma free metanephrines was 97% and 99% in hereditary and sporadic pheochromocytomas, respectively. The specificity was 96% and 82% in heredity and sporadic pheochromocytomas, respectively.[54] A normal plasma metanephrine level excludes the tumor, and a large elevation confirms its presence. However, the problem comes with marginally elevated values, as there may be at least a 15% false-positive rate. Marginally elevated plasma metanephrine values should undergo further evaluation via additional biochemical testing (repeat plasma metanephrines or urinary total metanephrine and catecholamines)[54] or pharmacologic testing (e.g., clonidine suppression or glucagon stimulation).[51] When interpreting metanephrine and catecholamine levels, physicians should be aware of medical conditions and

drugs, which can influence the results (Table 12–12). Care must be taken to eliminate these confounding factors.[54] Following biochemical confirmation, the next step is tumor localization with adrenal CT and MRI having comparable sensitivity and specificity (Fig. 12–1). As depicted in Figure 12–1, adrenal CT and MRI have comparable sensitivity and specificity. Metaiodobenzylguanidine (MIBG) scanning offers superior specificity to MRI and CT, and is particularly helpful in localizing extraadrenal masses. However, MIBG is not sensitive enough to exclude pheochromocytoma, as there is a false-negative rate of 13–25%.[50] Use of MIBG scanning in sporadic unilateral adrenal tumors has been questioned because in this clinical circumstance, the test rarely contributes additional information.[55] In patients with biochemical evidence of pheochromocytoma, but in whom the presence of the tumor cannot be excluded by CT, MRI, or MIBG, PET scanning may be performed for tumor localization.[50]

Preoperative Preparation

Preoperative preparation should be a joint venture involving the surgeon, the internist or endocrinologist, and the anesthesiologist. The major goal of preoperative preparation is to decrease cardiovascular morbidity and mortality resulting from excess catecholamine secretion. Pheochromocytomas may secrete norepinephrine, epinephrine, or dopamine.[56] The acute effects of catecholamine bursts and their chronic end-organ sequelae may influence postoperative outcome. A review of cardiovascular changes associated with pheochromocytoma reported that 6 of 25 patients initially presented with ischemic changes on electrocardiogram.[57] Chronically elevated catecholamine levels with pheochromocytomas were associated with a 38% incidence (24 of 63 patients) of preoperative transthoracic echocardiographic abnormalities.[58] Left ventricular hypertrophy was the most common abnormality (14 of 63 patients), followed by dilated cardiomyopathy (4 of 63 patients), valvular abnormalities (3 of 63 patients), and segmental wall motion abnormalities (2 of 63 patients).[58]

The optimal drug for preoperative preparation of the patient with pheochromocytoma is controversial. A common initial approach has been to use phenoxybenzamine for long-term α-blockade.[59] Preoperative treatment with phenoxybenzamine results in a significantly smoother course than in untreated patients. This drug has a long half-life (approximately 12 hours) and is highly lipid soluble. However, it has unpredictable absorption through the gut. Its primary side effect is orthostatic hypotension. The starting dosage is 10–20 mg daily in 2 doses. Every 3–4 days the dose is increased until either no marked symptoms of catecholamine excess are evident or the patient complains of side effects from postural hypotension and/or a stuffy nose, with a final dosage range of 40–100 mg/d. The adequacy of β-blockade may be assessed by determining if ongoing symptoms of catecholamine excess are occurring. Signs and symptoms of pheochromocytoma should be specifically sought (see Table 12–11). The preoperative cardiovascular evaluation should seek signs of orthostasis, evidence of heart failure or cardiomyopathy, and determine volume status. Preoperative preparation should include 1–2 weeks of α-adrenergic–blocker therapy. Volume replacement is important when starting α-blocker therapy, and patients often have a decreased hematocrit after beginning therapy.

There are several disadvantages to the use of phenoxybenzamine.[59] Adequate volume expansion after institution of the drug may take as long as 2–3 weeks. Thus, patients presenting for surgery who have been on phenoxybenzamine for a shorter time period should have their hypovolemia corrected preoperatively. Total elimination of cardiovascular changes is seldom achieved despite reaching therapeutic end points with phenoxybenzamine. α-Blockade with phenoxybenzamine is irreversible and depends

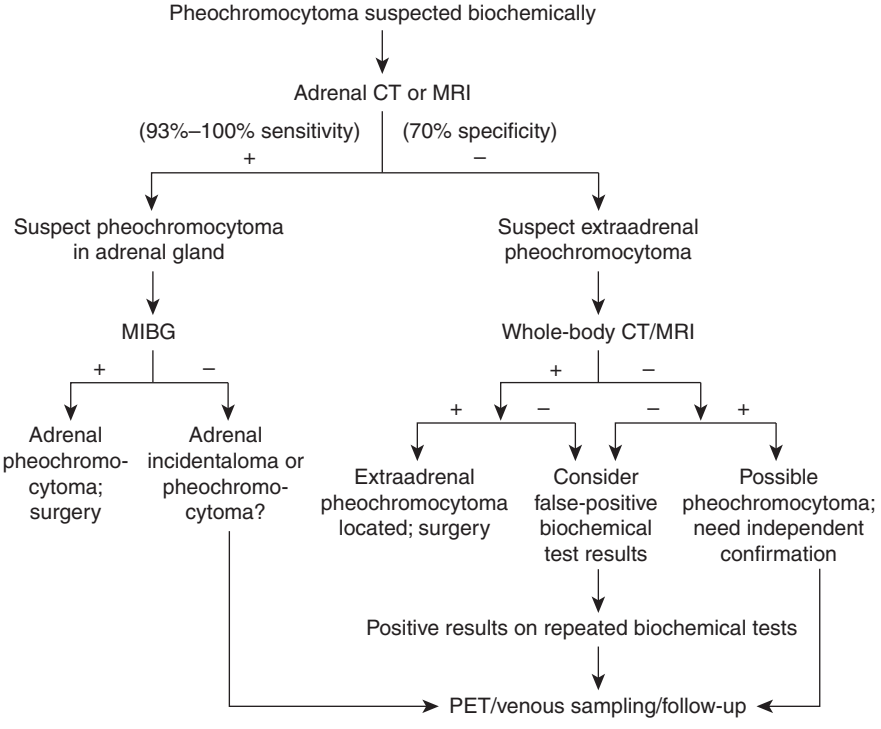

FIGURE 12–1. CT, computed tomography; MIBG metaiodobenzylguanidine; MRI, magnetic resonance imaging; PET, positron emission tomography. Imaging algorithm for patients whose results on biochemical tests are consistent with pheochromocytoma.

on synthesis of α-adrenergic receptors. Thus, there may be continued α-blockade following tumor removal, which can contribute to postoperative hypotension. Phenoxybenzamine causes significant orthostatic hypotension and reflex tachycardia.

Selective α_1-blockers, such as prazosin and doxazosin,[60] have been used with success for preoperative preparation. The rationale behind their selection is a shorter duration of action providing easier dose adjustment and potentially decreasing the postoperative hypotension period. Reflex tachycardia is decreased because the presynaptic α-receptors are not blocked.[52]

β-Blockers are administered for persistent tachycardia and for control of other peripheral β-adrenergic effects of catecholamine excess. These drugs should never be given before α-blockade because serious hypertensive sequelae may result. Both labetalol and atenolol have been suggested as appropriate drug choices.[61]

The drug α-methyltyrosine inhibits the synthesis of norepinephrine. The drug does not produce hypotension and preserves the tissue responsiveness to adrenergic agents when the dosage of 500–2000 mg 4 times daily is given. Adequate blockade is achieved in 1 or 2 weeks. α-Methyltyrosine without concurrent α-adrenergic–blocking agents does not prevent hypertensive crisis. α-Methyltyrosine has fallen out of favor, possibly because there is a high incidence of side effects with including somnolence, anxiety, agitated depression, and tremor.[62]

Calcium channel blockers also have been advocated for preoperative and intraoperative blood pressure control in patients with pheochromocytomas. In comparison to the α-adrenergic blockers, calcium channel blockers do not produce orthostatic or overshoot hypotension. In addition, therapy may be started as late as 24 hours prior to surgery and optimal cardiovascular effects are still obtained.[63] Several reports suggest that calcium channel blockers may be the drug of choice for antihypertensive therapy during preoperative preparation of the pheochromocytoma patient.[64]

PITUITARY DISORDERS

The pituitary diseases that are of special concern for the anesthesiologist include those associated with secondary metabolic alterations or diabetes insipidus.

Hypopituitarism

The pituitary gland is composed of the anterior portion (adenohypophysis) and the posterior portion (neurohypophysis). The adenohypophysis responds to hypothalamic release factors by secreting corticotropin, TSH, growth hormone, and gonadotropins. The neurohypophysis secretes vasopressin (ADH) and oxytocin. Hormone deficiencies leading to hypopituitarism may be caused by lesions in the brain, pituitary adenoma (especially macro adenoma), trauma, irradiation, or granulomatous disease. Gonadotropin deficiency is not of major significance to anesthetic management. Patients with hypopituitary disorders may present with hypothyroidism and inadequate corticotropin secretion. Steroid coverage or thyroid replacement may be required, although mineralocorticoid therapy usually is not necessary in these patients. Cranial diabetes insipidus (decreased vasopressin secretion) requires special consideration because volume status and electrolytes may be affected. Diabetes insipidus is one of several medical conditions characterized by polyuria and may be nephrogenic or cranial in origin. Cranial diabetes insipidus is an uncommon disease and usually is a result of hypothalamic tumors, infiltrative processes, cerebral aneurysm, ischemia, head trauma, or pituitary surgery.

The first step in diagnosis of diabetes insipidus is to determine that the patient indeed has polyuria. A 24-hour urine volume of more than 2.5 L characterizes polyuria of diabetes insipidus.[65] Once polyuria has been confirmed then routine blood tests can eliminate alternative diagnoses such as diabetes mellitus, chronic renal failure, hypercalcemia, or hypokalemia. The water deprivation test is the preferred diagnostic maneuver for diabetes insipidus. The water deprivation test involves two steps: fluid restriction and desmopressin administration. In normal individuals, water deprivation for approximately 8 hours produces a rise in plasma osmolality, stimulating a release of vasopressin, with a subsequent decrease in urine output and increase in urine concentration. Healthy persons will increase urine osmolality to greater than 700 mOsm/kg following water deprivation,[65] whereas patients with diabetes insipidus are unable to concentrate their urine. Following water deprivation, in patients with suspected diabetes insipidus, exogenous ADH (desmopressin) is administered either subcutaneously or intramuscularly. The desmopressin step distinguishes between cranial and nephrogenic diabetes insipidus. Patients with nephrogenic diabetes insipidus remain unable to concentrate their urine, whereas persons with cranial diabetes insipidus will respond to desmopressin by increasing their urine osmolality. In patients with diabetes insipidus, careful preoperative assessment of volume status, renal function, electrolytes, and plasma osmolarity is important. Management of diabetes insipidus is dependent on whether it is vasopressin responsive (cranial diabetes insipidus) or is not vasopressin responsive (nephrogenic diabetes insipidus). In both forms, however, an intact thirst mechanism helps to ensure adequate hydration. Cranial diabetes is managed with adequate hydration and oral desmopressin 0.05–8 mg once or more daily.[66] Nasal and intramuscular are alternate routes of administration. The management of nephrogenic diabetes insipidus is often more difficult and includes hydration, decreased sodium intake, thiazide diuretics, amiloride, and prostaglandin inhibitors such as indomethacin.

Hyperpituitarism

Hypersecretion by the pituitary gland presents specific problems for the anesthesiologist. Disease states related to excess secretion of thyroid-stimulating hormone or corticotropin are discussed above. Excess secretion of growth hormone is associated with acromegaly. Macroglossia and prognathism in this condition may be associated with airway management problems and difficulty with intubation. In a retrospective case series of 28 patients, acromegalic patients were more likely to be a difficult intubation, have enlarged tongue, and present with airway difficulty.[67] In addition, patients with acromegaly had a higher incidence of preoperative hypertension, diabetes, and cardiomegaly.[67] With this in mind, the anesthetic preevaluation should focus on both the airway and cardiovascular system.

TABLE 12–13.

Diseases Associated with the Syndrome of Inappropriate Secretion of Antidiuretic Hormone

Tumors	Bronchogenic cancer
	Mesothelioma
	Ureteric cancer
	Pancreatic cancer
	Duodenal cancer
	Lymphoma
	Endometrial cancer
	Leukemia
Pulmonary disease	Lung abscess
	Empyema
	Pneumonia
	Tuberculosis
	Aspergillosis
	HIV infections
	Positive-pressure ventilation
Central nervous system disorders	Cerebral tumors
	Cerebral abscess
	Hydrocephalus
	Subdural hematoma
	Subarachnoid hemorrhage
	Meningitis
	Encephalitis
Drugs	Phenothiazines
	Tricyclic antidepressants
	Chlorpropamide
	Ecstasy
	Carbamazepine
	Cyclophosphamide
	Selective serotonin reuptake inhibitors

TABLE 12–14.

Criteria of Syndrome of Inappropriate Secretion of Antidiuretic Hormone

- Hyponatremia with hypotonicity of plasma
- Urine osmolality in excess of plasma osmolality
- Increased renal sodium excretion
- Absence of edema or volume depletion
- Normal renal and adrenal function

TABLE 12–15.

Symptoms and Signs of Hyponatremia

Serum Sodium[a]	
<120 mmol/L	**<110 mmol/L**
Lethargy	Drowsiness
Anorexia	Confusion
Nausea, vomiting	Depressed reflexes
Irritability	Extensor plantar responses
Headache	Seizures
Muscle weakness	Coma
Cramps	Death

[a]The severity of the clinical features are determined by the absolute concentration in which serum sodium falls and its rate of fall.

The syndrome of inappropriate antidiuretic hormone secretion (SIADH) results from abnormal production or sustained release of ADH. SIADH is associated with normovolemic hyponatremia and has numerous causes (Table 12–13). Of note, SIADH is most often not the result of an intrinsic pituitary disorder.[68] The criteria for SIADH have been well described in the past (Table 12–14). The severity of signs and symptoms associated with SIADH are dependent on the degree of hyponatremia and how rapidly the drop in sodium occurs. The faster the rate of fall of serum sodium and the lower the concentration, the more severe the symptoms. The symptoms and signs are primarily neurologic (Table 12–15). The first step in treatment is to eliminate the underlying cause. Fluid restriction is the next step in correction of chronic hyponatremia. For patients with severe neurologic symptoms or hyponatremia, administration of hypertonic saline with or without furosemide may be required. In patients unable to tolerate fluid restriction, demeclocycline, a tetracycline that causes nephrogenic diabetes insipidus, has been used as adjunct therapy. Correction of serum sodium should be done gradually because of the possibility of neurologic complications. The rate of increase should not exceed 0.5 mmol/L/h.[69]

DIABETES

Definition and Classification

The American Diabetes Association[70] defines diabetes with reference to abnormal glucose tests, which have been confirmed with repeat testing on a different day. The 3 principal criteria used to define diabetes are (a) a fasting blood glucose concentration >126 mg/dL or (b) a nonfasting blood glucose concentration >200 mg/dL or (c) a blood glucose concentration >200 mg/dL in the 2-hour sample after an oral glucose tolerance test. Impaired glucose tolerance is a fasting blood glucose >110 mg/dL but <126 mg/dL, or a 2-hour postprandial glucose concentration >140 mg/dL but <200 mg/dL. Risk factors for diabetes include age older than 45 years; obesity (body mass index >27); high-risk ethnic group (Native American, African American, Hispanic, and Asian); gestational diabetes or delivery of a large infant over 9 lbs; impaired glucose tolerance; hypertension; and a low high-density lipoprotein (HDL) (<35 mg/dL) or elevated triglycerides (>250 mg/dL).[70]

Diabetes mellitus[71] is in essence a disease that is characterized by hyperglycemia. A variety of pathogenic mechanisms including defects in insulin secretion, insulin action, or both may be involved.[71] The American Diabetes Association has currently classified diabetes mellitus into 4 specific categories: (a) *type 1 diabetes*, which is caused by β-cell destruction and usually results in

insulin deficiency; (b) *type 2 diabetes*, which encompasses a range from insulin resistance with relative insulin deficiency to insulin secretory defects with insulin resistance; (c) *specific types* of diabetes such as genetic defects of β-cell function, genetic defects in insulin action, diseases of the exocrine pancreas, endocrinopathies, drug or chemical induced, infections, and genetic syndromes associated with diabetes; and (d) *gestational diabetes mellitus*.[71]

Type I diabetes results from β-cell destruction that leads to insulin deficiency accounts for approximately 5–10% of patients with diabetes mellitus.[71] Type I diabetes is further classified as immune mediated or idiopathic. Immune mediated is characterized by cell-mediated autoimmune destruction of pancreatic β cells with a subsequent decrease in insulin secretion and the risk for ketoacidosis. Ketoacidosis and hyperglycemia are often the initial presentation in conjunction with infection or stress. The rate of destruction of β cells may vary. Often this is manifested in childhood or adolescence, but may also present at any age even in elderly patients, including those in their 80s. Markers of autoimmune destruction such as autoantibodies to islet cells, insulin, glutamic acid decarboxylase (GAD65), and tyrosine phosphatases IA-2 and IA-2B are found in approximately 90% of these patients.[72] There is a strong human leukocyte antigen (HLA) association with the HLA-DR/DQ alleles. Some patients who present with autoimmune destruction of the β cells may be obese, but most tend to be thin. Patients with immune-mediated type I diabetes are prone to other autoimmune disease such as Graves disease, Hashimoto thyroiditis, Addison disease, autoimmune hepatitis, myasthenia gravis, and pernicious anemia.[71] In contrast, idiopathic diabetes mellitus comprises only a minority of type I diabetes usually in patients of African or Asian descent. Although this form is strongly inherited, there is no HLA association or indication of β cell autoimmunity and the requirement for insulin may come and go in affected patients.[71]

Type 2 diabetes[71] is the principal form of diabetes and approximately 90–95% of patients have this form of diabetes. Although the cause or causes of this form of diabetes may be varied, by definition as determined by the American Diabetes Association, patients who have type I diabetes, gestational diabetes, or specific type diabetes cannot be classified as type 2 diabetics. Type 2 diabetics are characterized by a range and progression of insulin resistance and relative insulin deficiency. Type 2 diabetes has a stronger genetic predisposition than type 1, but the genetic relationships are complex and ill defined. There is a greater risk of developing type 2 diabetes with increasing age, obesity, lack of exercise, hypertension, dyslipidemia, and gestational diabetes. Ketoacidosis is more characteristic of type 1 diabetes, but it can occur with type 2 diabetes in association with the stress of another illness or infection. Type 2 diabetes tends to go undetected for years with the result of developing microvascular complications.[71] It is for this reason that the American Diabetes Association advocates the adoption of the strict criteria discussed above for the definition of diabetes.

Blood glucose levels in the diabetic parturient are important in determining neonatal outcome during labor and delivery. The incidence of neonatal hypoglycemia—defined as a blood glucose concentration of >40 mg/dL in the first 12 hours of life—is influenced by maternal glucose control during labor and delivery. Maternal glucose concentrations >90 mg/dL during delivery significantly increase the frequency of neonatal hypoglycemia.[73,74] Consequently, glucose boluses should be avoided in the peripartum period and strict glucose control should be initiated. The results of multiple studies, including Diabetes Control and Complications Trial (DCCT), United Kingdom Prospective Diabetes Study (UKPDS), van den Berglte et al.,[75] and Umpierrez et al.[76] have led both the American College of Endocrinology and the American Diabetes Association to advocate tight control of in-hospital glucose use. The target level of fasting blood sugars is 110 mg/dL with a maximal level of 180 mg/dL.[77,78] Ideally, an aim of achieving a glycosylated hemoglobin ($HgbA_{1c}$) of less than 7 might be beneficial.

Medications

Five classes of oral glucose-lowering agents[78–81] with a variety of formulations are currently available.[82–85] The first class is the *sulfonylureas*, which act on the pancreas to increase insulin secretion from the β cells, reduce serum glucagon, and increase insulin binding to the insulin receptors on target tissues. They are protein bound, metabolized by the liver, and excreted by the liver and kidney. The currently used sulfonylureas are second-generation sulfonylureas, with peak action between 1 and 6 hours and half-lives varying between 4 and 10 hours, depending on the formulation, and include glyburide, glipizide, and glimepiride. These effects are more pronounced in the elderly because of reduced metabolism and elimination, putting them at greater risk of hypoglycemia. The second class is the *biguanides*, which decrease hepatic glucose production, reduce low-density lipoprotein (LDL) and very-low-density lipoprotein (VLDL) concentrations, and inhibit intestinal glucose absorption. They have a half-life of more than 12 hours, are not metabolized, and are excreted in the urine. Metformin is the currently used biguanide and it may decrease vitamin B_{12} absorption and occasionally cause diarrhea. Metformin may, on rare occasions, be associated with lactic acidosis, and should not be given to patients with renal failure, cardiac failure or infarction, hepatic disease, or hypoxic lung disease, and should be discontinued prior to surgery.[79] The third class, is the *α-glucosidase inhibitors*. Acarbose and miglitol are agents of this class and act by inhibiting α-glucosidase in the brush borders of the small intestine, decreasing the breakdown of oligosaccharides and disaccharides to glucose, thereby decreasing the amount of postprandial glucose. These drugs are metabolized within the gastrointestinal tract, have a half-life of 2 hours, and are excreted in the urine. These agents cause abdominal discomfort, flatulence, and diarrhea as the main side effects, rather than hypoglycemia. The fourth class, is the *thiazolidinediones*, of which troglitazone, rosiglitazone, and pioglitazone are currently used. These agents decrease hepatic glucose production, enhance insulin's action in the liver and skeletal muscle, and decrease insulin resistance by binding to nuclear receptors and subsequently activating or suppressing genes. These agents are metabolized in the liver and excreted by the kidney. Although liver function needs to be closely followed, the dosages are not affected by aging. The fifth class is the *meglitinides*, of which repaglinide and nateglinide are examples.

These agents are rapid acting with short half-lives and work by slowing adenosine triphosphate (ATP)-dependent potassium channels leading to an increase in insulin secretion. These agents are highly protein bound to albumin and are metabolized in the liver by cytochrome P450 (CYP) 3A4. The meglitinides are insulin secretogogues and as such are associated with hypoglycemia.

Insulin preparations are classified by their speed of action, with the principal categories being rapid acting, short acting, intermediate acting, mixed short and intermediate acting, and long acting. Lispro and Aspart are rapid-acting insulins whose onset is within minutes and peak effect is within an hour. Regular insulin is short acting. The onset is within an hour with peak effect in about 2 hours and a duration of about 4 hours. Neutral protamine Hagedorn (NPH) and Lente are intermediate-acting insulins with onset of action in about 3–4 hours, peak occurring in 8–10 hours, and duration of action lasting 12–14 hours. Glargine and ultralente are long-acting insulin's that have delayed onset, with duration of action lasting more than 24 hours. Linkeschova et al.[84] advocate the use of continuous insulin infusion to achieve better glycemic and metabolic control.

Not only are there multiple combinations of insulin now available, but newer delivery methods of insulin, such as inhaled insulin,[85] are approved for use in type 2 diabetics. Exenatide[85] is a synthetic exendin-4. This binds to the glucagon-like peptide-1 (GLP-1) receptor on pancreatic cells and increases insulin secretion. Exenatide belongs to the GLP-1 agonist class and is administered subcutaneously twice a day. It suppresses glucagon secretion, slows gastric motility, and may be associated with nausea, vomiting, diarrhea, and weight loss. Pramlintide[85] represents an amylin agonist. It is a synthetic analog of amylin, a β-cell hormone. It is administered subcutaneously before meals and slows gastric emptying, inhibits glucagon production, and decreases postprandial glucose elevations. It is also associated with nausea, GI side effects, and weight loss.

Perioperative Changes in Glucose Metabolism

The surgical stress response is characterized by increases in sympathetic tone, glucagon levels, pituitary hormone levels (notably corticotropin and growth hormone), and interleukin-1. During the perioperative period, increases in plasma norepinephrine and epinephrine also occur. Epinephrine and norepinephrine stimulate liver glycogenolysis and gluconeogenesis[86] and inhibit glucose uptake by insulin-dependent tissues. The α and β effects of the catecholamines may influence glucose metabolism. For instance, epinephrine increases metabolic rate through its β effects.[87] The α and β effects also have profound influences on pancreatic function. β-Receptor stimulation enhances insulin and glucagon release, whereas α-receptor stimulation inhibits the release of insulin. During the intraoperative and immediate postoperative course, α effects predominate, causing suppression of insulin secretion. Decreased insulin levels coupled with increased gluconeogenesis and insulin resistance cause hyperglycemia and glucose intolerance, prompting the term "diabetes of injury."

During the subsequent convalescent stage, there is increased gluconeogenesis, and glucose uptake by the peripheral tissues is normal and insulin secretion is increased. The pancreas is able to respond normally to the increased glucose loads. A contributing factor to this change in glucose kinetics is the hormonal shift from α- to β-adrenergic catecholamine effects.[88] Plasma glucagon levels increase after surgery and promote hepatic amino acid uptake, gluconeogenesis, and glycogenolysis.[89] Nonetheless, the increase in splanchnic glucose production with glucagon is a transient phenomenon, and it is only with the combined effects of all the stress hormones that hepatic gluconeogenesis is maintained.[90] Increased pituitary release of corticotropin leads to increased glucocorticoid levels, which can produce a moderate glycemic response.[91] Postoperative increases in growth hormone have an anabolic effect, causing nitrogen retention, protein synthesis, lipolysis, and decreased peripheral glucose uptake.[92] The net effects of the neuroendocrine response on metabolism during the convalescent stage after tissue injury include increased blood glucose, stimulation of lipolysis, and increased rate of gluconeogenesis.

During surgery, blood glucose concentrations in nondiabetic patients may increase to as much as 60 mg/d above preoperative levels.[93] The extent of operation stress is the primary determinant of the absolute increase in glucose values. Inadequate insulin secretion, coupled to the stress hormone milieu and the preoperative fasting state, makes the diabetic patient more susceptible to hyperglycemia, hypovolemia, osmotic diuresis, ketosis, and possible changes in acid–base balance. Hyperglycemia may have detrimental effects if it is unmanaged. Osmotic diuresis resulting from the osmotic activity of glucose occurs when the patient's blood glucose level exceeds the renal glucose threshold (approximately 180–250 mg/dL). This osmotic diuresis can result in dehydration, acidosis, and electrolyte abnormalities. Although hyperglycemia per se does not have direct effects on the patient's acid–base status, the ketone bodies that result from inadequate insulin therapy can elicit such effects. Acetoacetic acid and β-hydroxybutyric acid may alter pH status by the accumulated dissociation of hydrogen ions.

Diabetic Complications

Not only are there many causes of diabetes, but the complications that arise from diabetes are enormous because of the multiplicity of systems affected by the disease.[70,77–79,94] The cardiovascular complications of diabetes include coronary heart disease, congestive heart failure, diabetic cardiomyopathy, peripheral vascular disease, hyperlipidemia, and autonomic dysfunction. Renal complications include hypertension, microalbuminuria, proteinuria, type IV renal tubular acidosis, and, ultimately, end-stage renal disease. The gastrointestinal system is affected by gastroparesis and changes in motility that can result in diarrhea, constipation, and gastroesophageal reflux disease. The neurologic complications include peripheral neuropathy, radiculopathy, neurogenic bladder, erectile dysfunction, autonomic dysfunction, and orthostatic hypotension. Diabetics are at risk for ophthalmologic changes, including diabetic retinopathy. Infections are much more prevalent especially with organisms such as *Candida*, *Staphylococcus*, *Pseudomonas*, and fungi, as well as increased incidence of urinary tract infections and foot ulcers.

Cardiovascular Disease and Diabetes

The relationship between diabetes and cardiovascular disease is complex. Not only is cardiovascular disease a major complication of diabetes, but diabetes is one of the major risk factors for cardiovascular disease. Diabetes reduces overall life span.[95] Diabetics have a higher incidence of cardiovascular disease.[96–98] Diabetics are at increased risk of myocardial infarction with a greater risk of death from a myocardial infarction both prior to reaching the hospital and, also, once in the hospital.[99] The National Cholesterol Education Program has defined diabetes as a coronary risk equivalent and a higher mortality is associated with diabetes and coronary artery disease.[100] With intensive focus, the risk as a consequence of cardiovascular disease has decreased, but there has not been a decrease in patients with diabetes.[101] Thus risk factor modification assumes greater significance in diabetics.

Similarly, the relationship between diabetes and hypertension is complex and interrelated. Not only should diabetes be aggressively treated, but hypertension should also be aggressively addressed as revealed in two key studies—the UKPDS and the Hypertension Optimal Treatment (HOT) trial.[102–104] The UKPDS study found that although intensive glucose therapy was beneficial in reducing cardiovascular risk, there was an even more significant effect with reducing blood pressure, not only for cardiovascular events, but also cerebrovascular events. The HOT study demonstrated that aggressive diastolic blood pressure reduction reduced cardiovascular mortality. These findings have been incorporated into the Joint National Committee on Prevention, Detection, Evaluation, Treatment of High Blood Pressure 7th Report (JNC-7) guidelines.[105] In high-risk cardiovascular patients angiotensin-converting enzyme (ACE) inhibitors improve cardiovascular morbidity and mortality.[106,107] Despite all the recommendations and the higher prevalence of hypertension among diabetics, hypertension remains, for the large part, uncontrolled.[108]

Dyslipidemias are widely prevalent among diabetics and are part of the complex relationship between diabetes, and associated cardiovascular and cerebrovascular events leading to increased morbidity and mortality. Multiple studies—the Heart Protection Study,[96] the Scandinavian Simvastatin Survival Study,[110] the Veterans Affairs High-Density Lipoprotein Cholesterol Intervention Trial Study Group,[111] and the MRC/BHF Heart Protection Study[112]—show the clear benefit of aggressive lipid management. The American Diabetes Association used this information to help set its lipid goal recommendations:[78] LDL cholesterol in diabetics <100 mg/dL. The National Cholesterol Education Program (NCEP)[100] has set a more aggressive goal in high-risk patients: LDL <70 mg/dL, triglycerides <150 mg/dL, and HDL >40 mg/dL.[100] The Lescol Intervention Prevention Study found a marked reduction of more than 50% in major adverse cardiac events such as death or nonfatal myocardial infarction (MI) with the use of a statin.[114]

Diabetes is associated with a prothrombotic state that contributes to the increased risk of higher mortality from cardiovascular disease.[115,116] One of the early studies to show the benefits of aspirin was the Physicians Health Study,[117] which noted a marked reduction in myocardial infarctions among diabetic physicians on aspirin. Subsequent work, such as the HOT trial, continued to show a significant reduction in cardiovascular events, as well as myocardial infarction for patients on aspirin. The benefits of aspirin plus clopidogrel, as well as aspirin plus glycoprotein 2b/3a inhibitors, has been noted,[115] although the risk of bleeding is increased with these combinations versus aspirin alone.

Although recent studies[118] indicate that current assessment guidelines may miss a number of patients with silent ischemia, there is still no well-established data in asymptomatic patients that advanced testing with nuclear stress tests or stress echocardiography leads to better outcomes. The emphasis should rather be on risk reduction and adopting proven beneficial therapies—lipid reduction, blood pressure control, smoking cessation, weight reduction, increasing physical activity, and aspirin therapy. A detailed history and physical examination including laboratory and electrocardiogram (ECG) analysis should be done. Exercise capacity should be determined in accordance with the American College of Cardiologists/American Heart Association preoperative assessment guidelines.

Diabetic Neuropathy

Diabetic neuropathy is common, varied, and affects between 75% and 90% of all diabetics, with the elderly having more pronounced effects. There exists a multiplicity of classification systems for diabetic neuropathy.[119–121] The American Diabetes Association[122] uses a classification of neuropathies as (a) sensory neuropathies—acute sensory neuropathy and chronic distal symmetric polyneuropathy; (b) focal and multifocal neuropathies; and (c) autonomic neuropathy. The classification system used by Vinik and Mehrabyan[123]—small-fiber neuropathies, large-fiber neuropathies, and autonomic neuropathy—is somewhat more intuitive. A key point emphasized by the American Diabetes Association[122] is that early recognition and treatment of neuropathy is important, and that it is as equally important to determine which neuropathies are not attributable to diabetes and to correctly diagnose and exclude them.

The small-fiber neuropathies[123] are characterized by being electrophysiologically silent with preservation of reflexes and motor strength, but with loss of cutaneous nerve fibers on tissue staining. Allodynia with burning superficial pain of the c-fiber type is a characteristic; but later there is hypoalgesia. There is a decreased thermal sensation with impaired vasomotor and blood flow and decreased autonomic function, leading to decreased sweating, dry skin, and increased risk for foot ulceration and gangrene.

The large-fiber neuropathies encompass both sensory and motor nerves and are more amenable to diagnosis with electromyography, nerve conduction velocity studies and quantitative sensory tests.[119,121,123] Clinical manifestations include changes in perception presenting with impaired vibratory perception and position sense. There is depression of the deep tendon reflexes, sensory ataxia, and a deep-seated, dull, aching pain in the feet, and initially there is a feeling of warming in the feet because of increased blood flow. There is a shortening of the Achilles tendon and wasting of the small muscles of the feet with hammertoes, and subsequent weakening of the hands and feet. Distal muscle weakness can be seen as an inability to stand on the heels or toes. Distal symmetric neuropathy, diffuse motor neuropathy, and distal motor neuropa-

thy are part of the large-fiber neuropathy syndrome. It is important to exclude other causes of these types of neuropathies such as familial, B_{12} deficiency, folate deficiency, Lyme disease, heavy-metal poisoning, reaction to cytotoxins, immunologically mediated and those neuropathies caused by malignancy. In the elderly, there is an increase in proximal muscle neuropathy. These can present as pain in the buttocks, thighs, and hips that can have a variable initiation that is either abrupt or gradual onset. Symptoms can progress to weakness with inability to get up from a sitting position and can coexist with distal symmetric polyneuropathy. Fasciculations may be provoked by percussion or may occur spontaneously with electrophysiologic studies indicating a lumbosacral plexopathy. The elderly are also at greater risk for mononeuropathies. These tend to occur spontaneously, acutely, and with pain. They tend to effect the ulnar, median, peroneal nerves, and cranial nerves III, VI, and VII, and are characterized by a spontaneous remission and lack progression. These mononeuropathies must be distinguished from the nerve-entrapment syndromes such as carpal tunnel, which are more frequent in diabetics, but which tend to be gradual in onset, and progressive in nature.[119–123]

Autonomic neuropathy[119–123] has many clinical manifestations and involves multiple physiologic systems. Cardiovascular manifestations include resting tachycardia, exercise intolerance, orthostatic hypotension, cardiac degeneration and silent myocardial infarction, alterations in blood flow to skin and extremities, and temperature intolerance. The gastrointestinal system is affected with a variety of changes, including esophageal dysmotility, diarrhea, constipation, incontinence, and diabetic gastroparesis. Genitourinary syndromes include cystopathy, neurogenic bladder, and sexual dysfunction in women, and erectile dysfunction in men. Besides temperature intolerance, there are abnormalities of sweating. These include increased upper-body sweating, and increased gustatory sweating in response to certain foods such as cheeses and spicy foods. There is decreased lower-body sweating, with resulting skin dryness and cracking contributing to increased infections and ulcerations of the diabetic foot. Autonomic neuropathy affects metabolic response to glucose regulation with both a decreased ability to detect and respond to hypoglycemia. Ocular manifestations of autonomic neuropathy include Argyll-Robertson–like pupil and a decreased diameter of a dark-adapted pupil.[119–123]

As pointed out by Luukinen and Airaksinen,[124] orthostatic hypotension for older diabetics is predictive of a higher risk of vascular death. This increase in morbidity and mortality associated with autonomic neuropathy is one of the reasons the American Diabetes Association[122] advocates the performance of standard examinations for the diagnosis of autonomic neuropathy. Examination of the resting heart rate is key, because a resting heart rate >100 beats per minute is abnormal. Next an examination of fasting, nonhypoglycemic heart rate with an examination for heart rate variability is done with a patient monitored by ECG breathing 6 breaths per minute; the difference in heart rate between resting and supine should be greater than 15 beats per minute and if the heart rate variability is less than 10 beats per minute and the R-R interval ratio is not greater 1.17, then the heart rate variability is abnormal.

As noted by Cox et al.,[125] hyperglycemia impairs cognitive performance in diabetics. Arvanitakis et al.[114] note that diabetes, in addition to aging, contributes to the progression and worsening of rigidity and gait disturbance in the elderly. The DCCT trial[127,128] demonstrated the beneficial effect of tight glucose control on limiting the microvascular complications of diabetes; the goal advocated is an $HgbA_{1c}$ less than 7. In addressing the pain and discomfort associated with diabetic neuropathy, the American Diabetes Association[122] recommends a stepwise approach starting with an exclusion of nondiabetic causes, stabilizing the blood sugar, and then attempting to achieve a $HgbA_{1c}$ of less than 7. Tricyclics are the first-line drugs for pain control, then anticonvulsants, and finally opiates. However, Gilron et al.[129] recently demonstrated that the lower-dose combination of opiates and anticonvulsants achieves better analgesia than higher doses of either drug alone. The EURODIAB Study Group,[130] in addition to the findings of the UKPDS, emphasize the importance of addressing all modifiable risk factors so as to minimize diabetic neuropathy.

Nephropathy and Urologic Complications

Diabetic effects on the urologic system encompasses diabetic nephropathy, urologic cystopathy, erectile dysfunction, and infection. Diabetic nephropathy affects more than 40% of type 1 diabetics and more than 20% of type 2 diabetics.[77,131] The National Kidney Foundation[132] defines diabetes as a risk factor for chronic kidney disease and recommends screening and risk factor reduction. The effects of diabetes in leading to end-stage renal disease are worse for certain ethnic groups, namely Native Americans, Hispanics, and African Americans.[77] It appears that aggressive risk-factor reduction and tight blood pressure and glucose control[133] can decrease both the rate of progression to end-stage kidney disease and the renal complications of diabetes. The American Diabetes Association recommends the early diagnosis and treatment of microalbuminuria along with aggressive risk-factor reduction with blood glucose control so as to prevent the albuminuria, blood pressure elevation, and persistent decline in glomerular filtration rate (GFR) that is characteristic of diabetic nephropathy and which ultimately contributes to increased mortality and morbidity.

Diabetic cystopathy affects almost 50% of diabetics and increases with age.[122] In diabetic cystopathy there is impaired sensation of bladder fullness, an increase in bladder capacity, a reduction in bladder contractility, and an increase in residual urine. This residual urine increases the risk for urinary tract infections, urethral reflux, hydronephrosis, pyelonephritis, and urosepsis. A urologic evaluation for cystopathy may include cystometry, sphincter electromyography, uroflowmetry, and urethral pressure profile. Both cystopathy and erectile dysfunction result from microvascular changes of diabetes and the polyneuropathy associated with diabetes.[134]

Diabetic Ketoacidosis

Poorly controlled diabetes may cause severe metabolic abnormalities, including diabetic ketoacidosis or hyperglycemic hyperosmolar nonketotic state. The hyperosmolar nonketotic state is characterized by marked hyperglycemia, dehydration, and hyperosmolarity, but severe ketosis is absent. Patients unable to compensate

for hyperglycemia and dehydration are often elderly type 2 diabetics. The presence of diabetic ketoacidosis is suggested strongly by history and physical examination, along with a high blood sugar level and positive urine ketones, although the definitive diagnosis of diabetic ketoacidosis must be verified with arterial blood gases and consists of (a) hyperglycemia (>250 mg/dL), (b) decreased bicarbonate (<15 mEq/L), and (c) decreased arterial pH (<7.3) with ketonemia (positive at 1.2 dilution) and moderate ketonuria. The principal therapy includes hydration, IV insulin, potassium, phosphate, and bicarbonate therapy, and frequent monitoring of electrolytes, glucose, and acid–base status. The details of therapy have been summarized elsewhere.[135,136]

Diabetes Preoperative Evaluation

Diabetes is a disease with enormous physiologic impact, and the preoperative evaluation should be done in accordance with current American College of Cardiologists/American Heart Association guidelines. The preoperative evaluation should include assessment of the systemic manifestations noted above. The electrocardiogram should be analyzed. The rate, rhythm, presence of left and/or right atrial hypertrophy, ventricular enlargement, and ectopy, and signs of prior myocardial infarction should be noted. Any interval change since the prior electrocardiogram is important, bearing in mind the higher incidence of silent myocardial infarctions among diabetics. In examining the chest films, the lung characteristics, the size and position of the heart and great vessels, the degree of calcification of the boney structures and vertebrae, the presence or absence of fluid collections, and the characteristics of the diaphragm should be noted.

Because diabetic patients tend to be on multiple medications, obtaining a metabolic profile may be worthwhile. The levels of key electrolytes, sodium, and potassium should be determined. Current glucose levels both in reference to a patients baseline, and also, as a baseline for subsequent comparisons is useful. A hemoglobin A_{1c} is useful to indicate overall glycemic control with current American Diabetes Association recommendation being below 7 and values above 10 corresponding to plasma blood glucose in the 300 mg/dL range and poor control.[77] A fasting lipid profile provides information as concomitant cardiovascular risk rather than acute glycemic issues. The serum creatinine along with blood urea nitrogen (BUN) helps to provide information on volume status, and renal function. It must be borne in mind that as patients age, their muscle mass diminishes, as does the creatinine that one measures. A blood count provides information on the patient's hemoglobin, platelets, and the presence or absence of anemia, with blood cell indices providing even more detailed information as to the marrow's ability to produce the various cell lines. Because urinary tract infections tend to be common among diabetics, a urinalysis can provide insight as to the presence of infection, ketones, protein, and sediment.

Laryngoscopy and Intubation

Diabetes may be associated with a greater incidence of difficult laryngoscopy and intubation. In patients with diabetes, stiff joint syndrome can occur, affecting all joints, including those of the cervical and thoracic spine. The incidence of difficult laryngoscopy in long-term type 1 diabetic patients is reported to be 30–40%.[137–139] The diagnosis of stiff-joint syndrome is relatively easy. Besides evaluation of spine mobility, the wrists and elbows should be observed for incomplete extension and flexion. The hands should be assessed for thick, waxy skin and an inability to oppose the interphalangeal joints of the fingers assessed in the "prayer" position.[139]

Metabolic Syndrome

A variety of terms have been used to describe the clustering of metabolically related cardiovascular risk factors. Commonly used names to denote this relationship include "syndrome X," insulin resistance syndrome, and now metabolic syndrome. Recently, the International Diabetes Foundation defined the metabolic syndrome as (a) central obesity—ethnically specific increased waist circumference; *plus* any two of the additional findings of (b) increased triglycerides (>150 mg/dL); (c) reduced HDL cholesterol (<40 mg/dL in men and <50 mg/dL in women) or undergoing the treatment for lipid disorders; (d) elevated blood pressure (systolic ≥130, diastolic ≥85) or undergoing treatment for hypertension; and (e) elevated fasting plasma glucose (≥100 mg/dL) or undergoing treatment for diabetes.[140] This definition is fairly similar to that of NCEP Adult Treatment Panel III.[100] Even after adjusting for traditional risk factors, patients with metabolic syndrome are at increased risk for cardiovascular and cerebrovascular disease, as well as diabetes.[141–143] Whether this is a result of dyslipidemia, insulin resistance, vascular dysregulation, a proinflammatory state, a prothrombotic state, hormonal factors, or some other mechanism remains to be determined.

CHAPTER 13

Evaluation of the Patient with Renal Disease

Mark Stafford-Smith, MD, CM, FRCPC, George Lappas, MD, and Andrew D Shaw, MB, BS, FRCA

"The composition of the blood is determined not by what the mouth ingests but by what the kidneys keep...."[1] This is the well-known quote of the renal physiologist Dr. Homer Smith that highlights not only the kidneys' domain of influence, but why even minor renal perturbations can have widespread effects. Because the kidneys play a key role in whole-body homeostasis, review of kidney function is an essential part of even the most abbreviated perioperative assessment. Although the kidneys' actions are generally described in terms of filtration and clearance, these tasks comprise only a part of their involvement in maintaining homeostasis. Normal renal physiology and the consequences of impairment are reviewed below in the context of their implications for the perioperative physician.

THE NORMAL KIDNEY: CORRELATES OF STRUCTURE AND FUNCTION

The kidneys are paired mesoderm-derived retroperitoneal organs that weigh approximately 150 g each. Notably, renal tissue makes up only 0.4% of body weight but receives 25% of cardiac output; in comparison, this exceeds blood flow to muscle during heavy exercise by 8-fold and makes the kidney the most highly perfused major organ in the body. Unlike many tissues, metabolic demand is not the main determinant of blood flow to the kidney, and this "luxury perfusion" facilitates plasma filtration at rates as high as 125–140 mL per minute in adults. It is simplistic, however, to think that the kidneys receive excess nutrients and oxygen, as this ignores marked differences in blood flow that, paradoxically, make some kidney regions (i.e., the medulla) highly vulnerable to ischemic injury.

The functions of the kidney are numerous. The normal "resting" kidney is continuously processing filtered plasma to regulate composition, including feedback mechanisms that maintain body-fluid volume, osmolarity, electrolyte content and concentration, and acidity within narrow limits. Every 3 minutes an amount of water equivalent to a 12-oz soft drink is filtered, and all but 1%, or 4 mL, is returned to the circulation—the remnant is urine. Extracellular solutes are tightly regulated, including sodium, potassium, hydrogen ion, bicarbonate, and glucose. The kidney also generates ammonia and glucose, and eliminates nitrogenous and other metabolic waste, including urea, creatinine, and bilirubin, as well as toxins and many classes of drugs. Finally, circulating hormones secreted by the kidney influence red blood cell generation, calcium homeostasis, and systemic blood pressure.

The anatomy of the kidney has been extensively studied and is described in detail elsewhere.[2] In summary, each bean-shaped kidney is highly internally organized, including a superficial cortical layer, deeper medullary regions, and a network of ducts that feeds urine to the renal pelvis and onward to the ureter and bladder (Fig. 13–1). The parenchyma of each kidney contains approximately 1×10^6 tightly packed nephrons, the functional units of the kidney. The nephron is a tubular structure that is segmented into specialized parts, including the glomerulus, proximal convoluted tubule, loop of Henle, distal convoluted tubule, and collecting duct (Fig. 13–1). The cortex, or superficial outer por-

KEY POINTS

1. Kidney functions are centrally involved in whole-body homeostasis and normally keep body fluid volume, osmolarity, electrolyte content and concentration, and acidity within narrow limits.
2. Knowledge of normal kidney function is particularly important to interpret the physiology of the neonate, the parturient, and the elderly patient, where differentiating normal from abnormal may be challenging and even counterintuitive.
3. While the search for a substance with "ideal" properties (i.e., steady production, complete filtration, no secretion or absorption, convenient inexpensive measurement) to assess glomerular filtration rate through its clearance from the circulation continues, serum creatinine and creatinine clearance are the current clinical standards.
4. Kidney-mediated acid–base, electrolyte, and/or fluid disorders are common preoperatively and may be sufficiently important to require correction before surgery can proceed.
5. Familiarity with the spectrum of acute and chronic renal disorders that may be encountered in the perioperative patient is essential to logically anticipate perioperative problems and design rational therapeutic strategies.
6. Prevention is the most important tool in the approach to perioperative acute renal injury; this requires knowledge of potential insults, including the renoprotective value of meticulous attention to maintaining normoglycemia and minimizing hemodilution and transfusion.
7. Major renal injuries significantly impair the kidneys' ability to maintain the internal environment; in these situations, adherence to guidelines aimed at preserving volume, electrolyte, acid–base, and nutrition balance within the limits of the remaining renal homeostatic reserve may be sufficiently effective that dialysis can be avoided.
8. Patients with renal impairment have altered responses to normal medication dosing; a simple prescribing approach for water-soluble agents involves a calculated percentage reduction in drug dosage to match the reduction in glomerular filtration; however, drug-level measurement or algorithms for a specific drug dosing may be recommended.

The glomerulus is the site where plasma filtration occurs; approximately 20% of plasma entering the glomerulus (**D**) will pass through the specialized capillary wall into the Bowman capsule and enter the tubule to be processed and generate urine. DCT, distal convoluted tubule; PCT proximal convoluted tubule. From InterActive Physiology CD (ADAM) Urinary Physiology, Benjamin Cummings Publishing.

tion of the kidney, is made up primarily of glomeruli and proximal and distal convoluted tubules. The medulla is subdivided into an inner and outer (more superficial) layer and includes the loops of Henle and collecting ducts. Nephrons are grouped by location of their glomeruli into cortical and juxtamedullary types; the latter have loops of Henle that course deep into the medulla and participate in *countercurrent exchange*, a mechanism that makes possible the formation of highly concentrated urine (Fig. 13–2).

Like the tubules, the vasculature of the kidney is highly organized. The *renal artery* enters the kidney at the hilum, and then divides many times

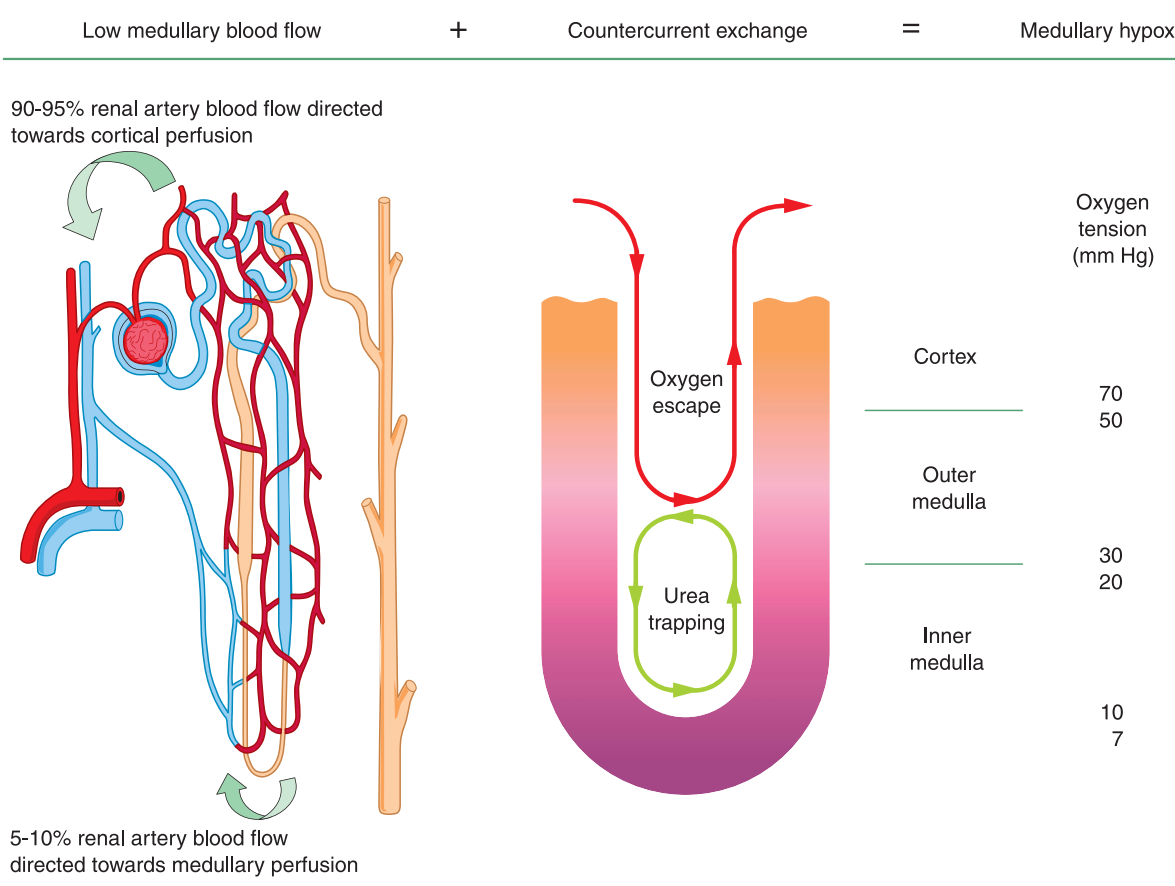

FIGURE 13–2. Medullary hypoxia refers to the physiologically very low PO_2 values (e.g., 10–20 mm Hg) in the renal medulla that are present even under normal conditions. Factors contributing to this state include a high rate of oxygen consumption, relatively poor blood supply, and inefficient oxygen delivery related to countercurrent O_2 "escape" as a result of the parallel arrangement of entering and exiting capillaries. Ironically, this same sluggish perfusion is also essential to create and maintain the urea gradient required to concentrate urine. Reprinted from Grocott HP, Stafford-Smith M. Organ protection during cardiopulmonary bypass. In: Kaplan JA, Reich DL, Lake CL, Konstadt SN, eds. Cardiac Anesthesia. 5th ed. Philadelphia: Elsevier, 2006:985–1022, with permission from Elsevier.

before producing the *arcuate arteries* that run along the boundary between cortex and outer medulla. *Interlobular arteries* branch from arcuate arteries toward the outer kidney surface, giving rise as they pass through the cortex to numerous *afferent arterioles* that each lead to a single *glomerular capillary tuft*. The barrier where filtration from the vascular to tubular space within the glomerulus occurs is highly specialized and includes fenestrated, negatively charged, capillary endothelial cells and tubular epithelial cells (podocytes) separated by a basement membrane. Normally, selective permeability permits approximately 25% of the plasma elements to pass into the Bowman capsule; only cells and proteins larger than 60–70 kDa cannot cross. However, abnormalities of this barrier can occur with disease that may permit filtration of much larger proteins and even red blood cells; these changes manifest as nephrotic syndrome (proteinuria >3.5 g/24 h) or glomerulonephritis (hematuria and proteinuria).

The glomerular capillaries exit the Bowman capsule and merge to form the *efferent arteriole* and *peritubular capillaries* that nourish the tubules. The renal vasculature is unusual in having this arrangement of two capillary beds joined in series by arterioles. Two major types of nephrons exist: the majority (85%) have glomeruli closer to the outer surface of the kidney, and tubular structures that remain predominantly in the cortex and are termed *cortical nephrons*, whereas nephrons with glomeruli located in the deep portion of the cortex (the *juxtamedullary glomeruli*) have associated loops of Henle, which form hairpin loops that pass deep into the medulla. The peritubular capillaries that accompany the medullary loops of Henle are known as *vasa rectae*. Collectively, the peritubular capillaries perfuse tubular cells and receive reabsorbed fluids before rejoining to form *venules*. Throughout the kidney, the venous system runs in parallel and close to the arterial vasculature, ultimately returning blood to the circulation through the *renal vein*. The vasculature of the kidney is strictly segmental, hence embolic obstruction of an arteriole will cause infarction of a "pizza wedge" of parenchyma encompassing the involved glomeruli and all cortical and medullary tubular elements of the affected nephrons.

In summary, the plasma fraction that has been filtered through the glomerular capillary membrane (~120 mL/min) enters the Bowman capsule and passes into the proximal convoluted tubule where active transport processes facilitate absorption of up to two-thirds of the water and electrolytes. The remaining tubular fluid then enters the loop of Henle and distal convoluted tubule where two-thirds of what remains is reabsorbed and further processing occurs. Finally, the effluent (5–10 mL/h) passes from the collecting duct, where more water is reabsorbed, into urine-collecting structures (1–2 mL/min).

To facilitate the specialized goals of the kidney, an important physiologic

TABLE 13–1.

Clinical Correlates of Glomerular Filtration Rate Values

GFR Value	Serum Creatinine (mg/dL)	Implication
120 mL/min	1.0	Normal (healthy, 20-year-old)
80 mL/min	1.2	Normal (healthy, 65-year-old)
60 mL/min	1.1	Normal (healthy, 85-year-old)
30–60 mL/min	1.3–2.5	Moderate renal dysfunction; dosage adjustments may be needed
15–29 mL/min	1.7–3.5	Severe decrease in GFR may reflect chronic disease, prerenal failure, or acute tubular necrosis
<15 mL/min	2.0–18.0	Renal failure (acute of chronic) requiring dialysis

Normal kidney filtration keeps serum creatinine levels stable with increasing age as a result of the roughly matched age-related decline in GFR (creatinine clearance) and the reduction in creatinine generation by muscle. In the elderly, moderate to severe degrees of renal impairment can be associated with only modest rises in serum creatinine.

compromise has evolved in the renal medulla that permits the formation of highly concentrated urine at the expense of diminished oxygen reserve; it is this precarious arrangement that underlies the extreme vulnerability of the renal medulla to ischemic injury (see Postoperative Renal Disorders below).[3] *Medullary hypoxia* is a key concept that refers to the fine balance between oxygen supply and demand that exists in the medulla, even during normal resting conditions. Factors necessary to create a urea gradient and allow countercurrent exchange conspire to make normal PO_2 values in the medulla very low (e.g., 10–20 mm Hg); these include sluggish blood supply (5–10% of renal blood flow) and high oxygen demand from active solute transport. Finally, medullary O_2 delivery is inefficient because of the unique hairpin loop anatomy of the vasa rectae that allows "O_2 escape" from entering or exiting capillaries (Fig. 13–2).[4,5]

CLINICAL ASSESSMENT OF THE KIDNEY

There is general agreement that measures such as urine output correlate extremely poorly with the rate of renal filtration;[6] however, much information about the state of the kidneys can be gained by evaluating how effectively they clear circulating substances. Urinalysis can also be informative.

Renal Function Tests

Filtration is the most clinically assessed renal function. As a key indicator of perioperative renal disease, knowledge of limited filtration capacity is important in preoperative risk stratification and guides drug management for agents cleared by the kidneys. In addition, acute declines in filtration capacity indicate renal injury and consistently predict a more complicated clinical course.[7] *Glomerular filtration rate* (GFR) refers to the plasma volume filtered by the kidneys per unit time, and normal values range from 90–137 mL/min. Normal glomerular filtration rates are proportionate to patient size and body surface area, and decline approximately 10% per decade after age 30 years (Table 13–1).[8] Generally men have GFR values approximately 10 mL/min higher than women. GFR values below 60 mL/min are considered moderately impaired, and individuals with GFRs below 15 mL/min often have uremic symptoms and may require dialysis.

Any substance used to assess GFR through its clearance from the circulation must have certain "ideal" properties, which include a steady supply to the circulation, free filtration by glomeruli, no reabsorption or excretion by the tubules, and, preferably, easily measured in blood and urine. Unfortunately, such an ideal substance has yet to be identified. The most precise and accurate GFR determination tools involve cumbersome "gold-standard" methodologies (e.g., inulin, chromium-51–labeled ethylenediaminetetraacetate [^{51}Cr-EDTA] or technetium-99–labeled diethylenetriamine pentaacetic acid [^{99}Tc-DTPA] clearance), while the most practical and inexpensive tests involve imperfect "ideal" substances (e.g., creatinine). Overall, despite creatinine's limitations as a marker, its relatively steady supply from muscle breakdown and modest tubular secretion make it the most clinically useful renal filtration marker currently available. Although more "ideal" substances are being sought as practical clinical tools, candidates currently under evaluation (e.g., cystatin C[9,10]) have yet to be generally accepted as superior to creatinine.

Estimates of GFR (eGFR) can be made by determining *creatinine clearance* (CrCl) from blood and urine creatinine tests. In stable, critically ill patients, 2-hour urine collections are sufficient to determine CrCl,[11] calculated using the following formula:

$$\text{CrCl (mL/min)} = U_{Cr}\ (\text{mg/dL}) \times V\ (\text{mL}) / P_{Cr}\ (\text{mg/dL}) \times \text{time (min)}$$

where U_{Cr} = urine creatinine; V = total volume of urine collected; P_{Cr} = plasma creatinine; and time = collection time.

However, GFR can also be predicted using a single steady-state serum creatinine value if patient characteristics are known. Importantly, predictive formulas are developed in stable nonoperative populations, and perioperative fluid shifts may introduce an "unsteadiness" to the operative patient that makes serum creatinine less useful to predict GFR. Nonetheless, serum creatinine remains a useful, inexpensive, and, so far, unsurpassed clinical tool, particularly for reflecting *trends* of change in renal filtration function and predicting outcome, even during the perioperative period.[12–14] Of the many predictive formulas that exist, the Cockroft-Gault equation has been the most validated and durable.[15] The Cockroft-Gault equation estimates GFR based on patient gender, age (years), weight (kg), and serum creatinine (mg/dL):

$$\text{Males: Cockroft-Gault eGFR (mL/min)} = (140 \times \text{age}) \times \text{weight (kg)} / (\text{Cr [mg/dL]} \times 72)$$

$$\text{Females: Cockroft-Gault eGFR (mL/min)} = (140 \times \text{age}) \times \text{weight (kg)} / (\text{Cr [mg/dL]} \times 0.85)$$

An estimating method from the Modification of Diet in Renal Disease (MDRD) study that adds knowledge of ethnicity (black versus nonblack) to standard components of the Cockroft-Gault equation may improve accuracy.[16] An abbreviated MDRD Formula is available that can estimate GFR measured in mL/min/1.73 m^2:

Nonblack males: eGFR = 186 × (serum creatinine mg/dL) $^{1.154}$ × (age) $^{0.203}$

Nonblack females: eGFR = 186 × (serum creatinine mg/dL) $^{1.154}$ × (age) $^{0.203}$ × 0.742

All blacks: eGFR = 186 × (serum creatinine mg/dL) $^{1.154}$ × (age) $^{0.203}$ × 1.210

However, even the most detailed MDRD eGFR equation under ideal conditions correlates poorly with GFR determined using "gold-standard" tools, with more than a 30% error in 10% of patients and 2% of results deviating more than 50%.[16]

Some consensus definitions for significant perioperative renal dysfunction have been published. For example, the Society of Thoracic Surgeons definition of postoperative renal failure includes either a new requirement for dialysis, a rise in serum creatinine to greater than 2.0 mg/dL, or at least a 50% increase in serum creatinine over baseline values.[17] Another definition requires serum creatinine to rise more than 25% or 0.5 mg/dL (44 μmol/L) within 48 hours.[18] The Acute Dialysis Quality Initiative Group definition for critically ill patients grades acute renal failure by an acute creatinine rise as follows: a rise of 50% = Risk; of 100% = Injury; of 200% = Failure (the RIFLE criteria).[19] Notably, serum creatinine does not usually rise significantly until GFR rates fall below 50 mL/min, so preoperative serum creatinine may be normal in patients even with some degree of renal dysfunction.

Blood urea nitrogen (BUN) remains widely used to assess renal function but possesses few of the characteristics of an "ideal" substance. Tubular transport of urea changes with some conditions (e.g., dehydration), and urea generation can also be highly variable, particularly in the postoperative period (e.g., catabolic state). In addition, perioperative hemodilution (e.g., cardiopulmonary bypass) may affect circulating BUN levels.

Urinalysis and Urine Characteristics

The examination of urine can reveal much information. Standard aspects of urinalysis include gross appearance, specific gravity, chemical tests for abnormal substances, and microscopic examination for cells and formed elements.

Urine inspection can reveal abnormal color, cloudiness, and unexpected odors. Because there are many available detailed descriptions of examination of the urine,[20] we provide only a summary here. Color changes reflect increased amounts of dissolved substances; this occurs most commonly with dehydration, but other causes include food colorings, drugs, and liver disease (e.g., bilirubin). In contrast, cloudy urine is caused by suspended elements such as crystals and/or white or red blood cells. Lightly centrifuged urine sediment will normally reveal up to 2 red blood cells per high-power field (400×). In addition, normal urine will contain up to 80 ± 20 mg protein per day. As noted above, high levels of red blood cells or protein reflect abnormal kidney function. Urine protein electrophoresis can trace proteinuria to a glomerular (filtering), tubular (reuptake), overflow (supply that saturates the reuptake system), or tissue (e.g., kidney inflammation) abnormality.[21] Unusual odors are less common but can also be diagnostic (e.g., maple syrup urine disease). Chromogenic "dipstick" chemical tests can determine urine pH and provide a semiquantitative analysis of protein, glucose, ketones, blood, urobilinogen, bilirubin, nitrites, and leukocyte esterase. In addition, urine microscopy can identify bacteria, crystals, cells, and casts from renal tubules.

Urine specific gravity refers to the weight of urine relative to distilled water; normal values range between 1.001 and 1.035. Specific gravity is often used as a surrogate for osmolarity (normal range 50–1000 mOsm/kg), with 1.010 reflecting a urine specific gravity the same as plasma osmolarity. High specific gravity (>1.018) implies a preserved concentrating ability of the kidney, unless substances that raise specific gravity without significantly changing osmolarity are present in large amounts (e.g., glucose, protein, contrast dye).

Although poor urine output (e.g., <400 mL urine/24 h) may reflect hypovolemia or impending *prerenal* failure, the majority of renal failure episodes develop in the presence of normal urine output.[6] The kidney's typical response to hypovolemia is to retain solute; this produces concentrated urine with a low sodium content (<20 mEq/L) through fluid and electrolyte retention. In contrast, if renal injury has impaired concentrating ability, urine will approach plasma osmolarity (isosthenuria) and have a higher sodium content (>40 mEq/L). Calculation of *fractional excretion of sodium* (FE_{Na}) evaluates the kidneys' ability to retain electrolytes by comparing sodium and creatinine excretion from a spot sample of urine and blood; this test can be useful to distinguish hypovolemia and renal injury:

$$FE_{Na} = U_{Na}/P_{Na} \times P_{Cr}/U_{Cr} \times 100$$

where U_{Na} = urine sodium; P_{Na} = plasma sodium; U_{Cr} = urine creatinine; and P_{Cr} = plasma creatinine.

FE_{Na} values less than 1% imply that sodium is being normally conserved by the tubules, whereas values greater than 1% are consistent with acute tubular necrosis.

THE NORMAL KIDNEY IN SPECIAL CIRCUMSTANCES: MATURATION, AGING, AND PREGNANCY

For additional discussion see Chaps. 19–22.

The Immature Kidney

Amniotic fluid (fetal urine) through the third trimester amounts to about a cup every hour. At birth, much of the anatomic development of the kidney has occurred, including growth of approximately 1 million nephrons per kidney. However, nephrons continue to increase in size and steadily gain function with some kidney activities reaching adult levels as early as a few weeks after birth (e.g., urine acidification), whereas other measures of renal function only attain adult levels by 1–3 years of age (e.g., renal blood flow, GFR, urea clearance, tubular excretion and concentrating capacity).[22] Renal development in preterm infants is correlated with conceptual age, and normal kidney function will be achieved in these children, but may be delayed. Children undergoing heart surgery are vulnerable to postoperative renal dys-

function relative to adults, and renal failure following surgery that requires dialysis carries a particularly grave prognosis.[23]

The Kidney during Pregnancy

Progesterone and relaxin, hormones secreted by the corpus luteum, are believed to mediate most of the renal effects of pregnancy. Renal blood flow, GFR, and clearance of nitrogenous waste rise early in pregnancy and are 50–60% increased at term, making typical serum creatinine and urea values 40% lower (and levels that are usually considered normal concerningly high) for pregnant patients. In addition, saturation of tubular uptake mechanisms may contribute to the aminoaciduria, proteinuria, and glycosuria that are common. Other renally mediated alterations include mild hyponatremia and mild alkalemia with bicarbonate and carbon dioxide tension (PCO_2) values 4 mEq/L and 10 mm Hg below normal, respectively. Maternal blood volume is doubled by 7 months, and at term the pregnant mother is 7.5 L of water and 900 mmol of sodium net-positive. Preterm labor can be precipitated by dehydration and sometimes halted by rehydration. Hormonal and obstructive factors (i.e., compression of the ureter between the pelvic rim and gravid uterus) cause dilation of all the urine-collecting structures from the first trimester to 3–4 months after delivery. The major practical concern from the resulting stasis is increased risk for urinary tract infection.

The Aging Kidney

An approximately parallel progressive decline of all renal functions with age starts around 30–40 years of age, including renal blood flow, GFR, tubular active transport, urine concentration, dilution, and acidification.[24] In addition, decreased thirst and impaired hormonal functioning of the renin–angiotensin system, vitamin D metabolism, and antidiuretic hormone response are also associated with aging. Because creatinine clearance and production of creatinine from muscle decrease at approximately the same rate (1% per year), it would be expected that serum creatinine values would also change; curiously, the values typically do not change with age (Table 13–1).[25,26] However, by the eighth decade, GFR is reduced by 33–50%.[27] The practical consequences of these changes include reduced renal reserve to deal with extreme challenges of any kind to the internal environment and changes in the pharmacokinetics of drugs that are cleared by the kidneys. Drug toxicity is a common problem in the elderly, and drug dosage decisions should be based on knowledge of kidney function. In addition, the aging kidney is more likely to be subjected to potentially harmful processes including chronic illness (e.g., hypertension, diabetes, atherosclerosis) and toxic drugs (e.g., nonsteroidal antiinflammatory drugs, antibiotics, and diuretics).[28]

ACID–BASE, FLUID, AND ELECTROLYTE DISORDERS

For additional discussion see Chap. 42.

Awareness of kidney-mediated acid–base, electrolyte and/or fluid disorders prior to a procedure may significantly reduce perioperative risk by influencing selection of intravenous fluids and choice of anesthetic agents, and, occasionally, by requiring that an operation be delayed to correct abnormalities; consequently, these conditions are reviewed below.

Sodium Disorders

Sodium is the principal electrolyte of the extracellular environment and derangements of this cation primarily affect normal functioning of excitable cells, including nerve and muscle tissue. Normal serum values are regulated by the kidney to between 135 and 145 mmol/L but may be falsely lowered as a consequence of hyperglycemia, hyperproteinemia, or hyperlipidemia; low serum osmolality differentiates true hyponatremia from pseudohyponatremia.

Hyponatremia

Hyponatremia is the most common electrolyte disorder.[29,30] Symptoms rarely occur unless sodium values are less than 125 mmol/L, and these include a spectrum ranging from anorexia, nausea, and lethargy to convulsions, arrhythmias, coma, and even death as a consequence of osmotic brain swelling.[31–33] These symptoms resemble those from local anesthetic toxicity, presumably because of the local anesthetic-related sodium channel blockade. Notably, excessively rapid correction of chronic hyponatremia can also produce severe neurologic deficit (central pontine myelinolysis) and death.[34] Hyponatremia may occur in the setting of an expanded, normal, or contracted extracellular fluid volume (Table 13–2). Volume status and urine sodium concentration are key markers in differentiating the large number of potential causes of hyponatremia. If water excess is a reason for hyponatremia, dilute urine (sodium >20 mmol/L) is expected, whereas avid sodium conservation (urine sodium <20 mmol/L) suggests sodium loss as a cause.

If hyponatremia is acute, the risk of neurologic complications is higher, and cautious treatment may be indicated to prevent cerebral edema and seizures. This should be accomplished with intravenous hypertonic saline and furosemide to enhance water excretion and prevent sodium overload. More conservative management, such as water restriction, is the usual treatment for chronic hyponatremia, which

CHF, congestive heart failure; GI, gastrointestinal; SIADH, syndrome of inappropriate antidiuretic hormone; TURP, transurethral resection of the prostrate.

should only be treated aggressively if symptomatic.

Hypernatremia

Hypernatremia (serum sodium >145 mmol/L) is generally the result of sodium gain or water loss, most commonly caused by a negative water balance as with respiratory losses, sweating, and urinary losses without replacement. Febrile infants have immature kidneys and a greater surface area per unit of body mass; as a result, febrile infants are particularly at risk for water losses. Dehydration of brain cells leads to symptoms ranging from confusion to convulsions and coma.

In evaluating the hypernatremic patient, laboratory studies often show evidence of hemoconcentration (increased hematocrit and serum protein concentrations). In addition, urine output is usually low (<500 mL/d) and hyperosmolar (> 1000 mOsm), with very low urine sodium concentration and evidence of prerenal failure (elevations of BUN and serum creatinine). Occasionally the urine is not maximally concentrated, suggesting an osmotic diuresis or an intrinsic renal disorder such as diabetes insipidus. The primary goal of treatment is restoration of serum tonicity that can be achieved with isotonic or hypotonic parenteral fluids and/or diuretics unless irreversible renal injury is present where dialysis may be necessary.

Metabolic Acid–Base Disorders

The balance between plasma bicarbonate (HCO_3) concentration and PCO_2 in the extracellular space is the primary factor that predicts serum pH. Acid–base homeostasis involves the tight regulation of HCO_3 and PCO_2. Primary extracellular pH derangements caused by abnormal bicarbonate reabsorption and proton (H^+) elimination by the kidney cause metabolic acidosis or alkalosis, whereas factors that abnormally affect respiratory drive influence PCO_2 tension, leading to respiratory acidosis or alkalosis (Fig. 13–3). Because combined problems are often seen in perioperative critically ill patients, an approach to both "pure" and "mixed" acid–base disorders is presented below.

Metabolic Acidosis

Accumulation of nonvolatile acid can result from numerous causes and is the basis for metabolic acidosis. The "anion gap" represents the concentration of all unmeasured anions and can be calculated from serum electrolyte values (anion gap = $[Na^+]$ – ($[HCO_3]$ + $[Cl]$)) to differentiate metabolic acidosis causes into normal anion gap (8 ± 4) and increased anion gap (>16 mmol/L) types. Only conditions that cause an increase in negatively charged ions other than bicarbonate and chloride (e.g., lactate, salicylate) will increase the anion gap. In contrast, typically nonanion gap metabolic acidosis results from renal or gastrointestinal bicarbonate loss and is associated with high chloride levels (*hyperchloremic metabolic acidosis*). A usual compensatory response to all types of metabolic acidosis is hyperventilation leading to a partial pH correction towards normal. *Winter's formula* predicts expected PCO_2 for a metabolic acidosis as follows:

$$PCO_2 = (1.5 \times [HCO_3]) + 8 \pm 2$$

Metabolic Alkalosis

Metabolic alkalosis is a very common primary acid–base disturbance associated with increased plasma HCO_3; an analysis of more than 13,000 arterial blood gas samples found metabolic alkalemia in 51% of those with an acid–base abnormality.[35] Increased extracellular HCO_3 is due to net loss of H^+ and/or addition of HCO_3. The most common cause of metabolic alkalosis is gastrointestinal acid loss because of vomiting or nasogastric suctioning; the resulting hypovolemia leads to secretion of renin and aldosterone and enhanced absorption of HCO_3. Diuretics are another common cause of metabolic alkalosis. Thiazides (e.g., hydrochlorothiazide) and loop diuretics (e.g., furosemide) induce a net loss of chloride and free water, without altering bicarbonate excretion, and can cause a volume "contraction" alkalosis. When metabolic alkalosis is persistent, it usually reflects an inability of the kidney to excrete HCO_3. Rare inherited renal causes of metabolic alkalosis exist (e.g., Bartter syndrome). A typical respiratory response to all types of metabolic alkalosis is hypoventilation leading to a pH correction towards normal.

Respiratory Acid–Base Disorders

Respiratory Acidosis

If the lungs fail to eliminate CO_2, hypercapnia and respiratory acidosis re-

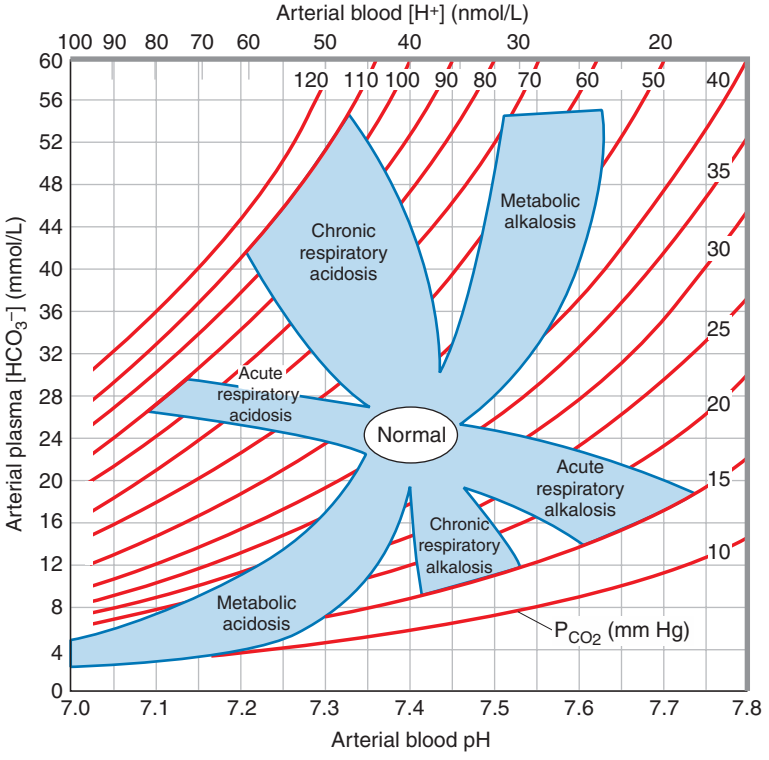

FIGURE 13–3. Acid–base map. Plotting plasma HCO_3 (from the serum chemistry panel) against the PCO_2 and H^+ (from the arterial blood gas) will fall in the *shaded* areas in a simple acid–base disorder. Should a mixed disorder exist, the values may fall in the *nonshaded* areas. Reprinted from DuBose TD Jr. Acid–base disorders. In: Brenner BM, ed. Brenner & Rector's The Kidney. 7th ed. Philadelphia: WB Saunders, 2004:938, with permission from Elsevier.

sult, characterized by increased PCO_2 and decreased blood pH. Acute and chronic etiologies can be differentiated by examining arterial pH, PCO_2, and HCO_3 values. In the early phase of respiratory acidosis, increased PCO_2 stimulates renal generation and secretion of H^+. The kidneys continue to adapt to the increased pH through greater titratable acid excretion (e.g., ammonium) and HCO_3 generation. Therefore, acute respiratory acidosis is characterized by an elevated PCO_2, acidemia, and a relatively normal HCO_3. In contrast, chronic respiratory acidosis is associated with an elevated HCO_3 caused by renal compensation. Important information about the cause of primary respiratory acidosis is usually available from the history and physical examination. In the acute postoperative period, respiratory effort may be labored (e.g., bronchospasm, pulmonary edema) or depressed because of medications such as opioids, sedatives, or residual volatile anesthetic agents. In contrast, obesity, restrictive and obstructive lung diseases, and neuromuscular diseases (e.g., myasthenia gravis, Guillain-Barré syndrome) are all potential causes of chronic hypoventilation and respiratory acidosis.

Respiratory Alkalosis

Increased minute ventilation is the primary cause of respiratory alkalosis, characterized by decreased PCO_2 and increased pH. Patients with acute, uncompensated respiratory alkalosis have normal plasma HCO_3. In chronic respiratory alkalosis, renal compensation will lead to decreased plasma HCO_3. The causes of respiratory alkalosis relate to abnormal respiratory drive because of stimulants or toxins (e.g., salicylate, caffeine, nicotine, progesterone), central nervous system abnormalities (e.g., anxiety, stroke, increased intracranial pressure), pulmonary abnormalities (e.g., pulmonary embolus, pneumonia), mechanical hyperventilation, or systemic conditions, such as liver failure and sepsis.

Mixed Acid–Base Disorders

It is common for a metabolic derangement to coexist with a respiratory derangement, particularly in the intensive care unit setting. For example, a patient subjected to an aggressive diuresis who is also overly sedated may have a "normal" blood pH in the presence of coexisting respiratory acidosis and metabolic (contraction) alkalosis. Although the patient's acid–base status is far from normal, the Henderson-Hasselbalch equation ($pH = pK \times \log([HCO_3]/(0.03 \times PCO_2))$) predicts that as long as a normal ratio exists between HCO_3 and $Paco_2$, blood pH will be normal. Conversely, a normal concentration of HCO_3 only predicts a normal pH if the $Paco_2$ is also normal.

A general approach to the diagnosis of mixed acid–base disorder requires a stepwise logical approach that begins with a focused history and physical examination. An arterial blood gas (ABG) and a simultaneously obtained "chemistry panel" that includes Na^+, K^+, Cl, and total CO_2 concentrations, should also be obtained, and use of an acid–base map will differentiate simple from mixed disorders (Fig. 13–3).

Potassium Disorders

It is critical that there be minimal fluctuation in extracellular potassium levels as even minor variations can lead to skeletal muscle weakness, gastrointestinal ileus, rhabdomyolysis, myocardial depression, malignant ventricular arrhythmias, and sudden death. Nearly 98% of total-body potassium (50 mEq/kg) is intracellular. Circulating potassium levels are tightly controlled chronically through renal and gastrointestinal excretion–reabsorption, as well as by short-term exchanges between the intra- and extracellular compartment under the influence of mediators such as insulin and β_2-adrenergic receptors. Dietary potassium ingested approximates 100 mEq per day and is normally balanced by the same amount of excretion by the kidneys (90–95%) and gut (5–10%) to regulate and maintain the extracellular potassium level between 3.5 and 4.4 mEq/L. In the kidney, 70% of potassium reabsorption occurs in the proximal tubule and another 15–20% in the loop of Henle. The collecting duct is responsible for potassium excretion under the influence of aldosterone. Renal potassium secretion is also influenced by the rate of distal tubule fluid flow and acid–base balance. Increased distal tubule flow increases, whereas metabolic acidosis (and to a lesser extent respiratory acidosis) suppresses, potassium secretion. Metabolic alkalosis has the opposite effect.

Hypokalemia

Low serum potassium may be a result of net potassium deficiency or of transfer of extracellular potassium to the intracellular space. Notably, total-body depletion may exist even with normal extracellular potassium levels (e.g., diabetic ketoacidosis). Causes of hypokalemia can be grouped into extrarenal loss (e.g., vomiting, diarrhea), renal loss (impaired processing caused by drugs, hormones, or inherited renal abnormalities), potassium shifts between the extra- and intracellular spaces (e.g., insulin therapy), and, rarely, inadequate intake. Clinical manifestations of hypokalemia include electrocardiogram (ECG) changes (flattened T waves, U waves, proarrhythmic state) and skeletal muscle weakness, and because hypokalemia interferes with the concentrating ability of the kidney, nephrogenic diabetes insipidus can also result. Hypokalemia treatment involves supplementation with intravenous or oral potassium; however, overly rapid potassium intravenous administration should be avoided as it can cause hyperkalemic cardiac arrest.

Hyperkalemia

If a patient has elevated serum potassium levels (>4.4 mEq/L), it is important to discover the duration of the condition as chronic hyperkalemia is better tolerated than acute rises. Beyond laboratory artifact (e.g., hemolyzed sample), causes of hyperkalemia can result from abnormal kidney excretion, abnormal potassium release from cells, or abnormal potassium distribution between the intra- and extracellular spaces. Table 13–3 lists some commonly encountered causes of hyperkalemia. The ECG is a useful test to evaluate the significance of hyperkalemia to a patient's cardiac conduction system, as a good example of the spectrum of acute hyperkalemic ECG occurs during cardiac surgery when high-potassium cardioplegia is administered. Changes include peaked T waves, shortened QT interval, and ST-segment depression with mild potassium elevations, widened QRS complex, increased PR interval, and decreased P-wave amplitude with moderate elevation, and absent P waves, sine wave QRS, ventricular fibrillation, and asystole when hyperkalemia is severe. The anesthesiologist must be aware of drugs that can acutely raise potassium levels (e.g., succinylcholine, β-blockers, certain antibiotics). Fortunately, several therapies can shift potassium

into the intracellular space to treat acute hyperkalemia (Fig. 13–4).

Calcium, Magnesium, and Phosphorus Disorders

Adults contain 1–2 kg of calcium. Most calcium is in bone (98%); the remaining 2% exists in 1 of 3 forms: ionized, chelated, or protein bound. Normal serum calcium values range between 8.5 and 10.2 mg/dL, but only the ionized fraction (50%) is biologically active and precisely regulated. Ionized extracellular calcium concentration (iCa^{2+}) is controlled by the combined actions of parathyroid hormone (PTH), calcitonin, and vitamin D, and further modulated by dietary and environmental factors. Hypocalcemia caused by reduced serum protein levels (e.g., hypoalbuminemia) is physiologically unimportant. Extracellular magnesium represents only 0.3% of total (mainly intracellular) stores, making normal serum levels (1.6–2.2 mg/dL) a poor reflection of total–body magnesium. Magnesium is an essential cofactor in adenosine triphosphate (ATP) reactions, DNA replication and transcription, and translation of messenger ribonucleic acid (mRNA), and deficits may have deleterious effects on energy production and protein metabolism. Phosphorus is a major intracellular anion that plays a role in regulation of glycolysis, ammoniagenesis, and calcium homeostasis, and is an essential component of ATP and red blood cell 2,3-diphosphoglyceric acid synthesis.

Hypocalcemia

Clinical manifestations of hypocalcemia are mainly neurologic and muscular, including cramping, numbness in the digits, laryngeal spasm, carpopedal spasm, bronchospasm, seizures, and even respiratory arrest. A positive *Chvostek sign* (facial muscle twitching in response to tapping the facial nerve) or *Trousseau sign* (carpal spasm induced by brachial artery occlusion) is classic for hypocalcemia but often absent. Mental status changes, including irritability, depression, and impaired cognition may also occur. Cardiac manifestations include QT interval shortening and arrhythmias. Dry skin, coarse hair, alopecia, brittle nails, and evidence of basal ganglia and cerebral cortex calcifications may develop with long-standing hypocalcemia.

Hypocalcemia may be caused by several mechanisms (Table 13–4), including a decrease in PTH secretion or action, a reduction in vitamin D synthesis or action, resistance of bone to PTH or vitamin D effects, or calcium sequestration. Administration of large amounts of citrate-containing blood may precipitate hypotension, particularly when given rapidly, and is the most common perioperative cause of symptomatic hypocalcemia.[36] Citrate used for regional anticoagulation with dialysis can also cause hypocalcemia and may also lead to hypomagnesemia from decreased PTH secretion. Deliberate or inadvertent parathyroidectomy during neck surgery will reduce PTH levels and is the most common cause of acquired

TABLE 13–3.

Causes of Hyperkalemia

Pseudohyperkalemia	Hemolysis
	Leukocytosis
	Thrombocytopenia
Decreased renal potassium excretion	Acute or chronic kidney failure
	Aldosterone deficiency
	Diabetic nephropathy
	Adrenal insufficiency
	Drugs (e.g., potassium-sparing diuretics, some antibiotics, spironolactone, β-blockers)
	Intrinsic kidney disease
Abnormal potassium distribution	Insulin deficiency
	Metabolic or respiratory acidosis
Abnormal potassium release from cells	Rhabdomyolysis
	Tumor lysis syndrome

Common Causes of Hypocalcemia

Hypoparathyroidism	Altered Ca^{2+}/parathyroid hormone set point (calcium receptor mutations)
	Parathyroid hormone gene defects
	Post parathyroidectomy
	Neck irradiation
	Infiltrative disease
	Hypomagnesemia/hypermagnesemia
	Autoimmune disease
Parathyroid hormone resistance	Hypomagnesemia
	Pseudohypoparathyroidism
	Pseudo-pseudohypoparathyroidism
Other	Vitamin D deficiency
	Altered vitamin D metabolism
	Drug induced
	Acute citrate toxicity

hypoparathyroidism.[37] Hypocalcemia in the nonacute setting can result from hypoparathyroidism, hypomagnesemia, renal failure, and vitamin D deficiencies. Medications that are used to treat hypercalcemia (e.g., bisphosphonates, mithramycin, and calcitonin) may also cause hypocalcemia. Other drugs associated with hypocalcemia include pentamidine, ketoconazole, asparaginase, cisplatin, and doxorubicin. Severe hypocalcemia from acute citrate toxicity responds to 1–3 g of calcium gluconate or calcium chloride given intravenously, whereas oral calcium supplementation may be sufficient for more chronic conditions. Because peripheral infiltration of an intravenous fluid containing calcium can cause tissue necrosis, whenever possible this electrolyte should be infused through a central line.

Hypercalcemia

Hypercalcemia occurs with elevation of the ionized fraction of total serum calcium. Clinical symptoms correlate with the acuity of hypercalcemia and include constipation, nausea and vomiting, drowsiness, lethargy, weakness, stupor, and coma. Cardiovascular manifestations include hypertension, shortened QT interval, heart block, and other arrhythmias. Hypercalcemia can also cause polyuria and polydipsia because of its effect on vasopressin-mediated water reabsorption; kidney stones are common. The most frequent causes of hypercalcemia are primary hyperparathyroidism and malignancy. Other causes include thiazide (an increase in renal calcium reabsorption) or lithium (inhibition of PTH release) drug usage and rarer medical conditions, including granulomatous disease, thyrotoxicosis, and multiple endocrine neoplasia types I and II.

Although hypercalcemia is usually chronic and treatment involves addressing the underlying cause, occasionally acute severe hypercalcemia (or acute worsening of chronic hypercalcemia) may require prompt intervention. Because hypercalcemic patients are often volume depleted, intravenous saline can both rehydrate and induce calcium diuresis.[38] Loop diuretics (e.g., furosemide) inhibit renal calcium reabsorption and can expedite treatment. In addition, drugs such as bisphosphonates (etidronate pamidronate, clodronate), gallium, and plicamycin (mithramycin) can lower serum calcium concentrations by impairing or inhibiting osteoclast function. In severely hypercalcemic patients, dialysis may be required.

Hypermagnesemia

Clinical manifestations of hypermagnesemia (>4–6 mg/dL) are serious and potentially fatal. Minor symptoms include hypotension, nausea, vomiting, facial flushing, urinary retention, and ileus. In more extreme cases, flaccid skeletal muscular paralysis, hyporeflexia, bradycardia and bradyarrhythmias, respiratory depression, coma, and cardiac arrest can occur. Hypermagnesemia generally occurs in two clinical settings: compromised renal function (GFR <20 mL/min) and excessive magnesium intake (e.g., excessive intravenous therapy in preeclamptic patients or oral magnesium-containing antacids and cathartics). An abnormally low (or even negative) serum anion gap may be a clue to hypermagnesemia.[39] Although mild hypermagnesemia in the setting of normal renal function can be treated with supportive care and withdrawal of the cause, in some cases dialysis is necessary.

Hypomagnesemia

Although low serum magnesium levels (<1.6 mg/dL) may be asymptomatic, clinically important problems may manifest, including neuromuscular (muscles cramps and weakness, positive Chvostek and Trousseau signs), cardiac (torsade de pointes and other arrhythmias), neurologic (apathy, seizures), and related electrolyte (hypokalemia and hypocalcemia) abnormalities. Causes of hypomagnesemia can be divided into four broad categories: decreased intake, gastrointestinal loss, renal loss, and redistribution. Many drugs (e.g., loop and thiazide diuretics, cisplatin, aminoglycosides, amphotericin, cyclosporine) induce renal magnesium wasting (24-hour urine magnesium excretion greater than 24 mg in the face of hypomagnesemia).[40] Nutritional deficiency can result from malabsorption syndromes, from patients receiving parenteral nutrition, and is present in 25% of alcoholics.[41–43] Redistribution occurs with acute pancreatitis, administration of catecholamines, and "hungry bone syndrome" after parathyroidectomy.[44] Magnesium can be supplemented orally or via the parenteral route. Over half of hypomagnesemic patients are also hypokalemic, and potassium deficits are usually refractory to repletion, unless magnesium also is supplemented.

Hypophosphatemia

Hypophosphatemia is more clinically relevant than hyperphosphatemia to the perioperative physician and can result in symptoms including muscle weakness, respiratory failure, and difficulty in weaning critically ill patients from mechanical ventilation when serum levels are less than 0.32 mmol/L. In addition, low phosphate levels may diminish oxygen delivery to tissues and rarely cause hemolysis. Hypophosphatemia can result from intracellular redistribution caused by

catecholamines, or an anabolic state, inadequate intake or absorption secondary to alcoholism or malnutrition, or increased renal or gastrointestinal losses.[45] Hypophosphatemia is common in alcoholic and poorly controlled diabetic patients, where increased urine phosphate excretion can occur. Intravenous and oral supplementation can be used to treat hypophosphatemia.

Hyperphosphatemia

Clinical manifestation of hyperphosphatemia (>5 mg/dL) is generally related to the hypocalcemia that often accompanies this disorder, although increased phosphorus levels may also lead to calcium precipitation and decreased intestinal calcium absorption.[46,47] Significantly elevated serum phosphate levels are most commonly a result of reduced excretion from renal insufficiency (GFR <25 mL/min), but can also result from excess intake or redistribution of intracellular phosphorus. Treatment of chronic hyperphosphatemia includes dietary phosphate restriction and oral phosphate binders.

Diuretics and Edema

Fluid overload occurs when salt or water intake exceeds renal plus extrarenal losses and is characterized by increased total body water and usually sodium. Fluid overload may be evenly distributed among the body compartments (e.g., congestive heart failure) or the interstitial space may be increased while the circulating blood volume may be normal or even decreased (e.g., posttraumatic or postoperative third-space fluid shifts). Pulmonary edema is a life-threatening complication of fluid overload. Edema results when Starling forces, which regulate fluid transfer between capillaries and interstitium, favor passage of fluid into the interstitial space. A variety of chronic medical conditions (congestive heart failure, renal failure, and hepatic cirrhosis) can lead to fluid overload and edema that might even require a procedure be delayed for treatment to reduce operative risk. The first line of therapy for fluid overload that includes all body compartments involves restriction of salt and water ingestion; however, diuretic therapy is often indicated.

Physiologic Basis of Diuretic Action

The different classes of diuretic agents have numerous effects that are important for the perioperative physician to consider and which extend beyond the common capability of these drugs to increase urine flow. Diuretics are grouped according to their site and mechanism of action (Fig. 13–5). Under normal conditions, kidney function assures that less than 1% of filtered Na^+ load enters the urine (i.e., FE_{Na} is <1%). The Na^+-K^+ adenosine triphosphatase (ATPase) pump on the basolateral surface (blood side) of renal tubular cells is primarily responsible for active pumping of Na^+ out of cells into blood in exchange for K^+. This pump causes net movement of positive charges out of the cell (2 K^+ in for every 3 Na^+ out) creating an electrochemical gradient that also causes Na^+ to enter the luminal (urine) side of the cell. Renal tubular cells in different portions of the nephron have different luminal "systems" to allow this Na^+ influx. These systems are the sites of action where the different diuretics work.

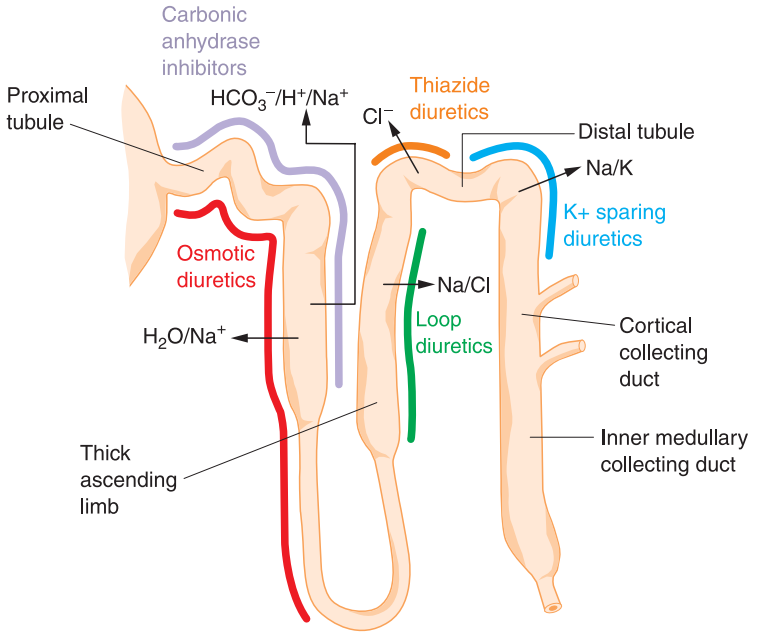

FIGURE 13–5. Site of action of commonly available diuretics. Available at: http://sprojects.mmi.mcgill.ca/nephrology/presentation/presentation3.htm. Last accessed August 10, 2006.

Proximal Tubule Diuretics

In the proximal tubule, a specialized luminal transporter exchanges protons (H^+) for sodium ions; the result is sodium reabsorption and acidification of the urine. The excreted H^+ combines with bicarbonate HCO_3 in the tubule to form carbonic acid:

$$H^+ + HCO_3 \rightarrow H_2CO_3$$

Carbonic acid converts to water (H_2O) and carbon dioxide (CO_2) in a reaction catalyzed by *carbonic anhydrase*:

$$H_2CO_3 \rightarrow H_2O + CO_2$$

The same enzyme, carbonic anhydrase, allows this reaction to occur in reverse within tubular cells, converting H_2CO_3 to HCO_3 and H^+, generating more H^+ for countertransport with Na^+, and releasing bicarbonate that passes into the circulation.

Carbonic anhydrase inhibitors are drugs that inhibit this enzyme; the net effect of these agents is that sodium and bicarbonate that would otherwise have been reabsorbed remain in the urine, resulting in an alkaline diuresis.

Although patients may develop metabolic acidosis when taking these agents, interestingly, compensatory processes in the tubule accommodate to the effects of carbonic anhydrase inhibitors so that their long-term use rarely causes this problem. However, these agents can be useful, for example, with contraction alkalosis from aggressive diuresis with loop diuretics (see Loop Diuretics below); administration of these agents can reduce $Paco_2$ and improve Pao_2 for these patients with little change in blood pH. Specific use for carbonic anhydrase inhibitors include the treatment of mountain sickness and open-angle glaucoma, and to increase respiratory

drive in patients with central sleep apnea.[48,49]

Osmotic Diuretics

Substances that are freely filtered at the glomerulus but poorly reabsorbed by the renal tubule, such as mannitol, will cause an osmotic diuresis. In the water-permeable segments of the proximal tubule and loop of Henle, fluid reabsorption occurs and filtered mannitol is concentrated. Eventually osmotic pressure in the tubular fluid resists further fluid reabsorption. Mannitol also draws water from cells into the plasma and effectively increases renal blood flow (RBF).

Mannitol has been widely used, especially for the prophylaxis of acute renal failure. In select patient populations, such as cadaveric kidney transplantation recipients, it is effective.[50] However, in a controlled trial of mannitol prophylaxis in patients with mild chronic renal failure, it was less effective than hydration alone in preventing contrast-associated nephropathy.[51] This trial has reduced enthusiasm for the prophylactic use of mannitol. Although animal studies showed initial promise, apart from acute renal failure (ARF) prophylaxis in kidney transplantation, there is no clear evidence that mannitol is effective in prevention or treatment of ARF.[52] However, as a therapy for cerebral edema, mannitol therapy is more effective than loop diuretics or hypertonic saline in reducing brain water content.[53]

As mannitol shifts water between fluid compartments, there can be effects on plasma and intracellular electrolyte concentrations, including hyponatremia and hypochloremia and intracellular increases in K^+ and H^+. Patients with normal renal function quickly correct these changes, but patients with renal impairment may develop significant circulatory overload with hemodilution and pulmonary edema, hyperkalemic metabolic acidosis, central nervous system depression, and even severe hyponatremia requiring urgent hemodialysis.[54]

Loop Diuretics

The electrochemical gradient established by the Na^+-K^+ ATPase in the loop of Henle drives the electroneutral transport of 1 Na^+, 1 K^+ and 2 Cl ions into the tubule cells from the tubular fluid. Because the thick ascending limb segment of the loop of Henle is water-impermeable, reabsorption of solute concentrates the interstitium and dilutes the tubule fluid. Loop diuretics, such as furosemide, bumetanide, and torsemide, directly inhibit the electroneutral transporter, preventing salt reabsorption from occurring. Because 25% of filtered NaCl is normally reabsorbed in the loop of Henle, loop diuretics cause a large salt load to pass to the distal convoluted tubule that is beyond the extra reserve of this tubular segment to reabsorb; consequently, large volumes of dilute urine ensue. Other effects of loop diuretics include a weak inhibition of carbonic anhydrase (see Proximal Tubule Diuretics) and an increase in the fractional excretion of Ca^{2+}.

Interestingly, hormones that stimulate cyclic adenosine monophosphate (cAMP), such as arginine vasopressin, enhance salt reabsorption by the thick ascending limb of the loop of Henle, making the effect of loop diuretics all the more impressive. Conversely, substances that stimulate cyclic guanosine monophosphate (cGMP), such as nitric oxide and atrial natriuretic peptide, inhibit thick, ascending-limb reabsorption and attenuate the loop diuretic response.[55,56]

Loop diuretics are a first-line therapeutic modality for acute treatment of congestive heart failure (CHF). Although diuretics have no proven mortality benefit, they reduce left ventricular filling pressures and effectively relieve symptoms of congestion, pulmonary edema, extremity swelling, and hepatic congestion.

Adverse loop diuretic effects include hypokalemia, hyponatremia, and acute renal dysfunction. Heart failure patients with atrial fibrillation may also be prescribed digitalis, which, in combination with furosemide, can lead to hypokalemia-induced arrhythmias. Loop diuretics, especially furosemide, may cause ototoxicity particularly in patients with renal insufficiency.[57]

Distal Convoluted Tubule Diuretics

Distal convoluted tubule diuretics, such as thiazides (e.g., hydrochlorothiazide) and metolazone, act in the earliest part of this segment to block the NaCl cotransport mechanism across apical plasma membranes. Because the distal tubule is relatively water impermeable, NaCl absorption causes urinary dilution. Distal tubule diuretics also increase magnesium excretion, but, unlike loop diuretics, they inhibit calcium excretion.

Clinically, distal convoluted tubule diuretics are used for the treatment of hypertension (often as sole therapy), volume overload disorders, and to relieve the symptoms of edema in pregnancy.

Adverse reactions associated with distal tubule diuretics include electrolyte disturbances and volume depletion. Hydrochlorothiazide specifically is associated with a number of other side effects, including pancreatitis, jaundice, diarrhea, aplastic anemia, and anaphylaxis.

Distal (Collecting Duct)-Acting Diuretics

Unlike in more proximal nephron segments, NaCl absorption in the collecting duct cells (also called principal cells) is electrogenic; that is, a net electrical gradient is maintained both by the Na^+-K^+ ATPase Na^+ ion channels and in the luminal membranes. As a result, the tubule lumen is negatively charged with respect to the blood. This normally causes K^+ secretion into the tubular lumen through K^+-specific ion channels. Distal K^+-sparing diuretics (e.g., amiloride and triamterene) directly inhibit luminal Na^+ entry, blocking this mechanism, and resulting in a K^+-"sparing" effect. In addition, H^+ secretion is inhibited.

A second class of distal-acting potassium-sparing diuretics includes the competitive aldosterone antagonists (e.g., spironolactone and eplerenone). Ordinarily, the mineralocorticoid hormone aldosterone is released by the body in response to angiotensin II or hyperkalemia. Aldosterone normally stimulates Na^+ reabsorption and K^+ excretion by the collecting duct. Inhibition of the aldosterone effect by these drugs causes a mild natriuresis and K^+ retention. Distal K^+-sparing agents are used primarily for K^+-sparing diuresis (e.g., in patients with volume overload receiving digitalis or with hypokalemic alkalosis). In addition, these drugs are especially useful in treating disorders involving secondary hyperaldosteronism, such as cirrhosis with ascites. Spironolactone treatment improves survival with volume overload and left ventricular dysfunction or heart failure.[58]

Hyperkalemia and hyperkalemic–hyperchloremic metabolic acidosis are significant complications of the injudicious use of spironolactone, triamterene, or amiloride. Metabolic acidosis itself can further contribute to

hyperkalemia. These effects are dose dependent, and the risk of their occurrence increases considerably with renal failure or therapy with K^+ supplements, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, β-blockers, heparin, or ketoconazole.[59] In addition, amiloride and triamterene accumulate with renal failure, and triamterene also accumulates with liver impairment.[60,61] Spironolactone can cause gastrointestinal distress and antiandrogenic effects (e.g., impotence, loss of libido, gynecomastia). Gynecomastia is a dose-related complication.[62]

Other Diuretics

Dopaminergic Agonists Intravenous low-dose infusion of dopamine (1–3 μg/kg/min) is natriuretic, owing primarily to a modest increase in the GFR and a reduction in proximal Na^+ reabsorption mediated by dopamine type 1 (DA1) receptors.[63] Fenoldopam is a selective DA1 receptor agonist with little cardiac stimulation. At higher doses, the pressor response to dopamine is beneficial in patients with hypotension, but it has little or no renal effect in critically ill or septic patients.[63,64] So-called renal-dose dopamine for the treatment of ARF, although advocated, has not been demonstrated to have significant renoprotective properties in numerous studies[65–67] and can cause worsened splanchnic oxygenation, impaired gastrointestinal function, impaired endocrine and immunologic system function, blunting of ventilatory drive, and increased risk of postcardiac operation atrial fibrillation.[68–70]

RENAL DISORDERS ENCOUNTERED IN THE PERIOPERATIVE PATIENT

Disorders of the kidney can selectively involve the glomerulus and/or tubule and reflect localized or systemic disease. Other considerations include a variety of inherited conditions and the transplanted kidney. These topics are extensively reviewed elsewhere,[20] but an abbreviated summary with focus on features important to the perioperative physician are discussed below.

Prerenal Azotemia

Prerenal azotemia accounts for approximately 70% of hospital-acquired acute renal failure.[71,72] Prerenal azotemia is a normal physiologic response to decreased renal perfusion pressure resulting in a hemodynamically mediated reduction in the GFR. No immediate injury occurs to the renal parenchyma, and the GFR rapidly returns to normal with reversal of the hemodynamic insult. Overt pathologic changes can occur if the renal hypoperfusion is sustained. The decrease in glomerular ultrafiltration pressure can be secondary to a true decrease in blood volume (e.g., hemorrhage, dehydration) or a decrease in the effective arterial blood volume (e.g., congestive heart failure, cirrhosis, capillary leak syndromes, sepsis). When mean arterial pressure falls below 80–90 mm Hg, there is a reduction in renal blood flow. Progression of the prerenal state can lead to acute tubular necrosis (ATN). Prerenal azotemia and ischemic ATN are manifestations of renal hypoperfusion. The severity and duration of the insult will dictate the likelihood of progression from prerenal azotemia to ischemic tubular damage.

In renal hypoperfusion states, GFR is maintained by the interplay of several neurohumoral systems. The renin–angiotensin axis increases the vasomotor tone of the efferent arteriole, whereas afferent arteriolar vasomotor tone decreases under the influence of nitric oxide, vasodilatory prostaglandins, and the kallikrein-kinin system. The sympathetic nervous system reacts to hypoperfusion with release of norepinephrine and antidiuretic hormone (ADH). With sustained reductions in renal blood flow, the ability of the kidney to maintain glomerular perfusion pressure is overwhelmed, and the GFR declines, resulting in azotemia and cellular hypoxia with ischemic tubular damage.

Nonsteroidal antiinflammatory drugs (NSAIDs) can influence renal perfusion. These drugs can be divided into nonselective inhibitors of both cyclooxygenase-1 (COX-1) and cylcooxygenase-2 (COX-2), or selective inhibitors of COX-2. Both classes of drugs cause inhibition of various prostaglandins and other substances, including some that are involved in the paracrine regulation of renal perfusion. Patients at greatest risk for NSAID-induced acute renal failure include the elderly and those with congestive heart failure, advanced liver disease, atherosclerotic vascular disease, or chronic kidney disease.[73,74] Special attention should be given to elderly patients treated with NSAIDs of any type. In a population-based study, the risk of acute renal failure in the elderly increased by 58% with prescription NSAID use.[75] The nonselective NSAIDs are inhibitors of the prostaglandins responsible for vasodilatation in the kidney and can promote prerenal azotemia in susceptible patients. The selective COX-2 inhibitors also cause a similar renal vasoconstriction. The renal safety profile of celecoxib (COX-2) is similar to ibuprofen. One selective COX-2 inhibitor, rofecoxib, was found to have a higher incidence of renal toxicity than the nonselective inhibitors or celecoxib.[76] The renal toxicity of NSAIDs is increased when they are used in combination with other medications with the potential to alter the kidneys' ability to autoregulate glomerular filtration pressure such as angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin receptor blockers (ARBs). The renal vascular changes associated with NSAID use are typically reversible, although prolonged use can lead to permanent renal injury. NSAIDs are also known to cause acute tubulointerstitial nephropathy (see Tubulointerstitial Nephropathies and Disorders of the Urinary Tract below), in which case there is often a sudden change in GFR that may persist for days to weeks.

ACEIs reduce blood pressure by inhibiting the proteolytic cleavage of angiotensin I to angiotensin II. ARBs occupy the angiotensin receptor. The renin–angiotensin system contributes to the autoregulation of glomerular perfusion pressure, and inhibition of this system has the potential to induce prerenal azotemia. Much like the prostaglandin inhibitors, ACEIs and ARBs increase the risk of ARF in patients on diuretic therapy who have volume depletion, congestive heart failure, or diabetes, and in the elderly.[77,78] Their use in conjunction with NSAIDs, cyclosporine, tacrolimus, and aprotinin put patients at an even greater risk for ARF.[77,79,80] The incidence of ARF is also higher in patients with chronic kidney disease of any etiology. Patients with chronic kidney disease usually depend on local angiotensin II production to maintain GFR in the face of decreased functional renal mass. Consequently, a decline in GFR when these patients receive ACEIs is not unexpected. The rise in serum

creatinine is typically less than 30% and does not constitute renal failure. More dramatic increases in serum creatinine suggest the presence of underlying renal vascular disease.

Glomerular Diseases

Glomerular disorders declare in numerous ways (Table 13–5), but the commonest presentations are either as a nephritic or nephrotic syndrome. Nephritic syndrome involves a collection of renal signs and symptoms that predominantly reflect inadequate and/or ineffective glomerular filtration, including accumulation of nitrogenous waste products (azotemia), fluid retention, edema, hypertension, oliguria/anuria, proteinuria, and hematuria. In contrast, nephrotic syndrome involves signs and symptoms that predominantly reflect excessively porous filtration and "escape" of substances into the urine that are normally retained in the circulation, including significant proteinuria (>3 g/d/1.73 m^2), hypoproteinemia, edema, lipiduria, and hyperlipidemia. With nephrotic syndrome, characteristic oval fat bodies appear in the urine, and these may help guide diagnosis. The nature and severity of the presentation is determined by the underlying glomerular insult; a definitive diagnosis almost always requires a renal biopsy. The two commonest primary diseases causing nephrotic syndrome are minimal change glomerulopathy and membranous glomerulopathy, but more commonly nephrotic syndrome arises in adults as a manifestation of diabetic glomerulosclerosis or systemic amyloidosis.

TABLE 13–5.

The Spectrum of Clinical Disorders Involving Glomerular Disease

Asymptomatic proteinuria
Nephrotic syndrome
Asymptomatic microscopic hematuria
Recurrent gross hematuria
Acute nephritis
Focal or diffuse proliferative glomerulonephritis
Type I and type II membranoproliferative glomerulonephritis
Fibrillary glomerulonephritis
Rapidly progressive nephritis
Pulmonary–renal vasculitic syndrome
Antineutrophilic cytoplasmic antibodies vasculitis
Chronic kidney disease

Tubulointerstitial Nephropathies and Disorders of the Urinary Tract

Tubulointerstitial nephritis (TIN) primarily involves the renal tubule and is a common problem, accounting for 10% of acute renal dysfunction in hospitalized cases.[81] The hallmark of TIN is an interstitial mononuclear cell infiltrate on renal biopsy including T- and B-lymphocytes, macrophages, and natural killer cells.[82]

Most TIN involves cell-mediated immune responses, although some cases are the direct consequence of infection.[83–87] The clinical features of TIN are variable and depend partly on the initiating process.[88] Disruption of the normal tubulointerstitial compartment is associated with a urinary concentrating defect, hyperchloremic metabolic acidosis, hypo- or hyperkalemia, hypomagnesemia, and, typically, modest proteinuria. A few triggering medications, such as NSAIDs, interferon-α, and methicillin, are sometimes associated with nephrotic range proteinuria. TIN can progress to acute renal failure requiring dialysis. Notably, TIN triggered by NSAIDs is much more common in women than men, and the onset may be weeks to months after the start of the offending agent. Although recovery usually occurs within days to weeks of drug cessation, up to 20% progress to chronic renal failure.

Drug-Induced Tubulointerstitial Nephritis

Drug reactions are a major cause of TIN in hospitalized patients; the most common agents are penicillins,[89] cephalosporins,[88,89] and NSAIDs.[90,91] Other offending agents include fluoroquinolones,[89,92] sulfonamides,[93] interleukin-2, and interferon-α.[94,95] Because of the variety of potentially nephrotoxic medications that many patients are exposed to, it is often difficult to establish a single responsible agent with certainty. Additionally, comorbid conditions capable of causing renal dysfunction may be present and, as renal biopsy is not routine, the diagnosis of TIN is often presumptive. TIN typically occurs within days to a few weeks of drug exposure and is unrelated to cumulative dose. The most common presentation is with symptoms of edema, hypertension, diminished urine output, and renal failure. Occasionally, flank pain is a prominent symptom. Classical allergic manifestations, such as skin rash, arthralgias, fever, eosinophilia, and eosinophiluria, are rarely present; eosinophiluria has only a 40% positive predictive value and a 70% negative predictive value.[89,96,97] The diagnosis of TIN requires a high index of suspicion and knowledge of the potential causes.

Primary treatment of drug-induced TIN is cessation of the causative agent. Although some reports indicate clinical response to corticosteroid administration,[88,98,99] there are no large, randomized, placebo-controlled trials to guide treatment, and steroids are generally restricted to patients with progressive renal failure despite stopping the offending drug. Renal biopsy is often performed in these cases to confirm the diagnosis of TIN.

Infection-Induced Tubulointerstitial Disease

Renal biopsy findings of TIN from infection usually have acute interstitial inflammatory cells and microabscesses. There are many causes, including bacterial,[100] fungal (candidiasis, histoplasmosis), and viral (adenovirus, polyomavirus, Epstein-Barr virus) sources.

Bacterial cases usually present with a history of ascending urinary tract infection superimposed on obstructive nephropathy. Pyelonephritis may cause renal failure as a result of direct bacterial effects (TIN) or of ATN from septic shock. The prognosis in acute bacterial TIN is significantly worse than for ATN. Whereas patients with ATN are expected to make full recovery, bacterial TIN often progresses to severe interstitial scarring and progressive chronic renal failure. Patients require prolonged antibiotic treatment to eradicate the infection and close monitoring to minimize chronic progressive renal damage.

Renal candidiasis is common in patients with a history of prolonged hospitalization, prior exposure to antimicrobial agents, corticosteroid therapy, the postoperative state, surgical wounds, chronic indwelling urinary catheters, and/or underlying malignancy. Renal candidiasis should be considered in vulnerable patients whenever unexplained progressive renal failure occurs, particularly if it is accompanied by flank pain, fever, candiduria, and microscopic hematuria.[101,102] A useful diagnostic test in the catheterized patient with candiduria involves bladder

washings with amphotericin B; this will clear the urine of colonization but not renal candidosis.[103] In septic patients, a positive urine culture for candida is considered proof of renal candidiasis.[104]

Most other viral and fungal causes are seen only in immunocompromised patients.[105–110] However, Epstein-Barr virus is associated with TIN and renal failure in both immunocompetent and immunocompromised patients.[111] Other renal lesions associated with Epstein-Barr virus and infectious mononucleosis include acute glomerulonephritis, hemolytic uremic syndrome, and rhabdomyolysis-induced ARF.[112]

The Kidney in Systemic Disease

The kidney may manifest abnormal function and disease as a consequence of the systemic effects of other disorders. Some of the more common conditions that are pertinent to the perioperative period are reviewed below.

Congestive Heart Failure

CHF is the one cardiovascular disease whose incidence and prevalence is still increasing in the Western world. In fact, the long-term prognosis for CHF is now worse than for many common cancers. Uniquely, the kidneys both suffer from and contribute to the pathophysiology of CHF; Figure 13–6 summarizes this. The underlying hormonal response to a low perfusion state with CHF is the normal response to hypovolemia (e.g., hemorrhage) and preserves circulating volume. Although the humoral response is very effective in retaining fluid, the primary cause of a reduced perfusion in the setting of CHF—pump failure—does not respond as hypovolemia, and the vicious cycle of more volume retention, edema, vasoconstriction, and increased myocardial oxygen consumption occurs, leading to further reductions in pump function. When congestive heart failure and pulmonary edema are diagnosed preoperatively, it is imperative that aggressive treatment occur prior to surgery as this condition, untreated, is highly predictive of early postoperative mortality.

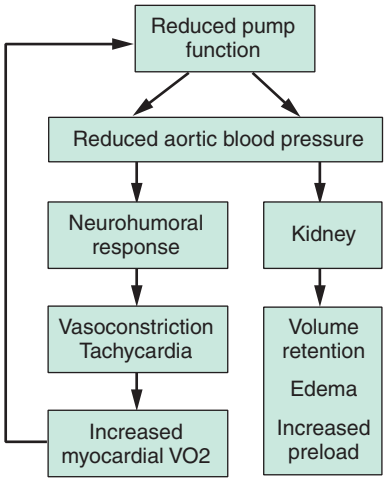

FIGURE 13–6. The pathophysiology of fluid retention that contributes to congestive heart failure.

Diabetes

Diabetes is the most common cause of kidney failure in the United States and accounts for more than 40% of all end-stage renal disease, of which more than 80% is caused by type II diabetes. Overwhelmingly, the most important feature in the management of diabetic kidney disease is blood pressure control. Together with good chronic glycemic control, this can postpone (but not prevent) the onset of end-stage renal disease.

Diabetic nephropathy develops because of exposure to chronically elevated levels of blood glucose. Glycemic control is the cornerstone of diabetes management in general, and this is also the case in the prevention of diabetic nephropathy. Although improved glycemic control reduces risk, there does appear to be a large genetic element also. Management of diabetic nephropathy also consists of aggressive blood pressure control, aiming for a level of 125/75 mm Hg, and often more than one drug is required. Antihypertensive drugs that inhibit the renin–angiotensin–aldosterone axis (such as ACEIs and ARBs) are effective for this purpose. Metformin is relatively contraindicated once renal disease develops because of the risk of significant lactic acidosis, and it may also be necessary to reduce the dose of other hypoglycemic drugs—including insulin—so as to avoid deleterious hypoglycemic episodes.

Liver Failure

Hepatorenal syndrome (HRS) involves the combination of renal vasoconstriction, declining GFR, and normal renal histology that occurs in the setting of liver failure. Without confounding renal injuries, renal failure from HRS will resolve with liver transplantation. The clinical picture associated with HRS is that of a prerenal azotemia, and the pathogenesis is not completely understood. Systemic and splanchnic vascular resistance is decreased leading to reduced effective arterial volume and renal hypoperfusion. Compensatory increases in mediators of renal vasoconstriction occur, including increased renin–angiotensin–aldosterone activity, ADH levels, sympathetic tone, and endothelin levels. The kidney responds by increasing salt and water retention, leading to worsening ascites and edema.[113,114] The diagnosis of HRS is a diagnosis of exclusion, characterized by liver failure and unexplained oliguric ARF with very low urine sodium and bland urine sediment. Other causes for the ARF should be ruled out, including causes of prerenal azotemia, intrinsic renal disease, and obstructive nephropathy. Major and minor criteria have been established for the diagnosis of HRS (Table 13–6). Liver transplant is the definitive therapy for HRS. However, patients who develop HRS prior to

TABLE 13–6.

Diagnostic Criteria for Hepatorenal Syndrome

Major Criteria
- Acute or chronic liver disease with advanced hepatic failure and portal hypertension
- Depressed GFR with a serum creatinine >1.5 mg/dL or a creatinine clearance <40 mL/min
- Absence of shock, ongoing bacterial infection, fluid loss, and treatment with nephrotoxic medications
- No sustained improvement in renal function after withdrawal of diuretics and fluid resuscitation with 1.5 L of isotonic saline
- Proteinuria <500 mg/d and no evidence of obstructive nephropathy on ultrasonogram

Minor criteria
- Oliguria
- Urine sodium <10 mEq/L
- Urine osmolality > plasma osmolality
- Urine red blood cells <50 per high-power field
- Serum sodium concentration <130 mEq/L

Reproduced with permission from Arroyo V, Gines P, Gerbes AL, et al.[122]

transplant have worse graft and patient survival.[115] Newer pharmacologic therapy with vasopressin analogues (e.g., ornipressin and terlipressin), which are splanchnic vasoconstrictors, has shown some benefit. However, the major complication associated with these medications is mesenteric ischemia.[116–118] Other potential therapies include oral midodrine (a selective α_1-adrenergic agonist) in combination with octreotide,[119] *N*-acetylcysteine,[120] and transjugular intrahepatic portosystemic shunting (TIPS).[116,121] Given the poor prognosis of HRS, patients with rapid onset of renal failure are rarely offered dialysis unless they are candidates for liver transplant or have a chance of hepatic recovery.[113,114,122]

Hereditary Renal Disorders

Autosomal dominant polycystic kidney disease affects between 1 in 400 and 1 in 1000 live births in the United States. It accounts for 5% of all end-stage renal disease in the United States and Europe. The genetic defect occurs in the polycystin gene on chromosome 16p13.3 (type I) and on chromosome 4q21.2 (type 2). The clinical hallmark is massive cystic enlargement of the kidneys, and the diagnosis is made in at-risk individuals by renal ultrasonography scan. Typically, the kidney volume must increase to greater than 1000 mL (normal: 150 mL) before there is an appreciable reduction in GFR. Reduced GFR occurs from stretching and narrowing of intrarenal blood vessels leading to ischemia. There is also interstitial fibrosis and cytokine release leading to inflammatory cell infiltration.

Autosomal dominant polycystic kidney disease presents clinically with flank and back pain (which may be acute if cyst hemorrhage occurs), and hematuria may also develop. Hypertension occurs early and commonly. The treatment of choice is transplantation, and autosomal dominant polycystic kidney disease patients in general respond well to this treatment, typically outliving their noncystic transplant peers. Of particular interest to anesthesiologists are the associated features of intracranial aneurysm formation, hepatic cyst formation, and secondary hypertension.

Contrast Nephropathy

Contrast-associated nephropathy occurs in 2–7% of patients and constitutes 10% of all in-hospital acute renal injury. The diagnosis is made when a significant rise in serum creatinine occurs within 5 days following intravascular contrast injection.[123,124] Typically, it is those with preprocedure renal impairment who are at greatest risk;[125] additionally, the pathophysiology is related to direct renal tubular cell injury and vasoconstriction. Notably in some patients, atheroembolism, caused by catheter manipulation and dislodgment of plaque within the aorta, may be misdiagnosed as contrast nephropathy. Prehydration and sodium bicarbonate (154 mEq/L, 3 mL/kg bolus 1 hour prior to the procedure, then 1 mL/kg infusion × 6 hours) are useful as prophylaxis for contrast-induced nephropathy.[126] Because some studies indicate that preoperative (< 48 h) contrast administration is predictive of postoperative renal complications,[127] avoiding an elective procedure immediately after contrast administration and permitting recovery of contrast-associated nephropathy before an operation seems prudent.

The Renal Transplant Patient

After corneal transplantation, kidney transplantation is the most common transplantation operation performed with more than 9000 procedures performed annually in the United States. Patients presenting for an operation with a transplanted kidney have filtration function ranging from normal to severely impaired and are typically receiving immunosuppressant medications with specific acute and chronic nephrotoxic effects. However, also pertinent to the perioperative physician is the concern of allograft rejection. The hallmark of allograft rejection is an unexplained rise in serum creatinine. Recognition of rejection and referral for effective treatment (i.e., increased immunosuppression) is a key aspect of the preoperative assessment of a patient with a renal allograft, because if it is missed, the patient may lose the graft and be obliged to return to chronic dialysis. The preoperative visit may be the time that an undesirable accumulation of nitrogenous waste is first discovered, particularly if the patient has been otherwise well.

Three types of allograft rejection are recognized: hyperacute, accelerated acute, and acute. Hyperacute rejection occurs within minutes to hours of transplant reperfusion and is a consequence of the effect of preexisting human leukocyte antigens (HLAs) and/or ABO blood-type antibodies. Antibodies bind to graft endothelium and to activate complement, inflammatory, and coagulation pathways, causing widespread thrombosis and subsequent loss of graft function. Hyperacute rejection is now rare as a consequence of improved matching of donors and recipients. In contrast, accelerated acute rejection occurs in the first 5 days following transplant reperfusion and is caused by activation of recipient T and B "memory" lymphocytes. The diagnosis is confirmed by graft biopsy, which demonstrates cells staining positively for C4d. Finally, acute rejection occurs between 5 days and 3 months after reperfusion. It is a cell-mediated process that classically presents as fever, chills, arthralgia, myalgia, and pain over the graft site. Modern immunosuppressive therapy with calcineurin inhibitors (e.g., cyclosporine, tacrolimus) has significantly reduced this clinical presentation, and diagnosis is usually made following renal biopsy prompted by a subacute rise in serum creatinine noted on routine testing.

In addition to procedure-related infectious risk, renal transplantation recipients are vulnerable to specific infections, including *Pneumocystis carinii* pneumonia, urinary tract infections, and sinusitis, and are prescribed trimethoprim-sulfamethoxazole therapy for a period after transplantation to protect against them. It is important that these antibiotics be continued through any subsequent (and unrelated) perioperative period.

The calcineurin-inhibitors cyclosporine and tacrolimus are widely used as immunosuppressants in solid organ and bone marrow transplantation. Cyclosporine and tacrolimus can cause both ARF and chronic renal failure. The vascular changes with cyclosporine and tacrolimus in the critically ill patient include a direct afferent arteriolar vasoconstriction that is reversible with discontinuation of the drug. Dose reduction is sometimes sufficient to reverse the decrease in glomerular filtration pressure and GFR. Chronic nephrotoxicity is a ubiquitous complication of prolonged use of the calcineurin-inhibitors that presents with proteinuria, tubular dysfunction, arterial hypertension, and rising serum creatinine values. Chronic changes may occur as soon as 6 months after

therapy is started, and includes arteriolar damage, interstitial fibrosis, tubular atrophy, and glomerulosclerosis. The pathologic changes of the chronic nephrotoxicity are irreversible.[128–130] A less common complication of cyclosporine and tacrolimus therapy is hemolytic uremic syndrome; patients may have partial recovery with drug discontinuation.[131–133] Calcineurin-inhibitors are also associated with hyperkalemia, although thought to be secondary to tubular resistance to aldosterone.[134]

POSTOPERATIVE RENAL DISORDERS

A recent study reported acute deterioration of renal function in 5% of all hospital patients and in 30% of those admitted to intensive care units.[71] Many of these patients sustain their acute renal impairment as a consequence of surgery or its complications. Some surgical procedures are highly associated with postoperative renal dysfunction. Significant renal injury complicates up to 30% of trauma, cardiac, vascular, and hepatobiliary procedures.[135] The importance of acute renal injury after an operation lies not only in the resulting physiologic derangements, but also in the strong predictive relationship of this condition with in-hospital mortality, even after adjustment for other contributing factors.[7,136,137] Not all surgical procedures are vulnerable to postoperative acute renal injury. Notably, some highly invasive procedures (e.g., thoracotomy)[138] are relatively rarely complicated by acute renal failure requiring dialysis. Even small perioperative declines in renal function are associated with increased risk of major complications and mortality, possibly as a result of, at least in part, the effects of acute renal injury on the normal functioning of many other organ systems.[139–141] Preoperative predictive factors include African American race,[142] advanced age,[7,143–147] obesity,[7] hypertension,[148,149] peripheral or carotid atherosclerotic vascular disease,[7,148] elevated preoperative serum glucose and diabetes,[7,146,149,150] obstructive pulmonary disease, and reduced left ventricular function.[7,143,148,151,152] Although preoperative genetic testing may be useful in the future,[153,154] there are no tests currently available as predictive tools.

The role of preexisting renal disease as an acute renal injury risk factor is complicated. It is undeniable that patients with severe baseline renal disease need only have a small additional renal insult to lose sufficient renal function to require dialysis, thus having acute renal failure. Postoperative patients requiring new dialysis *are* more likely to have preexisting renal dysfunction.[7,144,146–148] Interesting, however, is that patients with preexisting renal dysfunction *are not* more likely to sustain renal injury, described as a relative change in renal function perioperatively (e.g., 50% rise in serum creatinine).[145,155,156] This is often misunderstood as patients with high baseline serum creatinine values will have higher postoperative rises in serum creatinine, simply because of the nonlinear relationship between changes in renal filtration and serum creatinine rise. Patients with preexisting renal disease as a group have more associated comorbidities, and these individuals also have a higher risk for other major postoperative complications.[157–159]

The high metabolic demands and poor oxygen delivery to tubule cells in the outer medulla make this the most vulnerable region of the kidney.[5] As outlined in The Normal Kidney: Correlates of Structure and Function earlier, the medulla plays an important role in water and solute reabsorption but receives limited perfusion (5–10% renal blood flow). Normal oxygen extraction in the outer medulla is the highest in the body (79%), exceeding even that of the heart (65%). In the face of hypoperfusion (e.g., salt and volume depletion, dehydration), three components of renal homeostasis preserve body composition at the expense of further stress on the medulla. First, avid reabsorption of electrolytes by tubular cells increases metabolic requirements. Second, autoregulation preserves glomerular filtration at the "cost" of efferent arteriolar constriction, further reducing medullary perfusion. Finally, the vasa rectae hairpin loops within the medulla allow oxygen to "escape" from vessels entering to those leaving the medulla. As medullary perfusion drops, this so-called countercurrent exchange of oxygen increases such that medullary PO_2 may be as low as 10–20 mm Hg (Fig. 13–2).[4,5] Outer medullary oxygen supply–demand inequalities are believed to be an important substrate for onset of "acute renal failure" syndrome.[3] The outer medulla is also vulnerable as the site of concentration for many nephrotoxins. Unfortunately, although "renal angina" is an appealing concept, renal ischemia is a painless and, to date, a state that cannot be monitored.

RENAL FAILURE AND ITS THERAPY

Loss of adequate renal function may have occurred long before surgery and may be irreversible or acute, in which case renal recovery usually takes days or weeks; in both cases, the goal is to support the patient through this period.

Patients with serious renal impairment have limitations in their ability to regulate electrolyte, acid–base, and volume homeostasis. Approaches that avoid the complications of exceeding the renal homeostatic reserve with renal failure are outlined below. The most severe cases of renal impairment require rigorous adherence to guidelines aimed at limiting complications. When guidelines are inadequate, generally dialysis is required.

Volume Homeostasis

Free water deficit or excess is normally adjusted for by renal elimination of less or more dilute urine, respectively. When kidneys fail, they usually lose their ability to respond to these challenges and commonly produce a fixed amount of isosmotic urine. If this occurs, the clinician must maintain euvolemia without help from the kidneys through fluid management. To achieve this, meticulous attention must be paid to accurate assessment of volume status and review of fluid status (*ins* vs. *outs*). A fluids prescription should then be formulated. If the patient is euvolemic, then the volume of fluid should match the urine output plus an additional 500 mL/d for insensible losses. Fluid restriction or supplementation can occur if hyper- or hypovolemia are present.

Electrolyte Homeostasis

Because a major problem with renal failure is clearance of accumulated substances, fluid should contain supplemental electrolytes (e.g., potassium, magnesium, phosphorus) if deficits are identified. Sodium intake should be 2 g or less per day. Excess

potassium can be avoided by a restrictive diet and identifying other sources (e.g., fluids, parenteral nutrition, potassium penicillin). Hyperkalemia that causes cardiac dysrhythmias should be treated emergently (e.g., intravenous calcium chloride or calcium gluconate). Inhaled β-agonists and an infusion of sodium bicarbonate or insulin and glucose can also be used to shift potassium intracellularly. Although these approaches antagonize the cardiac effects of hyperkalemia, they do not reduce total body potassium. Elimination of excess body potassium in patients with ARF can only be accomplished with resins or dialysis. Potassium removal with peritoneal dialysis approaches 10–15 mEq/h compared with 50 mEq/h for hemodialysis.

Low calcium levels are common with ARF but rarely symptomatic. Hypocalcemia in these settings is often accompanied by hypomagnesemia. Because this inhibits parathyroid hormone release, calcium and magnesium should be supplemented when this is found. Functional hypoparathyroidism, together with the decreased vitamin D synthesis by the failing kidney, contribute to the hypocalcemia. Hyperphosphatemia is also common and requires phosphorus restriction and/or administration of calcium salts or aluminum hydroxide gels.

Acid–Base Homeostasis

When the inability of failing kidneys to reclaim filtered bicarbonate removes the ability to eliminate all the acid produced by protein breakdown, the result is an anion gap metabolic acidosis. Sometimes restricting protein intake to 0.6–0.8 g/kg of body weight is sufficient to treat this problem, but this might not be ideal in the healing phase for postoperative patients. Lactic- or ketoacidosis should always be considered as alternate causes of metabolic acidosis in the critically ill patients.

Uremia

Uremia results from the accumulation of nitrogenous waste products and is a syndrome characterized by lethargy, fatigue, nausea, anorexia, and hiccups. Blood urea nitrogen measurement can be used as a marker; values less than 70 mg/dL are rarely symptomatic, whereas values greater than 100 mg/dL are almost always associated with symptoms. When uremic symptoms develop, dialysis is usually required.

Nutrition

Adequate nutrition is essential to successful postoperative recovery, and any benefits of avoiding short-term dialysis by protein restriction should be weighed against this. Parenteral or enteral nutrition should provide a daily minimum of 30–35 kcal/kg and 1.0–1.2 g/kg of protein. Sodium bicarbonate or acetate should be added to buffer the acid generated by protein breakdown (60–80 mEq/d).

DRUG PRESCRIBING IN PATIENTS WITH RENAL IMPAIRMENT

For additional discussion see Chap. 47.

Patients with renal impairment have altered responses to normal dosing of medication. Although, particularly in the case of water-soluble agents, this is often a result of changes in rates of drug clearance from the circulation, other factors, such as effects on absorption, distribution, and metabolism, related to renal dysfunction may also be important.

If an agent relies solely on the kidney for clearance, then a simple prescribing approach involves a calculated percentage reduction in drug dosage that matches the reduction in GFR. Although GFR can be accurately measured, an estimated clearance derived from serum creatinine is usually adequate for these purposes. Unfortunately, clearance of most medications involves a more complex combination of both hepatic and renal function, and drug level measurement or algorithms for a specific drug dosing may be recommended.

Acute renal failure may affect drug absorption. For example, a reduced first-pass effect through the gastrointestinal tract and liver is attributed with the increased serum levels of oral β-blockers and opioids in patients with acute renal failure. Also, an increase in volume of distribution is seen in most patients with chronic renal failure caused by increased plasma volume and decreased plasma protein binding. However, plasma protein binding is highly variable, with acidic drugs (e.g., warfarin, phenytoin) reducing binding and basic agents (e.g., amide local anesthetics) increasing binding. Importantly, for drugs with less binding, "normal" drug levels may reflect dangerously high active (unbound) drug levels. For example, therapeutic phenytoin levels are 10–20 μg/mL normally, but 4–10 μg/mL with renal failure. Finally, liver metabolism of drugs is difficult to predict in the setting of renal failure; some hepatic enzymes are inhibited, whereas others are induced, and accompanying liver disorders may alter the relationship of drug clearance with GFR.

SUMMARY

Review of kidney function is an essential component of even the most hurried preoperative assessment for surgical candidates. To best manage patients, clinicians must be familiar with the kidney responses to hemodynamic stress and other homeostatic disturbances, and with normal states that influence kidney function, such as pregnancy, maturation, and aging. Special considerations are required in caring for surgical patients with kidney disease, and the consequences of kidney injury and postoperative renal dysfunction play importantly into the care of the critically ill patient. The well-being of the kidney throughout the perioperative period is highly associated with good outcome, and renal insult and injury are predictive of other complications. Thus, in the absence of effective interventions to treat acute renal injury, and with limited point-of-care tools to monitor renal stress, perioperative clinicians must act as ambassadors to protect the kidney throughout the perioperative period.

CHAPTER 14

Evaluation of Patients with Hepatic Disease

Richard A. Wiklund, MD

The liver is a unique vital organ because it serves multiple, independent functions each of which is necessary for sustaining life. These functions include synthesis of proteins required for coagulation (fibrinogen, prothrombin, factor VII) and fluid volume homeostasis (albumin), conjugation and excretion of metabolic products (bilirubin and ammonia), carbohydrate metabolism (glycogen storage and glucose release), drug metabolism (muscle relaxants, local anesthetics, narcotics, many others), and defense from pathogens (reticuloendothelial cells). When the liver fails, these functions are compromised and cause a cascade of effects that result in multiorgan failure. Patients with liver failure develop abnormal neurologic function (encephalopathy), altered cardiovascular performance and hemodynamics, altered metabolism with accumulation of waste products (jaundice), abnormal accumulation of extracellular fluid volume (ascites), and compromised immune and endocrine function. Some patients are at risk for acute renal failure (hepatorenal syndrome) and altered pulmonary physiology (hepatopulmonary syndrome or portopulmonary hypertension).

Despite advances in the perioperative care of high-risk surgical patients, patients with acute or chronic liver failure continue to experience an increased incidence of postoperative complications and excess mortality.[1] Identifying and addressing risk factors preoperatively may prevent postoperative morbidity and reduce mortality. This chapter reviews the fundamentals of hepatic anatomy, physiology, and biochemistry, and presents an overview of many and diverse liver diseases to provide a foundation to identify risk factors and improve preoperative conditions for anesthesia and surgery. A case scenario, a request for consultation, is included to emphasize the importance of the chapter content for a consulting anesthesiologist.

Anesthesia consultation requested for a patient with cirrhosis: An orthopedic surgeon has asked you to evaluate the risk of surgery for his patient and to make recommendations for preoperative optimization of the patient's

KEY POINTS

1. The Child-Pugh scoring system accurately assesses the high risk of surgery for patients with liver disease. This system requires knowledge of the patient's nutrition, control of ascites, history of encephalopathy, international normalized ratio (INR), plasma bilirubin level, and plasma albumin level.
2. The leading causes of perioperative death or complications for patients with advanced liver disease include hemorrhage secondary to coagulopathy, elevated intracranial pressure secondary to encephalopathy, sepsis secondary to peritonitis or pneumonitis, an ascites fluid leak at the site of surgical incision, and acute renal failure secondary to hemodynamic instability or hepatorenal syndrome.
3. Serious but rare complications of chronic liver disease include the hepatorenal syndrome, the hepatopulmonary syndrome, and portopulmonary hypertension. These may resolve following liver transplantation.
4. Most forms of chronic liver disease lead to cirrhosis, a histologic diagnosis that is characterized by fibronodular hyperplasia leading to compression and obstruction of sinusoidal capillaries and bile canaliculi. These histologic findings account for the development of portal hypertension that is manifested by ascites, esophageal varices, and hypersplenism. In a few patients, portal hypertension also leads to the development of the hepatopulmonary syndrome and/or the hepatorenal syndrome.
5. Autoimmune and uncontrolled inflammatory cellular mechanisms are key concepts for understanding the etiology of most forms of liver disease. Inflammatory mechanisms initiate hepatocellular dysfunction, hepatocyte necrosis, and portal fibrosis.
6. Laboratory testing for the evaluation of liver disease includes tests of plasma levels of synthetic proteins (INR, serum albumin, and other serum proteins), excretory function (plasma bilirubin levels), metabolic function (blood glucose, cholesterol, lipoprotein levels), evidence of bile duct obstruction (plasma alkaline phosphatase), and hepatocellular injury (plasma aspartate aminotransferase and alanine aminotransferase levels). Ultrasonography, computed tomography, and magnetic resonance imaging contribute to the ability to establish an anatomic cause of liver dysfunction.
7. The risk of transmission of viral infection by means of blood product administration has become extremely small as a result of the advances in routine immunologic and molecular screening of donors for various infectious diseases. Transmission to healthcare workers continues to be a hazard because of the lack of immunization against hepatitis C. Healthcare workers who are carriers of hepatitis B or C should limit the risk of transmitting their disease to their patients.
8. Nonalcoholic fatty liver disease is emerging as a leading cause of liver disease in the United States. Its prevalence is tied to the frequency of type 2 diabetes and the increasing problem of morbid obesity.
9. Liver transplantation offers improved chances of survival to patients following many forms of severe liver disease. Unfortunately, many patients with advanced liver disease die while waiting for suitable liver donors. Expanded criteria for suitable organ donation, organ donation immediately after cardiac death, and living-related liver segment donation have improved access to liver transplantation for patients with advanced or inherited liver disease.
10. Preoperative attention to the control of ascites, correction of coagulopathy, control of encephalopathy, improved nutrition, optimization of renal and pulmonary function, and reducing the risk of sepsis will reduce the risk of postoperative complications and improve survival rates following surgery in patients with liver disease.

medical problems. The patient is a 66-year-old male with an infected hip prosthesis that is eroding through the pelvis and impinging on the iliac vessels. The surgical procedure will be removal of prosthesis and possible reconstruction of the pelvic vessels. The patient has had autoimmune hepatitis since age 45 years. Aseptic necrosis secondary to steroid therapy led to hip arthroplasty 10 years ago. Currently, he is confined to a wheelchair and is severely depressed because of his limited activities of daily living. Medications include prednisone, azathioprine, propranolol, Prilosec, spirolactone, furosemide, and lactulose.

He has no known allergies. He has never smoked cigarettes, is abstinent from alcohol, and maintains a low-protein diet. He is a retired former chief financial officer for a large corporation.

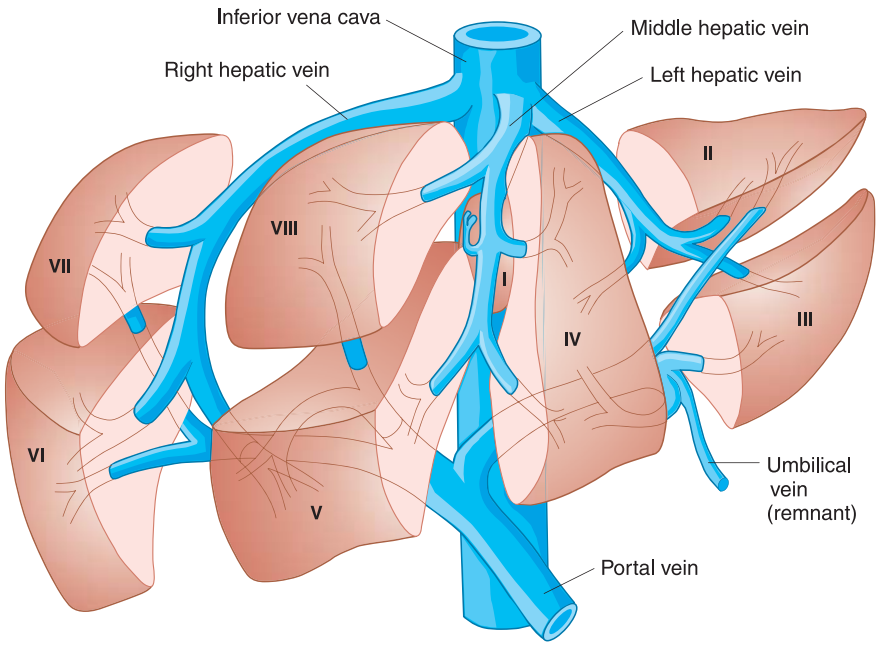

FIGURE 14–1. Segmental anatomy of the liver. The liver is divided into 8 segments based on the branches of the portal and hepatic veins. The left, middle, and right hepatic veins functionally divide the liver into 4 sectors, and these are further subdivided based on the portal inflow into a total of 8 segments. (Adapted with permission from Tanabe KK, Blaszkowsky LS, Chung R T, et al. Case 23–2005: A 57-year-old man with a mass in the liver. N Engl J Med 2005;353:401. Copyright 2005, Massachusetts Medical Society. All Rights Reserved.)

OVERVIEW OF THE LIVER

The liver is the largest solid organ in the body, normally weighing between 1200 and 1500 g. Unlike most organs, the liver is able to regenerate itself following injury. With repeated injury, however, regeneration is limited by surrounding fibrous scar tissue (cirrhosis). Early in the course of many hepatic diseases the liver becomes enlarged as a consequence of fatty infiltration, cellular infiltration, and fibronodular regeneration. With continued injury, however, it decreases in size as bridging fibrosis leads to cirrhosis.

Functional Anatomy of the Liver

The functional anatomy follows the vascular supply and biliary drainage. It is important because the anatomy forms the boundaries for hepatic resection of tumors and segmentectomy for living-related liver donation (Fig. 14–1). The branches of the vasculature and bile ducts describe the boundaries of the 8 liver segments. The hepatic acinus is the microscopic unit of the liver. The hepatic acinus is hexagonal in shape with the hepatic venule and bile canaliculus at the center and the hepatic arterioles and venules at the corners (Fig. 14–2).[2] Fibrosis leads to portal hypertension from compression of these blood vessels. Hepatocytes are described as being in zone 1, 2, or 3 based on their distance from blood flow with oxygen supply and available nutrients. Those in zone 3 are at greatest risk of ischemic, viral, and toxic injury as they are more remote from their source of oxygen and nutrients.[3] Zone 3 is the area of the hepatic acinus where bridging fibrosis first occurs following ischemic or metabolic injury.

Strategy for the Preoperative Assessment of a Patient with Advanced Liver Disease

- How severely impaired is the patient's hepatocellular function?
- Has the patient had any complications related to his liver disease?
- What is the objective evidence for stratification of his liver disease?
- What laboratory data do you need to stratify the risk of surgery?
- Should the patient develop acute liver failure postoperatively, is he a candidate for urgent liver transplantation?

Functions of the Liver

Hepatocellular function includes synthesis of proteins, production of bile, clearance of drugs and metabolites, glycogenesis and glycogenolysis, cholesterol and fatty acid metabolism (Table 14–1). Reticuloendothelial function includes phagocytosis (Kupffer cells), hematopoiesis (stem cells for both red and white blood cells), production of immunoglobulins (lymphoid tissue), and lipid metabolism (lipocytes). All of these functions can be impaired with liver disease.

Synthetic Function

Albumin, fibrinogen, prothrombin, other coagulation factors, glycoproteins, transferrin, pseudocholinesterase, and α-globulins (such as ceruloplasmin) are the major proteins synthesized in the liver. The liver also synthesizes cholesterol and glycogen.

Excretory Function

Bile excretion is the final pathway for the hepatic elimination of heme, cholesterol, and drug metabolites cleared from plasma. The principal mechanism of hepatic excretion is the conversion of nonpolar, lipid-soluble compounds to polar, water-soluble compounds by means of conjugation with glucuronic acid.

Heme molecules are oxidized and eventually conjugated to form bilirubin. Approximately 80% of bilirubin is derived from hemoglobin. The remainder comes from other heme molecules, such as those contained by myoglobin and cytochromes. Unconjugated bilirubin is tightly bound to albumin until it reaches the plasma membrane of hepa-

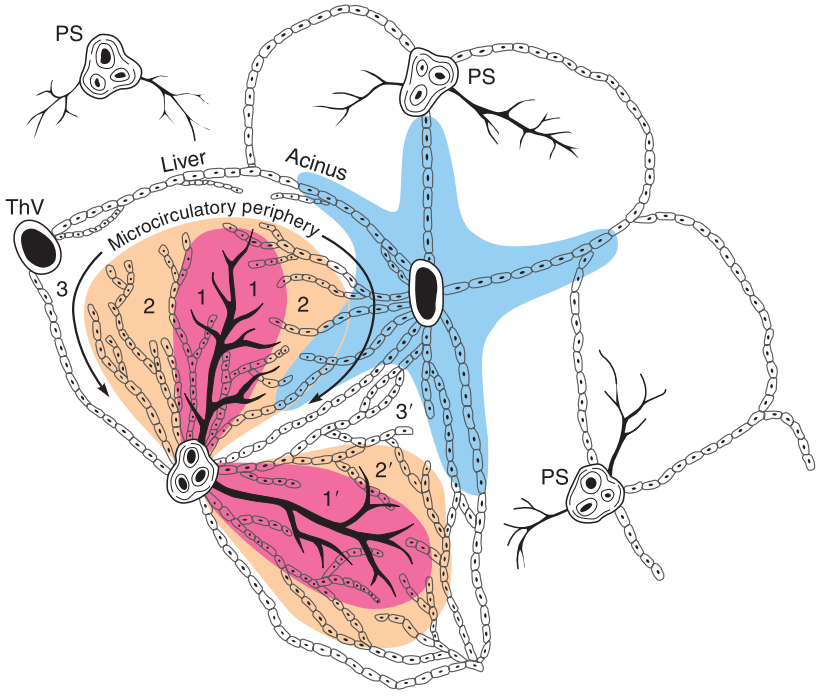

FIGURE 14–2. Anatomy of the hepatic sinusoids. The sinusoids are a collection of hepatocytes in a hexagonal arrangement with the final branches of the bile duct, hepatic artery, and portal vein in the center, and the hepatic venules at the periphery. The hepatocytes are divided into zones 1, 2, and 3, based on their proximity to the availability of oxygen supply. Those in zone 3 are most vulnerable to ischemic injury and this is the area where fibrosis first begins. Kupffer cells and lymphatics are located in the periphery. TABLE 14–1.

Physiologic and Biochemical Functions of the Liver

Liver Function	Examples
Protein synthesis	Albumin, fibrinogen, γ-globulin, ceruloplasmin, α_1-antitrypsin, α_1-fetoprotien, others
Bilirubin excretion	Active transport and conjugation with glucuronic acid
Coagulation	Factors II, V, VII, IX, X
Drug elimination	Phase I metabolism (oxidation, hydroxylation, dealkylation, demethylation, deamination, desulfuration, sulfoxide formation, dehydrogenation) involving microsomal P450 enzymes
	Phase II metabolism (glucuronidation, sulfonation, acylation, methylation)
	Highly extracted drugs, poorly extracted drugs, enterohepatic circulation, enzyme induction
Waste-product elimination	Ammonia conversion to urea, amino acid elimination, hemoglobin, myoglobin, others
Energy metabolism	Glycogen synthesis, glucose production, cholesterol formation, fatty acid metabolism
Hormone metabolism	Estrogens, androgens, thyroxine, TSH, ACTH, catecholamines
Immune response	Kupffer cell phagocytosis, γ-globulins, complement, protein C and S

ACTH, adrenocorticotropic hormone; TSH, thyroid-stimulating hormone.

tocytes, which may contain specific albumin receptors that enable transfer of bilirubin across the cell membrane.[4] Unconjugated bilirubin, a nonpolar, lipid-soluble compound, is released into the endoplasmic reticulum where it is conjugated by bilirubin uridine diphosphate (UDP) glucuronyl transferase to form conjugated bilirubin monoglucuronide. The same enzyme further conjugates bilirubin to conjugated bilirubin diglucuronide, the principal form of bilirubin found in bile following normal metabolism. Plasma levels of unconjugated bilirubin and conjugated bilirubin monoglucuronide are increased when high levels of free hemoglobin overwhelm conjugation or when there are reduced levels of bilirubin UDP glucuronyl transferase.

Excretion of conjugated bilirubin at the canaliculi requires energy and is a rate-limited process that occurs against a concentration gradient. Transport failure leads to direct hyperbilirubinemia. Bacteria in the colon convert conjugated bilirubin to urobilinogen, which can be reabsorbed by the ileum but not the colon. The liver normally metabolizes the small amount of urobilinogen reabsorbed in the small bowel (enterohepatic circulation).

Jaundice is more apparent with conjugated hyperbilirubinemia because it is water soluble and is able to diffuse easily through tissues. Rapidly appearing and severe jaundice causes pruritus but the symptoms can be relieved with cholestyramine, ursodeoxycholic acid, or rifampin. On the other hand, rifampin may cause drug-induced liver dysfunction and worsen the hepatic disease being treated.[5]

Jaundice can be prehepatic (a result of hemolysis), hepatocellular (metabolic, toxic, viral, alcoholic, cirrhotic), or cholestatic (sex hormones, hepatobiliary-pancreatic malignancies, gallstones). Unconjugated bilirubin is the primary component of hyperbilirubinemia with prehepatic disease, whereas conjugated hyperbilirubinemia is present with cholestatic disease. Both may be elevated with hepatic disease. History, physical findings, clinical course (encephalopathy, ascites, steatorrhea, etc.), and laboratory testing (plasma albumin and hepatic enzymes) can determine the cause of hyperbilirubinemia.

Metabolic Function

The liver, as a target for insulin, plays an important role in glucose metabo-

TABLE 14–2.

Key Biochemical Markers in Hepatic Systems and Function

System or Function	Marker	Site or Significance	Function
Hepatocyte integrity	AST	Liver, heart, skeletal muscle, kidney, brain, red blood cell	
	ALT	Liver	Aminotransferases catabolize amino acids for entry into the citric acid cycle
Cholestasis	Alkaline phosphatase	Bone, intestine, liver, placenta	Canalicular enzyme that plays a role in bile production
	γ-GT	Correlated levels with alkaline phosphatase indicate hepatobiliary origin	Catalyzes transfer of γ-glutamyl group from peptides to other amino acids
	Bilirubin	Elevations may indicate hepatic or extrahepatic disorder	Breakdown product of hemolysis taken up by liver cells and conjugated to water soluble product excreted in bile
Liver function mass	Serum albumin	Diet or liver	Liver synthesizes albumin
	Prothrombin time	Liver synthesizes vitamin K-dependent clotting factors	Bile salts are necessary for normal vitamin K absorption

ALT, alanine aminotransferase; AST, aspartate aminotransferase; γ-GT, gamma-glucuronyl transpeptidase.

lism and energy production. Insulin is also a hepatotropic growth factor contributing to hepatocyte regeneration following injury.[6]

Glucagon and β-adrenergic agonists are second-messenger hormones that stimulate production of cyclic adenosine monophosphate (cAMP) and release of glucose from hepatocytes. Both glucagon and insulin are secreted into the portal venous blood flowing into the liver. Drainage into the portal venous system is critical for the binding of insulin and glucagon and the release of glucose. Insulin and glucagon are much less effective in releasing glucose when pancreatic venous blood flow is extraportal (e.g. pancreatic transplantation) or when they are administered intravenously.

Insulin is not cleared effectively in cirrhosis.[7] Patients with diabetes and cirrhosis manifest hyperinsulinemia and continue to secrete glucose from the liver even in the face of severe hyperglycemia.[8] Hypoglycemia can occur in late acute liver failure but is rare in chronic liver failure

Assessment of Liver Function

The results of liver function tests should provide information about hepatocyte integrity, cholestasis, and liver function (Table 14–2). Other tests are valuable in establishing the extent of hepatocellular injury, as well as morphologic and histologic effects of disease.

Hepatic synthetic function is easily assessed by measurement of plasma albumin, fibrinogen and determination of the prothrombin time or the international normalized ratio.* Assay of plasma cholinesterase activity can be used to measure synthetic function but this test should not be confused with the determination of the dibucaine number.[9] The dibucaine number can remain normal in patients with decreased levels of the normal isoform of pseudocholinesterase.

In acute liver failure, plasma proteins decrease late in the time course of the disease because of a long half-life (albumin = 22 days). Factor VII, however, has a short half-life (approximately 4–6 hours)[10] and is a better index of hepatocellular synthetic function in the face of acute hepatocellular injury or graft function following transplantation. Serum albumin and the prothrombin time are the standard tests of synthetic function and are used in the algorithm establishing the Child-Pugh score (see below).[11]

The best laboratory tests of hepatic excretion are serum levels of indirect and direct bilirubin (Table 14–3), another laboratory test used to compute the Child-Pugh score. Although most forms of liver disease will eventually produce an elevation of bilirubin, it is most common with biliary obstruction or secondary autoimmune biliary disease.

Cellular enzymes are used to diagnose hepatocellular injury and bile duct obstruction (Table 14–4). The pattern of enzyme elevation helps distinguish between hepatocellular injury (ischemic, toxic, inflammatory), biliary obstruction, and alcohol abuse. Beyond that, they are relatively nonspecific and do not provide sufficient information to discriminate amongst the different liver diseases.[12]

With any form of bile duct obstruction, alkaline phosphatase, which is normally excreted in bile, leaks into the systemic circulation. Patients with bile duct obstruction will develop elevated plasma levels of alkaline phosphatase before hyperbilirubinemia. Bile duct obstruction at the level of the canaliculi can occur with granulomatous disease, amyloidoses, and infections, as well as with infiltrative disease such as leukemia and metastatic malignancies. Cholelithiasis is the most common cause of extrahepatic bile duct obstruction but other causes include tumors, strictures, infection, inflammation, or extrinsic compression.

Serum aspartate aminotransferase (AST) and alanine aminotransferase (ALT) are hepatic mitochondrial en-

*(INR: INR = [PTpatient/PTmidrange control]ISI where ISI is the international standardization index and PT is prothrombin time. The ISI shows the relative activity of the reagents used to generate prothrombin. The ISI correction allows the comparison of the INR from one laboratory with that of another laboratory. Most clinical laboratories use reagents with an equal to 1.)

TABLE 14–3.

Causes, Clinical Features and Biochemical Abnormalities of Hyperbilirubinemia

Type	Cause	Clinical Features and Biochemical Abnormalities
Unconjugated hyperbilirubinemia	Hemolysis	Decreased hemoglobin and haptoglobin levels
	Gilbert syndrome	None
	Hematoma absorption	Increased CK and LDH levels
	Ineffective erythropoiesis	Bone marrow abnormalities
Conjugated hyperbilirubinemia	Bile duct obstruction	Preceded by marked increase in AST/ALT levels
		Presence of abdominal pain
	Hepatitis	Increase in AST/ALT levels
	Cirrhosis	AST/ALT normal or slightly elevated
		Presence of physical findings of chronic liver disease
	Autoimmune cholestasis	Marked elevation of ALP with normal AST/ALT levels
	Parenteral nutrition	Increased ALP and γ-GT
	Toxic hepatitis	Concomitant increase in ALP levels
	Vanishing bile duct syndrome	Associated with drug reactions or liver transplantation

ALP, alkaline phosphatase; ALT, alanine aminotransferase; AST, aspartate aminotransferase; CK, creatine phosphatase; γ-GT, gamma-glucuronyl transpeptidase; LDH, lactate dehydrogenase.

TABLE 14–4.

Biochemical Features of Common Causes of Moderate to Marked Increase in Aminotransferase Levels

Cause	AST/ALT Level Increase (value × reference limit)	Bilirubin Level Increase (value × reference limit)	Comments
Ischemic injury	>10 to >50	<5	AST > ALT; rapid decrease of both after initial peak; ALT: LDH <1; presence of comorbid conditions
Toxic injury	>10	<5	Pattern of enzyme alteration similar to that of ischemic hepatitis
			History suggestive of toxic injury
Acute viral hepatitis	5–10 to >10	5–10	Slow decrease of AST/ALT levels
			Presence of risk factors
Acute biliary obstruction	5–10	5–10 to >10	AST/ALT increase precedes cholestasis
			Presence of typical symptoms
Alcoholic hepatitis	5–10	5–10 to >10	AST:ALT >2
			May occur as both acute and acute-on-chronic injury

ALT, alanine aminotransferase; AST, aspartate aminotransferase; LDH, lactate dehydrogenase.
Reprinted and adapted from Giannini EG, Testa R, Savarino V. Liver enzyme alteration: a guide for clinicians. CMAJ 2005;172:367–379, by permission of the publisher. ©2005 CMA Media Inc.

zymes. Elevated levels indicate hepatocellular injury from a variety of causes, including viral infection, alcohol abuse, and obesity (Fig. 14–3). The highest elevations of the transaminases occur with ischemic or toxic liver injury and acute viral hepatitis. Gamma-glutamyl transpeptidase (γ-GT) and lactate dehydrogenase are enzymes that can be elevated in both hepatocellular injury and bile duct obstruction.

The serum liver enzyme response to hepatocellular injury can be confusing because elevations occur in the early phase of injury. Decreasing enzyme levels may indicate either recovery or worsening to severe, irretrievable injury. A good example is the fulminant hepatic failure seen with acetaminophen overdose. Falling enzyme levels can lead to a false sense of security and lower the sense of urgency for liver transplantation. In this situation, factor VII levels can be helpful.

Closed liver biopsy, guided by imaging, can be performed percutaneously or transvenously. Percutaneous liver biopsy is simple and safe as long as established guidelines are followed.[13] It is usually contraindicated in patients with a coagulopathy, thrombocytopenia, encephalopathy and tense ascites. The risks include hemorrhage from penetration of a major intrahepatic vessel, bile leak with peritonitis, pneumothorax, and hemothorax. Hemobilia may follow transfixion of adjacent hepatic arteries and bile ducts and may require embolization for control of bleeding.

Transvenous liver biopsy via a catheter passed from the internal jugular vein and wedged into a branch of the hepatic vein allows measurement of the intrahepatic capillary wedge pressure, a surrogate for portal venous pressure, as well as the opportunity to obtain a transcatheter needle biopsy of liver parenchyma. Transjugular biopsy may be indicated in patients with very small livers, patients with coagulopathy, or patients who are uncooperative.[14]

Chronic hepatitis is the most common indication for liver biopsy. Serial liver biopsies are helpful in following the progression or resolution of disease, as well as gauging the effects of treatment. Percutaneous imaging and a guided biopsy can establish the diagnosis of hepatocellular carcinoma, metastatic malignancy, or other invasive diseases of the liver.

Needle biopsy helps establish the severity of cirrhosis of the liver by

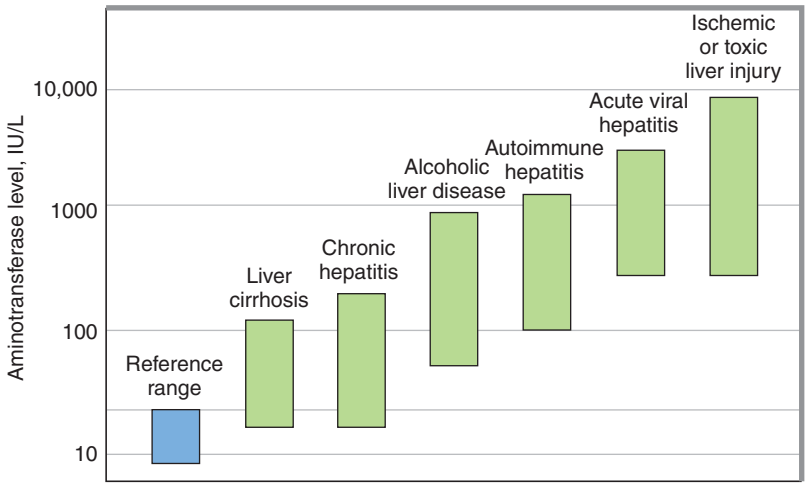

FIGURE 14–3. Serum aminotransferase levels in various liver diseases. The early elevation of the level of aminotransferase corresponds to the extent of inflammatory response in the hepatic sinusoids. (Reprinted and adapted from Giannini EG, Testa R, Savarino V. Liver enzyme alteration: a guide for clinicians. CMAJ 2005;172:367–379, by permission of the publisher. ©2005 CMA Media Inc.)

grading the extent of fibrosis in areas of fibronodular hyperplasia.[3] Ishak grade 0–2 reflects no or minimal fibrosis; Ishak grade 3–4 reflects incomplete bridging fibrosis; and Ishak grade 5–6 reflects precomplete and complete cirrhosis (Fig. 14–4).

High-resolution ultrasonography and Doppler ultrasonography examinations of the liver are noninvasive, uncomplicated, and simple to perform.[15] They give detailed information about the liver parenchyma, liver blood vessels, and lesions of the liver. Doppler examination can demonstrate the patency or occlusion of the hepatic artery, portal vein, hepatic veins, and inferior vena cava. Lesions as small as 1 cm can be identified with high-resolution ultrasonography and ultrasonographic imaging can guide needle biopsy with good accuracy. Intraoperatively, ultrasonograph guidance can be used to guide hepatic segmentectomy. Ultrasonography is most helpful in determining the cause of cholestatic jaundice and in locating gallstones.[16] It is less helpful in obese patients and in patients with gaseous distension of the stomach or intestines.

Computed tomography (CT) and magnetic resonance imaging (MRI)[15] have advantages over ultrasonography. Hard copy images are produced and can be readily interpreted. The spiral CT has greatly improved liver imaging because a complete scan with high resolution can be obtained during voluntary breath holding, thus eliminating motion artifacts.[17] Blood vessel anatomy is enhanced with oral or intravenous contrast material and CT scanning.[18] CT and MRI studies also provide additional information about surrounding structures, such as the spleen, kidney, collateral circulation, and shunts. CT with blood vessel enhancement provides better definition of liver segments for future resection. High-resolution ultrasonography and serum α-fetoprotein are the most sensitive and specific means of surveillance for patients at risk for hepatocellular carcinoma.[19]

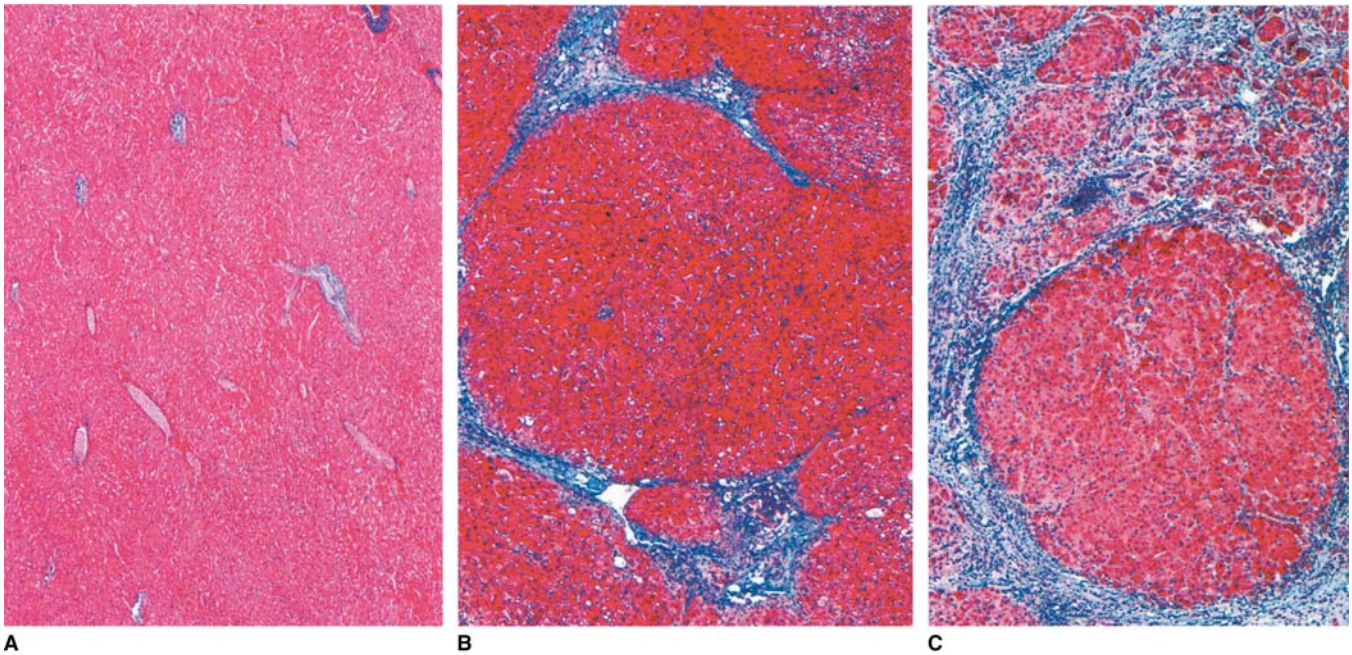

FIGURE 14–4. Ishak classification of cirrhosis. **Panel A:** There is minimal fibrosis and no bridging between areas of fibrosis. Synthetic and excretory functions are maintained. These findings do not cause significant portal hypertension and they are compatible with Child-Pugh class A. **Panel B:** There is moderate fibrosis with incomplete bridging between segments. Synthetic function is diminished and hyperbilirubinemia may be present. These findings are compatible with Child-Pugh class B and there may be mild portal hypertension. **Panel C:** There is complete bridging fibrosis and nodular hyperplasia. Patients will have portal hypertension with ascites, varices, and encephalopathy. They meet the criteria for Child-Pugh class C. (Used with the permission of the Department of Pathology, Massachusetts General Hospital, Boston, Massachusetts.)

MRI is highly specific and sensitive for iron overload in hemochromatosis and can be used to gauge the effectiveness of iron depletion therapy.[20]

HEPATIC DRUG METABOLISM

Hepatic Metabolism of Highly Extracted Drugs

Hepatic drug extraction occurs at the level of the hepatocyte with its dual, afferent blood flow. Systemically administered drugs arrive at the hepatic sinusoid via the hepatic artery, whereas most orally administered drugs are absorbed in the small intestine and arrive at the liver via the portal vein (Fig. 14–5). When a drug is absorbed in the small intestine, the liver has the opportunity to remove it from the bloodstream before the drug can exert systemic effects. Drugs can be divided into two groups based on the ability of the liver to remove them from the circulation: highly extracted, lipid-soluble (nonpolar) compounds and poorly extracted, water-soluble (polar) compounds. In reality, the distinction between these two groups is imperfect, but it serves to help us understand hepatic drug clearance.

Hepatic clearance is expressed as

$$CL_H = Q_{THBF}\,[(C_{THBF} - C_{HV})/C_{THBF}]$$

where Q_{THBF} is total hepatic blood flow, C_{THBF} is the drug concentration in the mixed portal venous blood and hepatic arterial blood, and C_{HV} is the concentration in hepatic vein blood.

If a drug is completely extracted from either, or both, the hepatic artery or portal venous blood, the concentration in the hepatic vein is zero and the value of $[(C_{THBF}\ C_{HV})/C_{THBF}]$ is 1. Then CL_H is proportional to Q_{THBF}. Thus, clearance of highly extracted drugs is proportional to total liver blood flow. Liver disease, abnormal hemodynamics and drugs can decrease both hepatic artery and portal vein blood flow and will exaggerate the systemic effects of a drug that is normally highly cleared by the liver. Also, intraabdominal surgery and inhalational anesthetics can reduce liver blood flow by more than 80%.[21] Because cirrhosis of the liver markedly decreases total hepatic blood flow as a result of fibrosis at the portal triad, patients with cirrhosis can be expected to have increased sensitivity to highly extracted drugs.

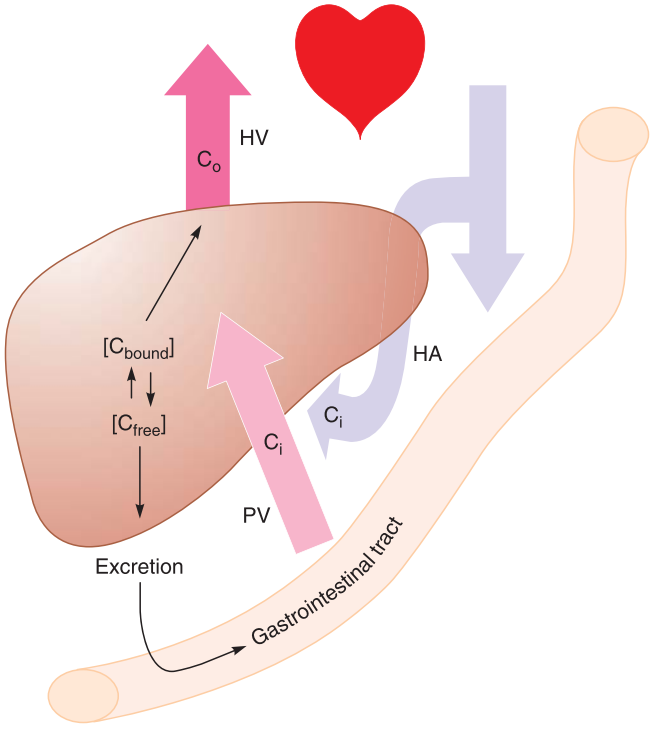

FIGURE 14–5. Hepatic drug metabolism. Drugs are cleared by the liver from blood flow via the hepatic artery (*HA*) and the portal vein (*PV*). Drug concentration (C_o) in the hepatic vein (*HV*) of highly extracted drugs approaches zero. Thus clearance is dependent on the concentration of drug (C_i) in blood from the total hepatic blood flow (HA + PV). Total hepatic blood flow is proportional to cardiac output. Poorly extracted drug blood concentration is dependent on the extraction ration (C_o/C_i). The extraction ratio is decreased with diminished hepatocellular microsomal function. (Courtesy of Richard A. Wiklund, MD.)

For example, propranolol, which decreases total hepatic blood flow and is commonly prescribed for esophageal varices, will increase the sensitivity of patients to highly extracted drugs.

Nitroglycerine is also highly extracted. It undergoes first-pass hepatic clearance when it is administered orally. Consequently, it is most effective when given sublingually or intravenously. Examples of other highly extracted drugs include labetalol, metoprolol, morphine, verapamil, and acetaminophen.

Protein Binding of Drugs Metabolized by the Liver

In practice, the clearance of highly extracted drugs, such as lidocaine, is more complex because of the role of protein binding. Protein binding limits the availability of lidocaine for hepatic extraction. Despite this, lidocaine is highly extracted. In fact, very little lidocaine reaches the systemic circulation when it is administered orally. Lidocaine is rapidly absorbed in the small bowel and is delivered to the liver via the portal veins. The near complete extraction of lidocaine is called "first-pass clearance," a phenomenon common to orally administered highly extracted drugs. Similarly, systemically administered drugs that are highly extracted are rapidly cleared from blood because the total hepatic blood flow is equivalent to 30% of the cardiac output.

Hepatic Metabolism of Poorly Extracted Drugs

The same clearance expression can be used to understand the role of the liver in the metabolism of poorly extracted drugs:

$$CL_H = Q_{THBF}\,[(C_{THBF}\ C_{HV})/C_{THBF}]$$

where Q_{THBF} is total hepatic blood flow, C_{THBF} is the drug concentration in the mixed portal venous and hepatic arterial blood, and C_{HV} is the concentration in the hepatic vein blood. In this case, however, C_{HV} is not zero and Q_{THBF} is not as important as the ability of the liver to extract drugs:

$$C_{HV} = C_{THBF} * ER \sim C_f{:}C_b$$

where ER is the extraction ratio, C_f is the concentration of free drug (unbound), and C_b is the protein bound

concentration of the drug. The ER is a hepatocellular microsomal function.

Hepatic microsomal enzymes are responsible for the metabolism of many of the drugs cleared by the liver. Because the activity of microsomal enzymes is dependent on normal hepatocellular function, hepatic metabolism is decreased after hepatocellular injury and in cirrhosis of the liver. The principal hepatic microsomal enzymes include the monooxygenases, cytochrome c reductase, and cytochrome P450. Oxidation and hydroxylation by these enzymes convert drugs into polar, water-soluble compounds. Alternatively, alcohols can be converted to acetaldehydes by alcohol dehydrogenase. Once these reactions have occurred, the drugs' metabolites are conjugated with glucuronic acid and undergo active excretion (energy requiring) into the bile. Patients with cirrhosis are more sensitive to these drugs as the process can be saturated because of compromised hepatocellular function. Some examples of drugs that are poorly extracted and are enzyme dependent for their metabolism include certain barbiturates, benzodiazepines, nonsteroidal antiinflammatory drugs (NSAIDs), diphenylhydantoin, caffeine, theophylline, and warfarin.

The cytochrome P450 system is a complex collection of endoplasmic heme proteins capable of producing toxic drug metabolites. Many of the P450 enzymes are inducible by drugs (ethanol, phenobarbital, omeprazole, isoniazid) and enzyme induction leads to abnormal responses to drugs that undergo hepatic metabolism (acetaminophen, β-blockers, neuroleptics, benzodiazepines). This is important for causing increased sensitivity to acetaminophen-induced acute liver failure and is brought on by chronic alcohol abuse (see Acetaminophen Toxicity) or isoniazid therapy.

Other Pharmacokinetic Abnormalities in Liver Disease

Liver disease leads to other intrinsic and extrinsic effects that alter the plasma half-life or pharmacokinetic profile of drugs. First, hypoalbuminemia is a characteristic finding in advanced liver disease. The normal liver is capable of producing 10 g of albumin per day, and this may be limited to less than 4 g per day in advanced cirrhosis. Albumin is the principal plasma protein capable of drug binding. Severe hypoalbuminemia will increase the unbound concentration of any polar drug.

Hypoalbuminemia and portal hypertension lead to an accumulation of extracellular fluid in the form of peripheral edema, abdominal ascites, and pleural effusion. The apparent volume of drug distribution is greatly increased in the patient with a large volume of ascites.

Cirrhosis secondary to chronic alcohol abuse will lead to increased effect of drugs that affect the central nervous system, especially the benzodiazepines.[22] This is caused not only by generalized cerebral cortical atrophy but also by the accumulation of benzodiazepine-like substances and ammonia in the central nervous system, leading to hepatic encephalopathy. Benzodiazepine antagonists improve mental function in advanced encephalopathy.[23] Benzodiazepine therapy for agitation should be used with caution in patients with any evidence of hepatic encephalopathy.

The kidney shares the load of drug excretion with the liver, especially of lower-molecular-weight conjugated compounds. Renal blood flow is diminished in advanced liver disease by virtue of the increased abdominal pressure seen with uncontrolled ascites. Acute renal failure (hepatorenal syndrome, see Chronic Liver Failure) can be a complication of severe, usually acute, liver failure.

Muscle Relaxants

The metabolism of muscle relaxants deserves special attention. Succinylcholine is metabolized by plasma pseudocholinesterase. Patients with advanced liver disease may have decreased plasma levels of pseudocholinesterase leading to a prolonged duration of neuromuscular blockade following succinylcholine administration. Pseudocholinesterase has a high affinity (low K_m [Michaelis constant]) for its substrate (succinylcholine) and metabolizes it rapidly (high V_{max} [maximal velocity]). Even very low concentrations of plasma pseudocholinesterase will result in only moderately prolonged paralysis. This is an unlikely cause of clinical problems. Purified pseudocholinesterase has been administered to homozygotes for atypical pseudocholinesterase that have received ester muscle relaxants.[24] This resulted in significant acceleration of recovery from neuromuscular blockade.

Most of the nondepolarizing muscle relaxants are metabolized in the liver and metabolites are excreted either in bile or urine or both. Active metabolites of vecuronium accumulate in the plasma of patients with advanced liver disease. Although there are theoretical advantages of using steroidal muscle relaxants such as atracurium in patients with cirrhosis, the prolonged paralytic effects of repeated doses of vecuronium is not an important clinical problem.

HISTORY OF SURGICAL RISK

Child-Pugh Stratification of Liver Disease

In 1964, Child and Turcotte[25] described the features of advanced liver disease leading to a high mortality rate in a group of 128 patients undergoing a portocaval shunt. Mortality was increased in patients with jaundice, malnutrition, encephalopathy, elevated serum bilirubin levels, or decreased serum albumin levels. Mortality was proportional to the extent of these abnormalities. All patients had variceal bleeding and had failed conservative treatment. The mortality rate for patients with advanced cirrhosis was 53%; it was only 4.3% for patients with earlier stages of cirrhosis.

Pugh and Murray-Lyon modified Child's classification 10 years later.[11] Because their 38 patients with variceal bleeding were considered to be at too high a risk to safely undergo portal decompression, transthoracic ligation was performed for variceal bleeding as a bridge to portocaval shunting. Of the 38 patients, 21 died from either continuing hemorrhage or acute liver failure. Pugh then added the prolonged prothrombin time as an additional laboratory measurement that was predictive of a poor outcome. Estimation of the severity of encephalopathy, malnutrition, ascites, hyperbilirubinemia, hypoalbuminemia, and prolongation of the prothrombin time became the basis for the Child-Pugh score. Each abnormality was graded as minimal (score = 1), moderate (score = 2), or severe (score = 3). Child-Pugh class A patients had an aggregate score of 5–6; class B patients, 7–9; and class C patients = 10–15 (Table 14–5). The operative mortality was 77% for patients in class C, 38% in class B, and 29% in

TABLE 14-5.

Child-Pugh Scoring System for Staging the Severity of Liver Disease

Child-Pugh Class	A	B	C
Ascites	None evident (1 point)	Adequate control (2 points)	Poorly controlled (3 points)
Nutrition	Well nourished (1 point)	Poorly nourished (2 points)	Malnourished (3 points)
Encephalopathy	None evident (1 point)	Grade 1–2 (2 points)	Grade 3–4 (3 points)
Albumin	>3.5 g/dL (1 point)	3.0–3.5 g/dL (2 points)	<3.0 g/dL (3 points)
Bilirubin	<2.0 mg/dL (1 point)	2–3 mg/dL (2 points)	>3.0 mg/dL (3 points)
Prothrombin time (INR)	<4 sec > control (INR <1.7) (1 point)	4–6 sec > control (INR = 1.7–2.2) (2 points)	>6 sec > control (INR >2.2) (3 points)
Total score	6 points	7–12 points	13–18 points

class A. None of the patients in class C survived for more than 1 year, and the overall mortality was 68% at 6 months.

Garrison et al.[26] reviewed 100 consecutive patients with cirrhosis undergoing intraabdominal surgery (Table 14–6). No patient had variceal hemorrhage. The authors correlated preoperative, intraoperative, and postoperative variables with survival without complications, survival with complications, and in-hospital death. Surgery included open cholecystectomy, common duct exploration, gastrectomy, intestinal resection, liver biopsy, splenectomy, pancreatectomy, vascular surgery, and exploratory laparotomy. Multivariate analysis showed that the features that correlated well with intraoperative and postoperative complications and death were similar to those factors in the Child-Pugh classification. Poor outcome was associated with malnutrition, uncontrolled ascites, late stages of encephalopathy, perioperative sepsis, coagulopathy, and abnormal liver function tests. The average Child-Pugh class (not score) was 2.4 (equivalent to Child-Pugh class C) in nonsurvivors, 1.6 (equivalent to Child-Pugh class B) in survivors with complications, and 1.25 (equivalent to Child-Pugh class A) in survivors without complications. Garrison's study added two new parameters to those of Child and Pugh that need consideration in evaluating the risk of surgery for patients with chronic liver disease. Sepsis, as evidenced by elevated circulating white blood cell (WBC) counts and reoperative surgery were highly predictive of complications and death. Their data suggest that patients with chronic liver disease are at high risk for sepsis syndrome whenever they develop respiratory, urinary, or intraabdominal infections in the perioperative period. The mortality rate was 100% for exploratory laparotomy, most likely because these patients had developed spontaneous bacterial peritonitis. Reoperative surgery, for the most part, was performed to control ascites leaking out via the surgical wound, providing another portal of entry for infection.

In 1997, Mansour et al. reported results of 92 patients who were undergoing elective and emergency surgery.[27] The mortality rate for Child-Pugh class A was 10%; Child-Pugh class B, 30%; and Child-Pugh class C, 82%. For all three groups, mortality rose significantly following emergency surgery (26% overall for elective cases; 50% after emergency surgery). Furthermore, Aranha et al. reported an 83% mortality rate associated with cholecystectomy and common duct exploration for patients with liver disease and a prothrombin time more than 2.5 seconds greater than the control.[28] Cholecystostomy and retrograde cholangiography were recommended as options with a much lower mortality (14%).[29]

There are reports of improved outcome following laparoscopic cholecystectomy in patients with cirrhosis. Fernandes et al. compared liver disease patients with matched controls.[30] The patients with cirrhosis had greater length of stay, longer duration of surgery, greater need for transfusion, more frequent complications, and a higher rate of conversion of open cholecystectomy. Mortality, however, was not significantly greater. There were no Child-Pugh class C patients in this series. In fact, 80% were Child-Pugh class A.

Shaw reviewed the role for portosystemic shunting and showed a low mortality rate (5–7%) for selected candidates, and for those with early cirrhosis or uncontrolled alcoholism or advanced age precluding transplantation.[31]

Model of End-Stage Liver Disease

The Model for End-Stage Liver Disease (MELD)[32,33] has been recommended as a better predictor of outcomes for patients with liver disease than the Child-Pugh strategy for risk assessment. It is widely used for evaluation of the suitability for hepatic transplantation and it is discussed in detail in Chap. 56.

The risk of complications and death following major surgery for patients with cirrhosis is high (Table 14–7) and there has been little reduction in these risks despite the advances in surgery, anesthesia, intensive care, and blood component therapy that have evolved over the past 4 decades. Intraabdominal surgery is associated with a high-risk of complications and death in patients with early, moderate, and advanced liver disease. The increased risk is proportional to the extent of liver disease, which is readily estimated by simple clinical and laboratory data. The traditional risk factors of encephalopathy, uncontrolled ascites, malnutrition, abnormal serum albumin and bilirubin, and prolonged prothrombin time should be expanded to include the presence of sepsis and emergency surgery.

BRIEF OVERVIEW OF LIVER DISEASES

Congenital and Infantile Liver Disease

Biliary Atresia

Biliary atresia results from destruction of bile ducts in utero. Infants do not survive childhood with complete atresia. Surgical correction of a distinct

TABLE 14–6.

Variables Associated with Morbidity and Mortality following Intraabdominal Surgery

Preoperative

Preoperative Variable	Survivors without Complications	Survivors with Complications	Nonsurvivors
Ascites	12.5%	33%	70%

Estimated Risk of Major Intraabdominal Surgery[a] for Patients with Cirrhosis

Child-Pugh Classification	Mortality
A	10%
B	30%
C	80%

[a]Does not include orthotopic liver transplantation.
Data derived from Child CG and Turcott JG;[25] Pugh RN, Murray-Lyon IM, Dawson JL, et al;[11] Garrison RN, Cryer HM, Howard DA, and Polk HC Jr;[26] and Mansour A, Watson W, Shayani V, and Pickleman J.[27]

segment of biliary atresia with a choledochojejunostomy or Kasai procedure (hepatic portoenterostomy) may provide relief from severe jaundice and liver failure until liver transplantation can be performed.

Reye Syndrome

Reye syndrome is an acute encephalopathy precipitated by aspirin therapy for children with acute viral infection. In the United States, the incidence of Reye syndrome has been tied to salicylate ingestion and the incidence has fallen as acetaminophen is substituted for salicylates in children with viral illness.

Wilson Disease

Wilson disease consists of progressive lenticular degeneration associated with cirrhosis of the liver. It is an autosomal recessive abnormality of copper metabolism and results in characteristic, greenish Kayser-Fleischer rings in the cornea. The plasma ceruloplasmin level is decreased. However, Wilson disease is not a failure to produce ceruloplasmin; it is a failure of copper transport followed by coupling to ceruloplasmin. Penicillamine therapy chelates copper, leading to improvement of the neurologic symptoms and prevention of cirrhosis. Fulminant hepatic necrosis can occur in 25% of cases, and requires urgent liver transplantation. Patients with Wilson disease require uninterrupted penicillamine therapy in the perioperative period.

Hemochromatosis

Chronic excessive iron exposure causes hepatic fibrosis (hemochromatosis) irrespective of whether the accumulation is the result of multiple transfusions or abnormal absorption and accumulation of dietary iron. Hemochromatosis leads to cirrhosis and hepatocellular carcinoma.

Hereditary hemochromatosis results in macronodular cirrhosis, diabetes from pancreatic fibrosis, and cardiac iron deposition, often with heart failure, conduction abnormalities, and coronary atherosclerosis. This disease is an autosomal recessive metabolic disorder. Although present from birth, tissue injury does not begin until age 30 to 40 years. Iron toxicity is controlled by aggressive removal of blood. Multiple organ (heart, liver, pancreas) transplantation may be required.

α_1-Antitrypsin Deficiency

α_1-Antitrypsin is an enzyme inhibitor produced in the liver that inhibits key proteases (such as trypsin) and neutrophil elastase. Two genes (Pi or protease inhibitor gene), one received from each parent, control the produc-

Potential Complications of Advanced Liver Disease That Should Be Explored during the Consultation with the Patient

- *Ascites:* The patient's diuretic therapy would suggest that the patient has long-standing ascites with poor control.
- *Variceal Hemorrhage:* The patient has a history of one episode of variceal hemorrhage. This is suggested by the patient's therapy with propranolol.
- *Jaundice:* The patient has not been jaundiced but jaundice is unusual in patients with autoimmune hepatitis.
- *Malnutrition:* The patient weighs 220 lb and is 74" tall. Some of the patient's weight is attributable to the patient's ascites. On examination the patient shows some evidence of muscular wasting.
- *Encephalopathy:* The patient was hospitalized once for grade II hepatic encephalopathy (see Table 14–9). The patient is on a low-protein diet and is being treated with lactulose, both of which suggest that the patient is at risk of developing encephalopathy.
- *Hepatorenal Syndrome:* The patient has no history of renal dysfunction.
- *Hepatopulmonary Syndromes:* The patient has no evidence of hepatopulmonary hypertension or hepatopulmonary syndrome.
- *Spontaneous Bacterial Peritonitis:* The patient has no history of hospitalization for peritonitis or unexplained abdominal pain.
- *Sepsis:* The patient has an infected hip prosthesis.
- *Hyperdynamic Circulation:* The patient's blood pressure is 105/75 mm Hg, and the patient's pulse is 85 beats/min. These are consistent with hyperdynamic circulation but confirmation will be obtained at the time of pulmonary artery catheterization.

tion of α_1-antitrypsin. There are many alleles but only two are associated with disease. M is the normal allele; S and Z are the two alleles that are clinically significant. Silent genes result in complete lack of α_1-antitrypsin production. The normal genotype is PiMM. The abnormal genotype, PiZZ, causes emphysema and, in approximately 20% of patients, cirrhosis. The PiSS and PiMZ do not cause lung disease. The PiSZ genotype presents some increased risk of lung disease. Liver disease can be associated with the PiMZ and PIZZ genotypes.

Other Inherited Liver Diseases

Hereditary tyrosinemia is an autosomal recessive inborn error of metabolism that results in progressive liver disease and possible acute liver failure early in life.

There are at least 10 defects in glycogen synthesis or storage that affect the liver, skeletal muscle, and red and white blood cells.[34] For the most part all result in excessive amounts of glycogen stored in these tissues.

The mucopolysaccharide storage disorders are a group of lysosomal storage disorders associated with deficiencies of the lysosomal enzymes required for normal sequential degradation of glycosaminoglycans. Abnormal lysosomal enzymes lead to lysosomal storage diseases such as Hurler syndrome, another autosomal recessive abnormality.

Nutritional Liver Disease

Nonalcoholic Fatty Liver Disease

Nonalcoholic fatty liver disease (NAFLD) is prevalent in the obese population.[35] In a prospective study of 1124 asymptomatic patients referred for evaluation of abnormal liver function tests, 73 of 81 patients without markers for liver disease (infection, metabolic, autoimmune, hereditary, alcoholic, toxic) were found to have some degree of steatosis on liver biopsy.[36] NAFLD is believed to be the most common cause of abnormal liver function tests in the United States.[37] It is most prevalent in morbidly obese patients with type 2 diabetes mellitus.[38] Paradoxically, it occurs frequently following bariatric surgery.[39]

In its earliest stage, NAFLD is manifested by macrovesicular fatty infiltration of less than one-third of hepatocytes (grade 1), mostly in zone 3, with minimal inflammation (Fig. 14–6). Serum transaminases are elevated and ultrasonography demonstrates a diffuse increase of echogenicity. Zone 3

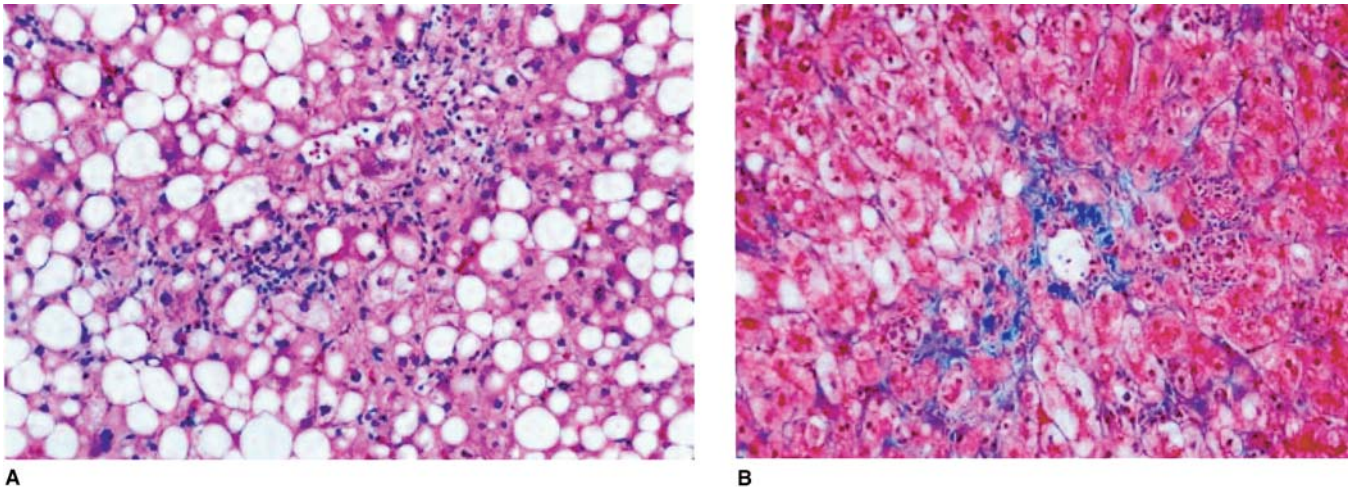

FIGURE 14–6. Histologic findings with nonalcoholic fatty liver disease. **A.** Photomicrograph shows macrovesicular fatty infiltration, an inflammatory infiltrate, Mallory hyaline deposits, and hepatocyte ballooning. **B.** This panel shows zone 3 fibrosis in a pattern typical of nonalcoholic liver disease as opposed to that seen in alcoholic liver disease. fibrosis may be focal or extensive (stage 1 fibrosis). Grade 2 steatosis is a more advanced form of NAFLD, involving up to two-thirds of the hepatocytes with extensive fibrosis in the periportal areas. Grade 3 (more than two-thirds of hepatocytes), stages 3 and 4 (bridging fibrosis and cirrhosis), is an advanced form of the disease.[40] In this respect, NAFLD is difficult to distinguish from alcoholic liver disease. It is hypothesized that NAFLD is an abnormality of lipid uptake, synthesis, degradation, or secretion resulting from insulin resistance.[35] Although NAFLD is an infrequent indication for liver transplantation,[41] it has the potential to be a precipitating cause of postoperative liver dysfunction.

Acquired Liver Disease

Viral Hepatitis

Viral hepatitis is a broad collection of illnesses that have hepatic dysfunction as the only common thread. The etiology, modes of transmission, clinical course, and late complications are different (Table 14–8).[42]

All forms of viral hepatitis show diffuse acute inflammation with leukocyte and histiocyte infiltration followed by hepatic necrosis and regeneration with recovery. Zone 3 hepatocytes suffer the greatest injury. Inflammation may be limited to zone 3 in mild forms of viral hepatitis, or it may extend to the entire acinus in fulminant hepatic necrosis. When the entire acinus is involved the patients will eventually develop postnecrotic scarring with fibrosis (bridging fibrosis).

Hepatitis A is the least severe of the known forms of viral hepatitis. The fecal–oral route as a contaminant of drinking water or food, especially uncooked shellfish, causes hepatitis A. The incubation period for the disease is approximately equal to or greater than 15 days and plasma transaminases and bilirubin levels may not rise until several weeks into the course of disease.

Although recovery may take several weeks to months, most patients with hepatitis A have an unpleasant course but uncomplicated recovery. Fulminant hepatic necrosis with liver failure requiring transplantation is extremely rare with hepatitis A infection.

Hepatitis E is a form of viral hepatitis that is very similar to hepatitis A. It occurs in developing countries where there is fecal contamination of the drinking water. Fulminant hepatic failure following hepatitis E infection can be a serious complication of the third trimester of pregnancy.[43]

Hepatitis B is often an anicteric illness; however, hepatitis B can lead to either fulminant hepatic necrosis and liver failure or chronic hepatitis. Hepatitis B is a viral infection of the liver caused by a complex virion that contains double-stranded DNA, DNA polymerase, a surface antigen (HBsAg), a core antigen, and the e antigen. HBsAg was first identified in two patients who had received multiple transfusions for hemophilia when their serum, which had antibodies to HBsAg, was tested in a panel that contained an antigen from an Australian aborigine. The antigen was called the "Australian Antigen" and was sub-

sequent identified as the antigen of viral hepatitis B.

The antigens and antibodies found in patients with hepatitis B form the basis for both diagnosis and prognosis. HBsAg is present in the bloodstream during the acute phase of the disease and persists for more than 6 months if the patient becomes a carrier of hepatitis B. HBsAg disappears with recovery and is replaced with the antibody (anti-HB) to HBsAg. Antihepatitis antibodies (anti-HBs) persist and are evidence of prior hepatitis B infection or exposure. Serum IgM antibodies to the core antigen (HBcAb) rise during the acute phase of infection and then disappear. Hepatitis B is spread by sexual contact or exposure to blood products. Evidence of exposure to blood products by positive anti-HBs has been a common finding in surgeons and anesthesiologists who have been in practice for years prior to the availability of hepatitis B immunization and the adoption of universal precautions. Today, hepatitis B vaccination of healthcare workers is mandated by institutional regulation. Body fluids, including blood, urine, saliva, and semen, have been shown to carry hepatitis B virus (HBV) DNA in samples obtained from HBsAg-positive patients. HBsAg is found in approximately 0.1% of potential first-time blood donors. In other areas of the world, especially Africa and Asia, the incidence is higher. HBsAg is routinely tested for by radioimmunoassay in all donors in the United States and Europe. High-risk populations are identified by predonation questionnaires. Testing has contributed significantly to the reduction in the risk of viral hepatitis from the transfusion of blood or blood products.

There are reports of healthcare workers who become carriers for hepatitis B and have transmitted the disease to patients,[44] and of a cardiac surgeon who transmitted hepatitis C virus.[45]

Hepatitis D is a severe viral infection of the liver that occurs as a coinfection of a patient with acute hepatitis B or as a superinfection in a patient with chronic hepatitis B, but hepatitis D does not cause hepatitis independently. In western cultures, it occurs most often in patients with a history of intravenous drug abuse, but healthcare workers and transfusion recipients are also at risk, as are other patients who have acquired acute or chronic active hepatitis B.

The virus of hepatitis C is an enveloped single-stranded RNA virus. Immunologic identification of infection with the hepatitis C virus (HCV) can be difficult. Antibodies against hepatitis C may not be present for long periods following initial infection. This has important public health implications because of the prevalence of asymptomatic carriers, approximately 0.5–1.0% of blood donors in the United States. Routine testing of donated blood for HCV and HIV by polymerase chain reaction (PCR) has reduced the incidence of transmission of hepatitis C and HIV to approximately 1:2,000,000 transfusions. PCR testing is not available for HBV, thus the incidence is much higher at 1:75,000. Testing for HBV does include HBsAg and HBcAb. Additional blood testing to meet current FDA and American Association of Blood Banks standards includes screening for syphilis, human T-cell leukemia, anti-HB_{core}, and HIV-Ab (human immunodeficiency virus antibody).

Much like hepatitis B, those patients at increased risk of hepatitis C include recipients of blood products, intravenous drug abusers, hemophiliacs, and healthcare workers following hollow needle sticks. Sexual transmission of hepatitis C may be possible.

Hepatitis C rarely causes fulminant hepatic failure; in fact subclinical, chronic, nonicteric infection is fairly common. Unfortunately, about half of the patients with acute hepatitis C infection will have evidence of ongoing hepatitis after 1 year. At least 20% of these patients will eventually develop cirrhosis. These patients are also at high-risk of developing hepatocellular cancer through several possible immunologic and genetic events.[46] There is no vaccine yet to prevent hepatitis C infection.

An RNA virus has been identified in the serum of blood donors and blood recipients that may be responsible for the remaining portion of cases of transfusion hepatitis. This virus has been classified as non-A, non-B, and non-C.[47] However, many of the patients who have received blood products containing this RNA virus did not develop clinical or laboratory signs of hepatocellular injury. In the few cases that have been followed for months to a few years, hepatitis G virus RNA has been present in the serum of some patients, suggesting the possibility of a persistent viral infection, but the target organ may not be the liver.[48] To add to the confusion on this issue, the so-called hepatitis G virus may be an agent that coexists with the hepatitis C virus.

Hepatitis can occur from systemic infections caused by other viruses such as the Epstein-Barr virus (infectious mononucleosis) and cytomegalovirus. These are important infections of immunocompromised patients.

Chronic Hepatitis

The histologic findings on needle biopsy of the liver will define several types of chronic hepatitis including, in order of severity, chronic persistent, chronic lobular, mild chronic active, and severe chronic active hepatitis. The extent of portal hepatitis, the degree of necrosis, and the presence of fibrosis all indicate increasing severity. Viral hepatitis, autoimmune hepatitis, and drug-induced hepatitis are the most common causes of chronic hepatitis. Of the viral diseases, hepatitis B and hepatitis C are the most important.

When all other causes of hepatitis have been eliminated, there remains a group of patients with cirrhosis with no identifiable etiology. These patients are given the diagnosis of cryptogenic cirrhosis, a diagnosis of exclusion, but one with the features of advanced cirrhosis.

The role of liver transplantation for the treatment of chronic hepatitis is discussed in Chap. 56.

Toxic Liver Disease

Alcoholic Liver Disease

The excessive daily consumption of alcohol can lead to alcoholic hepatitis, especially in individuals with a low-calorie and low-protein diet. Ingestion of 80 g of alcohol a day places the individual at risk for alcoholic hepatitis, a precirrhotic lesion. Chronic consumption of lower doses of alcohol may lead to fatty infiltration of the liver and, eventually, to cirrhosis of the liver.

Alcohol is metabolized by alcohol dehydrogenase to acetaldehyde. Acetaldehyde dehydrogenase is the rate-limiting step in eliminating acetaldehyde, but it can be overwhelmed when large amounts of alcohol are ingested. Acetaldehyde, when it cannot be rapidly eliminated, is toxic to a number of

cellular components and can lead to zone 3 hepatic necrosis. Alcohol can also be metabolized by the microsomal ethanol-oxidizing system, an alcohol-inducible P450 enzyme that also metabolizes acetaminophen.

The metabolism of acetaldehyde alters the reduced form of nicotinamide adenine dinucleotide (NADH):nicotinamide adenine dinucleotide (NAD) ratio in the cytoplasm of hepatocytes. This change in energy metabolism leads to fatty acid accumulation in zones 2 and 3 cells, an early feature of alcoholic hepatitis. Severe hepatitis secondary to alcohol ingestion alone is rare; however, a fatty liver and chronic alcoholic hepatitis will lead to cirrhosis. Advanced cirrhosis secondary to long-term alcohol abuse is irreversible and patients will demonstrate the cardinal features of portal hypertension secondary to obliteration of portal venules. In early stages, patients with alcoholic cirrhosis do well, as compared to other causes of cirrhosis, if they can abstain from alcohol and correct their nutritional deficiencies (primarily vitamins and protein) that are associated with alcohol abuse. However, the 5-year survival rate in patients with ascites, jaundice, and variceal bleeding and who are from higher socioeconomic backgrounds, is 50% overall, 40% with continued alcohol abuse, and 60% with abstinence. With patients in lower socioeconomic groups the chance of survival is lower, as low as 50% at 33 months. Chronic alcohol abuse of greater than 90 g per day for more than 5 years can lead to alcoholic cardiomyopathy in addition to cirrhosis of the liver. Alcohol abuse is the leading cause of nonischemic cardiomyopathy in the United States.[49] Cardiac performance may improve with abstinence from alcohol.

Many patients with alcoholic cirrhosis often have concomitant risk factors for coronary atherosclerosis, others may have cardiac valvular abnormalities requiring valve replacement. Cardiac surgery performed using cardiopulmonary bypass has a high mortality rate, especially in Child-Pugh class B and class C patients.[50]

Acetaminophen Toxicity

Suicide attempts are the most common cause of acetaminophen-induced hepatic necrosis and subsequent fulminant hepatic failure. The lethal adult dose of acetaminophen is approximately 10 g but this can be greatly reduced in patients with concomitant alcohol abuse or preexisting liver disease. Acetaminophen is metabolized by the P450 system in the macrosomes of hepatocytes to metabolites (*N*-acetyl-*p*-benzoquinone) binding to cellular macromolecules (Fig. 14–7). Glutathione normally binds to and clears the metabolites of acetaminophen and its depletion may lead to accumulation of toxic acetaminophen metabolites. Acetylcysteine can increase the production of glutathione and may prevent hepatic necrosis if given within the first few hours after acetaminophen ingestion.[51]

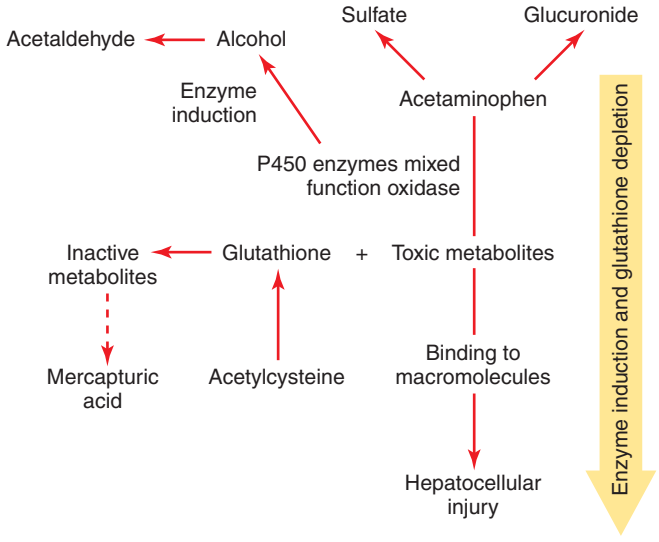

FIGURE 14–7. Mechanism of acetaminophen hepatotoxicity. Acetaminophen can be conjugated to a sulfate or a glucuronide prior to excretion. Alternatively, it can be oxidized to highly reactive compounds by P450 mixed function oxidases. Binding to glutathione inactivates these toxic compounds. When glutathione is depleted, the reactive metabolites bind to hepatocellular macromolecules and cause cell necrosis. P450 enzyme activity is induced by chronic alcohol ingestion. Increased P450 enzyme activity can deplete glutathione and enhance the toxic binding to macromolecules. Acetylcysteine can augment glutathione and prevent hepatic necrosis if given early after the ingestion of a lethal dose of acetaminophen. (Courtesy of Richard A. Wiklund, MD.)

Fulminant hepatic necrosis and acute liver failure can occur 2–3 days following an acetaminophen overdose. Plasma transaminases are markedly elevated during the first few days after ingestion. Coagulopathy can become severe when the international normalized ratio (INR) increases. Severe coagulopathy and encephalopathy are signs of a poor prognosis. The outcome of acetaminophen-induced hepatic necrosis can be predicted by measuring the plasma level of acetaminophen 4 hours after ingestion. Blood levels greater than 300 μg/mL predict that hepatic necrosis will occur. Blood levels less than 120 μg/mL usually do not result in hepatic necrosis. Acetylcysteine is most effective when given intravenously or orally within 24 hours after the ingestion of acetaminophen, but it may be effective even if given up to 72 hours after ingestion.

Halothane and Other Halogenated Anesthetics

Halothane was the first of the modern generation of nonflammable halogenated anesthetic agents that changed the practice of anesthesiology. Halothane, a halogenated alkane, was introduced in the late 1950s. It was followed by methoxyflurane, the first of the halogenated methyl-ethyl ethers, which now include enflurane, isoflurane, desflurane, and sevoflurane. A series of case reports describing fulminant hepatic necrosis following surgery led to a review of 850,000 halothane anesthetics and the famous report of the National Halothane Study.[52,53] After other causes of severe acute liver failure were ruled out, 7 cases were identified wherein exposure to halothane was the probable cause. The controversy about the continued use of halogenated anesthetics gradually faded with the subsequent introduction of isoflurane and the replacement of halothane. As much as

17–20% of an administered dose of halothane undergoes oxidative and reductive metabolism, mostly in the liver. Reactive metabolites bind to hepatocellular proteins as haptens to produce antigens that can rarely provoke an immune response evidenced by the appearance of immunoglobulins, an inflammatory response in the liver, eosinophilia and hepatic necrosis. The immunologic basis of halothane hepatitis has been challenged by other theories suggesting hepatic oxygen deprivation (decreased supply and increased demand) or direct toxicity of metabolites may be responsible. Massive hepatic necrosis was seen more often in patients with prior or frequent exposures to halothane. Few patients survived massive hepatic necrosis believed to be caused by halothane, which usually occurred before the era of liver transplantation.

Drug-Induced Liver Disease

Many other drugs are hepatotoxic; their toxicity mimics other liver diseases. Carbon tetrachloride, for one, causes zone 3 hepatocyte necrosis. Valproic acid causes fatty infiltration of the liver. Drugs such as NSAIDs, methyldopa, amiodarone, nifedipine, and isoniazid may mimic acute viral hepatitis and chronic active hepatitis. Methotrexate may cause hepatic fibrosis and portal hypertension. Antibiotics, tranquilizers, and sex hormones may cause cholestasis. Sex hormone therapy may also cause thrombosis of portal and hepatic veins. In most cases of drug-induced hepatic dysfunction, recovery occurs following withdrawal of the drug. Recovery may be prolonged with a drug like amiodarone because of its long half-life and the extremely long time required to eliminate metabolites. Furthermore, some drugs can become "locked" in the enterohepatic circulation by the intestinal reabsorption of their toxic metabolites.

Autoimmune and Inflammatory Liver Disease

Autoimmune hepatitis, primary biliary cirrhosis, and primary sclerosing cholangitis appear to result from autoimmune mechanisms.[54] At times they are difficult to distinguish from each other or from other inflammatory disease such as viral hepatitis. Patients with these autoimmune diseases often do well following liver transplantation.

Autoimmune Hepatitis

Autoimmune hepatitis is a disease characterized by autoantibodies against a variety of liver antigens, including mitochondrial and nuclear antigens. It is most common in young women.[55] Blood testing shows elevated γ-globulins and positive antinuclear antibodies. Early treatment with corticosteroids and antiinflammatory drugs can slow the progression of this disease and delay or prevent the need for liver transplantation.[56] Consequently, it is important to distinguish autoimmune hepatitis from other forms of hepatitis with similar histology on liver biopsy.

Patients with autoimmune hepatitis may develop cirrhosis and hepatocellular carcinoma if the autoimmune process is not controlled. Jaundice is not common in autoimmune hepatitis and patients often remain well nourished, making them good candidates for liver transplantation. Corticosteroids may produce a remission in the disease and often reduce plasma bilirubin, transaminases, and γ-globulin levels. Azathioprine therapy can be used to decrease the dose and side effects of corticosteroid therapy and may eliminate the need for corticosteroids once remission is achieved.[57]

Primary biliary cirrhosis (PBC) is an inflammatory disease of the intrahepatic bile ducts.[58] Ninety percent of patients are women, with onset occurring between the ages of 30 and 70 years. PBC is characterized by severe jaundice, disproportionate to the other features of liver disease and, thus, higher bilirubin levels are used for the Child-Pugh stratification. Human leukocyte antigens (HLAs) expressed in bile ducts appear to be a target for the lymphocytes. Other ductal glands (lacrimal glands, pancreas) are also targets in this disease. Patients with PBC have high serum cholesterol levels. They develop disabling cutaneous xanthomas of their hands and feet and severe pruritus. They may have other autoimmune diseases, such as rheumatoid arthritis, systemic lupus erythematosus, scleroderma (CREST [calcinosis cutis, Raynaud phenomenon, esophageal motility disorder, sclerodactyly, and telangiectasia] syndrome) and Sjögren syndrome. PBC can also cause interstitial lung disease with giant cell granulomas.

Serum bilirubin levels rise dramatically as the disease progresses and are predictive of the length of survival. Once serum bilirubin levels exceed 6 mg/dL, expected survival is less than 2 years.[59] However, these patients appear clinically healthier than patients with similar levels of jaundice secondary to alcoholic cirrhosis. PBC patients can do well after transplantation. It is unclear whether they are at risk of developing recurrent PBC in the transplanted liver.

Primary sclerosing cholangitis (PSC) is another inflammatory disease of the intra- and extrahepatic bile ducts of undetermined etiology affecting more men than women.[60] It may be difficult to distinguish in the early phases from primary biliary cirrhosis. Serum antimitochondrial antibodies are positive in primary biliary cirrhosis and negative in primary sclerosing cholangitis. This inflammatory disease will eventually obliterate the bile ducts and cause jaundice and eventually liver failure. Cholangiography reveals a characteristic beading and stenosis of the common bile duct. Ulcerative colitis is diagnosed in as many as 70% of patients with primary sclerosing cholangitis.[61] In addition, PSC patients are at increased risk of developing cholangiocarcinoma. The only successful treatment of primary sclerosing cholangitis is liver transplantation.

Infiltrative Liver Disease

Amyloidosis is often not a single-organ disease and its variants can involve single or multiple organs.[62] Each variant involves infiltration of a fibrillar, insoluble protein with a unique pleated structure.[63] The liver is involved in most forms of amyloidosis, but infiltration of the kidneys or heart may produce for most of the clinical symptoms. Treatment includes chemotherapy for primary amyloidosis and treatment of the underlying disease in secondary amyloidosis. The causes of death from the amyloidoses include sepsis from the underlying disease, renal failure, or cardiac failure, but not usually liver failure. In rare cases of slowly progressive primary amyloidosis (multiple myeloma), liver transplantation may be recommended for liver dysfunction.[64]

Malignant Liver Disease

Hepatocellular carcinoma (HCC) is rare in Western countries, but common in Asian and African countries. It can present as a discrete encapsulated

mass (most common in Asian countries), as an infiltrative disease, or as a multicentric disease (most common in the United States). Predisposing factors for HCC include chronic active viral hepatitis and hemochromatosis, although it may also be associated with other forms of cirrhosis. Hepatitis C is the leading risk factor for HCC in the Western world whereas hepatitis B is the leading risk factor in Asian and African patients. Other risk factors for HCC include long-standing heavy alcohol abuse, cigarette smoking, diabetes, and fatty liver.[65] The incidence of HCC in Asian and African countries correlates closely with dietary exposure to aflatoxin, a carcinogen produced by *Aspergillus flavus*, a mold that contaminates food in these continents.[66]

α-Fetoprotein is a biochemical marker for HCC. Serial plasma levels correlate with the growth of HCC, as well as with improvement following tumor mass resection. Ultrasonography, CT scanning, and MRI are helpful in diagnosing and localizing HCC tumors for diagnosis and biopsy, but their value is decreased in patients with cirrhosis characterized by large areas of fibronodular regeneration.

Hepatic resection for HCC in patients with intact synthetic liver function offers a 26% 5-year survival rate. Predictors of survival include excellent preoperative hepatocellular function, the presence or absence of multiple tumors, resection margins free of tumor, and the need for blood transfusion during surgery.[67] Liver transplantation as a therapy for limited HCC is now an established therapy (see Chap. 58).

Cholangiocarcinoma is a highly malignant disease that is rare in the Western world, but endemic in Asia and those regions where patients are at risk for parasitic infection with the liver fluke (*Clonorchis sinensis*).[68] It is also associated with primary sclerosing cholangitis (see Autoimmune and Inflammatory Liver Disease) and ulcerative colitis. Liver transplantation is contraindicated for patients with cholangiocarcinoma. Patients are often jaundiced and without other signs of liver failure. Diagnosis is established by ultrasonography and CT imaging, and by endoscopic retrograde cholangiopancreatography and biopsy. When the tumor involves the secondary branches of the left and right hepatic ducts it is not resectable, but palliation can be achieved with stenting of the bile ducts by an endoprosthesis.[69]

Vascular Diseases of the Liver

Hepatic vein thrombosis (Budd-Chiari syndrome) is usually secondary to another systemic disease, often a myeloproliferative disorder.[70] This syndrome can be acute or chronic and can be asymptomatic or lead to chronic liver failure. MRI or ultrasonography diagnoses thrombosis of the hepatic vein. Treatment options include anticoagulation in the absence of a coagulopathy, thrombectomy, thrombolysis, transjugular intrahepatic portosystemic shunting (TIPS), or liver transplantation.[71,72]

Portal vein thrombosis is most often a complication of orthotopic liver transplantation.

Physical Findings Suggestive of Advanced Cirrhosis

- Scleral icterus: mild scleral icterus is seen.
- Fetor hepaticus: none appreciable
- Asterixis: not evident on testing
- Neck vein distension: not appreciable
- Spider angiomata: angiomata seen on the extremities, thoracic and abdominal walls
- Caput medusa: some increased venous distension on the abdominal wall
- Abdominal distension with demonstrable fluid wave: present
- Palpable liver with appreciable nodular hyperplasia: not appreciated
- Splenomegaly: moderate splenomegaly

LIVER FAILURE

Acute Liver Failure

Acute liver failure or fulminant hepatic failure (FHF) is a catastrophic illness resulting from many of the liver diseases described in this chapter; it develops within 2 weeks of the onset of disease and carries a poor prognosis without transplantation. It occurs so rapidly that patients may not have developed jaundice. Subfulminant hepatic failure, with onset occurring up to 8 weeks after the onset of jaundice, has a better prognosis with some chance of complete recovery. Transaminase levels rise rapidly with FHF but they may fall to normal levels after massive necrosis occurs. Coagulopathy can become progressively more severe.

The common features of fulminant hepatic failure include a severe coagulopathy, metabolic acidosis, hypoglycemia, rapidly progressive encephalopathy, and acute renal failure.[73] Encephalopathy with severe cerebral edema is the usual cause of death, which may occur while the patient awaits a donor liver (Table 14–9).

The most common cause of FHF is acute viral hepatitis (A, B, others). FHF in patients with hepatitis B can be precipitated by suprainfection with hepatitis D. Immunocompromised patients are at high-risk for FHF with acute viral hepatitis, including hepatitis A, B, herpes simplex, Cytomegalovirus, Epstein-Barr, and varicella.[74]

There is another cause of FHF that needs to be considered in surgical patients. Alterations of total hepatic blood flow during anesthesia and surgery may precipitate FHF in patients with stable, underlying chronic liver disease. In these patients, acute liver failure is usually noticed on the second or third postoperative day and can be manifested by an unexplained encephalopathy. These patients have adequate hepatocellular function preoperatively but with very little reserve to combat acute stress associated with anesthesia and surgery. Small decreases in hepatic oxygen supply associated with decreased total hepatic blood flow during surgery cause acute hepatocellular ischemic injury and failure.

The encephalopathy of FHF is different than that noted with chronic liver failure and the blood ammonia levels are much higher. In addition, amino acids, which can contribute to the encephalopathy, accumulate in the central nervous system and are excreted in the urine as tyrosine and leucine crystals, FHF with grade 3 or worse encephalopathy is associated with an 80% mortality rate. In contrast, two thirds of patients survive if encephalopathy does not proceed beyond grade 2.[75] The principal causes of death are cerebral edema, hemorrhage secondary to a severe coagulopathy, and sepsis syndrome secondary to pneumonia.

Metabolic derangements seen in FHF may include severe hypoglycemia, hyperinsulinemia, hyponatremia,

TABLE 14–9.

Grading of Hepatic Encephalopathy

Grade	Consciousness	Cognition	Signs	Electroencephalogram (EEG)
0	Normal	Normal	None	Normal
Subclincal	Normal	Normal	Abnormal on psychometric testing	Normal
1	Restless; abnormal sleep pattern	Forgetful, confused, agitated	Tremor, ataxia, uncoordinated, impaired handwriting	Abnormal
2	Lethargic	Disoriented at times; uninhibited, inappropriate behavior	Asterixis, dysarthria, ataxia, hyporeflexia	Abnormal
3	Somnolent but rousable, confused	Disoriented, aggressive	Asterixis, hyperreflexia, Babinski sign, muscle rigidity	Abnormal
4	Coma	None	Decerebration	Abnormal

Modified with permission from Riordan SM, Williams R. Treatment of hepatic encephalopathy. N Engl J Med 1997;337:473. Copyright 1997, Massachusetts Medical Society. All rights reserved.

hypokalemia, and lactic acidosis. Respiratory alkalosis may be caused by hyperventilation. Acute renal failure (hepatorenal syndrome) is seen in as many as 55% of patients with FHF. Acute respiratory failure may be caused by aspiration pneumonitis or form part of the multi-organ failure associated with sepsis.

Survival is frequent with transplantation but many patients die while awaiting the availability of a donor organ.

Chronic Liver Failure

Chronic liver failure eventually can impair most of the organ systems in the body. Many of the manifestations are caused by the hepatic fibrosis that follows hepatocellular injury. Portal fibrosis produces compression of the portal venules, capillaries, biliary canaliculi and obliteration of hepatocytes. The result is portal hypertension, obstructive jaundice, coagulopathy, encephalopathy and metabolic abnormalities. If the underlying cause of fibrosis is treated effectively, fibrosis of the liver may be reversible.[76] In the early stages of chronic liver failure (Child-Pugh class A), ascites is controlled with diuretic therapy. In later stages, ascites is uncontrolled and patients develop the protuberant abdomen with a fluid wave on physical examination that is typical of advanced cirrhosis. Portal hypertension leads to abnormal renal function with marked sodium reabsorption in response to a decreased effective circulating plasma volume. Volume receptor stimulation increases renin secretion and aldosterone production. Urinary excretion of sodium is limited and total body sodium is greatly increased, yet the patients show mild hyponatremia. This forms the basis for therapy with loop diuretics, such as furosemide, and aldosterone antagonists, such as spironolactone. Renal blood flow and glomerular filtration rate can be decreased in chronic liver failure because of the increased intraabdominal pressure caused by ascites, diuretic therapy, and other hemodynamic abnormalities.

Ascites is associated with spontaneous bacterial peritonitis (SBP), another life-threatening complication of chronic liver failure. An aerobic gram-negative organism is the usual cause of the peritonitis. It may be truly spontaneous and caused by incidental bacteremia but often follows paracentesis to reduce the volume of ascites. The 30-day mortality rate for SBP is approximately 32%; 1-year mortality 78%.[77] Survivors are at high risk of recurrence.

Portal hypertension can lead to the development of collateral circulation with large veins in the abdominal and chest walls, the mediastinum, stomach, and esophagus. In extreme cases these venous collaterals can anastomose with pulmonary vessels, leading to portopulmonary shunting. This can produce a high-blood volume, high-blood flow state with intrapulmonary shunts, the so-called hepatopulmonary syndrome (HPS). The collateral circulation that occurs with portal hypertension can produce esophageal, gastric, and intestinal varices that are prone to rupture and bleeding.

Obstructive jaundice is a late finding in most forms of cirrhosis and indicates a poor prognosis. Severe jaundice predicts death within a few years. Severe jaundice is usually accompanied by poor synthetic function with coagulopathy, progressive encephalopathy, and severe malnutrition.

There are two causes of the coagulopathy associated with chronic liver disease. The first is decreased production of coagulation factors produced in the liver (all except factor VIII); the second

Laboratory Testing Used to Stratify Hepatocellular Function

- Emphasized findings are elements of the Child-Pugh classification of liver disease (Table 14–5).
- CBC: hemoglobin = 10.2g/dL ; hematocrit = 32%; white blood count = 9500 cells/mm^3
- Blood urea nitrogen = 22 mg/dL; serum creatinine = 1.5 mg/dL
- Serum sodium = 132 mEq/dL; chloride = 90 mEq/dL; bicarbonate = 28 mEq/dL; potassium = 3.1 mEq/dL
  INR = 1.4; partial thromboplastin time = 28 seconds
- **Serum bilirubin** = 4.0 mg/dL; **albumin** = 3.0 g/dL (consider measuring fibrinogen level and factor VII activity)
- Aminotransferases: AST = 200 IU/L; ALT = 300IU/L (aminotransferases are nonspecific; see Fig. 14–3)

is the hypersplenism resulting from portal hypertension. Measuring the INR, plasma fibrinogen level, or direct measurement of coagulation factor activity readily assesses coagulopathy secondary to impaired synthetic function. Hypersplenism with sequestration of platelets is common in advanced liver disease, and results in platelet concentration equal to or less than 70,000/mm^3. Bleeding from thrombocytopenia is uncommon unless it is complicated by other causes of thrombocytopenia, such as active bleeding with either a consumption coagulopathy or a dilutional coagulopathy.

Metabolic abnormalities include hypoglycemia, hyperinsulinemia, aminoacidemia and aminoaciduria, respiratory alkalosis, lactic acidosis, hyponatremia, and hypokalemia. If patients require rapid multiple transfusions, hypocalcemia secondary to citrate toxicity may become a problem.

Encephalopathy in chronic liver failure is associated with elevation of the plasma ammonia level. However, encephalopathy and neurological manifestations of chronic liver disease are much more complex than simple ammonia intoxication. Ammonia is only one of the many potentially neurotoxic compounds that are produced in the intestines and reach the brain by virtue of the collateral porto-systemic shunting of chronic liver disease. Other compounds that contribute to encephalopathy include octopamine and the aromatic amino acids, tyrosine, phenylalanine, and tryptophan. Normally, the liver extracts all of these compounds from portal vein blood. Central nervous system γ-aminobutyric acid (GABA), an inhibitory neurotransmitter, is also increased in chronic liver disease, as are GABA and benzodiazepine receptors in the brain.[78]

There are other causes of abnormal neurologic findings in chronic liver disease. There can be generalized cortical atrophy and the increased presence of astrocytes often associated with Alzheimer disease. The electroencephalogram (EEG) shows generalized slowing. Vitamin deficiencies can lead to Wernicke encephalopathy (inadequate thiamine and B_1), which also contributes to the neurologic findings of chronic liver disease. Portal-systemic encephalopathy is characterized by depressed consciousness, personality changes, slurred speech, apraxia, and a flapping tremor. Severity is graded from minimal confusion through coma (Table 14–9).[79] Grade 4 coma is usually a terminal event.

The circulation in chronic liver disease is hyperdynamic and characterized by a markedly increased cardiac index, a low systemic vascular resistance, mild tachycardia, a normal to increased stroke volume, a high mixed venous oxygen saturation, and a poor oxygen extraction ratio. Patients with a normal cardiac index at cardiac catheterization should be considered to have a cardiomyopathy and the differential diagnosis should include ischemic cardiomyopathy, alcoholic cardiomyopathy, and cardiomyopathy secondary to hemochromatosis. Systemic precapillary arteriovenous shunting can cause the hemodynamic changes seen in chronic liver disease. Circulating blood volume is reduced and extracellular fluid volume is often markedly increased.

Coronary artery disease in patients with advanced liver disease may require coronary revascularization. Patients who are Child-Pugh class A may tolerate coronary artery bypass grafting (CABG) with cardiopulmonary bypass without an increased mortality, but patients who are class B or C have an elevated risk of death.[80] Combined CABG and orthotopic liver transplantation has been performed, but there are insufficient data to support this as a standard approach.[81]

Two pulmonary syndromes are noted in patients with advanced liver disease. The first is the HPS; the second is portopulmonary hypertension (PPH).[82] HPS, as described above, is characterized by pulmonary precapillary and capillary vasodilatation and direct pulmonary arteriovenous communications. This syndrome is associated with 3-fold elevation of exhaled nitric oxide as compared to control subjects.[83] The patients are short of breath, cyanotic, and display systemic arterial hypoxemia. Dyspnea with tachypnea and oxygen desaturation is worsened in the upright position, a syndrome described as platypnea and orthodeoxia.[84] This is a high-volume/low-pressure pulmonary blood state with normal right ventricular function and a low pulmonary vascular resistance.[85] PPH, on the other hand, is a high-pressure state similar to primary pulmonary hypertension. The right ventricle is often dilated, cyanosis is absent, right ventricular ejection fraction is low, and systemic hypoxia is rare. These patients may acutely respond to inhaled nitric oxide. Patients with HPS fare better after liver transplantation than do those with PPH.[86]

Hepatorenal syndrome is a form of renal failure associated with liver disease. It is more common in acute liver failure but also occurs in patients with chronic liver failure. Hepatorenal syndrome is the result of intense renal arteriolar vasoconstriction in response to the functional hypovolemia caused by splanchnic vasodilatation and other physical changes of liver failure.[87] Type 1 hepatorenal syndrome typically evolves over less than 1 week and is an indication for urgent liver transplantation.[87] Type 2 hepatorenal syndrome develops over a period of months and is less of an emergency. Standard treatment of hepatorenal syndrome includes intravascular volume expansion with administration of albumin, and the reduction of intraabdominal pressure by relieving tense ascites. The prognosis of the hepatorenal syndrome is poor. The administration of a vasopressin analogue, terlipressin, may improve renal function by its action as a splanchnic vasoconstrictor.[88] Portal venous pressure reduction by TIPS has been used for hepatorenal syndrome but it is not recommended on the basis of controlled clinical trials.[89]

APPROACH TO MANAGEMENT

Correction of Coagulopathy

Fresh-frozen plasma infusion and/or cryoprecipitate administration greatly improve the coagulopathy of either acute or chronic liver failure.[90] Recombinant factor VII may also improve the coagulopathy.[91,92] Therapy should be guided by measurement of the INR, plasma fibrinogen levels, and specific coagulation factor analysis when available. Patients may require infusion of large volumes of fresh-frozen plasma, which can itself contribute to circulatory overload. If there is evidence of a consumption coagulopathy, aprotinin or ε-aminocaproic acid can be administered. It is important to avoid the inadvertent administration of small doses of heparin via monitoring lines to patients with a coagulopathy secondary to liver disease. Platelet transfusion is not indicated unless the platelet count is less than 70,000/mm^3. Plate-

Stratification of the Patient's Liver Disease Using the Child-Pugh Criteria (Table 14–5)

- Ascites: poorly controlled on diuretics = 3 points
- Nutrition: mild malnutrition = 2 points
- Encephalopathy: well controlled on diet and lactulose = 1 point
- INR; moderately prolonged = 2 points
- Albumin: hypoalbuminemic = 2 points
- Bilirubin: moderately elevated = 2 points
- Total = 12 points, Child-Pugh class C, high risk for surgery especially in view of patient's sepsis

lets can be sequestered in the spleen when the patient has hypersplenism.

The coagulopathy can be monitored by the use of the thrombelastogram (TEG).[93,94] Coagulopathy (Fig. 14–8) is manifested on the TEG by a delayed onset of coagulation (prolonged R time), decreased or flattened slope (A), and a decreased maximum amplitude (MA). A useful technique to rule out inadvertent heparin administration is to perform a dual assay using heparinase in 1 cuvette of the TEG assay. A normal tracing in the presence of heparinase and an abnormal tracing without suggests a significant heparin anticoagulant effect.

Varices and Variceal Hemorrhage

Endoscopic band ligation therapy is the mainstay of treatment to reduce esophageal varices and prevent variceal hemorrhage.[95] Treatment with nonspecific β-adrenergic blockers, particularly propranolol and nadolol,[96,97] may decrease the size of esophageal varices. However, these agents do not reduce the portal hypertension, which caused the development of the varices.

Portal decompression can be accomplished surgically (portocaval shunt, mesocaval shunt, splenorenal shunt) or by means of a transjugular intrahepatic portal vein-to-hepatic vein shunt.[98] TIPS has a high complication rate and a mortality rate that is similar to that reported by centers with extensive experience in surgical shunting.[99] Preexisting encephalopathy may preclude any form of portal shunting because of the decrease in ammonia extraction that follows the decrease in portal vein blood flow to the liver.[100]

Octreotide is a somatostatin analogue[101] that has been used for control of nonvariceal upper and lower gastrointestinal bleeding secondary to portal hypertension.[102] It is administered as a continuous infusion and produces vasoconstriction of the portal circulation vessels.

Ascites

Ascites is the accumulation of an extracellular colloidal fluid in the abdominal cavity as a result of longstanding portal hypertension. It is a consistent finding in patients with cirrhosis, and it is a poor prognostic finding as only 50% of patients with ascites will survive for 2 years.[103] The diagnosis of ascites can be made by ultrasonography when it is not apparent on physical examination. Ascites can be controlled by restriction of sodium intake in the diet, by the administration of diuretics, or by abdominal paracentesis. Dietary sodium restriction is often difficult to maintain because of noncompliance. Diuretic therapy includes the use of furosemide and spironolactone or amiloride. Optimal diuretic therapy requires several weeks during which time the balance of sodium intake versus renal excretion of sodium is monitored. Potassium balance is achieved with the use of potassium-wasting diuretics (furosemide) and potassium-sparing diuretics (spironolactone or amiloride). If diuretic therapy is ineffective, invasive procedures may be necessary to relieve tense abdominal swelling. These procedures include large volumes of fluid removal by paracentesis, peritoneovenous shunting (LeVeen shunt), or TIPS. Large-volume paracentesis leads to progressive wasting of protein but not usually to hemodynamic instability. Slow removal of ascites by paracentesis can relieve the symptoms of massive ascites and improve quality of life for these patients.[103]

Currently, peritoneovenous shunting is performed infrequently because of the risks associated with the procedure and the lack of advantages over paracentesis and TIPS.[104] The risks include hepatic failure secondary to a major surgical procedure in patients with marginal hepatocellular function, the risk of bacterial contamination with subsequent peritonitis, and the risk of a postoperative ascites leak. The procedure can be complicated by thrombosis followed by nonfunction of the shunt. Fluid overload is another consideration in patients who may have a concomitant cardiomyopathy.

Control of Encephalopathy

Encephalopathy is present in the majority of patients with cirrhosis, although at times it may only be demonstrated by psychometric testing.[105] Because encephalopathy can progress rapidly from subclinical findings to overt coma, it should be anticipated in any patient with cirrhosis undergoing surgery. Encephalopathy is graded according to the level of consciousness, personality and intellectual features, neurologic signs, and electroencephalographic findings (Table 14–6 "Preop-

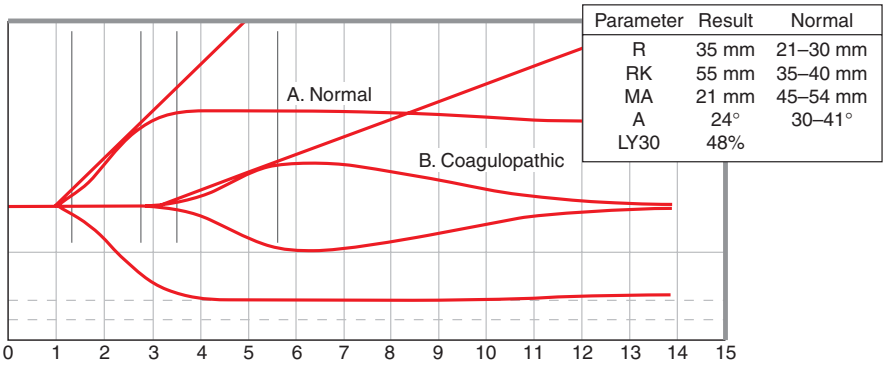

FIGURE 14–8. Thrombelastogram. **A:** Normal onset of coagulation, normal platelet function, no significant fibrinolysis. **B:** Delayed onset of coagulation (prolonged R value and diminished angle A), evidence of decreased platelet function (diminished maximum amplitude or MA), and early onset of marked fibrinolysis (decreased amplitude at 30 minutes [LY30]). (Courtesy of Richard A. Wiklund, MD.)

erative Values").[79] Standard therapy for the cerebral edema contributing to grade 3 and grade 4 encephalopathy includes endotracheal intubation, moderate hyperventilation, and monitoring and control of intracranial pressure (ICP). ICP monitoring involves substantial risk of intracranial hemorrhage in coagulopathic patients. Control of ICP may prevent seizures, which lead to elevated ICP.

Encephalopathy can be improved in the short-term by limiting protein in the diet. Obviously this counters the objective of improving protein nutrition in chronic liver disease, but limitation of protein in the diet will decrease the amount of nitrogenous waste and ammonia produced in the bowel. Ammonia is an uncharged molecule that readily passes into the blood from the gut. It can be converted to ammonium ion in the presence of excess hydrogen ions; ammonium ion does not cross the gut mucosa. Conversion of ammonia to ammonium ion can be achieved by the oral administration of lactulose, an enzyme that increases the acid content of the colon.[106] Acidification of the stool traps ammonia as ammonium ion in the gut contents. Neomycin can reduce the number of bacteria producing ammonia from protein.

If encephalopathy is life-threatening, charcoal hemoperfusion can be used to eliminate the responsible metabolites from the blood. So can exchange transfusion and extracorporeal organ perfusion.[107,108] However, these are experimental therapies used as a strategy that may worsen the coagulopathy and are only a bridge to transplantation.

SUMMARY

The liver is a complex organ that serves multiple functions, including protein synthesis, carbohydrate and lipid metabolism, excretion of waste products, drug metabolism, and phagocytosis. Recognizing that each of these vital functions can be impaired with liver disease leads to an understanding of the primary features of liver failure, namely ascites, jaundice, coagulopathy, encephalopathy, altered metabolism, and abnormal fluid balance. Cirrhosis is the final common histologic manifestation of most forms of liver disease.

In the preadmission anesthesia assessment clinic, the severity of liver disease and the risk of surgery can be estimated using the Child-Pugh scoring system, substituting the INR for the prothrombin time. It includes three clinical and three laboratory assessments. The clinical features are the degree of malnutrition, the control of ascites, and the history of encephalopathy; laboratory assessments are determination of the INR, and plasma albumin and bilirubin levels. Each of these 6 parameters can be assessed as normal or near normal (class A), moderately abnormal or fairly well controlled (class B), and markedly abnormal or poorly controlled (class C). The surgical mortality rate, particularly for intraabdominal and other major surgery, is near 10% for patients assessed to be class A, up to 30% for class B, and up to 70% for class C.

Preoperative preparation includes correction of coagulopathy by the administration of fresh-frozen plasma or cryoprecipitate, control of ascites with diuretic therapy or paracentesis, and correction of encephalopathy by limiting protein intake and the administration of lactulose. Transfusion of packed red blood cells may be necessary to correct blood loss from bleeding esophageal varices. Preoperative platelet transfusion is usually unnecessary unless the platelet count is less than 70,000/mm^3. Prevention of sepsis by minimizing invasive procedures and use of strict sterile technique for the insertion of lines and surgery is extremely important. These steps may reduce the risk of complications or death for surgical patients with acute or chronic liver disease.

Acute liver failure should be anticipated in the postoperative period in patients presenting with marginal liver function, especially following intraabdominal procedures, because of the effects of surgery and anesthesia to decrease total hepatic blood flow.

Hepatitis B and C viruses are highly infective following exposure. Immunization against hepatitis B virus is critically important for all healthcare workers, especially anesthesiologists and certified registered nurse anesthetists, because it is effective and safe. Hepatitis B can be a fulminant illness with high mortality. Immunization against hepatitis C virus is not available. Exposure caused by accidental hollow-needle sticks can cause acute hepatitis C infection, which has a high risk of evolving into chronic active hepatitis, cirrhosis, and hepatocellular carcinoma. Most hospitals offer the options for prophylaxis against viral infection following inadvertent needle stick. These include the administration of hyperimmune γ-globulin for prophylaxis against transmission of hepatitis C. Universal precautions are effective in controlling the risk of transmission of hepatitis B and C.

With current testing standards in the United States, viral infection following the administration of blood products is rare, approximately 1:75,000 to 1:2,000,000 transfusions.

CHAPTER 15

Anesthetic Considerations for the Patient with Anemia or Coagulation Disorders

Edwin G. Avery, IV, MD

ANEMIA

Anemia is a common blood disorder of perioperative patients.[1,2] The physiologic consequence of severe anemia to the surgical patient is inadequate delivery of oxygen that may lead to tissue hypoxia, biochemical imbalance, organ dysfunction and ultimately organ damage.[3,4] Mismanagement of the anemic surgical patient can adversely affect perioperative morbidity and mortality.[5–7] To provide optimal care for anemic surgical patients, the anesthesiologist should understand the laboratory techniques used to assess anemia, as well as the various etiologies and classifications of anemia.

Anemia Defined and Measured

Anemia is defined as a reduction of the body's total red cell mass (RCM). Both hematocrit (Hct) level and hemoglobin (Hgb) concentration measurements reflect the RCM present in the body but do not define it. The Hct level, defined as the fractional volume of sampled blood that erythrocytes occupy, is an indirect measurement of the body's RCM. The Hct is a simple, inexpensive, commonly used test to indirectly assess the severity of anemia as well as whole-blood viscosity, oxygen-carrying capacity, and RCM.[8] Hgb, the predominant component of a red blood cell, serves as the major carrier to transport oxygen within the blood.[9] Hgb concentration is a directly measured value that is also used to indirectly assess RCM.[10]

RCM is most accurately measured using isotopic dilution assays of erythrocytes and albumin that take into account the total volume of red cells and plasma present in any patient. In everyday clinical practice, Hct level and Hgb concentration are simple assays that are used to estimate RCM because of the impractical nature of using the more costly and complex isotope labeled assays.[9,11]

Although measurement of Hgb and Hct values generally provide reliable estimates of a patient's RCM, they inaccurately reflect the total circulating erythrocyte mass under certain conditions.[12,13] The importance of considering the measured Hct and Hgb values in the context of overall plasma volume cannot be over emphasized. Hgb and Hct values are influenced by dynamic changes of the plasma volume and thus are subject to error under certain physiologic conditions. Examples of the Hgb or Hct value misrepresenting the RCM are clinical scenarios involving major, acute blood loss. In this situation, the concurrently obtained circulating Hgb and Hct values will overestimate the RCM because the body has not had sufficient time to redistribute fluid from the interstitial space into the intravascular compartment. The Hct and Hgb values will spuriously indicate an increased RCM. A second example of a failure of the Hct and Hgb values to adequately reflect RCM occurs in the physiologic anemia of pregnancy. During normal pregnancy, both the RCM and the plasma volume expand. The plasma volume increases more rapidly and to a greater extent than the RCM and creates an apparent anemia termed the physiologic anemia of pregnancy.[13] Beginning in the first trimester of pregnancy, the reduced Hct value does not represent a decrease in RCM. A third pertinent example of Hct and Hgb values misrepresenting the RCM is in the clinical setting of dehydration. In the dehydrated patient an apparently normal or elevated Hct or Hgb value leads the clinician to overestimate the patient's RCM.[8,9]

Thus, there are two necessary considerations when attempting to correctly identify anemia in an individual patient. First, the laboratory values of HgbAHgb and/or Hct must be compared to a standard set of age- and sex-

KEY POINTS

1. Anemia is common in surgical patients.
2. Hemoglobin (Hgb) concentration and hematocrit (Hct) level are appropriate tests to rapidly assess the severity of anemia.
3. Treatment of anemia should be based on the physiology and etiology of anemia. Maintenance and restoration of normovolemia and cardiac output are necessary but insufficient aims in treating anemia.
4. Tachycardia and hypotension are important clinical signs of hypovolemia and anemia, but compensatory increases in heart rate and cardiac output may be impeded by insufficient cardiac reserve or anesthetic-induced sympathectomy.
5. Consideration of the physiologic signs and laboratory evidence of inadequate tissue oxygen delivery is mandatory before making a decision to transfuse red blood cells (RBCs).
6. Because evidence-based outcomes supporting a specific transfusion trigger level of Hgb or Hct are lacking for perioperative patients, further clinical investigation is needed.
7. Alternatives to transfusion of allogeneic RBCs are available and are appropriate to integrate into a blood-conservation strategy in selected surgical patients.
8. Given the broad range of congenital and acquired disease states as well as the multiple pharmacotherapies that can result in a hypocoagulable state, serious attention to these pathologies are needed by anesthesiologists in order to avoid the adverse effects of transfusions, excessive perioperative bleeding and the depletion of community blood bank resources.
9. The perioperative management of hypercoagulable disorders is also a responsibility of the anesthesiologist in that many of these patients require perioperative management of their anticoagulant regimens.
10. Hematology consultation is indicated for the perioperative management of many of the hypocoagulable and hypercoagulable disorders so as to avoid exposing the patient to unnecessary perioperative morbidity and mortality.

TABLE 15–1.

Normal Red Blood Cell Values

	Hemoglobin (g/dL)		Hematocrit (%)		Red Cell Count (10^{12}/L)		MCV (fL)		MCH (pg)		MCHC (g/dL)	
Age	Mean	−2 SD	Mean	−2 SD	Mean	−2 SD	Mean	−2 SD	Mean	−2 SD	Mean	−2 SD
Birth (cord blood)	16.5	13.5	51	42	4.7	3.9	108	98	34	31	33	30
1–3 days (capillary)	18.5	14.5	56	45	5.2	4.0	108	95	34	31	33	29
1 week	17.5	13.5	54	42	3.1	3.9	107	88	34	28	33	28
2 weeks	16.5	12.5	51	39	4.9	3.6	105	86	34	28	33	28
1 month	14.0	10.0	43	31	4.2	3.0	104	85	34	28	33	29
2 months	11.5	9.0	35	28	3.8	2.7	96	77	30	26	33	29
3–6 months	11.5	9.5	35	29	3.8	3.1	91	74	30	25	33	30
0.5–2 years	12.0	11.0	36	33	4.5	3.7	78	70	27	23	33	30
2–6 years	12.5	11.5	37	34	4.6	3.9	81	75	27	24	34	31
6–12 years	13.5	11.5	40	35	4.6	4.0	86	77	29	25	34	31
12–18 years												
Female	14.0	12.0	41	36	4.6	4.1	90	78	30	25	34	31
Male	14.5	13.0	43	37	4.8	4.5	88	78	30	25	34	31
18–49 years												
Female	14.0	12.0	41	36	4.6	4.0	90	80	30	26	34	31
Male	15.5	13.5	47	41	5.2	4.5	90	80	30	26	34	31

normalized reference values (Table 15–1).[10,14] Second, the patient's overall plasma volume status must be assessed to determine if the patient is significantly plasma volume contracted or expanded.

Prevalence of Anemia in Surgical Patients

The prevalence of anemia in various surgical populations has been reported to range from 5–75%, depending on both the underlying clinical status and the severity of disease.[1,2] As one might expect, the prevalence of anemia decreases with more stringent criteria. Anemia may be produced or exacerbated by the surgical procedure and postoperative care.[15–17]

Red Blood Cell Maturation

Normal red blood cells (RBCs) mature by proliferation and differentiation of precursor stem cells in the bone marrow in a process termed *erythropoiesis*.[18] A mature RBC will circulate for a period of approximately 100–120 days, after which time it will be removed from the circulation by the body's reticuloendothelial system. The body replenishes the total RCM with the goal of achieving a constant steady state, depending on the rate at which RBCs are being produced and removed or lost. The kidney plays a vital role in this process by producing the hormone erythropoietin. This process is upregulated when the kidney senses a decrease in receipt of oxygen because of a contracted RCM (Fig. 15–1). Optimal erythropoiesis can only occur when the body possesses sufficient substrate (e.g., folate, iron, vitamin B_{12} and other nutrients) to produce new erythrocytes.[10]

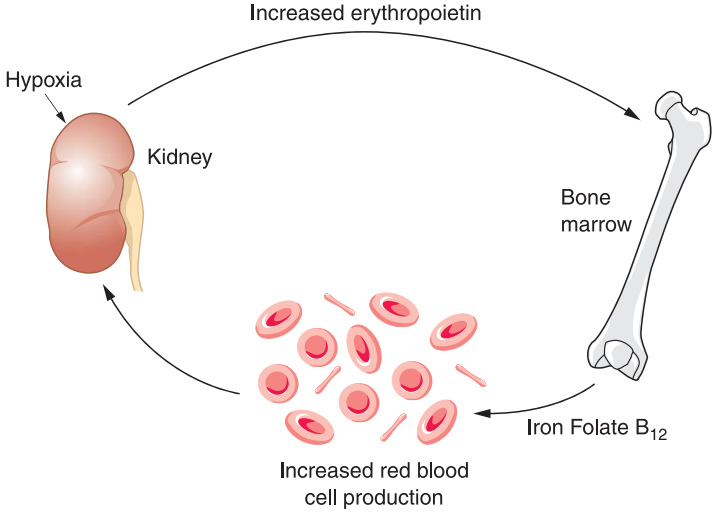

FIGURE 15–1. Regulation of erythropoiesis. Reproduced with permission from Felgar RE and Ryan DH.[10]

TABLE 15–2.

Usefulness of the Reticulocyte Count in the Diagnosis of Anemia

Diagnosis	Value
Hypoproliferative anemias	Corrected reticulocyte <2% or absolute reticulocyte count <100,000 μL
Anemia of chronic disease	
Anemia of renal disease	
Congenital dyserythropoietic anemias	
Effects of drugs or toxins	
Endocrine anemias	
Iron deficiency	
Marrow replacement	
Maturation abnormalities	
Vitamin B_{12} deficiency	
Folate deficiency	
Sideroblastic anemia	
Appropriate response to blood loss or nutritional supplementation	Corrected reticulocyte ≥2% or absolute reticulocyte count >100,000 μL
Hemolytic anemias	
Hemoglobinopathies	
Immune hemolytic anemias	
Infectious causes of hemolysis	
Membrane abnormalities	
Metabolic abnormalities	
Mechanical hemolysis

Classifications of Anemia

Anemias can be divided into 3 classes: hemorrhage-related, hypoproliferative, and hyperproliferative anemias. Anemias are either primary or secondary. Secondary anemias result from a separate disease process that precipitates the decreased RCM. Many RBC-related laboratory parameters may help determine the etiology of an anemia, including the reticulocyte count, mean corpuscular volume, and RBC distribution width. Examination of the peripheral smear using light microscopy can also aid in determining etiology. This section provides an introduction to various RBC parameters enabling classification of anemia, not a comprehensive review of all of the known anemia diagnoses and their associated RBC parameter findings. The association of these parameters with the various classes of anemia is summarized in tabular form (Tables 15–2, 15–3, and 15–4).[10]

Hemorrhage-Related Anemia

Anemias related to acute or chronic loss of RCM are frequently encountered by the anesthesiologist.[2] The anesthetic implications for the various classes of anemias are discussed in The Decision to Transfuse Red Blood Cells below.

Hypoproliferative Anemia

Hypoproliferative anemias are common in surgical patients and are attributed to impaired RBC production. These anemias result from the body's inability to synthesize an adequate number of erythrocytes in response to a physiologic stimulus (e.g., increased plasma erythropoietin levels). Hypoproliferative anemias are commonly caused by acquired nutritional deficiencies (e.g., iron-deficiency anemia) and/or systemic disease (e.g., anemia of chronic disease). A corrected reticulocyte count of less than 2% (or an absolute reticulocyte count of less than 100,000/μL) is frequently found in patients with hypoproliferative anemias (Table 15–2).[10]

Hyperproliferative Anemia

Hyperproliferative anemias are commonly termed *hemolytic anemias*. These anemias occur as a consequence of the premature destruction of RBCs and may be attributable to a host of disorders, either congenital or acquired, such as sickle cell anemia, β-thalassemia major, glucose-6-phosphate dehydrogenase deficiency, autoimmune hemolytic anemia, and microangiopathic hemolytic anemia. Sickle cell anemia is an exam-

TABLE 15–3.

Usefulness of the Mean Corpuscular Value (MCV) and Red Blood Cell Distribution Width (RDW) in the Diagnosis of Anemia

	Low MCV (<80 fL)	Normal MCV (80–99 fL)	High MCV (>100 fL)
Normal RDW	Anemia of chronic disease	Acute blood loss	Aplastic anemia
	α- or β-Thalassemia trait	Anemia of chronic disease	Chronic liver disease
	Hemoglobin E trait	Anemia of renal disease	Chemotherapy/antivirals/alcohol
Elevated RDW	Iron deficiency	Early iron, folate or vitamin B_{12} deficiency	Folate of vitamin B_{12} deficiency
	Sickle cell, β-thalassemia	Dimorphic anemia (e.g., iron + folate deficiency)	Immune hemolytic anemia
		Sickle cell anemia	Cytotoxic chemotherapy
		Sickle cell disease	Chronic liver disease
		Chronic liver disease	Myelodysplasia
		Myelodysplasia	

Reproduced with permission from Felgar RE and Ryan DH.[10]

TABLE 15–4.

Combining the Reticulocyte Count and Red Blood Cell Parameters for Diagnosis

	Corrected Reticulocyte Count <2%	Corrected Reticulocyte Count ≥2%
Low MCV, normal RDW	Anemia of chronic disease	
Normal MCV, normal RDW	Anemia of chronic disease	
High MCV, normal RDW	Chemotherapy/antivirals/alcohol Aplastic anemia	Chronic liver disease
Low MCV, high RDW	Iron-deficiency anemia	Sickle-cell, β-thalassemia
Normal MCV, high RDW	Early iron, folate, vitamin B_{12} deficiency Myelodysplasia	Sickle cell anemia, sickle cell disease
High MCV, high RDW	Folate or vitamin B_{12} deficiency Myelodysplasia	Immune hemolytic anemia Chronic liver disease

MCV, mean corpuscular volume; RDW, red blood cell distribution width.

ple of a hemoglobinopathy that has important implications for anesthetic management and is discussed in detail in Special Anesthetic Considerations in Patients with Sickle Cell Anemia. In contrast to hypoproliferative anemias, the corrected reticulocyte count in patients with hyperproliferative anemias is usually greater than or equal to 2% (or an absolute reticulocyte count of greater than 100,000/μL) (Table 15–2).[10]

Anesthesia and Anemia

The perioperative management of the anemic patient frequently requires a decision of whether to transfuse RBCs or to consider alternatives to transfusion (e.g., employ RBC salvage techniques). Making the correct transfusion decision involves considering the balance of the risks and merits of transfusing allogeneic and/or autologous RBCs. A consensus conference of the National Institutes of Health (NIH) and the Food and Drug Administration (FDA) was convened in June 1988 to determine the appropriate Hgb concentration or Hct level to trigger the administration of a perioperative RBC transfusion to a surgical patient.[19] The conference concluded that insufficient data existed to suggest a single transfusion trigger and there was a lack of data demonstrating that mild-to-moderate reductions in RCM contribute to perioperative morbidity. Furthermore, because perioperative transfusion of allogeneic erythrocytes is associated with a risk of immunologic changes and infections, alternatives to RBC transfusion may reduce the need for this therapy in the future.

Hgb concentration and Hct level are important predictors of the risk for transfusion; consequently, it is prudent to continue to use these tests in concert with wise clinical judgment to make a transfusion decision for an individual patient.[20–22] The conclusions of the NIH-FDA consensus conference reinforce the importance of understanding the physiology of anemia so as to make an informed decision regarding erythrocyte transfusion. The subsequent sections of this chapter on anemia review the physiology of anemia, present an approach to determining an individual patient's transfusion threshold that is supported by the limited current body of literature, discuss alternatives to RBC transfusion, discuss risks of RBC transfusion, and describe special anesthetic considerations for patients with sickle cell disease.

Physiology of Anemia

The physiologic response to anemia should be considered from at least 2 vantage points: acute anemia and chronic anemia. The physiologic response to acute anemia, most often a result of hemorrhage, will depend on the extent and rate of acute blood loss. Baroreceptor reflexes mediate the initial response to acute blood loss; chemoreceptors do not play a significant role.[23] Heart rate and minute ventilation initially increase after hemorrhage in the absence of volume replacement. Hyperventilation and tachycardia serve to increase cardiac output, which, in turn, increases blood flow to tissues. The increased heart rate augments cardiac output more directly than hyperventilation, which increases cardiac output by increasing right-heart filling.[24] Acute hyperventilation reduces $Paco_2$, increasing arterial pH (pHa) and both of these changes increase the oxygen saturation of arterial Hgb via the Bohr effect; these changes favor a higher affinity of oxygen for the Hgb molecule and decrease oxygen unloading to the tissues.[23,25] The reduced $Paco_2$ causes a left shift in the oxyhemoglobin dissociation curve, which speeds the uptake of oxygen in the pulmonary capillaries, but ultimately decreases the amount of oxygen that can be unloaded at any partial pressure of oxygen (Fig. 15–2). The increased cardiac output that accompanies this left shift of the oxyhemoglobin dissociation curve can compensate for the higher affinity of oxygen for the Hgb molecule. If insufficient cardiac reserve exists to increase cardiac output under these conditions, tissue hypoxia can worsen.

Concurrent with the baroreceptor-mediated response to acute blood loss is the near-immediate release of catecholamines, angiotensin II, and vasoactive hormones.[23] These biochemical mediators increase systemic vascular resistance and thereby increase systemic blood pressure. The increase in systemic vascular resistance is selective in that blood flow is increased to a lesser extent to gut, skin, muscle and renal tissue than to the heart and brain, so these organs receive preferential blood flow.[26] The increase in catecholamines will also confer a positive inotropic and chronotropic effect on the heart that will further augment cardiac output.

Decreased intravascular volume stimulates the renin–angiotensin–aldosterone axis, which contributes to increasing cardiac output and improving tissue oxygen delivery by water retention. Water retention augments cardiac preload.[26] Acute hemorrhage is associated with redistribution of

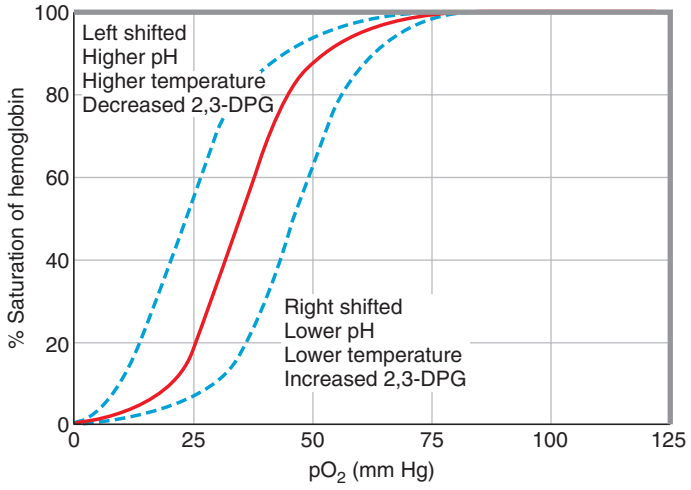

FIGURE 15–2. Oxyhemoglobin dissociation curve. O_2 consumption to O_2 delivery relationship. The *solid line* demonstrates the biphasic relationship between O_2 consumption and O_2 delivery. The *dashed line* illustrates the postulated changes in the relationship with diseases such as sepsis and acute respiratory distress syndrome (ARDS). The anaerobic threshold is shifted to the right, suggesting that patients require increased levels of O_2 delivery to avoid ongoing ischemic damage to vital organs. Reprinted from Hébert PC, Van der Linden P, Biro G, Hu LQ. Physiologic aspects of anemia. Crit Care Clin 2004;20:187, with permission from Elsevier.

water from the extravascular space into the intravascular space, accompanied by decreased Hgb concentration. As intravascular volume is replenished, Hgb concentration and Hct level decline, producing decreased blood viscosity. Redistribution of water occurs rapidly with severe hemorrhage; a significantly lower Hgb concentration is measurable within 2 minutes with an acute loss of 40% of the circulating blood volume. Complete fluid redistribution, however, takes hours. The rapid redistribution of water is attributable to the decreased hydrostatic pressure of the intravascular compartment and increased plasma oncotic pressure due to acute mobilization of albumin from the interstitial matrix as well as increased hepatic production of glucose and amino acids.[27,28] The resulting lower blood viscosity serves to reduce resistance to blood flow and increase venous return to the right heart; these changes help maintain or increase cardiac output. Reduced resistance to blood flow reduces myocardial work and oxygen consumption despite the overall increase in cardiac output.[29]

If the rate of blood loss is too severe for these compensatory changes to be effective in restoring blood flow to tissues, or if cardiac performance cannot be increased secondary to preexisting cardiac pathology (e.g., cardiomyopathy), then unmet tissue oxygen needs can result in lactic acid production and decreased pHa. Under these conditions acidosis results in a decreased Hgb–oxygen affinity that augments the delivery of oxygen to hypoxic tissues (i.e., there is a right shift of the oxyhemoglobin dissociation curve) (Fig. 15–2).[30–32]

Another compensatory mechanism for acute anemia occurs within the erythrocyte; RBCs can increase their intracellular concentration of 2,3-DPG (diphosphoglycerate), a product of anaerobic metabolism within RBCs. Increased levels of 2,3-DPG reduce the affinity of Hgb for oxygen, thereby favoring decreased oxygen uptake in the pulmonary capillaries but resulting in increased tissue oxygen delivery (Fig. 15–2).[25,26,33] Stored allogeneic RBCs have lower 2,3-DPG levels immediately following transfusion (i.e., there is a left shift of the oxyhemoglobin curve) and therefore do not readily unload oxygen to tissues.

Subsequent to these physiologic compensations (e.g., hyperventilation, decreased $Paco_2$, increased 2,3-DPG levels, and, ultimately, an increased cardiac output) there is an increase in erythropoiesis that appears to be linked to the renal sensitivity to oxygen flux (Fig. 15–1). Increased erythropoietin concentration and an increase in the circulating reticulocyte count can be detected in as little as 2 days after a hemorrhagic event. The Hgb concentration will start to increase within 7 days after a major hemorrhage. This continuum of physiologic responses occurs in the healthy surgical patient. An individual patient's ability to mount these physiologic responses largely depends on the patient's ability to increase cardiac output and augment tissue oxygen delivery.[31] The compensatory physiologic response to acute, unreplaced volume loss is reduced under general anesthesia, emphasizing the importance of maintaining intravascular volume.[34] The extent of the sympathetic stimulatory response to acute anemia is impaired during general anesthesia in that the heart rate does not increase to the same degree as in unanesthetized patients and the systemic vascular resistance is lower.[35,36] The inability to appropriately increase heart rate and augment cardiac output during general anesthesia, or because of medications (e.g., β-blockers), must also be considered when determining an individual patient's transfusion threshold. Anesthetized patients with marked impairment of their compensatory responses to anemia should be treated with a more liberal transfusion threshold despite limited data supporting this approach.

Chronic anemia is associated with expansion of plasma volume, hyperventilation, and an increased cardiac output.[31,37] In determining whether to transfuse a chronically anemic patient the clinician should inquire about signs and symptoms of anemia (e.g., fatigue, decreased exercise capacity, and increased frequency of angina in patients with ischemic cardiac disease). For anesthetized patients who are chronically anemic but who have had partial volume repletion, electrocardiographic evidence of myocardial ischemia or systemic acidosis should prompt the clinician to transfuse erythrocytes. However, rapid transfusion of physiologically compensated chronically anemic patients can precipitate congestive heart failure because of intravascular volume overload even in patients with normal myocardial function.

To understand the physiology of anemia, one must consider oxygen delivery ($\dot{D}o_2$), volume of oxygen consumption ($\dot{V}O_2$) and the relationship between them ($\dot{V}O_2$:$\dot{D}o_2$) or the oxygen extraction ratio). $\dot{D}o_2$ is calculated by the formula:

$$\dot{D}o_2 = \text{cardiac output} \times (\{SaO_2 \times k1 \times [Hgb]\} + \{k2 \times Pao_2\})$$

where SaO_2 is arterial oxygen saturation (%); $k1$ is the oxygen-carrying capacity of Hgb and equals 1.34 $mL \cdot g^{-1}$; [Hgb] is the hemoglobin concentration; $k2$ is the plasma oxygen dissolution coefficient at body temperature and equals 0.23 $mL \cdot L^{-1} \cdot kPa^{-1}$; and Pao_2 is the partial pressure of oxygen in arterial blood.[22] $\dot{V}O_2$ is determined by multiplying the oxygen content difference between the arterial and venous blood by cardiac output. Unfortunately all the data required for these calculations are not routinely available. When these data are available, they can aid in determining the transfusion trigger. Additional information on physiologic transfusion triggers is provided in The Decision to Transfuse Red Blood Cells below.

Anemia and Intravascular Volume

Simultaneously restoring normovolemia and maintaining oxygen delivery are principal goals of treating surgical blood loss. A patient's requirement for RBC transfusion should only be considered after intravascular volume status has been restored to normal. The ability to tolerate a lower Hgb concentration in the perioperative period is integrally dependent on an adequate intravascular volume.[26,29,35]

Crystalloid versus Colloid for Nonerythrocyte Fluid Replacement

Crystalloidal solutions (e.g., normal saline, lactated Ringer, hypertonic saline) possess a lower viscosity compared with the more viscous colloidal solutions (e.g., 5% albumin, hetastarch) and although the crystalloidal solutions can theoretically be delivered more rapidly, contemporary rapid infusion devices help to make this difference in viscosity clinically negligible. Normalizing blood volume with crystalloid solutions requires a ratio of approximately 3 mL of crystalloid per 1 mL of whole blood as most goes quickly to the extravascular space. Crystalloids avoid the risk of infectious disease such as hepatitis and AIDS, and are far less expensive than colloid-based solutions. Synthetic starch-based solutions (e.g., hydroxyethyl starch [HES] or Hespan) are the least-expensive colloids (Table 15–5). Although administration of large volumes of crystalloid can produce a dilutional coagulopathy, HES colloidal solutions carry a greater risk of producing a coagulopathy and other unwanted side effects (e.g., pruritus) as described later in Drug-Induced Hypocoagulable States below.[38,39]

TABLE 15–5.

Hospital Acquisition Costs for Intravenous Volume Replacement Solutions

Fluid	Volume (mL)	Cost[a] (U.S. Dollars)
0.9% Sodium chloride	1000	$3.50
Lactated Ringer	1000	$3.50
Hespan	500	$16.25
5% Albumin	250	$20.00

[a]Fluid costs reflect high volume purchasing through the Partners Healthcare System, Inc. in January 2006.

The Decision to Transfuse Red Blood Cells

After establishing normovolemia the anesthesiologist should incorporate physiologic data from the patient as well as assess the patient's ability to compensate for a given degree of anemia (loss of RCM) when weighing the risks (e.g., immunosuppression, infection, and mistransfusion) and benefits (e.g., relieving organ ischemia) of administering a RBC transfusion.[40–43] Strong consideration should be given to the patient's ability to increase the cardiac output, given the important role that augmented systemic oxygen delivery plays in compensating for anemia. Physiologic indications of inadequate tissue oxygenation include electrocardiographic or echocardiographic evidence of myocardial ischemia (e.g., new ST-segment elevation/depression, new regional wall motion abnormalities, or new spectral Doppler evidence of significant diastolic dysfunction), systemic acidosis related to tissue lactic acid production, an increase in the calculated oxygen extraction ratio, $\dot{V}O_2:\dot{D}o_2$ (i.e., normal $\dot{V}O_2:\dot{D}o_2$ is 20–30%; a $\dot{V}O_2:\dot{D}o_2$ >50% may indicate global inadequate tissue oxygenation), a mixed venous oxygen saturation (SvO_2) <50%, a low mixed venous partial pressure (PvO_2) <32 mm Hg or tachycardia unrelated to hypovolemia and/or inadequate anesthesia (Table 15–6).[22] Often these more specific indicators of tissue hypoxia are not available. Consequently, clinicians consider systemic acidemia in the setting of tachycardia and hypotension to indicate a requirement for augmenting a patient's RCM.

Since 1988 only a single multicenter, prospective, randomized, controlled trial has been conducted to assess the effect of RBC transfusion on morbidity and mortality. This study, the Transfusion Requirements in Critical Care (TRICC) trial,[36] enrolled 838 intensive care unit (ICU) patients that were randomized to either a restrictive (i.e., [Hgb] 7.0–9.0 g/dL) or liberal (i.e., [Hgb] 10.0–12.0 g/dL) transfusion strategy. The overall 30-day mortality was lower in the restrictive transfusion strategy group (18.7% vs. 23.3%), but this difference was not statistically significant (P = 0.11). A priori subgroup analysis of subjects who were less acutely ill and ages older than 55 years demonstrated a significantly lower mortality in the restrictive group. Although the TRICC trial is the largest study of its kind, it was stopped prematurely by its executive committee because of less than 20% of projected enrollment, consequently falling far short of its anticipated potential to examine the question of an appropriate transfusion strategy in critically ill patients. The authors concluded that a restrictive approach to RBC transfusion is as effective and potentially superior to a liberal transfusion strategy for ICU patients, with the possible exception of patients with unstable angina and acute myocardial infarction.[36] Unfortunately, the TRICC trial was conducted at a time when leukoreduction of transfused blood was not a common practice. A review of the importance of this practice suggests that it may improve the clinical outcomes of transfused patients.[44]

Three large observational studies in varied patient populations have been completed since the NIH-FDA consensus conference.[45–47] In one study, the number of transfused RBC units was found to be an independent risk factor for hospital length of stay, mortality, and number of complications.[45] In another large study, mortality was significantly higher in patients with similar levels of organ dysfunction in whom RBCs were transfused.[46] A large (n =

TABLE 15–6.

Physiologic Transfusion Trigger Parameters

Hgb-based and physiologic transfusion triggers as a function of patient-related and logistical factors (modified according to Marcucci et al.[49]). RBC transfusion is indicated if one of the criteria given in the table is reached: Hgb threshold, circulation criterion, myocardial ischemia, or one of the oxygenation variables (PvO_2, O_2ER, SvO_2, or $\dot{V}O_2$). For all physiologic transfusion triggers, normovolemia, optimization of the anesthesia and the correction of tachycardia (if present) is assumed and anemia should be the only probable cause. Includes all patients except the subcategories patients age >80 y, patients with CAD, patients with CVD, and patients with fever/hypermetabolism. One may choose not to transfuse the individual patient without any physiologic transfusion triggers.

Situation	Patients	Hgb (g/dL)	Circulation	Myocardial Ischemia	PvO_2 <32 mm Hg, O_2ER >50%, SvO_2 <50%, decrease in $\dot{V}O_2$ >10%
Intraoperative, ICU	All patients	6	Rel. inc. HR/dec. BP	ST-segment changes	Yes
	>80 y	7	Rel. inc. HR/dec. BP	ST-segment changes	Yes
	CAD	8	Rel. inc. HR/dec. BP	ST-segment changes	Yes
	CVD	7	Rel. inc. HR/dec. BP	ST-segment changes	Yes
	Fever/hypertension	7	Rel. inc. HR/dec. BP	ST-segment changes	Yes
Ward	All patients	6	Rel. inc. HR/dec. BP	Clinical signs	NA
	>80 y	8	Rel. inc. HR/dec. BP	Clinical signs	NA
	CAD	9	Rel. inc. HR/dec. BP	Clinical signs	NA
	CVD	8	Rel. inc. HR/dec. BP	Clinical signs	NA
	Fever/hypertension	8	Rel. inc. HR/dec. BP	Clinical signs	NA

CAD, coronary artery disease; CVD, cardiovascular disease; O_2ER, oxygen extraction ratio (%); PvO_2, partial venous pressure of oxygen (mm Hg); Rel. inc. HR, relative increase in heart rate defined as heart rate >120–130% of baseline or >110–130 beats/min; Rel. dec., relative decrease in systemic blood pressure defined as a mean arterial pressure <70–80% of baseline or <60 mm HG (<55 mm Hg in young healthy patients, <70–80 mm Hg in patients with CAD or CVD and in hypertensive patients, and even higher in severely hypertensive patients); SvO_2, venous oxygen saturation (%); VO_2, oxygen consumption; ST-segment changes, new ST-segment depression >0.1 mV or ST-segment elevation >0.2 mV that is to be confirmed with ECG and/or troponin measurement if possible in a timely fashion; NA, not applicable.

8787) observational study of elderly, orthopedic surgical patients found that postoperative transfusion did not influence 30- or 90-day mortality after adjusting for the transfusion strategy (i.e., transfusion trigger between 8 and 10 $g \cdot dL^{-1}$ or $< 8\ g \cdot dL^{-1}$), cardiovascular disease, and other risk factors.[47] These large observational studies suggest a clear relationship between RBC transfusions and worse outcome. However, it remains unclear whether patients who received transfusions were more ill.

Undesirable Effects of Red Blood Cell Transfusion

Presently, human error, or mistransfusion, accounts for the greatest incidence of adverse transfusion effects (Fig. 15–3).[43] RBC transfusion can produce other undesirable clinical effects including immunodepression and infection in surgical patients.[41–43,48,49] Prion-associated transfusion infection (e.g., variant Creutzfeldt-Jakob disease) and transfusion-related acute lung injury (TRALI) are additional clinical problems that may result from RBC transfusion.[50–53]

Alternatives to Transfusion

Acute Normovolemic Hemodilution

Acute normovolemic hemodilution (ANH) involves prehemorrhage, intraoperative removal of a specified quantity of an individual patient's blood (i.e., up to 50% of select patients' total circulating RCM can be safely removed) while intravascular volume is concurrently replaced.[35] Because the RCM is

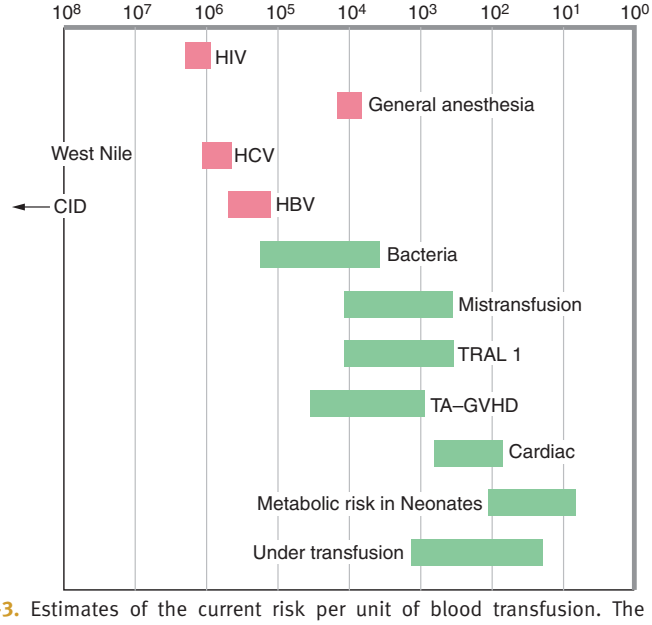

FIGURE 15–3. Estimates of the current risk per unit of blood transfusion. The vertical bars represent log risk estimates (1–10, 1–100, etc.). Reproduced with permission from Gafou A, Georgeopoulos G, Bellia M, et al.[43]

decreased before intraoperative bleeding begins, there is a smaller net loss of RCM per unit blood loss during hemorrhage. Additionally, the benefit of transfusing the shed autologous whole blood, including functional platelets and coagulation proteins, exists for the patient at any point during or after the operative procedure.[54] Individuals with religion-based aversion to RBC transfusion (e.g., Jehovah's Witness) are a population of patients that can benefit from ANH if the shed blood is kept in a parallel circuit connected to the patient.

Red Blood Cell Substitutes

Further development of RBC transfusion alternatives is needed before they can be considered as a viable alternative to erythrocyte transfusion. Extensive laboratory and clinical research has been done with Hgb-based oxygen-carrying solutions.[55–57] Despite many years of concentrated research efforts with Hgb-based oxygen-carrying solutions, there is no FDA-approved product for any human clinical indication. Currently at least 2 general types of Hgb-based oxygen-carrying solutions are under investigation. One is derived from bovine Hgb and presents the advantage of being available in an abundant supply, while another is manufactured from outdated banked human blood.[55] Problems that have impeded the development of Hgb-based oxygen-carrying solutions include renal toxicity, gastrointestinal symptoms, systemic hypertension, coronary vasoconstriction, pulmonary hypertension, short half-life of the transfused molecules, methemoglobin production and fear of infection (e.g., prions and bovine spongiform encephalitis) from bovine-derived Hgb. The vasoconstrictor effects of these molecules appear to be related to their small size, tendency to migrate into the interstitium, and ability to scavenge nitric oxide from the vascular endothelium.[55] The small size of some Hgb molecules results in their being filtered out through the glomerulus. Modifications of the Hgb molecule, including polymerization into a larger molecule and liposome encapsulation, appear to have resulted in some success in solving these problems. However, there is limited evidence that they are equivalent to banked RBCs.[56–59] Perfluorocarbons are a non-Hgb–based RBC substitute; these synthetic solutions are not available for clinical use.[55,60]

Red Blood Cell Salvage

Red cell salvage techniques are associated with a significant reduction in allogeneic transfusion requirements and a cost benefit in some patients.[61–63] Autologous RBC salvage involves the collection of blood from a wound site, processing (e.g., centrifugal washing and/or filtering through a 20-µm filter) of scavenged blood, and reinfusion into the same patient.[64] Centrifugal washing concentrates the salvaged blood to allow the infusion of an autologous product with a high Hct level (e.g., 45–65%) and removes undesirable components of shed blood (e.g., free Hgb, tissue debris, and fibrin split products).[65] Cell salvage requires specialized equipment and device-specific disposable units (Fig. 15–4). The processed blood primarily contains morphologically normal erythrocytes suspended in normal saline. Centrifugal washing removes coagulation proteins, although some leukocytes and a small number of platelets are retransfused.

Alternatively, the collected shed autologous blood is passed through a filter with 20-µm–sized pores and retransfused without centrifugal washing.[66,67] Red cell salvage with centrifugal washing within certain guidelines has been studied and found to be generally safe.[64,66–70] Malignancy, infection at the operative site, or the use of microfibrillar collagen materials are presently considered contraindications to the use of RBC salvage techniques.[71–73]

Antifibrinolytic Therapy

Antifibrinolytic therapy (e.g., aprotinin, ε-aminocaproic acid, and tranexamic acid) can reduce blood loss in certain patients at risk for major hemorrhage (e.g., cardiac surgical patients, orthotopic liver transplantation patients, and selected orthopedic surgery patients).[74–76] The results of several prospective, randomized, controlled trials indicate aprotinin therapy can reduce transfusion requirements. Tranexamic acid and ε-aminocaproic acid are also effective in blood conservation for selected patient populations, although there is less supportive data for their efficacy in reducing RBC transfusion requirements.[77] Aprotinin was recently associated with an increased mortality rate, myocardial infarction, decreased coronary graft patency, and renal failure.[78–80] One of the largest observational studies of aprotinin demonstrated significant associations of

FIGURE 15–4. Haemonetics Cell Saver device.

aprotinin administration with increased risk of renal failure, myocardial infarction or heart failure, and stroke or encephalopathy. However, the same study did not raise safety concerns about tranexamic acid or ε-aminocaproic acid.[78] The results of this study resulted in an FDA practice alert surrounding the use of aprotinin and the validity of the data is under investigation.[81] Some evidence suggests that aprotinin treatment may produce a reduced risk of stroke and plans are currently underway to study this.[76]

Special Anesthetic Considerations in Patients with Sickle Cell Anemia

Sickle cell disease (SCD) is prevalent among the African American population. Patients with this hemoglobinopathy can exhibit both anemia and a functional defect of their circulating Hgb. Hgb is composed of globin chains combined with a heme molecule. Four distinct types of globin chains are normally produced in the human body including alpha (α), beta (β), gamma (γ), and sigma (σ) globin chains. Normally the body will produce three types of Hgb using different combinations of these four distinct globin chains including HgbA ($\alpha_2\beta_2$), HgbF ($\alpha_2\gamma_2$), and HgbA$_2$ ($\alpha_2\sigma_2$). In early infancy, 97% of the circulating Hgb exists as HgbA. Hemoglobinopathies result from the decreased synthesis of normal globin chains (e.g., thalas-

semia syndromes), or in the case of SCD, the functional defect of the Hgb complex involves a qualitative defect in globin synthesis.[82]

The pathophysiology of SCD and sickle cell trait (SCT) is caused by an alteration in the synthesis of β-globin chains by a substitution of the amino acid valine for glutamine at the sixth amino acid location, resulting in the production of HgbS when these β-globin chains are combined with the α-globin chains. In individuals with both chromosomes directing HgbS synthesis (homozygous SS disease), the normal HgbA is substituted by HgbS. Increased production of $HgbA_2$ and HgbF are minimally effective in alleviating the pathophysiologic changes associated with SCD. A major percentage (80–95%) of the synthesized Hgb is in the HgbS form for patients afflicted with homozygous SS disease.[82,83] SCT represents the heterozygous state and is produced by 1 sickle cell gene locus and 1 normal gene locus. SCT results in few clinical problems despite the HgbS level rising to nearly 40% of circulating Hgb.[82] Among African Americans in the United States, 0.4% possess the homozygous state of SCD, while a prevalence of 6–8% of heterozygotes is reported.[84–86]

There is a spectrum of tissue oxygen-delivery-related sequelae that result from the pathophysiologic mechanisms of SCD. Patients with SCD exhibit an abnormal change in the conformation of the deoxygenated HgbS molecule that reduces the solubility of the molecule and results in intraerythrocyte precipitation of HgbS.[87] The precipitated intraerythrocyte deoxyhemoglobin S alters red cell function, resulting in damage to the intracellular contents and to the cell membrane. These cellular changes result in reduced capillary blood flow and early cell destruction.[83,87] Specifically, the normally pliable, biconcave-shaped erythrocyte is transformed into a smaller, less compliant, characteristically shaped, sickled erythrocyte that is pathognomonic of this disease (Fig. 15–5).[83,87,88] Erythrocytes in patients with SCD have a reduced circulating life span of approximately 10–20 days, which contributes to the patient's anemia.[89] Sickled erythrocytes increase the viscosity of blood and along with thrombus formation in the blood vessels can create a vasoocclusive crisis.[90,91] The goal of SCD treatment is to prevent initiation of the sickling process as this process is irreversible once intracellular HgbS has precipitated.[86]

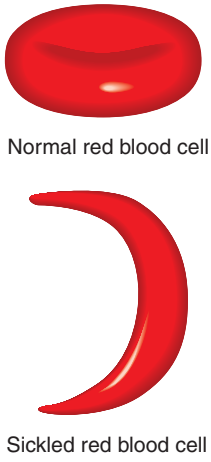

FIGURE 15–5. Diagram art of a normal RBC and a sickled RBC. Reproduced with permission from Lewin J. Electron Microscopy Unit, Royal Free Hospital School of Medicine, London, UK. Available at: http://healthgate.partners.org/browsing/LearningCenter.asp?fileName=11561.xml&title=Sickle%20Cell%20Anemia. (*Google Images*). Last accessed 1/04/2007.

Vasoocclusive crisis can result in damage to multiple organs (e.g., renal papillary necrosis, renal medullary infarction, retinal or vitreous hemorrhage, aseptic necrosis of the femoral head, and splenic infarction).[92–94] Central nervous system and pulmonary infarctions are also common and are most likely related to emboli of sickled cells and platelet aggregates that form in distant tissue beds.

Patients with SCD should be treated to prevent perioperative hypoxia, dehydration, and hypothermia, which can result in a vasoocclusive crisis. Preventative measures are the mainstay of treatment for individuals with this disorder.[88] General anesthesia per se does not overtly increase the risk of the precipitation of sickled erythrocytes.[86]

One approach used to avoid a perioperative vasoocclusive crisis is to reduce the percentage of HgbS to less than 30–40% before surgery by exchange and standard transfusions.[86] As with other chronic anemic states, there is physiologic compensation that results in an increased intravascular volume and augmented cardiac output. The increase in intravascular volume places the anemic SCD patient at risk for volume overload if they are rapidly transfused with allogeneic blood; consequently, a cautious approach to transfusion is mandated. The benefit of transfusion has been demonstrated to persist for weeks into the postoperative period as evidenced by a reduced incidence of sickling episodes.[95,96]

Perioperative mortality in SCD patients is most commonly caused by fulminant infection related to immunosuppression associated with prior splenic infarction.

COAGULATION DISORDERS

The coagulation system of the human body maintains a delicate balance between hemostasis and the distribution of fluid blood to the tissues. Pathologic changes within the coagulation system may result in either a hypocoagulable state (i.e., a tendency to hemorrhage inappropriately) or a hypercoagulable state (i.e., a tendency to inappropriately form thrombus). The coagulation system relies on the appropriate level and function of several blood components to allow normal clotting. The process of blood coagulation relies on the interaction of platelets, vascular endothelium, vascular smooth muscle, soluble coagulation proteins, and various local and systemic biochemical mediators to produce a hemostatic clot.[97]

Hypocoagulable States

It is crucial to recognize and treat a preexisting hypocoagulable state to avoid massive hemorrhage and potentially unnecessary blood product transfusion. Optimal treatment of a hypocoagulable disorder is best accomplished by selectively transfusing the blood component(s) that is/are deficient (e.g., transfuse factor VIII concentrate into a hemophiliac requiring surgery rather than fresh-frozen plasma). Hypocoagulable states are usually either congenital or acquired; both can occur simultaneously in the same patient. Knowledge of both the coagulation cascade and the biologic half-life of a particular coagulation element are needed to effectively treat many hypocoagulable disorders (Fig. 15–6, Table 15–7). It is of paramount importance to combine a history and physical examination with appropriate laboratory testing to discover congenital and/or acquired hypo-/hypercoagulable disorders in surgical patients. After direct questioning of whether a patient has a known coagulation disorder, one must ask specific questions to elicit the presence or absence of these disorders (Table 15–8). If a patient answers "yes" to any of these questions, inquire as to the details and frequency of the problem. Depending on the complexity of the presenting hypo- or hy-

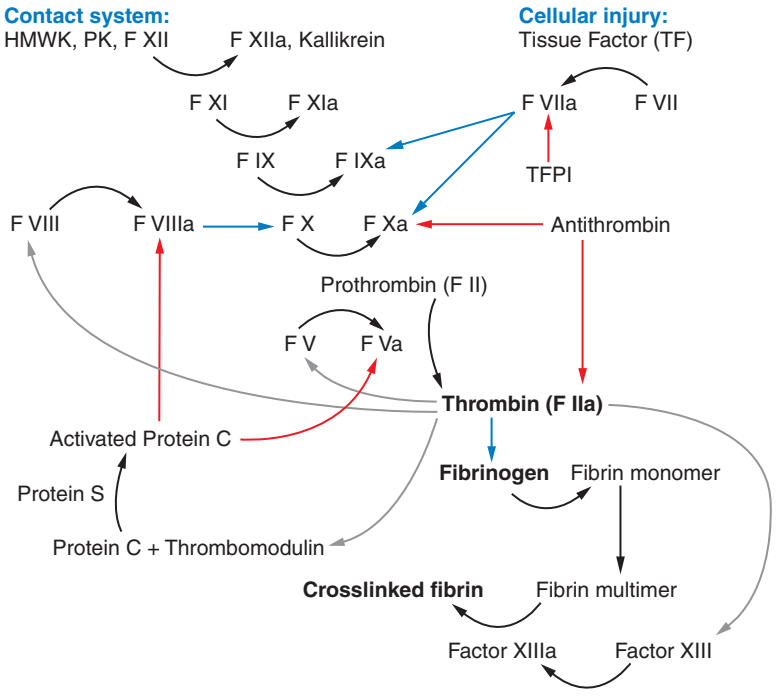

FIGURE 15–6. The coagulation cascade.

percoagulable state, a hematology consultation might be indicated.[98]

Factor VIII Deficiency (Hemophilia A)

Patients with factor VIII deficiency, or hemophilia A, can require urgent surgical intervention for bleeding episodes (e.g., craniotomy to decompress an intracranial hemorrhage or fasciotomy to relieve a compartment syndrome). Hemophilia A is an X-linked recessive trait that occurs with a frequency of 1 in 5000 live male births.[99,100]

Individuals with hemophilia A manifest a range of bleeding symptoms and symptom severity inversely correlates with their plasma activity level of factor VIII. Normally, factor VIII activity ranges from 50–150% (or 0.5–1.5 U/mL). Mild hemophilia is present in patients with factor VIII activity levels greater than 5%. Moderate hemophilia is present in patients with factor VIII activity levels from 1–5%, and severe hemophilia symptoms manifest with levels less than 1% (or 0.01 U/mL).

Spontaneous hemarthroses are the hallmark of severe hemophilia; they do not generally occur until the child walks. Recurrent joint hemorrhage produces a painful degeneration of the cartilage (hemophilic arthropathy) that eventually destroys the joint.[101] Hemophiliacs with 1–5% factor VIII activity do not generally have spontaneous bleeding events, but trauma and surgery can precipitate a hemorrhagic episode.

Intracranial and intracerebral bleeding are the most common causes of death in hemophiliacs. Approximately half of intracranial hemorrhages in hemophiliacs occur spontaneously.[102] Gastrointestinal and oropharyngeal bleeding may also occur. Oropharyngeal bleeding is of great importance because this can lead to airway compromise.[103] Finally, in severe hemophilia, recurrent hemorrhagic episodes may produce an enlarged pseudotumor that might invade local soft tissue and bone. Operative removal of pseudotumors is associated with a high mortality despite provision of recommended perioperative therapies.[103,104]

TABLE 15–7.

Summary of Clotting Factor Deficiencies

	Prevalence and Biologic Half-Lives			Screening Abnormalities	
Factor Deficiency	Biologic Half-Life	Estimated Incidence	Type of Bleeding	Abnormal	Normal
I	2–4 days	1:1 million	None to severe	PT, PTT, TCT, BT	None
II	3 days	Very rare	Mild-moderate	PT, PTT	TCT, BT
V	36 hours	1:1 million	Moderate	PT, PTT, BT	TCT
VII	3–6 hours	1:500,000	Mild-severe	PT	PTT, TCT, BT
X	40 hours	1:500,000	Mild-severe	PT, PTT	TCT, BT
XI	80 hours	Rare	Mild-moderate	PTT	PT, TCT, BT
XII	50–70 hours	Unknown	No bleeding	PTT	PT, TCT, BT
XIII	9 days	1:5 million	Moderate-severe	None	PT, PTT, TCT, BT
PK	35 hours	Unknown	None	PTT	PT, TCT, BT
HK	150 hours	Very rare	None	PTT	PT, TCT, BT
α_2-Pi	3 days	Unknown	Mild-moderate	None	PT, PTT, TCT, BT
α_1-ATP	—	Very rare	Variable-severe	PT, PTT, TCT, BT	None
Protein Z	2–3 days	Unknown	None	None	PT, PTT, TCT, BT

α_1-ATP, alpha$_1$-antitrypsin Pittsburgh; α_2-Pi, alpha$_2$-plasmin inhibitor; BT, bleeding time; HK, high–molecular-weight kininogen; PK, prekallikrein; PT, prothrombin time; PTT, partial thromboplastin time; TCT, thrombin clotting time; ZPI, protein Z–dependent protease inhibitor.

TABLE 15–8.

Preanesthetic Assessment Coagulation Disorder Queries

- Is there a family history of making blood clots inappropriately or of excessive bleeding after dental or surgical procedures?
- Do you bleed excessively after having a blood sample drawn?
- Have you ever required a transfusion for any reason? If yes, why was the transfusion administered?
- Do you have problems with bleeding gums when you brush your teeth?
- Do you bruise easily?
- Do you have a history of nosebleeds, blood/red-tinged urine, or tarry, black stools?
- Do you experience heavy bleeding with menstruation?
- Are you taking any medications or herbal supplements? If yes, which ones?

In the United States, the diagnosis and management of hemophilia A is achieved with an activated partial thromboplastin time (aPTT)-based one-stage assay. The aPTT is abnormally prolonged in all hemophiliacs. The prothrombin time (PT), thrombin time (TT), bleeding time, platelet count, and platelet function are all usually normal in hemophiliacs.[102]

Hemophilia A is treated by administration of factor VIII concentrate. The goal of chronic therapy is to maintain the trough factor VIII activity at a level (approximately 3%) that reduces the incidence of spontaneous intracranial hemorrhage and minimizes spontaneous intraarticular hemorrhage.[102] Plasma-derived and recombinant factor VIII concentrates are available, and both substances provide equally effective treatment (Table 15–9). The treatment goal for acute, life-threatening, bleeding episodes (e.g., intracranial hemorrhage or limb-threatening hemorrhage) is to attain a factor VIII activity of 50–100% of normal, as estimated by the aPTT-based one-stage assay.

One anesthetic consideration for patients with hemophilia A involves increasing preoperative factor VIII activity levels to approximately 100% of normal. Additionally, it seems sensible to avoid using nonsteroidal antiinflammatory drugs (e.g., Toradol) as these drugs have precipitated spontaneous gross hematuria in hemophiliacs.[102] Patients requiring a lumbar puncture should first be restored to approximately 100% of normal factor VIII activity levels; specific data regarding spinal anesthesia are not available but a similar therapeutic goal seems warranted if the benefits of spinal anesthesia outweigh the risks to a patient.[102] Administration of factor VIII concentrates to hemophiliacs with an active pharyngeal hemorrhage may not provide acute airway protection and elective intubation may be indicated to protect against life-threatening airway obstruction.[103] Additionally, a complete history and physical examination will reveal whether the hemophiliac patient has developed narcotic tolerance associated with the prior treatment of painful complications related to their disease (e.g., hemophilic arthropathy or ureteral blood clots).

Factor IX Deficiency (Hemophilia B)

Factor IX deficiency, also termed hemophilia B or Christmas disease, results in a similar clinical syndrome to hemophilia A. Hemophilia B is transmitted as an X-linked recessive trait and occurs in 1 of 30,000 live male births. The clinical manifestations of hemophilia B are similar to those described for hemophilia A. Mild, moderate, and severe forms of hemophilia B are defined by the same criteria used for hemophilia A (i.e., severe hemophilia B is defined by a factor IX activity level of less than 1% or 0.01 U/mL). Severity will correlate with the factor IX plasma activity; patients with less than 1% activity will exhibit spontaneous hemarthroses, intramuscular hemorrhages, and gross hematuria among their symptoms. The diagnosis of hemophilia B is also made with an aPTT-based one-stage assay. The aPTT will be prolonged in patients with hemophilia B, but will correct when the patient's plasma is mixed in equal parts with plasma from a normal individual.[102]

Hemophilia B is treated by administration of concentrated factor IX. Factor IX concentrates are available as either recombinant or plasma-derived preparations. The plasma half-life of transfused or endogenous factor IX is approximately 18 hours. The same levels of factor activity replacement are targeted as described in the preceding section on hemophilia A. Development of inhibitory antibodies can complicate treatment of both factor VIII and IX deficiency. They arise more commonly in patients treated with ultrahigh-purity factor concentrates (i.e.,

TABLE 15–9.

Factor VIII Concentrates Licensed in the United States

Type/Product Name	Manufacturer	Specific Activity (IU/mg Protein, Discounting Albumin)
Ultrapure Recombinant		
Recombinate	Baxter Hyland	>3000
Kogenate FS	Bayer	>3000 (albumin-free formulations)
Helixate FS	Aventis-Behring	>3000
Re Facto	Genetics Institute (American Home Products)	11,200–15,500 (albumin-free formulations)
Ultrapure Plasma Derived		
Monoclate P	Aventis-Behring	>3000
Hemofil M	Baxter Hyland	>3000
Monarc M	Immuno Baxter (using volunteer donor plasma collected by American Red Cross)	>3000

the incidence is approximately 1–4% in patients with severe factor IX deficiency).[105] Recombinant activated factor VII (rVIIa) is FDA approved for the treatment of both hemophilia A and hemophilia B in patients with inhibitors to factors VIII and IX, respectively.[106] The anesthetic implications for factor IX deficiency are analogous to those of hemophilia A.

von Willebrand Disease

von Willebrand disease (vWD) is a platelet function disorder caused by a deficiency of normally functioning von Willebrand factor (vWF).[107] vWD can result in a hypocoagulable state that manifests as bleeding episodes.[108] vWD is a congenital disorder with an equal male-to-female distribution ratio that is inherited by an autosomal dominant pattern and occurs with an incidence of approximately 1%.

vWF plays two major roles in the hemostatic process. First, vWF acts as a bridge between platelet receptors and exposed collagen in disrupted endothelium. Platelet binding to exposed collagen in disrupted endothelium initially occurs via a glycoprotein Ib–vWF and collagen interaction, and soon thereafter by firmer adhesion of the platelet to the collagen molecule via the glycoprotein IIb/IIIa–vWF and collagen interaction. vWF enables platelets to create a primary plug in the disrupted endothelium and start the hemostatic process at the site of vessel injury. vWF also acts as a bridge between platelet receptors, specifically between glycoprotein IIb/IIIa receptors, for the purpose of platelet aggregation.[109] Second, vWF circulates in the plasma to create a complex bound to factor VIII and provides protection to factor VIII against proteolytic cleavage.[110]

There is a broad range of severity in bleeding associated with vWD. Individuals with moderate or severe vWD tend to bleed abnormally in childhood or young adulthood. The majority of affected individuals have only mild or moderate disease. Symptoms of vWD include easy bruising, epistaxis, and bleeding of mucous membranes. Gastrointestinal bleeding and menorrhagia occur in vWD. Severe gastrointestinal bleeding can be life-threatening in vWD.[111] Surgical procedures can also be associated with excessive bleeding in patients with vWD.[108]

The diagnosis of vWD is complex and is made with a battery of tests that includes vWF antigen (accomplished with the enzyme-linked immunosorbent assay), vWF activity (commonly measured as ristocetin cofactor), factor VIII activity (accomplished with a modified aPTT assay), and the bleeding time. These tests are followed by a second series of assays to determine the classification of vWD and include a ristocetin-induced platelet aggregation assay, as well as vWF multimer studies.[108,112,113]

The treatment of vWD depends on the type of vWD that is diagnosed (Tables 15–10 and Table 15–11). Use of nonsteroidal antiinflammatory drugs can further impair an already compromised level of platelet function and are contraindicated in vWD. Because the correlation of the degree of diagnostic laboratory test abnormalities in vWD with the severity of bleeding is poor, an empirical goal of treatment is pursued. The treatment goal for the perioperative period should be to increase the activity of vWF and factor VIII to 50–100% of normal, an analogous goal to the treatment of bleeding episodes in vWD.[108]

vWF and factor VIII activity levels are increased in patients with vWD through the intravenous administration of DDAVP (1-deamino-8-D-arginine-vasopressin or desmopressin) and the administration of vWF-rich plasma-derived blood products. The use of topical hemostatic agents (e.g., fibrin glue, Gelfoam or Surgicel soaked in thrombin) will also promote hemostasis in these patients.[108] Alternatively, vWF concentrates (e.g., Humate-P, a heat-treated, highly purified vWF concentrate) can be administered intravenously for patients who do not respond positively to DDAVP therapy.

Pregnant patients with vWD merit special consideration. Although evidence-based recommendations for central neuraxial blockade do not exist, consideration must be given to the fact that spinal or epidural hematoma related to instrumentation can be permanently debilitating. vWF levels increase 2–3 times above the baseline

TABLE 15–10.

Classification of von Willebrand Disease

Type	Inheritance	Frequency of vWD Type	vWF Activity	RIPA	Multimer Pattern
Type I (classic)	Autosomal dominant	70–75%	↓	↓	Uniform ↓ All multimers present
Type 2 (variant)					
2A	Autosomal dominant (and recessive)	10–15%	↓	↓	↓ Large and intermediate multimers
2B	Autosomal dominant	5%	↓	↑	↓ Large multimers
2M	Autosomal dominant (and recessive)	Infrequent	↓	↓	Normal multimers
2N	Autosomal recessive	Infrequent	Normal	Normal	Normal multimers
Type 3 (severe)	Autosomal recessive	Rare	↓↓	↓↓	Undetectable (usually cannot visualize)

vWD, von Willebrand disease; vWF, von Willebrand factor; RIPA, ristocetin-induced platelet aggregation; ↓, decrease; ↑, increase; ↓↓, marked decrease.

TABLE 15–11.

von Willebrand Disease Treatment Approaches

Medication	Dose	Comments
DDAVP (desmopressin)	IV: 0.3 μg/kg in 50 mL saline over 20 min (maximum 20 μg)	Useful in most patients with type 1; variable in type 2; not useful in type 3; patient should have therapeutic trial before invasive procedure; may repeat dose after 12 hours and q24h; tachyphylaxis and hyponatremia may occur—need to monitor patient
	Nasal spray: Weight >50 kg = 300 μg (1 spray each nostril) Weight <50 kg =150 μg (1 spray in only 1 nostril)	
vWF concentrates containing all vWF multimers	20–30 IU/kg q12h to keep vWF levels 50–100% or to control clinical bleeding; levels should be maintained 3–10 days for major surgery	Dose and duration based on clinical experience
Antifibrinolytic agents:		Use alone or in conjunction with other therapy
ε-aminocaproic acid	50 mg/kg (maximum 5 g/dose) QID	Especially useful for mucosal bleeding (often for dental procedures)
Tranexamic acid	25 mg/kg TID	
IVIg (for use in immune-acquired inhibitors of vWF)	1 g/kg daily for 2 days; infusion over 8–12 hours	Use after trial of DDAVP or other measures in patients with acquired vWD, particularly when associated with autoimmune diseases

DDAVP, 1-desamine-8-D-arginine vasopressin; Type 2, thrombocytopenia may worsen in some type 2B patients; vWF, von Willebrand factor.

during the second and third trimesters of a pregnancy and may provide some protection from bleeding complications. The increased levels should be verified with the assays previously described because the increase in vWF is not universal and some patients with qualitative vWF defects will not correct their vWF activity during pregnancy.[113] DDAVP can be administered to laboring vWD patients who are known to have a positive response to this therapy. vWF replacement therapy can be employed for individuals who are still bleeding following DDAVP administration. Individuals who are known nonresponders to DDAVP should be treated with vWF concentrates.[108]

Factor V Deficiency

Congenital deficiency of factor V is rare; the estimated incidence is 1 in 1 million live births. It is inherited as an autosomal recessive trait that is characterized by an absent or decreased level of factor V activity. Factor V is synthesized by the liver and circulates in plasma. Factor V deficiency can range from mild to severe. Severely affected individuals have less than 1% of factor V activity and may present in infancy with umbilical stump hemorrhage or later with epistaxis, easy bruising, trauma-related hemarthroses, menorrhagia, and obstetrical-related hemorrhage.[114] Thrombotic complications have also been reported in patients with congenital factor V deficiency.[115]

Congenital factor V deficiency is diagnosed definitively with a specific factor V assay. Additionally, the PT, aPTT, and bleeding time are prolonged in this disorder; the TT is normal.[114] Factor V deficiency can occur in an acquired form (e.g., as a result of hepatic synthetic dysfunction) or can present concurrently with other congenital coagulation factor deficiencies (e.g., a combination syndrome exists of factor V and VIII deficiencies). An acquired form of factor V deficiency can also occur as a result of the formation of antibodies to factor V.[116]

The treatment of surgical patients with factor V deficiency will depend on the magnitude of the reduction in functional factor V activity. There are no commercially available factor V concentrates, so treatment is by administration of fresh-frozen plasma at a loading dose of 15–20 mL/kg followed by 3–6 mL/kg every 24 hours for patients who exhibit either mild or moderate hemorrhagic events. Factor V has a half-life of approximately 36 hours. In the preoperative preparation of a patient with a severely reduced level of factor V activity, plasma exchange transfusion may be needed to avoid fluid overload.[117] Mild bleeding episodes have been treated with local measures and antifibrinolytic therapy (e.g., tranexamic acid or ε-aminocaproic acid).[114]

Factor VII Deficiency

Factor VII deficiency has an estimated incidence of 1 in 500,000 live births without an apparent sex or racial predilection; inheritance occurs as an autosomal recessive trait. Factor VII and tissue factor complex are needed for the initiation of coagulation in vivo (Fig. 15–6); significant deficiencies of this protein can result in severe hemorrhage.[118] Factor VII deficiency can present with a low antigen level and low functional activity of factor VII

(accounting for more than half of patients) or low functional activity in the setting of measured normal antigen levels of factor VII.

Factor VII deficiency presents with a range of clinical manifestations that do not necessarily correlate with the measured plasma level of factor VII.[119] Patients that demonstrate a measured factor VII activity of less than 10% have a higher tendency to exhibit bleeding episodes (e.g., soft-tissue hemorrhage, epistaxis, easy bruising, menorrhagia, menometrorrhagia, and postpartum hemorrhage). Postoperative bleeding is of particular concern in patients with severely reduced factor VII activity. Individuals with less than 1% of normal factor VII activity are most likely to exhibit hemarthroses, muscle hematomas, retroperitoneal hemorrhage, and mortal intracranial bleeds.[118,120] Thrombotic events have been described in patients with factor VII deficiency.[121]

The definitive diagnosis of factor VII deficiency is made with a specific factor VII assay. Affected individuals will also have a prolonged PT along with a normal aPTT, TT, and bleeding time.[114] Congenital factor VII deficiency should be differentiated from the acquired forms of factor VII deficiency that most commonly arise from hepatic dysfunction, coumarin therapy, vitamin K deficiency, and acquired factor VII inhibitors such as antibodies directed specifically toward factor VII.[122]

Individuals with factor VII activity levels less than 25% of normal require preoperative treatment to avoid perioperative life-threatening hemorrhage. The treatment of choice for these patients is the administration of rVIIa (NovoSeven) in an initial dose of 20–30 μg/kg with supplementary doses if bleeding persists. NovoSeven is not FDA approved for treatment of factor VII deficiency because of insufficient safety data.[123–125] Fresh-frozen plasma treatment of factor VII deficiency can be effective but has the disadvantage of requiring the administration of large volumes of plasma as the half-life of factor VII is 3–4 hours.[126]

Factor X Deficiency

Factor X deficiency is an inherited autosomal coagulation disorder with an estimated incidence of 1 in 500,000 live births. Patients with factor X deficiency produce abnormal factor X in either normal or reduced amounts. The clinical bleeding manifestations of factor X deficiency vary and correlate with the measured level of factor X activity. Individuals with less than 1% of measurable factor X activity will exhibit hemorrhagic episodes similar to those seen in hemophilia A.[114,127] Individuals with factor X activity that is 15% or higher exhibit fewer bleeding episodes but may exhibit perioperative hemorrhage.[114]

Factor X deficiency is diagnosed by a specific factor X assay. Affected individuals demonstrate a prolongation of the PT and aPTT, and may describe a lifelong history of bleeding problems. Acquired factor X deficiency is most commonly seen in patients with hepatic pathology, vitamin K deficiency, and, rarely, in patients with amyloidosis.[128]

Perioperative factor X activity levels should be maintained at approximately 50% of normal; higher levels may precipitate a thrombotic complication.[114] Factor X may be administered through the transfusion of fresh-frozen plasma (an appropriate loading dose is 15–20 mL/kg followed by 3–5 mL/kg every 24 hours) or prothrombin complex concentrates (an appropriate loading dose is 20–30 U/kg every 24 hours). It is crucial to define the chosen biologic's precise concentration of factor X to avoid overtreatment of the deficiency and the risk of thromboembolic events. Individuals who require chronic supplementation of their factor X levels may develop antibodies to factor X that will limit the effectiveness of exogenous sources of factor X. In such cases, the use of prothrombin complex concentrates may be more effective than fresh-frozen plasma. Amyloidosis may impede the effectiveness of exogenously administered factor X because of the absorption of factor X to the amyloid fibrils. Plasma exchange, chemotherapy, and splenectomy have all been attempted in the treatment of amyloidosis.[128–131]

Factor XI Deficiency

Congenital factor XI deficiency is a rare, autosomal recessive disorder that occurs without a sex predilection, most commonly among Ashkenazi Jews. Individuals with factor XI deficiency may not exhibit a bleeding tendency in the surgical setting, although patients with less than 20% of factor XI activity can exhibit excessive bleeding but will not manifest episodes of spontaneous hemorrhage or hemarthroses.[114] A mild bleeding tendency (e.g., hematuria, epistaxis, hematomas, postpartum hemorrhage, menorrhagia, increased bleeding after aspirin administration and following dental or prostate surgery) is seen in some individuals with this disease.[114,132,133]

Definitive diagnosis is made with a specific factor XI assay. Individuals with factor XI deficiency have a prolonged aPTT; the PT and TT are normal. Factor XI deficiency has been observed in association with Noonan syndrome, hemophilia A, factor IX deficiency, vWD and other platelet disorders.[114]

A preoperative factor XI level of 45% is recommended for major surgical procedures and a 30% level is recommended for minor surgery. Individuals with a diagnosis of factor XI deficiency and no history of bleeding problems following trauma or surgery may not require any replacement therapy perioperatively.[114,134,135] Factor XI's half-life is approximately 50 ± 22 hours. Consequently, treatment is accomplished by a loading dose of 15–20 mL/kg of fresh-frozen plasma followed by 3–6 mL/kg every 12 hours. Plasma exchange has been used in individuals with uncontrolled bleeding.[114] Antifibrinolytic agents (e.g., ε-aminocaproic acid and tranexamic acid) have been recommended alone or in conjunction with fresh-frozen plasma administration to control bleeding in factor XI-deficient patients.[114] Tranexamic acid is effective in patients undergoing dental procedures.[136] Finally, perioperative treatment of factor XI deficiency can be complicated by the presence of inhibitors, specifically alloantibodies, which can prolong bleeding episodes.[137,138] NovoSeven, or rVIIa, treatment has been recommended for individuals with inhibitors at a dose of 100–120 μg/kg every 2–4 hours until the bleeding stops, although rVIIa is not FDA approved for this indication.[139] Immunosuppressants (e.g., prednisone) and chemotherapeutics (e.g., cyclophosphamide) have also been tried as therapies for patients with inhibitors to factor XI.[114]

Contact Factor Deficiency

Factor XII, high-molecular-weight kininogen, and prekallikrein constitute the contact factors of the coagulation cascade (Fig. 15–6); definitive diagnosis is made with a specific assay for the

deficient contact factor.[114] Contact factor deficiencies are not associated with bleeding, although these individuals demonstrate a prolonged aPTT. No specific perioperative treatment is required for these disorders.

Factor XIII Deficiency

Factor XIII is important for the structural stabilization of a fibrin clot; it creates cross-linking peptide bonds between the fibrin strands within a blood clot (Fig. 15–6). Blood clots that lack these cross-linked peptide bonds are unstable, permeable to blood, susceptible to fibrinolysis, and provide a poor framework for wound healing.[114] Although three different forms of congenital factor XIII deficiency have been described, they are all rare (estimated incidence of 1 in 5 million live births). All share the tendency for excessive perioperative bleeding, as well as a lifelong history of bleeding problems when factor XIII activity is less than 1%.[140] Hemorrhage may be seen from birth and throughout life. Although most bleeding episodes are triggered by trauma in these patients, spontaneous intracranial bleeding can occur.[141]

Definitive diagnosis of factor XIII deficiency is made with a specific clot solubility assay and an assay to quantify the level of factor XIII deficiency.[142] An acquired version of factor XIII deficiency exists that involves the generation of a factor XIII autoantibody in affected individuals.[114]

The treatment of factor XIII deficiency is accomplished by the administration of fresh-frozen plasma or cryoprecipitate. In Europe, factor XIII concentrate (Fibrogammin-P, Aventis-Behring) is available for the treatment of this disorder. Normal hemostasis occurs with factor XIII levels of approximately 5%. Preoperative preparation of individuals with factor XIII activity levels of less than 5% are treated with 2–3 mL/kg of fresh-frozen plasma or with 1 bag of cryoprecipitate per 10–20 kg of body weight. The long half-life of factor XIII (9–10 days) obviates the need to redose frequently. Lifelong supplementation of factor XIII is indicated in individuals with very low levels to prevent intracranial hemorrhage even if an operation is not planned.[143] The treatment of individuals who have developed inhibitory antibodies to factor XIII is more complex and may involve exchange transfusion, administration of platelets (platelets are known to contain factor XIII), or administration of immunosuppressants (e.g., intravenous γ-globulin, steroids, and cyclophosphamide).[114,144]

Afibrinogenemia

Fibrinogen serves as the precursor molecule for the proteinaceous fibrin scaffolding of a blood clot. Congenital or acquired deficiency of fibrinogen can result in clinically important bleeding disorders, especially in the surgical patient. Congenital homozygous afibrinogenemia is a rare (estimated incidence of 1–2 in 1 million live births), autosomal recessive disorder without a sex or race predilection that is associated with a varying severity of bleeding problems (e.g., easy bruising, mucosal hemorrhage, hematuria, hemarthroses, hemopericardium, hemoperitoneum, menometrorrhagia, obstetrical complications, intracerebral hemorrhage, and spontaneous splenic rupture) in afflicted patients.[145] Afflicted individuals have no detectable serum fibrinogen as manifest by an infinitely prolonged PT, aPTT, TT, occasional thrombocytopenia, and a fibrinogen assay that reveals no detectable fibrinogen.[146,147]

Fibrinogen levels must be restored to between 50 and 100 mg/dL preoperatively through the use of cryoprecipitate. To bring fibrinogen levels into the therapeutic range of 50–100 mg/dL, 5–10 bags of cryoprecipitate are needed. A single bag of cryoprecipitate contains approximately 250–300 mg of fibrinogen. Fibrinogen levels will persist for 2–4 days following infusion. Operations associated with postoperative hemorrhage result in decreased levels so they should be monitored perioperatively on a daily basis. Thrombosis has been reported in patients who have had their fibrinogen levels normalized via cryoprecipitate infusion.[148–150]

Dysfibrinogenemia

Many variants of congenital dysfibrinogenemia exist. They share the common feature of abnormal conversion of fibrinogen to fibrin. The polymerization defects that account for the most common dysfibrinogenemias are usually inherited in an autosomal dominant pattern with high penetrance.[151] Most individuals with dysfibrinogenemias are heterozygous and usually produce nearly 50% of the normal fibrinogen level, enabling effective hemostasis. Some dysfibrinogenemia variants result in fibrinogen levels that are well-below normal or, despite near-normal levels of fibrinogen, that are associated with bleeding problems if the abnormal variant affects the function of the structurally normal fibrinogen.

Clinical manifestations of dysfibrinogenemia include the following: thromboses (17%), mild bleeding after trauma (20%), both thrombotic and hemorrhagic manifestations (20%), no hemorrhagic phenomenon, or asymptomatic (43%). Affected individuals that demonstrate bleeding problems usually manifest them as soft-tissue bleeding, easy bruising, menorrhagia, and, most commonly, perioperative bleeding.[114] Individuals that manifest thromboses can experience either venous (e.g., deep venous thrombosis, pulmonary embolism) or arterial involvement (e.g., thrombosis of the aorta and carotid arteries).[151] Individuals with thrombotic manifestations can possess concurrent disorders within other portions of the coagulation axis (e.g., factor V Leiden mutation, protein S deficiency, other thrombophilias) that contribute to their propensity to inappropriately clot. Poor surgical wound healing can be associated with dysfibrinogenemia.[152]

Standard laboratory tests of the coagulation system (e.g., PT, aPTT, and TT) are usually prolonged despite normal levels of fibrinogen because of a functional defect in the circulating fibrinogen. Reptilase time is often prolonged and fibrinogen immunoelectrophoresis using agarose gels can reveal an abnormal pattern of protein migration. Acquired dysfibrinogenemia associated with hepatic disease can be differentiated from congenital dysfibrinogenemia because it demonstrates decreased levels of other clotting factors that are synthesized by the liver.

Symptomatic dysfibrinogenemia is treated by administering cryoprecipitate in a manner similar to that described in Afibrinogenemia above (i.e., the goal is to restore functional fibrinogen levels to 50–100 mg/dL). Fresh-frozen plasma or fibrinogen concentrates (not available in the United States) can also be administered to restore functional levels of fibrinogen to normal. The thrombotic variants of dysfibrinogenemia require treatment by intravenous anticoagulation with

unfractionated heparin and conversion to oral anticoagulants.[114]

Prothrombin (Factor II) Deficiency

Prothrombin deficiency consists of either a quantitative (hypoprothrombinemia) or qualitative (dysprothrombinemia) defect. Prothrombin (factor II) is normally converted to thrombin (factor IIa) (Fig. 15–6). Thrombin is needed for the conversion of fibrinogen to fibrin, which serves as the proteinaceous scaffolding of a blood clot. Dysprothrombinemia is an extremely rare, autosomal recessive disorder that can be either homozygous, heterozygous, or compound heterozygous.[153]

Heterozygous individuals generally have prothrombin activity levels of 50%, normal quantitative levels of prothrombin, and are asymptomatic or have only minor bleeding symptoms (e.g., may develop bleeding only after surgical procedures). Homozygous or compound heterozygous individuals demonstrate a lifelong history of bleeding.[154,155]

Dysprothrombinemia is definitively diagnosed using an assay of functional prothrombin activity. PT and aPTT are prolonged; both will correct when mixed 1:1 with normal plasma. Disordered hepatic function may cause acquired dysprothrombinemia. Acquired dysprothrombinemia is distinct in that multiple hepatic synthetic defects are present in the absence of a lifelong history of bleeding problems.[114]

Symptomatic dysprothrombinemia may be treated by administration of fresh-frozen plasma at a loading dose of 15–20 mL/kg followed by 3 mL/kg every 12–24 hours (an appropriate regimen for individuals with severe bleeding), administration of prothrombin complex concentrates with a loading dose of 20 U/kg prothrombin followed by 5 U/kg every 24 hours, or plasma exchange transfusion to restore near-normal levels of prothrombin.[156,157] Knowledge of the precise quantity of prothrombin in each individual prothrombin concentrate product is necessary to avoid the risk of precipitating thromboembolism from oversupplementation.[156]

Drug-Induced Hypocoagulable States

Thrombotic complications associated with surgery and percutaneous coronary interventions have stimulated development of intravenous, subcutaneous, and oral anticoagulant drugs over the past decade. There are two general classes of anticoagulant drugs: the antiplatelet agents and the antithrombotic agents.[158,159]

Knowing the pharmacodynamic and pharmacokinetic profiles of drugs that affect the coagulation system is necessary to make safe decisions regarding the timing of surgical procedures. Safe conduct of regional anesthesia mandates knowledge of how these drugs affect coagulation. An anticoagulant's half-life may not predict the duration of its effects on the coagulation axis if it irreversibly inhibits one or more aspects of the coagulation system. For example, aspirin has an elimination half-life of 15–20 minutes but irreversibly inhibits platelet activation through a select pathway.[160] Consideration of the route of elimination and the individual patient's level of organ function is necessary to predict a drug's effect. For instance, compromised renal function will prolong the elimination half-life of a drug that relies on the kidney to clear its active form. In some instances suppression or supplementation of select components of the coagulation system will be necessary to allow the safe conduct of an invasive procedure (i.e., patients that are systemically anticoagulated with unfractionated heparin may require the administration of protamine to neutralize the effects of the heparin–antithrombin complex on factor II and activated factor X).

The Antithrombotic Agents

The antithrombotic agents include 5 subcategories of drugs: unfractionated heparin (UFH), low-molecular-weight heparin (LMWH), activated factor X inhibitor, direct thrombin inhibitors, and coumarins. Antithrombotic agents are used both to treat thrombotic events and to prevent them.[158]

UFH, a large molecule that is extracted either from porcine intestine or bovine lung, exerts its antithrombotic effect primarily through its interaction with antithrombin. The heparin–antithrombin complex permits an approximately 1000-fold increase in the ability of heparin to inhibit factor II (prothrombin) activity and activated factor X activity.[161] The result of UFH's action is suppression of the coagulation cascade as reflected in a dose-dependent prolongation of the aPTT and the activated clotting time (ACT). The half-life of the anticoagulation effect of UFH as estimated by the aPTT is approximately 1.5 hours, irrespective of the heparin dose. In contrast, the functional half-life varies with the magnitude of the administered dose from approximately 40–150 minutes, with larger doses yielding a longer duration. UFH's elimination half-life is not affected by renal dysfunction as the drug is cleared from the plasma by transfer to the extravascular space, most likely to the reticuloendothelial system.[162] UFH dosage is calculated according to actual body weight; depending on the anticoagulation goal, different dosing schemes are used (e.g., initiation of cardiopulmonary bypass requires a bolus of approximately 300 U/kg, whereas treatment of a venous thrombosis requires a bolus of approximately 5000 U plus an infusion).[161] Laboratory monitoring is required (e.g., the aPTT, ACT or anti-factor Xa activity) because some individuals exhibit insensitivity to heparin.[163] An elapsed time of 4 hours following intravenous heparin therapy cessation may be required to achieve an aPTT of less than 35 seconds, indicating abatement of UFH's anticoagulant effects, before safely initiating an elective surgical procedure or attempting central neuraxial blockade. Alternatively, protamine sulfate can be administered to rapidly neutralize UFH's anticoagulant effect.

LMWH was developed to create an antithrombotic agent that does not require anticoagulant monitoring in the absence of renal insufficiency. LMWH is produced from UFH by a process that decreases the size of the polysaccharide chains on the heparin molecule, resulting in a smaller molecule with potent antiactivated factor X activity. Both UFH and LMWH require antithrombin to exert their effect on activated factor X.[161,166] A number of LMWH preparations are available for clinical use: enoxaparin (Lovenox), dalteparin (Fragmin), ardeparin (Normiflo), and tinzaparin (Innohep). Patients with renal insufficiency receiving LMWH require dose adjustment and plasma monitoring of antiactivated factor X activity.[164] Because the elimination half-lives of the various preparations of LMWH vary from 3–5 hours, waiting 24 hours after administration is recommended following higher doses (i.e., any dose of enox-

aparin >1 mg/kg or dalteparin >120 U/kg) of LMWH before initiating an elective surgical procedure or attempting central neuraxial blockade.[165] Although the anticoagulant effect of LMWH can be partially reversed by protamine sulfate,[166] one retrospective study of enoxaparin in cardiac surgical patients found that preoperative use was associated with increased red cell and platelet use, early reoperation for bleeding, and higher chest tube output in the first 24 hours postoperatively despite protamine reversal.[167]

The activated factor X inhibitor fondaparinux (Arixtra) requires interaction with antithrombin to exert its anticoagulant effect. Once bonded with antithrombin the fondaparinux–antithrombin complex selectively increases antithrombin's ability to inhibit activated factor X by approximately 300-fold. The molecule is smaller than that of LMWH and does not elicit formation of or react with the platelet factor 4 (PF4) antibody associated with heparin-induced thrombocytopenia type II. The elimination half-life is 17–21 hours. No definite recommendations exist for management of this drug before attempting neuraxial blockade, although it is recommended to use a single-needle atraumatic placement technique and avoid an indwelling catheter if a neuraxial procedure is mandated. Although no evidence-based recommendations exist, delaying an elective operation for approximately 5 half-lives, or 4 days, is a conservative management strategy for patients treated with this drug. Because there is minimal metabolic breakdown and the primary route of elimination is renal, dose adjustment is required in patients with renal insufficiency. Anti-activated plasma factor X levels are not required in the absence of renal insufficiency.[168]

Direct thrombin inhibitors include lepirudin (Refludan), argatroban, and bivalirudin (Angiomax). They exert their effect by interacting with free or clot-bound thrombin to inhibit conversion by thrombin of fibrinogen to fibrin. Direct thrombin inhibitors do not rely on the presence of antithrombin to exert their effects. They are used for treatment and prevention of thrombotic events, including treatment of patients undergoing percutaneous coronary interventions (PCIs) with, or who are at risk for, heparin-induced thrombocytopenia (argatroban), or for PCI (bivalirudin).[158] The half-lives of these drugs vary (Table 15–12). Bivalirudin was recently demonstrated to be a safe and effective option for anticoagulation of cardiac surgical patients requiring cardiopulmonary bypass.[169,170] Although no evidence-based recommendations exist, conservative management suggests that patients on continuous intravenous infusions of direct thrombin inhibitors should have the drug discontinued 5 elimination half-lives before an operation or neuraxial blockade. Direct thrombin inhibitors do not elicit formation of, or cross-react with, the PF4 antibody associated with heparin-induced thrombocytopenia type II and are therefore useful to prevent and treat thrombotic events in patients afflicted with this syndrome. Clinical effects of direct thrombin inhibitors are commonly followed with the aPTT or the ACT.

Coumarins, a subclass of antithrombotics that are orally administered, exert their anticoagulant effect by inhibiting the hepatic synthesis of vitamin K-dependent coagulation factors. Specifically, coumarins inhibit the synthesis of factors II, VII, IX, and X, as well as proteins C and S. Assessment of the PT or international normalized ratio (INR) can quantify low levels of these specific coagulation proteins. Because these vitamin K-dependent factors participate in the extrinsic and common coagulation pathways (Fig. 15–6), the PT is the best test to assess coumarin effects. PT is reported as an INR to avoid interlaboratory variation in absolute PT results.[159] Coumadin is the only coumarin approved by the FDA. It is metabolized by the liver and possesses an elimination half-life of 20–60 hours. Anticoagulant effects of Coumadin take several days to abate, depending on the level of Coumadin effect at discontinuation. Administration of vitamin K decreases the time for the effects of Coumadin to abate, but may make it difficult to reinstitute a therapeutic Coumadin effect, complicating perioperative anticoagulation therapy. Alternatively, administration of fresh-frozen plasma acutely reverses the anticoagulant effects of Coumadin. However, anticoagulation may recur several hours later because of the longer half-life of Coumadin than of the coagulation factor levels that it affects (e.g., the half-life of Coumadin is 20–60 hours whereas the half-life of factor VII is approximately 6 hours). Excessive operative hemorrhage and neuraxial anesthesia associated with spinal or epidural hematoma may occur if Coumadin is not neutralized. Individuals at increased risk for a serious thrombotic event should be anticoagulated with a second intravenous or subcutaneous antithrombotic agent (e.g., UFH, LMWH or a short-acting direct thrombin inhibitor) before Coumadin is discontinued or neutralized. Titration of antithrombotic therapy is complex in the presence of more than one antithrombotic agent or when a preexisting factor deficiency is present. A hematology consultation should be considered for these patients.

TABLE 15–12.

Direct Thrombin Inhibitor Elimination Half-Lives

Drug	Half-Life (Minutes)
Argatroban[a]	30–51
Bivalirudin (Angiomax)[b]	25
Lepirudin (Refludan)[c]	48–120

Data from [a] Casserly IP, Kereiakes DJ, Gray WA, et al;[220] [b] Thomson MICROMEDEX;[222] and [c] Francis CW and Berkowitz SD.[158]

Antiplatelet Agents

The 5 subcategories of antiplatelet agents are nonsteroidal antiinflammatory drugs; glycoprotein IIb/IIIa receptor inhibitors; platelet adhesion inhibitors; platelet adenosine diphosphate (ADP)-receptor antagonists and platelet-production-limiting agents. Because platelets can be activated by more than one stimulus, not all antiplatelet agents clearly place surgical patients at increased risk for bleeding. Indeed antiplatelet drugs are beneficial to patients with cardiovascular disease.[171,172] The increasing use of herbal medications in the United States has drawn attention to the anticoagulant effects of garlic, ginkgo, ginseng, ginger, dong quai, feverfew, and fish oil; limited evidence-based data exists describing interactions of herbal medications with other medications and their effect on the clinical course of surgical patients.[173,174]

Nonsteroidal Antiinflammatory Drugs

Aspirin exerts its antiplatelet effects by creating irreversible inhibition of platelet cyclooxygenase. This prevents the

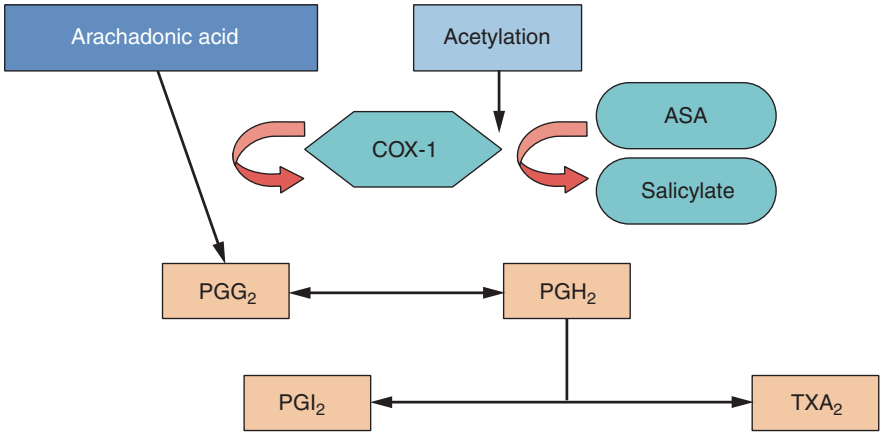

FIGURE 15–7. Pharmacodynamics of aspirin.

formation of thromboxane A_2 from arachidonic acid for the life of the platelet, which, in turn, blocks the platelet activation, aggregation, and internal mediator release that would propagate further platelet activation (Fig. 15–7). Because normal platelets have an average circulating life span of approximately 10 days, it may take up to 5 days for half of the normal platelet function to return after treatment with aspirin, despite measurement of a normal platelet count. Aspirin's half-life is 15–20 minutes in the plasma and it undergoes primarily hepatic metabolism, although it also undergoes plasma esterase metabolism. Other nonsteroidal antiinflammatory drugs (NSAIDs), such as ibuprofen and naproxen, produce reversible platelet cyclooxygenase inhibition. Thus the return of platelet function correlates with the drug's half-life and perioperative management of these antiplatelet agents is easily accomplished when one considers that permitting 5 half-lives to elapse following the last dose will eliminate the effects of these particular NSAIDs. For aspirin a separate perioperative treatment strategy is needed. Provided that aspirin blood levels do not exist, antiplatelet effects of aspirin can be overcome by platelet transfusion.[160] Doubt exists whether NSAIDs result in significant surgical hemorrhage. If an NSAID is the only inhibitory influence on the coagulation cascade central neuraxial blockade can be safely undertaken.[165,175] In selected patients with severe peripheral arterial vascular disease, it is advisable to continue perioperative aspirin.[176]

Glycoprotein IIb/IIIa Receptor Inhibitors

The glycoprotein IIb/IIIa (GP IIb/IIIa) receptor inhibitors are available only in intravenous preparations and are among the most potent inhibitors of platelet function. Currently, the following GP IIb/IIIa receptor inhibitors are approved for clinical use in the United States: abciximab (ReoPro), eptifibatide (Integrilin), and tirofiban (Aggrastat). Platelets are activated by several different stimuli, including thromboxane, ADP, epinephrine, serotonin, and mechanical shear stress. The final common pathway of platelet activation involves platelet aggregation via interaction of GP IIb/IIIa receptors and either fibrinogen or vWF as an intermediate molecule. Complete inhibition of this final step of platelet aggregation could render a patient completely thrombasthenic.

Abciximab (ReoPro) is the Fab portion of the chimeric human–murine monoclonal antibody 7E3 that is directed against the platelet GP IIb/IIIa receptor. In therapeutic doses, it creates a marked decrease in the ability of platelets to aggregate. In approximately 1–2% of patients, it produces significant thrombocytopenia.[177] Abciximab also inhibits thrombus formation by suppressing tissue factor-induced thrombin generation. It is FDA approved for use as an adjunct in PCI and as an adjunct in the treatment of refractory angina. Abciximab has a 30-minute plasma half-life. However, once bound to the platelet GP IIb/IIIa receptor, it remains in the circulation for up to 15 days. The putative mechanism for this is migration from platelet to platelet. The antiaggregation effect lasts for 12–48 hours. Platelet transfusion may partially restore platelet function if significant bleeding occurs 12–48 hours after infusion.[177] Central neuraxial blockade is contraindicated within 24–48 hours of abciximab administration. Delaying a cardiac operation in the stable patient treated with abciximab for 12–24 hours allows the return of platelet function.[165]

Tirofiban (Aggrastat), a nonpeptide chemical antagonist of the platelet GP IIb/IIIa receptor, produces a greater than 90% reduction in platelet aggregation that is reversible. Tirofiban is FDA approved for the treatment of acute coronary syndrome (ACS) in patients undergoing angioplasty or being medically managed.[178] The half-life is reported as 90–180 minutes; it undergoes renal excretion largely as unchanged drug. Central neuraxial blockade should be delayed for 8 hours in patients who are receiving tirofiban.[165] It does not appear to confer an increased risk of hemorrhage following emergent or urgent coronary surgery.[178] No specific recommendations are available for general surgical patients at this time.

Eptifibatide (Integrilin), a heptapeptide molecule that inhibits the platelet GP IIb/IIIa receptor, is a potent inhibitor of platelet aggregation with FDA approval for use in PCI and for the treatment of ACS. The drug is cleared from the circulation by the kidneys with a half-life of 2.5 hours. Approximately 71% of the drug is eliminated unmetabolized.[179] A delay of 4–8 hours is recommended after discontinuation of this drug before attempting central neuraxial blockade.[165] One large trial suggested that it was safe to perform a coronary operation within 2 hours of the discontinuation of eptifibatide; the drug was also associated with a platelet-sparing effect in these patients.[180] No evidence-based recommendations are available for general surgical patients at this time.

ADP Antagonists

Clopidogrel (Plavix) and ticlopidine (Ticlid), the only two FDA-approved ADP-receptor antagonists, selectively and irreversibly inhibit ADP-induced platelet aggregation by blocking the P2Y12 ADP receptor on the platelet surface. These oral agents do not affect prostacyclin and thromboxane synthesis and work by preventing the ADP

platelet P2Y12 receptor from transmitting a signal to the platelet to activate its GP IIb/IIIa receptor complexes.

Clopidogrel is FDA approved for the reduction of thrombotic events related to recent myocardial infarction, stroke and established peripheral arterial disease. Additionally, clopidogrel is approved for both the medical management and PCI performed for the treatment of ACS. Clopidogrel and ticlopidine both undergo extensive hepatic metabolism. Clopidogrel is excreted in both the urine and feces in a balanced fashion. The half-life of clopidogrel is reported to be 8 hours.[181,182] The irreversible nature of clopidogrel's effect on platelets requires a full 5–7 days to elapse following drug cessation before a population of functional platelets are available to participate in the coagulation process. A delay of 7 full days is recommended following treatment with this drug before attempting central neuraxial blockade.[165] Clopidogrel-treated patients bleed more and require significantly higher rates of blood product transfusion following cardiac surgery.[182] Evidence-based recommendations do not exist for general surgery patients at this time.

Ticlopidine is FDA approved for the placement of coronary stents in conjunction with aspirin therapy. Ticlopidine is also FDA approved for the prophylaxis of thromboembolic stroke. At least 1 metabolite of ticlopidine is a potent inhibitor of ADP-induced platelet aggregation. This metabolite is excreted primarily in the urine. Ticlopidine has a reported half-life of 12.6 hours, which increases dramatically to 5 days with repeated dosing. Ticlopidine is used less frequently than clopidogrel because of hematologic toxicity (e.g., neutropenia, agranulocytosis, and thrombotic thrombocytopenic purpura). A delay of 14 days is recommended following discontinuation of this drug before attempting central neuraxial blockade.[165] Evidence-based recommendations do not exist for general surgery patients at this time.

Platelet-Adhesion Inhibitors

Dipyridamole (Persantine), Aggrenox, and cilostazol (Pletal) are the three available drugs classified as platelet-adhesion inhibitors. Their mechanisms of action differ from those previously described. Dipyridamole, available in oral and intravenous preparations, suppresses platelet aggregation by inhibiting the ability of the platelet to take up adenosine. The increased concentration of adenosine local to the platelet stimulates the platelet A_2-receptor which potentiates the platelet's production of cyclic-3',5'-adenosine monophosphate (cAMP). Additionally, dipyridamole has been found to inhibit cellular phosphodiesterase activity which is also speculated to increase intraplatelet cAMP levels. The increased intraplatelet levels of cAMP act to inhibit platelet aggregation by blocking the activation of platelets by 3 different stimuli—ADP, platelet-activating factor, and collagen. Dipyridamole also inhibits phosphodiesterase in other tissues and results in vasodilatation as a result of its effects on vascular endothelium.[183] It is FDA approved to be used as an adjunct with Coumadin for the prophylaxis of thromboembolic complications associated with cardiac valve replacement and for use with thallium in myocardial imaging studies. It is also employed to prevent thromboembolic events associated with coronary surgery. Dipyridamole primarily undergoes hepatic metabolism and has a reported half-life of approximately 9–13 hours.

Dipyridamole administration is associated with bleeding. The risk is greater when dipyridamole is combined with aspirin therapy.[183,184] A combination of dipyridamole and aspirin, Aggrenox, is commercially available. Aggrenox is FDA approved for the prophylaxis of cerebrovascular accidents in patients with a previous history of stroke or transient ischemic attacks. It may be prudent to delay central neuraxial anesthesia for 7 days following Aggrenox therapy to allow for approximately 50% of normal platelet function to return. Published literature does not present the use of dipyridamole alone to be a direct contraindication to proceeding with elective surgery or neuraxial blockade; however, given that dipyridamole works by suppressing the platelet's ability to be activated by ADP, collagen and platelet-activating factor it may be prudent to avoid elective surgery and neuraxial blockade for 4 days. A meta-analysis concluded that among antiplatelet drugs dipyridamole was associated with the lowest incidence of bleeding complications.[185] In one large trial of antiplatelet drugs used for the prevention of stroke in medical patients, dipyridamole was indistinguishable from placebo in terms of bleeding complications.[186]

Cilostazol (Pletal) increases intracellular cAMP by inhibiting the enzyme phosphodiesterase III. An increase in levels of cAMP results in the reversible inhibition of platelet aggregation that is normally stimulated by thrombin, ADP, collagen, epinephrine, arachidonic acid, and shear stress. Cilostazol's phosphodiesterase inhibition also causes systemic vasodilatation. It is FDA approved for the reduction of symptoms of intermittent claudication. It is extensively metabolized by the liver into active metabolites that are primarily cleared by the kidneys and has a reported elimination half-life of 11–13 hours. Because no evidence-based recommendations exist, a conservative management approach may be to delay elective surgery or central neuraxial blockade for 48 hours following administration.[187]

Herbal Therapies

Self-medication with herbal therapies has been increasing in the United States for the past several years.[173] Specific herbal therapies are now recognized as having deleterious effects on elements of the coagulation cascade, although there is a paucity of sound research.[174] Garlic, ginkgo, ginseng, ginger, feverfew, fish oil, and dong quai have all been implicated in inhibiting normal hemostasis; several of these biologics have been proven to interfere with platelet aggregation.[165,174] Anesthesiologists should routinely inquire during the preoperative evaluation whether patients are taking any herbal supplements. Patients taking these supplements should be advised to discontinue their use perioperatively. The current lack of literature makes it difficult to impossible to recommend delaying elective surgical procedures or neuraxial blockade in patients using these supplements.

Hypocoagulable Effects of the Synthetic Colloid Infusions

HES, a synthetic colloid solution derived from amylopectin, is a useful volume expander that has a well-recognized profile of anticoagulant effects.[38] Hespan, a commercially available HES solution, is FDA approved for use in leukophoresis and as volume expander in hypovolemic adults and children

undergoing surgery or in patients in shock secondary to hemorrhage or sepsis. The reported half-life is between 67 hours and 17 days, depending on the size of the molecule. As an alternative to banked blood products, it avoids infection, immunosuppression, and transfusion reactions. Patients prone to develop procedure-associated coagulopathy (e.g., cardiac surgery patients undergoing cardiopulmonary bypass or hepatic transplant patients) may be poor candidates for HES. A meta-analysis comparing HES to albumin in patients undergoing cardiopulmonary bypass concluded that HES was associated with greater postoperative blood loss.[188] One literature review demonstrated that adhering to the recommended HES dose of 20 mL/kg was still associated with adverse effects, particularly in intensive care and cardiac surgical patients. This review confirmed that bleeding is associated with the administration of artificial colloids and that protracted pruritus is a commonly reported troublesome reaction. Non–life-threatening anaphylactoid reactions are more likely with HES than with albumin. Additionally, the authors concluded that albumin appears to be the safest option among albumin, dextran, HES, and gelatin (unavailable in the United States) for colloid-based plasma volume expanders.[189]

Hypercoagulable States

Thrombophilias, or hypercoagulable states, put surgical patients at increased risk for experiencing a postoperative thrombotic event. Many of these hypercoagulable states are managed with either temporary or lifelong systemic anticoagulation therapy. Environmental influences (e.g., trauma, surgery, infection, or administration of a drug) will increase the likelihood of a patient with either a congenital or acquired hypercoagulable disorder to develop a thromboembolic event and thus will affect the perioperative management of these patients.[190,191] Several thrombophilias are currently recognized and anesthesiologists should be familiar with them to aid in the provision of optimal perioperative care. Discontinuation and reinitiation of systemic anticoagulation in the perioperative period is most safely managed in concert with a hematologist.

Antithrombin Deficiency

Antithrombin (also termed antithrombin III) is a plasma protein made by the liver that prevents hypercoagulability by binding to and neutralizing thrombin (factor IIa) and to factors IXa, Xa, XIa, and XIIa (Fig. 15–6).[192] Antithrombin (AT) deficiency is associated with a predilection for thrombosis. AT deficiency is a congenital disorder inherited as an autosomal dominant trait that is estimated to occur in the general population with a prevalence of between 1 in 250–500 people.[192,193] Individuals with a history of an unexplained thrombotic event should be evaluated to rule out this disorder.

AT deficiency may be a result of a decreased synthesis (type I) of the protein or a decreased activity of the protein in the presence of normal levels (type II).[194] AT levels are reported to be between 75% and 120% in normal individuals.[195] AT levels are measured by a specific assay. Disease states associated with a reduction in AT activity include sepsis, disseminated intravascular coagulation, burns, acute thrombosis, hepatic disease, severe trauma, and nephritis.[192]

Patients with an AT deficiency have a predisposition to develop deep vein thromboses and therefore are often maintained on Coumadin. Perioperative management of anticoagulation should be tailored to the invasiveness of the planned intervention or surgical procedure. Surgery induces a prothrombotic state and increases the risk of perioperative thrombosis.[196] Preoperative discontinuation and postoperative reinstitution of systemic anticoagulation therapy in these patients should be done in conjunction with a hematologist.

Anticoagulation with UFH is frequently required for cardiac, endovascular and open vascular surgical procedures. Importantly, many AT-deficient patients exhibit a relative resistance to UFH as UFH anticoagulation requires coupling with AT to induce a several-fold increase in AT's neutralizing effect on the procoagulant factors IIa, IXa, Xa, XIa, and XIIa.[197] ACT or aPTT assays will reveal heparin resistance in patients with an AT deficiency. Heparin resistance in this context is defined as a failure of UFH to produce the expected degree of ACT or aPTT prolongation. Heparin resistance caused by AT deficiency is most efficiently treated with plasma-derived, purified AT III concentrate (Thrombate III). Bolus Thrombate III administration of 50 IU/kg has been recommended. In practice, 1–2 vials of purified AT concentrate are often administered and the biologic's effect is ascertained by performing the ACT assay. If Thrombate III is not available (or not desired), heparin resistance can be treated with 2–4 units of fresh-frozen plasma; the effect of this therapy can be verified with the ACT assay.[198]

Protein C Deficiency

Protein C is a hepatically synthesized vitamin K-dependent protein that, when converted to its active form (activated protein C), exerts an anticoagulant effect through interaction with factors Va and VIIIa. Protein C deficiency may be caused by a quantitative or qualitative defect. It is estimated to occur in the general population with a prevalence of between 1 in 200–500.[199]

Many individuals with protein C deficiency will exhibit a prothrombotic tendency and hence require systemic anticoagulation. Protein C deficiency is diagnosed by an aPTT-based clotting assay.[192] The diagnosis of protein C deficiency in patients who were recently treated with Coumadin is complex.[200] Individuals with protein C deficiency presenting for surgical intervention require perioperative modification of their anticoagulation therapy, which is best accomplished in consultation with a hematologist.

Protein S Deficiency

Proteins S is synthesized primarily in the liver, and functions as a cofactor for activated protein C.[201] Quantitative and qualitative congenital protein S deficiencies have been described.[202] Individuals with protein S deficiency can exhibit a prothrombotic tendency and may be maintained on systemic oral anticoagulation as outpatients. Perioperative management should be accomplished in conjunction with a hematologist.

Factor V Leiden (Activated Protein C Resistance)

Factor V Leiden, also termed activated protein C resistance, is associated with recurrent venous thromboembolic events.[203] It is caused by a single point mutation in the gene that encodes for factor V.[204] This mutation is common among patients who experience thrombotic events; Griffin et al. found that 50% of patients with unexplained

thrombotic events demonstrated activated protein C resistance.[205] It is commonly diagnosed by an aPTT-based assay. Because individuals with the factor V Leiden mutation may be on either temporary or lifetime systemic oral anticoagulation,[206] perioperative management should be determined in consultation with a hematologist.

Prothrombin G20210 Mutation

Prothrombin, or factor II, is an essential element of the coagulation cascade. A single base pair substitution mutation results in affected individuals expressing higher plasma prothrombin activity, which is associated with the occurrence of thromboembolic disease in these patients.[192,207,208] This disorder is the second most common thrombophilia, with a prevalence of 2% in whites, with considerable geographic variation.[209] It is commonly diagnosed using a polymerase chain reaction-based test.[192] Hematologic consultation is advisable in the perioperative period.

Heparin-Induced Thrombocytopenia

Heparin-induced thrombocytopenia (HIT) involves an immune-mediated response to either LMWH or UFH administration that results in pathologic platelet activation causing arterial and/or venous thrombosis with or without associated tissue ischemia and infarction. There are two types of HIT. Type I is a non–immune-mediated activation of platelets in heparin-treated patients causing a mild reduction in circulating platelets.[210]

HIT type II, or heparin-induced thrombosis-thrombocytopenia syndrome (HITTS), is immune mediated. It is caused by the interaction of a heparin-dependent IgG antibody with the molecular complex of PF4 and heparin. The heparin-PF4–bound IgG antibody stimulates platelet activation via the platelet FcγIIa receptor.[211] Once platelets are activated, they release internal biochemical mediators that induce platelet aggregation and stimulate other platelets to become activated. The same biochemical mediators that are released from the activated platelets also stimulate thrombin generation.[212] The heparin-PF4 IgG antibody-induced platelet aggregation, along with the thrombin that is generated, contributes to the formation of thrombus. Although venous thrombosis occurs most commonly in HIT type II, arterial thrombosis is also observed. Thrombi can cause organ ischemia and/or infarction. Thrombotic emboli may damage organs distant to the site of thrombus formation. Loss of limbs and damage to vital organs, such as renal failure or strokes, are recognized complications of this disorder.[213]

Numerous features of HIT type II are not well understood. Only a portion of the patients who are exposed to heparin develop the IgG antibody directed against heparin and PF4 (commonly termed the PF4 antibody). Only a small percentage of the patients who develop the PF4 antibody develop thrombocytopenia and a recognized thrombotic event.[214] At least a 50% decrease of platelet count from the preheparin administration baseline is required to establish the diagnosis of HIT type II.[213] Using the absolute laboratory criterion of less than 150,000 platelets/mm^3 is not completely appropriate to diagnose HIT type II. Patients who are generating the PF4 antibody upon initial exposure to heparin characteristically take at least 5 days to develop PF4 antibody sufficient to cause thrombocytopenia. Patients previously exposed to heparin who have generated PF4 antibody in the past 100 days may develop thrombocytopenia more rapidly.[215] In contrast, the thrombocytopenic response and thrombotic event can occur several days to weeks following the discontinuation of heparin therapy.[216]

HIT type II may be diagnosed using either an antigen assay or a platelet activation assay; these tests are indicated in patients with a history of thrombocytopenia temporally related to heparin administration or in patients receiving heparin with previously documented HIT type II. The antigen type assays use the enzyme-linked immunosorbent assay to detect the presence of the PF4 antibody, which has proven to be highly sensitive for PF4 antibody detection.[211,217,218] The activation assays detect the PF4 antibodies by detecting their ability to activate platelets in the presence of heparin.[211] The platelet serotonin release assay is an example of an activation assay that detects HIT type II by quantifying the release of ^{14}C-labeled serotonin from platelets activated by heparin in the presence of the PF4 antibody.[219]

Treatment of HIT type II consists of immediate and complete discontinuation of heparin by any routes. Additionally, immediate systemic anticoagulation is indicated in the setting of thrombosis; the current agents of choice are the direct thrombin inhibitors (e.g., argatroban, bivalirudin, or lepirudin). After systemic levels of a direct thrombin inhibitor are achieved, oral anticoagulation with a coumarin may be established and the direct thrombin inhibitor discontinued. Oral coumarin therapy must not be established until effective thrombin suppression has been achieved to avoid precipitating warfarin-induced skin necrosis.[210,215]

Given the widespread use of heparin, HIT type II is an important consideration for anesthesiologists. Cardiac and vascular anesthesiologists as well as intensivists will be challenged by this clinical disorder on a regular basis.[218] Heparin should be scrupulously avoided in patients with HIT type II and an elevated PF4 antibody titer in order to avoid precipitation of a thrombotic event. Patients with a distant history of an elevated PF4 antibody titer should not be treated with heparin unless the clinical situation mandates systemic anticoagulation (e.g., acute need for cardiac surgery requiring cardiopulmonary bypass [CPB] at an institution that is not experienced with using a direct thrombin inhibitor in the same clinical setting). Alternatives for vascular and other noncardiac surgical procedures that require systemic anticoagulation include argatroban and bivalirudin. Argatroban, a univalent direct thrombin inhibitor, is approved by the FDA for systemic anticoagulation in patients diagnosed with HIT type II.[220] Bivalirudin (Angiomax), a bivalent direct thrombin inhibitor, is also an option despite lack of FDA approval. Bivalirudin is the first safe and effective alternative to heparin in cardiac surgical patients with HIT type II.[169,170,221] No reversal agents are available for either argatroban or bivalirudin; their suppression of activated factor II abates only after the drug has cleared from the circulation. Argatroban is primarily cleared by hepatic metabolism, whereas bivalirudin is partially metabolized by plasma enzymes and then cleared by renal metabolism.[222] The use of bivalirudin in CPB surgical procedures is complex and requires both an in-depth understanding of the drug and training for the entire cardiac sur-

gical team (e.g., cardiac anesthesia, surgery, nursing, and perfusion) in order to be used safely. The use of bivalirudin in patients on CPB mandates that blood continuously flow in all native and extracorporeal circulations to avoid thrombus formation in areas of blood stagnation because the drug is metabolized by thrombin itself. Both argatroban and bivalirudin can be titrated with the aPTT if the desired level of systemic anticoagulation is between 1.5 and 3 times the baseline aPTT.[220,222] If higher levels of systemic anticoagulation are desired, then the ACT is currently the preferred method to titrate the effect of these drugs.[223]

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is presently recognized as a deviation from the normal physiologic balance between the processes of thrombus formation and fibrinolysis. Pathologic hemorrhage, pathologic thrombosis, or both may occur in DIC. Numerous disease processes have been identified as being associated with DIC (Table 15–13).[224] All of these disease states have in common the production of intense, sustained stimulation of the coagulation axis, achieved by inflammatory mediators resulting in dysregulation of coagulation and/or fibrinolysis.[225,226] The association of DIC with inflammation helps to explain why this condition can be associated with multiorgan dysfunction syndrome (MODS) and adult respiratory distress syndrome, two disorders that also involve inappropriate regulation of the inflammatory response. The pathophysiologic mechanism of DIC is incompletely understood. Pathologic thrombosis at the microcirculatory level results in organ malperfusion, ischemia, infarction, and dysfunction, as well as pathologic consumption of essential coagulation elements (e.g., platelets, fibrinogen, and soluble coagulation proteins). Dysregulation of fibrinolysis can contribute to DIC-associated thrombosis (i.e., there is oversuppression of fibrinolysis from excessive plasminogen activator inhibitor type 1) or to DIC-associated hemorrhage (i.e., there is overstimulation of fibrinolysis from high levels of inflammatory mediators, including interleukin-1, interleukin-6, interleukin-10, and tissue necrosis factor).[227,228]

The diagnosis of DIC is approached from two vantage points. First, because DIC is the manifestation of a primary disease process, one must investigate potential clinical causes that may give rise to DIC (Table 15–13). Second, although DIC is often initially suspected as a clinical diagnosis, central laboratory values may help to establish the diagnosis. Some authorities advocate for the more readily available central laboratory tests including the aPTT, PT, TT, fibrin degradation products (FDPs) level, D-dimer level and complete blood count. Although measured elevation in FDPs, elevation in D-dimers, prolonged aPTT, PT, and TT, and decreased platelet counts are not universally seen in DIC, they can be very helpful in making the diagnosis if a high level of clinical suspicion exists.[224,229]

The treatment of DIC is most appropriately directed at the underlying cause of the disorder. For example, DIC in a septic patient with an intraabdominal abscess is most effectively treated by abscess drainage. An obstetrical patient who develops DIC in association with abruptio placentae is best treated with uterine evacuation. Exhaustive efforts to correct laboratory abnormalities may not be needed in all cases of DIC, especially those in which patients require surgical treatment.

Perioperative goals include maintaining the platelet count in the range of 25,000–50,000/μL and the fibrinogen level greater than 50 mg/dL. However, few data exist on the effective management of the patient with DIC.[224] Presently, with the exception of Trousseau syndrome (occurrence of thrombophlebitis migrans with visceral cancer), anticoagulation is not recommended as a treatment for DIC. Intravenous administration of antithrombin concentrate, although advocated by some, is presently not recommended.[230–232] Hemorrhaging DIC patients should be volume resuscitated as appropriate to restore intravascular volume to a level consistent with organ perfusion. As previously stated, coagulopathy is not expected to fully correct until the underlying cause of DIC is appropriately addressed.

TABLE 15–13.

Processes That Can Induce Disseminated Intravascular Coagulation

Tissue Damage	Obstetric Conditions
Trauma	Abruptio placentae
Crush injuries	Placenta previa
CNS injuries	Uterine atony
Heat stroke	Therapeutic abortion
Burns	Toxemia of pregnancy
Hemolytic transfusion reaction	Retained dead fetus syndrome
Acute transplant rejection	Amniotic fluid embolism
Neoplasia	Miscellaneous
Cancers	Shock
Leukemias	Cardiac arrest
Cancer chemotherapy	Near drowning
Tumor lysis syndrome	Fat embolism
Infections	Aortic aneurysm
Gram-positive bacteria	Giant hemangiomas
Gram-negative bacteria	Snake bites
Spirochetes	
Rickettsia	
Protozoa	
Fungi	
Viruses

Hyperhomocysteinemia

Hyperhomocysteinemia is an independent risk factor for stroke, myocardial infarction, carotid artery disease, and venous thrombosis.[233–236] Plasma homocysteine levels are partially genetically determined, but are also influenced by environmental factors, specifically by dietary intake of folic acid, vitamin B_{12}, and vitamin B_6. Hyperhomocysteinemia is present in 10–20% of patients who develop venous thrombosis. Hyperho-

mocysteinemia is diagnosed by measuring plasma levels of homocysteine.[196] No specific recommendations exist for the perioperative management of patients with hyperhomocysteinemia, although vitamin supplementation does reduce plasma homocysteine levels in the elderly population.[237] However, reduction of homocysteine levels by vitamins does not decrease the risk of vascular disease. It might be prudent to employ postoperative venous thrombotic prophylaxis, especially in patient populations considered at risk for the development of a postoperative thrombosis (e.g., orthopedic surgical patients). However, no specific recommendations as to a particular antithrombotic or antiplatelet treatment regimen currently exist.

CHAPTER 16

Evaluation of the Patient with Perioperative Malnutrition

Jacob T. Gutsche, MD, and Clifford S. Deutschman, MS, MD, FCCM

As a result of advances in medical and surgical care, operative intervention is now provided for older and sicker patients. These individuals frequently suffer the consequences of disease-induced altered metabolism and nutritional depletion. Consequently, today's anesthesiologist requires a solid working knowledge of perioperative metabolic abnormalities and their effects on organ function, drug metabolism, and patient outcome. This chapter addresses (a) definitions of malnutrition, (b) assessment of malnutrition, (c) the incidence of malnutrition in surgical patients, (d) the effects on organ system function, (e) the consequences of attempted reversal on organ system function, and (f) the association of reversal with improved outcome.

DEFINITION AND SCOPE OF PROTEIN-ENERGY MALNUTRITION

Inadequate intake of macronutrients (carbohydrate, protein, fat) is referred to as protein-energy malnutrition (PEM). The hallmark of this process is a reduction in lean body cell mass. Original work on PEM centered on children in underdeveloped nations and in adults receiving experimental diets designed to mimic famine or "life-raft" conditions. A brief review of these two different conditions is important because the clinical presentation of the two conditions is different, and because nutritional management principles derived for use in starvation are ineffective (and can lead to complications) in the presence of stress. However, what is most often seen in surgical patients reflects the interplay of metabolic changes resulting from starvation with those occurring as a result of "stress" (inflammation, infection, surgery, trauma, and neoplasia). In fact, as detailed by Bistrian[1] and Bistrian et al.,[2] PEM in sick adults represents a broad spectrum of abnormalities.

Starvation

In the initial period of fasting, metabolic rate decreases to conserve endogenous substrate, especially nitrogen. Glucose is the predominant fuel of early starvation and continues to be made available to those tissues that require it (brain, fibroblasts, erythrocytes, leukocytes, renal medullary tissue). Other tissues quickly alter metabolism to adapt to alternative substrate. Glucose is derived initially from glycogen, but following the depletion of stores (about 24 hours of fasting) hepatic and renal gluconeogenesis from amino acids supplied by muscle catabolism predominate.[3] Insulin secretion decreases because gluconeogenesis is unable to maintain blood glucose concentration at prestarvation values.[3] Decreased insulin promotes lipolysis (by activation of a hormone-sensitive lipase) and ketonemia. Ketones inhibit pyruvate dehydrogenase and prevent the conversion of pyruvate to acetyl coenzyme A (CoA), thereby blocking use of the end products of glycolysis in the tricarboxylic acid cycle. As a consequence, the primary fuel for most tissues switches to acetyl CoA derived from fat or ketones. This change is reflected in a decrease in the respiratory quotient (carbon dioxide production/oxygen consumption).[3] In addition, the decrease in glucose is associated with secretion of epinephrine, cortisol, and glucagon. The effect of these three "counterregulatory" hormones is stimulation of proteolysis, lipolysis, and gluconeogenesis.[3] Muscle-derived gluconeogenesis provides fuel for tissues

KEY POINTS

1. Although the incidence of malnutrition is unclear, the problem in patients presenting for surgery may be widespread. In addition, a large number of patients acquire protein-energy malnutrition (PEM) during hospitalization, which can alter the response to anesthetics.
2. In contrast to starvation, acute stress metabolism involves extensive neurohumoral modulation. Inflammation, surgery, trauma, or infection activates monokines, lymphokines, prostanoids, hormones, neural pathways, complement, and other endogenous mediators that "drive" metabolism and increase energy expenditure.
3. PEM is a metabolic disorder that affects virtually every organ system.
4. Decreased total circulating albumin has wide implications for drug administration and volume of distribution.
5. As a result of decreased microsomal enzyme activity and altered cytochrome P450/nicotinamide adenine dinucleotide phosphate (NADPH)-dependent transport mechanisms protein deficiency may reduce drug metabolism. Decreased transformation of compounds that are hepatically detoxified may lead to pathologic responses that require dosage alteration.
6. A number of studies confirm that decreased serum transport protein levels, anergy, and weight loss are associated with poor postoperative outcomes.
7. Accurate estimation of the presence and severity of PEM remains problematic for the anesthesiologist whose evaluation of the patient is often brief. The most useful tool for assessing a patient's nutritional status is a well-performed history and physical examination.
8. Abnormalities of plasma proteins are associated with an increased incidence of bowel anastomotic dehiscence.
9. The anesthesiologist should ensure that the patient presenting for elective surgery is in the best possible condition to tolerate the operation and postoperative course. The relatively poor outcome associated with malnutrition, coupled with the apparent benefits of repletion in the severely depleted individual, constitutes one more problem that must be addressed to improve overall patient outcome.

that are obligate glucose users. If allowed to continue unchecked, such a process would culminate in rapid depletion of endogenous protein, primarily because of the demands of neural tissue. To counter this effect, brain tissue adapts to the use of ketones, permitting a further decrease in glucose demand and some sparing of lean body mass.[4]

In starvation, adaptation to exogenous substrate is effective; when given glucose, a starved individual responds to the increase in serum glucose by increasing insulin secretion and decreasing levels of counterregulatory hormones. This decreases levels of proteolysis, lipolysis, and gluconeogenesis. The resulting reliance on the externally supplied glucose spares endogenous tissues and decreases ketosis (blocked by insulin).[3] Similar patterns are observed when exogenous fuel is supplied as fat or protein. When demand for energy increases, as in exercise, anaerobic metabolism of glucose also increases.

Primary use of branched-chain amino acids by muscle may help meet the new demand.[3] Lactate from anaerobiosis and amino acids derived from proteolysis (which result, in part, from increased catecholamines) are released by exercising muscle and are recycled by the liver via the gluconeogenic pathway. The newly synthesized glucose can return to skeletal muscle and again be metabolized to lactate. These processes make metabolic rate responsive to tissue demand and exogenous substrate availability with only modest neuroendocrine modulation.[5] Prolonged fasting metabolism eventually results in a clinical picture similar to the form of PEM described in children as marasmus. This is characterized by uniform loss of fat and muscle mass in all tissues and a concomitant loss of water in proportion to nonaqueous mass.

Stress Hypermetabolism

In contrast to starvation, acute stress metabolism involves extensive neurohumoral modulation.[6] Inflammation, operation, trauma, or infection activates monokines, lymphokines, prostanoids, hormones, neural pathways, complement, and other endogenous mediators that "drive" metabolism and increase energy expenditure. Part of the source for this alteration appears to be derived directly from the energy and substrate demands of hepatic macrophages and the leukocyte infiltrate in wound tissue.[7] After a specific injury, this response follows a regulated time course, with a peak in metabolic rate about 2–3 days after the insult and a gradual decline to baseline by postinjury day 7.[6,8] The response will persist if a new activating event occurs or if the source of the initial event (e.g., an undrained abscess) is not removed.[6,8] The magnitude of the response is proportional to the magnitude of the injury.[6,8]

The liver responds to neurohumoral stimulation by generating substrate for the increased metabolism. Amino acids from proteolysis, lactate from devascularized tissues and glycerol from lipolysis are directed into gluconeogenic pathways.[8] Amino acids are also used to synthesize enzymes and structural proteins, while free fatty acids provide an alternate energy source. Endogenous mediators, stimulated in part by devascularized wound tissue, mediate this process. Because the response is initiated and driven by this internal source, it remains relatively unresponsive to exogenous substrate.[9] The hormonal pattern is characterized by increased glucagon, cortisol, and epinephrine that appear to be driven by demands from damaged tissue and infiltrating leukocytes. As blood glucose levels increase, insulin secretion is stimulated. This pattern of metabolism leads to depletion of visceral protein (in excess of muscle mass) and fat and is associated with an expansion of the extracellular fluid compartment.[10] Physical findings (edema, hypoalbuminemia, fatty liver) are similar to those noted in childhood kwashiorkor.[1]

Assessment of Protein-Energy Malnutrition

Protein-energy malnutrition can significantly alter perioperative physiology. Therefore, it is important to identify the presence of PEM and quantify it's severity. This is best accomplished by direct measurement of body cell mass, which, unfortunately, requires the use of multiple isotopic techniques and is not realistic clinically.[11] Less-precise estimates involve the use of indirect parameters that are believed to correlate with body cell mass. Anthropometrics, biochemical markers (most often circulating hepatic-derived proteins), and test of immunologic function all have been used. Unfortunately, each is associated with serious limitations that make their validity in the perioperative period questionable. We review each of these methods briefly and recommend how they might be used in clinical perioperative practice.

Most anthropometric measures were developed for the assessment of malnutrition in childhood starvation.[12] Consequently, parameters that are of key importance in adults but are negligible in children (frame size, build, fat patterning) are neglected and 95% confidence intervals have not been determined.[1,12] Furthermore, because edema is a prominent characteristic in stress-induced PEM, the interpretation of anthropometric measurements becomes difficult. Changes in specific hepatic-derived transport proteins (albumin, transferring, prealbumin, retinal-binding protein), also often used to detect PEM, are common in any stress state and reflect the interplay of decreased synthesis, tissue extravasation and extracellular fluid expansion, both from endogenous and exogenous sources.[13] The relationship between actual depletion of body cell mass and these biochemical markers is unclear. In stress states, serum proteins will decrease irrespective of the extent of loss of body cell mass.[13] Serum protein concentrations are often only mildly decreased in pure starvation PEM despite significant loss in body cell mass because the loss of mass and water is proportional.[14] Despite this, serum proteins are frequently used in the metabolic assessment of the chronically malnourished patient. Low serum albumin may be associated with increased mortality in surgical and chronically ill patients.[15] Serum albumin has a half-life of 14–20 days making it insensitive to acute changes in nutritional status. It is also affected by albumin transfusion, dehydration, inflammation, and liver disease. Serum albumin less than 3.5 g/dL is suggestive of malnutrition, and less than 2.5 g/dL of severe malnutrition. Serum transferrin is also somewhat useful for evaluating malnutrition. It has a half-life of about 9 days, which is midway between albumin and prealbumin. Unfortunately, unlike albumin and prealbumin, transferrin increases whenever there is bleeding. This decreases its reliability in the perioperative state. Serum prealbumin is the most reliable of the hepatic-derived transport pro-

teins to signal acute malnutrition. It has a half-life of 24–48 hours. Prealbumin is a negative acute phase reactant and in the postoperation setting, prealbumin levels decline. Abnormalities of cell-mediated immunity and absolute lymphopenia have also been touted as indices of PEM. The presence of these abnormalities in such diverse disease states as cancer, collagen-vascular disease, sepsis, uremia, and cirrhosis, as well as the alterations produced by drug administration, make them particularly nonspecific. Finally, all three of these commonly used measures lack specificity and are derived from population studies that may have little bearing on individual patients.[12]

Alternative approaches have been advocated to overcome the deficiencies inherent in the standard assessment of malnutrition. Forse and Shizgal[16] used isotopic techniques to measure the ratio of exchangeable potassium to exchangeable sodium, which should estimate the ratio of extracellular to intracellular mass and thus estimate lean body mass. The problem with this approach is that there may be variability in potassium from tissue to tissue. Studies to determine normal exchangeable potassium values have never been performed. Other individuals have recommended following multiple parameters over time.[6] Composite prognostic indices calculated from a series of unrelated variables have been formulated to classify and stratify the extent of PEM.[17] Nonetheless, these indices lack specificity. Prognostic indices are capable of identifying patients at risk for complications, but it is not clear that these complications are related to PEM. Several clinicians have proposed that a thorough history and physical examination, coupled with evidence of weight loss or the presence of known "catabolic" disease, is as valid as any sophisticated test or technique.[18] New studies are directed at assessing PEM using indirect calorimetry. This technique directly measures oxygen consumption and carbon dioxide production and uses these values to calculate resting energy expenditure. In one small trial, use of indirect calorimetry improved nitrogen balance and outcome.[19] Further testing is required to fully assess the usefulness of this modality.

Accurate estimation of the presence and severity of PEM clearly remains problematic, especially for the anesthesiologist whose evaluation of the patient is often brief. The presence of a severe disease producing rapid depletion of body cell mass (e.g., aggressive malignancy) or a prolonged disease that limits intake or absorption (vomiting, diarrhea, upper gastrointestinal obstruction) makes PEM likely. New developments offer promise. Functional testing of recovery time from isolated twitch in somatic muscle, direct measurement of extracellular compartment size, and quantification of T-cell subpopulations, particularly killer cells, are promising techniques and may soon be routinely available.

Malnutrition, as detailed in the following sections, is often present in patients presenting for surgery and has profound effects on organ function and physiology, Consequently, the anesthesiologist should suspect the presence of PEM and recognize its potential for precipitating difficulties in perioperative management.

Incidence of Malnutrition in Hospitalized Surgical Patients

Malnutrition in the hospitalized patient does not represent a new concern; true recognition of the presence of a serious nutritional problem can be traced to the work of Bistrian et al.[2] These researchers identified abnormalities of anthropometrics or biochemical markers consistent with malnutrition in 50% of general surgical patients[2] and 44% of general medical patients[20] in a large urban hospital. Numerous other investigations confirm these findings in various hospital settings and patient populations. Nonetheless, the use of anthropometrics, biochemical markers and demonstration of altered delayed hypersensitivity as diagnostic criteria for malnutrition is of uncertain specificity and value and may overestimate the extent of the problem. In a study conducted at a Veterans Administration hospital, an abnormality of one or more of these variables was present in 97% of patients.[21] Such an estimate seems unreasonable. Symreng et al.[22] found that 28% of surgical patients had, on admission to the hospital, three or more abnormalities consistent with depleted body cell mass. This would appear to be a more valid estimate and is consistent with data reported elsewhere. Another study validates this data, noting that 38% of surgical patients admitted for treatment of benign abdominal processes had biochemical or anthropomorphic evidence of PEM.[23] Perhaps of even greater significance is a study noting that 75% of patients admitted to the hospital without PEM developed abnormalities consistent with PEM during hospitalization.[24] Together these findings suggest that, although the actual incidence of malnutrition is unclear, the problem exists on a relatively wide scale in hospitalized patients and may develop or worsen over the course of hospitalization. For the anesthesiologist, there are two key points. First, PEM represents a real and not uncommon problem that alters normal physiology. Second, PEM acquired over the course of hospitalization may alter a patient's response from one anesthetic episode to the next.

Effects of Protein-Energy Malnutrition and Nutritional Repletion on Individual Organ System Function

The effects of protein-energy malnutrition and its correction on individual organ systems are reviewed in this section. When possible, human data is cited; otherwise, appropriate animal studies are presented. An attempt has been made to separate the effects of starvation from stress, but the former is disproportionately represented.

Cardiovascular Changes

Starvation PEM is associated with morphologic, functional, and electrical abnormalities of the cardiovascular system. Heart size decreases in proportion to loss of body mass[25] and the left ventricular free wall is thinned.[26] Histologic examination reveals myocardial atrophy and interstitial edema.[27] Left atrial, aortic root, and left ventricular end-systolic and end-diastolic dimensions are decreased relative to normal controls valves,[28] and left ventricular compliance is reduced.[26]

Functionally, resting heart rate, blood pressure and pulse pressure are reported to decrease in PEM[29] and a subnormal response is noted in each of these parameters during exercise testing.[28] Cardiac index and ejection fraction remain at prestarvation levels[26,28] and appear to increase appropriately with exercise[28] or β-adrenergic stimulation.[26]

On electrocardiography (ECG), amplitude is diminished, axis shows a rightward deviation, PR and QT intervals are prolonged, T waves are inverted to flat-

tened, ST-T segments are depressed, and nodal escape beats and ventricular tachycardia have been reported.[28]

Echocardiographic studies done in anorexic patients reveal decreased ventricular mass with associated ventricular dysfunction.[30] Also common in the anorexic population is the finding of prolonged QT and QTc with ventricular arrhythmias.[31] In one study, treatment and weight recovery resulted in normalization of ventricular mass and improvement in ventricular function in adolescents with anorexia.[31]

Stress metabolism in cachectic humans is associated with a somewhat different picture than noted in isolated starvation. Heart rate and indexed ventricular mass (per kilogram of body weight) are increased.[32] This suggests that stressed myocardium is spared from some of the protein-depleting aspects of PEM. It is logical to assume that the heart in stress can respond normally to increased demand for work even when other tissues are being wasted. This may result, in part, because the heart can use virtually any fuel (glucose, fat ketones, lactate) to support energy requirements.

Protein and calorie repletion in previously healthy adults subjected to semistarvation results in a rapid increase in heart size.[28] With refeeding, heart rate, blood pressure, and pulse pressures initially increase to above prestarvation levels and gradually return to baseline. Ejection fraction and cardiac output and index may decrease and congestive failure has been reported. The cause of these abnormalities is unknown but may reflect mobilization of interstitial fluid coupled with the inability of depleted cardiac muscle to handle the fluid load. ECG amplitude and QT interval abnormalities persist for variable periods despite repletion.[28]

To date, only one study has focused on the effects of correction of stress-induced PEM on cardiac function.[32] Ventricular mass, heart rate, end-diastolic volume, cardiac output, and ejection fraction all increased, but congestive heart failure developed in 3 of 5 patients and pericardial effusion developed in a fourth patient.

Pulmonary Changes

Relative cell mass (lung weight/body weight) appears to increase in cases of PEM, but overall wet and dry lung weights decrease with depletion.[33] Morphologic changes similar to those observed in emphysema are characteristic; distances between alveolar walls are increased, the surface area for gas exchange is decreased and air space is grossly enlarged as a result of disruption of alveolar septae.[34] Peripheral lung tissue is more affected than central mass and a significant loss of collagen and elastin is noted.[34] The phospholipoprotein content of surfactant is grossly depleted.[35] In the early stages of depletion, pressure-volume relationships are normal,[35] but after prolonged starvation surfactant concentrations decrease, active surface forces increase, and exposure of alveolar surfaces leads to an altered functional residual capacity.[36]

Diaphragmatic muscle mass decreases in direct proportion to the loss of body weight.[37] As a result, the tension developed in isolated diaphragmatic muscle strips is reduced. Mechanical efficiency appears to be unchanged.[38] Observed changes in the time to achieve 50% tension reduction following 20- or 100-Hz tetanus indicate that diaphragmatic fatigability is reduced.[37] Animal studies indicate a selective depletion of fast (glycolytic) fibers with sparing of the slow oxidative fibers, a finding that supports the notion of decreased fatigability.[37]

After an acute period of mild starvation in otherwise healthy adult women, forced vital capacity, forced expiratory volume, inspiratory pressure, and maximal voluntary ventilation were normal.[39] A prolonged course of severe depletion in both human and animal subjects results in decreases in all lung volumes, maximal pressure generation and maximal ventilatory effort.[40] Respiratory rate is decreased, perhaps reflecting altered carbon dioxide production; the ventilatory response to carbon dioxide is preserved but hypoxic ventilatory drive is markedly attenuated.[41] The number of alveolar macrophages and their ability to clear aerosolized *Staphylococcus aureus* is decreased.[42] Refeeding in rats leads to a return to normal lung weight and normal levels of lung hydroxyproline, elastin, and surfactant contents.[33] Parenchymal emphysematous changes are incompletely reversed.[33] Diaphragmatic contractile force is regained as body weight is regained.[40] Respiratory muscle function, maximal inspiratory pressure, and phagocytic capacity improve also, but abnormalities of hypoxic ventilatory drive are not prevented despite the provision of amino acid formulas sufficient to prevent negative nitrogen balance.[43] The effects of repletion on lung volumes and hypoxic ventilatory drive are unknown.

Renal Changes

During starvation, renal mass is lost in proportion to body mass and renal protein content is reduced. Clearance of creatinine and free water are decreased and effective renal plasma flow, glomerular filtration rate, and filtration fraction decrease dramatically, although total renal blood flow is not reduced. The ability to concentrate the urine in response to water restriction is impaired.

Total body water is decreased by starvation PEM but exchangeable sodium remains normal, implying that cellular mass and exchangeable potassium are decreased.[44] Free water clearance and sodium excretion are increased early in the course of starvation but decline after several days. Renin and aldosterone are increased in this early natriuretic period. Their role in sodium homeostasis during PEM is uncertain. Titratable acid excretion is decreased whereas serum bicarbonate and urinary ammonia concentrations increase. Refeeding following starvation PEM improves glomerular filtration rate, filtration fraction, concentrating ability, and free water clearance.[45] Sodium and acid excretion increase, as do plasma and extracellular volume. After a period of refeeding, accompanied by increasing plasma osmolality, interstitial water moves into the intravascular compartment. This is associated with a diuretic phase.

Surgical or traumatic stress activates renal mechanisms to conserve salt and water,[6,11] and thus expand the vasculature to improve substrate delivery. Both antidiuretic hormone and aldosterone are involved in this response, and plasma volume contraction in this setting can produce a metabolic alkalosis. The effects of prolonged stress are unknown and no data exist regarding repletion.

Gastrointestinal Changes

Intestinal mass, a rapid turnover tissue, is lost at a proportionately greater rate than body weight in starved rats.[46] Small intestine as a whole, and mucosal cells in particular, have de-

creased contents of DNA, RNA, and nitrogen. Epithelial cell renewal and migration are reduced and villus size and crypt cell number, size, and mitotic rate are decreased. Gastric ulceration, gastric and intestinal atrophy, and mucosal hemorrhage are all present to a great extent, perhaps reflecting mucosal breakdown either as a result of increased lysosomal acid hydrolase[47] or failure to synthesize mucosal glycoproteins. Gastrin concentrations decrease. Long-term fasting appears to be required for mucosal changes to occur; Knudsen et al.[48] found normal histologic conditions following a 7-day fast in obese individuals.

Mucosal transport, reflected in decreased uptake of oral mannitol, may be impaired. Sucrase and maltase (but not lactase) activities are decreased, with these changes most prominent in the proximal gastrointestinal tract. Glucose transfer across the mucosa decreases but mucosal-to-serosal transport of both glucose and histidine increase. Loss of brush border enzymes impairs absorption and promotes bacterial overgrowth.

Healing of mucosal ulcerations has been reported in depleted patients with Crohn disease who receive parenteral nutrition. Increased nitrogen retention and improved gastric motility in starved individuals has been noted.[49] Cell populations and absorptive capacity improve, activity of brush border enzymes is restored,[47] and lysosomal enzyme activities decrease to normal.

Enteral feeding seems to be more effective than parenteral nutrition in restoring gastrointestinal function postoperatively.[50] Mucosal integrity, brush border enzyme levels, and absorptive capacity all improve rapidly in depleted animal that are refed orally.[51] Use of glutamine is implicated in this improvement; it appears that even parenterally administered glutamine (which is not present in most total parenteral nutrition formulas) is of benefit.[52]

In critically ill patients there is a concern that bacteria may overgrow and translocate from the intestinal lumen to the systemic circulation leading to infection. In theory, part of the benefit of early enteral nutrition in the critically ill is to prevent this overgrowth. While multiple animal studies support this theory, a study by Moore et al. failed to find bacteria or endotoxin in the blood from the portal vein in severely injured trauma patients.[53] Indeed, careful examination of most of the work on translocation in animals demonstrates (a) at least two insults (overgrowth of a single bacterial species and some form of injury) are required for translocation and (b) bacteria translocate to the intestinal lymph nodes and occasionally, the liver but rarely beyond.[54] Thus, the clinical importance of translocation is unlikely to be great.

Pancreatic Changes

Pancreatic mass decreases in direct proportion to body mass and acinar atrophy, loss of architecture, fibrosis, and exocrine duct dilation are all noted in response to starvation PEM.[3] Rough endoplasmic reticulum and mitochondria are decreased. Amylase and trypsinogen content in the pancreas falls and lipase is increased.[3] Duodenal aspirates show a sequential decrease in level of lipase, trypsin and amylase as PEM progresses. Bicarbonate secretion also decreases in adults. Loss of structural integrity is reflected in increased serum amylase levels and indices of amylase production in patients with anorexia nervosa.[55] Following PEM in rats, the exocrine pancreas shows decreased responsiveness to carbachol stimulation and insulin responsiveness to glucose stimulation is attenuated.[56,57] Insulin secretion, exocrine responses to carbachol, and serum amylase and lipase values return to normal after refeeding.[57]

Hepatic Changes

In humans, starvation results in a rapid loss of liver glycogen. Because of defective triglyceride excretion and carnitine-limited uptake, reesterification of free fatty acids in the periportal region occurs.[3] Prolonged PEM will eventually deplete even the periportal fat deposits. In chronic protein deficiency in rats, liver mass and rough endoplasmic reticulum are lost.[46] Loss of RNA, water, fat, and protein, as well as cellular atrophy, have been reported, but it appears that hepatocytes are remarkably resistant to loss of structure or number.[3] Patients with weight loss as great as 55 kg have had histologically normal liver biopsies, although the presence of pigment deposits, fibrosis, and fatty infiltration has also been reported.[3] In pure starvation, hepatic enzymes and bilirubin may be normal or increased;[58] albumin synthesis and total albumin content decrease, but concentrations may be normal. Urinary nitrogen loss decreases, reflecting activation of amino acid-conserving enzymes and decreased urea cycle activity.[59]

Protein deficiency often reduces drug metabolism, reflecting decreased microsomal enzyme activity and altered cytochrome P450/nicotinamide adenine dinucleotide phosphate (NADPH)-dependent transport mechanisms.[20] Thus, decreased transformation of compounds that are hepatically detoxified may lead to pathologic responses that require dosage alteration. Conversely, compounds that are biotransformed into toxic metabolites are better tolerated.[60]

Many products of hepatic protein synthesis are altered during stress. Messenger ribonucleic acid (mRNA) is increased for acute-phase products, such as fibrinogen, or α_1-antiproteases, whereas synthesis of transport proteins such as albumin is decreased.

Liver size and function return to normal with refeeding; gross and ultrastructural morphology are restored after several weeks of repletion. Serum hepatocellular enzymes increase initially with refeeding but then return to normal.[61] Effects of repletion on drug metabolism are unknown.

Immunologic Changes

Protein-energy malnutrition is associated with a reduction in the mass of lymphoid tissue in excess of loss of body mass. Both small lymphocytes and germinal centers are affected. Total circulating polymorphonuclear (PMN) cell counts are reduced but the fraction of total erythrocytes that are PMNs is increased. Macrophage and PMN chemotaxis, bacterial engulfment, and intracellular killing are impaired. Serum levels and activity of complement components C3 and C5 are normal in stress, but all other components of both the direct and indirect pathways are reduced in stress and all components are reduced in starvation.[62]

Circulating B-cell numbers are reduced but account for an increased percentage of the total lymphocyte count. Serum immunoglobulin may be low, normal, or high. Impairments of antibody binding and antigen specificity have been reported.[63] Impaired cell-mediated immunity is one charac-

teristic of the malnourished state.[63] Absolute numbers of T cells and the ratio of T cells to total leukocytes is reduced.[63] The proportion of T-helper and T-suppressor cells is normal in starvation but reduced in stress; T-killer cells are reduced in both states.[64]

Lymphoid tissue mass, cell populations, and germinal center populations respond well to nutritional repletion. Phagocytosis and chemotaxis improve, but the effects of refeeding on engulfment and intracellular killing are unknown.[63] Delayed hypersensitivity to skin testing,[65] antibody levels (circulating or fixed),[65,66] and complement levels return to normal with nutritional therapy.[66] Short-term repletion has no effect on T-cell subpopulations in stress or starvation.[64] The effects of longer treatment are unknown.

Nervous System Changes

Peripheral nerve conduction velocity is decreased and associated sensory abnormalities have been reported in PEM.[67] In moderate PEM, nerve biopsies are normal but severe depletion is associated with segmental demyelination.[67] Chronic malnutrition may lead to lethargy, confusion, and impaired initiative.[68] Cerebral atrophy, ventricular dilatation and diffuse electroencephalographic slowing have been noted.[3] In adult rats deprived of protein, the phosphatidylglycerol and sphingophospholipid fraction are decreased but other myelin components are present in normal quantities.[69] Refeeding appears to restore nerve conduction and structure[70] and to improve mental status.[68]

Anesthetic Implications of Organ System Dysfunction

The dysfunctions caused by PEM have important perioperative implications. Cardiac reserve may compromised, as evidenced by subnormal blood pressure and heart rate responses to stress testing, but appropriate increases in cardiac output in response to exercise or β-adrenergic stimulation argue against this. The potential for myocardial depression caused by volatile anesthetics should be considered in patients with PEM. In addition, the partially repleted patient may be at risk for pulmonary edema when mobilization of fluid occurs because the cardiac response to fluid challenges may be inadequate. Cardiac dysfunction and renal abnormalities make it important to watch fluid balance. Assisting postoperative diuresis may be necessary.

Pulmonary disease resembling emphysema may impair gas exchange, whereas respiratory muscle failure may preclude early extubation, especially with residual paralysis. The selective depletion of fast muscle fibers may alter the ability to respond to acute increases in carbon dioxide. It may be prudent to mechanically ventilate the severely depleted patient for some time postoperatively. In the healthy individual, resistance to pulmonary infection is maintained by bacterial clearance (ciliary action and coughing) and macrophage function. Both are impaired in PEM and further decreased by general anesthesia.

Renal abnormalities may reduce the clearance of both solute and solvent, resulting in retention of water as well as toxic byproducts. Thus fluid loads may be poorly tolerated and clearance of drugs and cellular debris impaired. Altered gastric motility increases the risk of aspiration. In addition, because of the loss of brush border enzymes and depletion of gastrointestinal mucosa, oral absorption of drugs may be altered.

Blood sugar values should be monitored perioperatively because of the relatively impaired insulin response to hyperglycemia.

Hepatic drug metabolism may also be altered but this is unpredictable. Clearance of some drugs (e.g., vecuronium) may be impaired, but tolerance for others with toxic metabolites (e.g., nitroprusside) might be noted. Metabolism of inhalational anesthetics may be decreased. Perhaps most important, decreased total circulating albumin has wide implications for drug administration and volume of distribution. Table 16–1 is a partial list of commonly used drugs that might be affected by decreased total circulating albumin.

Other effects occur as well. For example, the increased risk of infection mandates the use of careful sterile technique for even routine vascular access. Use of inhalational anesthetics may further depress leukocyte function. Finally, the associated peripheral neuropathy may alter the effects of conduction anesthesia, and mental status changes associated with PEM may impair rapid recovery from general anesthesia.

TABLE 16–1.

Commonly Used Drugs That are Plasma-Protein Bound

Drug	Protein Bound (%)
Narcotics	
Morphine	30
Meperidine	60
Fentanyl	84
Sufentanil	92
Alfentanil	92
Barbiturates	
Thiopental	72–86
Phenobarbital	40–60
Benzodiazepines	
Diazepam	96–98
Midazolam	96–98
Lorazepam	96–98
Nonbarbiturate Induction Agents	
Etomidate	76
Propofol	98
Local Anesthetics	
Tetracaine	80
Lidocaine	70
Mepivicaine	77
Bupivicaine	95
Etidocaine	95
Prilocaine	55
Cardioactive Drugs	
Digitalis	25
Labetalol	50
Propranolol	90–95
Nadolol	40–60
Pindolol	<50
Captopril	25–30
Others	
Phenytoin	90

Effects of Perioperative Protein-Energy Malnutrition on Outcome in Surgical Patients

Effects of Malnutrition on Mortality

In 1936, Studley[71] reported that when preoperative weight loss exceeded 20% of premorbid weight, the mortality after operation for peptic ulcer disease was 33%. This early and unsophisticated study first underscored the influence of nutritional status on surgical outcome. More recent studies, which focused on alterations in anthropomet-

rics, transport proteins, and leukocyte parameters, confirmed these data. Reinhardt et al.[72] found that serum albumin values less than 3.0 mg/dL were associated with a 30-day mortality of 24% and that levels below 2.0 mg/dL were associated with a mortality of 62% in patients undergoing intraabdominal surgery. In a study on similar patients, Seltzer et al.[73] noted that albumin values less than 3.5 mg/dL were associated with 4-fold increases in mortality and morbidity, whereas lymphocyte counts of less than 1500/mm^3 were associated with a 4-fold increase in mortality alone. Concurrent abnormalities of both albumin and lymphocyte counts were associated with an 18-fold increase in mortality relative to patients with normal indices.

Impaired cell-mediated immunity also appears to be an important marker for increased mortality. Meakins et al.[74] noted a perioperative death rate of 3.1% in general surgical patients with normal delayed hypersensitivity (assessed by intradermal injection of a battery of antigens), whereas anergy was associated with a mortality of 35%. The development of anergy following normal initial testing was invariably fatal. A number of studies have confirmed the association of anergy and poor postoperative outcome. Anergy is associated with numerous other factors, however, all of which may increase perioperative risk independent of malnutrition.

In an attempt to improve specificity, Harvey et al.[75] developed a discriminate function that was used to predict the development of sepsis and surgical mortality. This function was based primarily on delayed hypersensitivity testing, transferring, albumin, and total lymphocyte counts. Prospective evaluation of the index has not been reported. Mullen et al.[21] developed a "prognostic nutritional index" (PNI) based on a number of nutritionally relevant variables. Patients identified by this index as high risk had a mortality of nearly 60%; those categorized as low risk had mortalities of only 3%. Prospective evaluation of this index has confirmed its usefulness for identifying high-risk patients, but the true relationship between the variables studied and malnutrition is unclear.

Effects of Malnutrition on Complications

Surgical complications occur more frequently in patients with markers for PEM. Patients with preoperative anergy and patients in whom anergy developed postoperatively have greatly increased rates of postoperative sepsis.[74] Preoperative anergy is further associated with a doubling of nonseptic postoperative complications,[74] and anergy is a predictor of prolonged hospitalization. Rhoads and Alexander[76] associated hypoproteinemia in surgical patients with twice the rate of wound infections and an increased incidence of other infectious complications. In both patients and experimental animals, punch biopsies of wound tissue in starvation showed evidence of impaired collagen synthesis[77]; Cruse and Foord[78] concluded that malnutrition increased the incidence of clean wound infections from 1.8% to 16.6%.

Abnormalities of plasma proteins and albumin are associated with an increased incidence of bowel anastomosis dehiscence. Starved rats with low serum proteins and albumin were reported to have decreased colonic collagen content and decreased colonic wall-bursting tension, as well as loss of tensile anastomotic strength and collagen content.[79] These final findings could not be confirmed by a second group of investigators.[80] The use of nutritional indices in predicting complications requires further testing.

The uniform association of abnormalities of weight loss, serum proteins, and leukocyte function with mortality and morbidity in the perioperative period is impressive. Animal studies of PEM demonstrate similar results. Nonetheless, human studies have used nonspecific markers that may correlate with not only PEM, but also with other risk factors not tested for independence. Thus, the true impact of PEM as an independent risk factor for surgical outcome is unknown.

Effect of Nutritional Repletion on Outcome

Although nutritional repletion may reverse many of the abnormalities that develop in individual organ systems as a result of malnutrition the overall effect of perioperative alimentation on outcome is unclear. Most studies that address the issue were poorly designed—patients were not randomized, investigators were not blinded, and patient populations lacked uniformity. Most studies compared different alimentation regimens without an untreated control group. Finally, the end points are not objective measures of outcome. Despite these limitations, some conclusions can be drawn.

Patients with mild to moderate preoperative depletion do not appear to benefit from combined preoperative and postoperative alimentation as compared to postoperative support alone. In comparing nonrandomized, mildly depleted patients with gastrointestinal malignancies to undepleted control patients, Thompson et al.[81] were unable to demonstrate that combined preoperative and postoperative repletion altered mortality or morbidity.

Outcome appears to be improved when significant malnutrition is corrected prior to surgery. When comparing combined preoperative and postoperative intravenous alimentation to postoperative support alone, both Mullen et al.[21] and Smale et al.[82] reported reductions in mortality (9% vs. 47%) and morbidity (23% vs. 56%). Muller et al.[83] confirmed these findings in a randomized study of patients with cancer. Outcome is significantly affected by the duration and efficacy of therapy. Thus, Rombeau et al.[84] retrospectively studied patients undergoing surgery for inflammatory bowel disease and noted that only 5% of patients who had received hyperalimentation for 5 or more days had postoperative complications, whereas 46% of those receiving less than 5 days of therapy had complications.[84] Grimes et al.[85] noted similar findings in general surgical patients who were severely depleted. In another study, only 4% of patients who responded to 1 week of repletion had a perioperative complication, whereas 9 (45%) of 20 who did not respond had perioperative morbidity.[86] When therapy in nonresponders was continued for an additional 4–6 weeks, until a response consistent with improved nutritional status was noted, the complication rate was 13%. Thus it appears that preoperative repletion of appropriate duration to improve nutritional status also improves perioperative outcome. Questions of methodology in all the studies cited mandate that conclusions be drawn cautiously.

The blueprint for a well-designed, randomized, prospective trial unfortunately led to results that are difficult to interpret.[87] Only 395 patients were studied; this fell short of the original projection. Patients were randomized to receive either 7–15 days of preoperative total parenteral nutrition (TPN)

followed by 3 days of postoperative TPN or no TPN until the third postoperative day. No differences in major complications or mortality were noted. However, when patients were stratified by the extent of preexisting malnutrition (based on the PNI), severely malnourished patients receiving TPN had fewer complications. Unfortunately, there was no assessment of the efficacy of nutritional support to demonstrate improved nutritional status before surgery as a result of TPN. Thus the conclusions are difficult to interpret and the role of TPN remains to be fully elucidated.

Finally, there remains the patient with normal preoperative nutritional status about to undergo an extremely stressful procedure or who will be unable to eat for a prolonged period after surgery. Despite the myriad studies addressing nutritional support, there exists no reasonably designed, well-performed study that deals with such patients relative to a meaningful control group. Thus, although it seems self-evident that appropriate support of the catabolic patient should improve outcome, no data exist to support this hypothesis.

Implications of Altered Outcome for the Anesthesiologist

The anesthesiologist should ensure that the patient presenting for elective operation is in the best possible condition to tolerate the operation and postoperative course. The relatively poor outcome associated with malnutrition, coupled with the apparent benefits of repletion in the severely depleted individual, constitutes one more problem that can be addressed to improve overall patient outcome. An appropriate course of repletion in a highly malnourished individual may well be necessary, and calling attention to this potential problem and its remedy is part of a comprehensive anesthesia evaluation and plan.

Immunonutrition

Recent advances in nutritional support include the addition of "pharmaconutrients" or "immunonutrients" to standard nutritional formulas. These additives improve outcome in animal models and in several human studies. There are several commercially available formulas that include a combination of arginine, glutamine, omega-3 fatty acids, and RNA nucleotides. We first introduce the evidence supporting each individual pharmaconutrient and then provide the evidence for use in individual surgical groups.

Arginine

Arginine is a conditionally essential amino acid. It is an intermediate of the urea cycle and is the precursor for creatine, a substrate for energy metabolism in muscle. Of critical importance, the guanidino nitrogen atom of L-arginine provides the nitrogen used to synthesize nitric oxide (NO). Because NO modulates cytokine production and other aspects of white cell function and, as a free radical, can kill pathogenic bacteria, it has been proposed that arginine is essential for host defense. In addition, it is an essential element of the system that regulates vascular tone. A relative arginine deficiency state is theoretically produced where induced nitric oxide synthase activity increases; it has been shown that septic patients with low systemic arginine levels have a greater mortality rate.[88] In addition, arginine may have beneficial effects on wound healing This has led to the inclusion of arginine in the immunonutrition formulas.

Omega-3 Fatty Acids

Lipids are included in most nutritional formulas to provide calories and to avoid essential fatty acid deficiency. The human body is able to manufacture all of the lipids necessary for existence with the exception of the long-chain fatty acids (LCFAs) in the omega-3 and omega-6 family. Omega-6 fatty acids have immune-stimulating effects whereas omega-3 fatty acids have immune-suppressive effects. This has led to investigations examining the ratio of omega-3 to omega-6 fatty acids in critically ill surgical patients. In septic rats, substitution of omega-3 fatty acid for omega-6 fatty acid lowered prostaglandin E_2 production in Kupffer cells and decreased mortality.[89] It is possible to modulate the human immune response in a similar manner. However, outcome data are lacking.

Glutamine

Glutamine is a nonessential amino acid that is synthesized from glutamate and glutamic acid in large quantities. It is used as a fuel source in rapid turnover cells and is the preferred fuel source in the rat gastrointestinal tract. Glutamine is also a precursor to the antioxidant glutathione. Glutamine is now included in immunonutrition supplements to prevent gut mucosal atrophy and perhaps prevent immune dysfunction. In septic rats, glutamine-enriched parenteral nutrition decreases mortality[90] and increases jejunal villus height. Glutamine may also decrease bacterial translocation,[91] but other studies show no effect.[92] Critically ill humans fed with glutamine supplemented parenteral feeds have greater intestinal absorptive capacity compared with patients receiving a conventional solution.[93] In a meta-analysis of randomized clinical trials on surgical and critically ill patients, glutamine was shown to be beneficial.[94] In surgical patients glutamine supplementation reduced infectious complications and hospital length of stay. However, no treatment effect was seen with enteral glutamine with respect to reduction in mortality or length of stay.

Nucleotides

RNA nucleotides include the purines adenine and guanine and the pyrimidines cytosine and uracil. They are not considered essential nutrients because they are synthesized endogenously. Their inclusion in immunonutrition formulas is based on evidence from animal studies. In the murine model injected with *Candida albicans*, mice supplemented with RNA nucleotides had an increased survival time.[95] Other studies demonstrate an increased type 1 response to antigen,[96] and a decreased intestinal mucosa atrophy.[97] To date, no studies have been published looking at nucleotide supplementation alone in any human patient population.

Immunonutrition Studies

Immunonutrition consists of formulations of the pharmaconutrients arginine, glutamine, omega-3 fatty acids, and nucleotides in a solution of protein and carbohydrates. Data from multiple studies randomizing patients to immune-enhanced early enteral nutrition (IEEN) versus standard enteral nutrition have been analyzed in multiple patient groups (Table 16–2). In some, such as elective gastrointestinal surgery patients, clear benefit has been shown. However, no benefit has been demonstrated in heterogenous populations of critically ill patients. Combining studies using meta-analysis also failed to reveal a benefit.

TABLE 16–2.

Recommendations on Immune Enhanced Diets (Combinations of Arginine, Glutamine, Omega-3 Fatty Acids, and Nucleotides)

Surgery	Patient Group	Recommendation
Elective GI surgery	Esophageal, gastric, pancreatic, hepatobiliary	Patients with moderate to severe malnutrition (Albumin <3.5 g/dL) benefit from preop immunonutrition for 5–7 days[98]
	Colonic and rectal surgery	Patients with severe malnutrition (Albumin <2.8) benefit from periop immunonutrition
Trauma patients	Blunt and penetrating	ISS >20 or ATI >25 benefit of reduced length of stay and septic morbidity[99]
Burn patients	Blunt and penetrating	Theoretically beneficial, lack of sufficient number of studies
Coronary artery	Elderly patients	Small study shows benefit of reduced infection[100]
Critically ill patients	Heterogeneous group	No benefit[101]
Severe sepsis		May harm patient[102]

Intraoperative Management of the Patient Receiving Nutritional Support

Box 16–1 summarizes the principles that guide intraoperative nutritional support. Total parenteral nutrition should be continued throughout surgery. Most formulas have some form of carbohydrate, putting the patient at risk for hyperglycemia. Careful evaluation of blood glucose should be continued throughout the perioperative period.

Critically ill patients frequently have trouble reaching the goal level of nourishment. Often the cause is discontinuing the enteral nutrition in anticipation of procedures to reduce the risk of aspiration. This can be a serious problem in the patient undergoing multiple procedures, such as in the burn and multiple-trauma population. Moncure et al. prospectively evaluated patients undergoing nonabdominal procedures with jejunal tube nourishment.[103] There were no cases of aspiration. Jenkins et al. studied 40 duodenally fed patients undergoing a total of 161 surgical procedures in whom the duodenal nourishment was continued.[104] Again, no aspiration was documented. Consequently, postpyloric enteral nutrition should be continued in critically ill patients brought to the operating room. Gastric nourishment should be withheld starting 6–8 hours before any procedure requiring anesthesia. Patients requiring anesthetic for procedures are usually in a supine position without elevation of the head of bed increasing the risk of aspiration.[105]

BOX 16–1.

Intraoperative nutritional support

1. Parenteral nutrition should be continued whenever possible.
2. Postpyloric enteral nutrition should be continued with the possible exception of intraabdominal procedures.
3. Gastric enteral nutrition should be discontinued 6–8 hours before procedures requiring general anesthesia and endotracheal intubation

SUMMARY

As the field of anesthesiology grows in scope and practice, the extent of knowledge of the anesthesiologist also must expand. Malnutrition constitutes another area in which patient disease might alter function under anesthesia and outcome after operation. Knowledge of these effects and their reversal by repletion therapy is useful and potentially lifesaving.

CHAPTER 17

Principles of Antimicrobial Therapy

Richard Teplick, MD, and
Robert H. Rubin, MD,
FACP, FCCP

In general, antimicrobials may be used in three different modes: therapeutic, prophylactic, and preemptive. In the therapeutic mode, they are prescribed to treat established clinical infection. The appropriate therapeutic use of antimicrobial drugs requires the prompt diagnosis of clinical infection and a clear understanding of the pharmacologic principles governing treatment of such infections. In the prophylactic mode, antimicrobials are prescribed to all members of a given population prior to an event, for example, an operation, to prevent infection. Successful prophylactic programs require that the antimicrobial therapy be sufficiently nontoxic, inexpensive, and efficacious to justify the intervention. Finally, in the preemptive mode, antimicrobial therapy is administered to the subgroup of individuals based on either laboratory markers or clinical epidemiologic characteristics that place them at significant risk of a serious clinical infection. Effective preemptive therapy requires the careful delineation of the factors that justify antimicrobial intervention at a point when clinical disease is not yet manifest.[1,2] This chapter presents the pharmacologic and clinical principles that underlie all three forms of antimicrobial use, distinguishing between that which is known and that which needs further study. Reviews of specific antibiotics can be found in a series published in the *Mayo Clinics Proceedings*.[3–12] Information on newer antibiotics, such as cyclic lipopeptides, glycylcyclines, ketolides, oxazolidinones, streptogramins, and newer fluoroquinolones can be found in specific review articles and newer textbooks such as Mandell.[13] However, there are important differences among classes of antibiotics, which are discussed below. First, some antibiotics are bacteriostatic, for example, tetracyclines. That is, they prevent bacteria from growing but generally require leukocytes to kill them. Another important distinction is their mechanisms of action, especially the distinction between antimicrobials that directly affect cell-wall synthesis and those that affect protein or nucleic acid synthesis. β-Lactams and vancomycin are examples of the former whereas aminoglycosides and fluoroquinolones are examples of the latter. There are other important distinctions, such as the rate of development of resistance, presence of postantibiotic effect, and pharmacokinetics and pharmacodynamics.

When antimicrobials are used prophylactically in surgical patients, initial therapy is often empirical, directed against the most likely organisms and their antimicrobial resistance patterns in a particular hospital or area within the hospital, such as an intensive care unit. Most commonly, surgical antimicrobial prophylaxis is directed against the organisms most likely associated with a particular type of surgery. Other important considerations in selecting a prophylactic antimicrobial agent are its toxicity, its spectrum, its antimicrobial properties (i.e., bacteriostatic or bacteriocidal), postantibiotic effect, the likely source of bacteria (e.g., colon, skin, biliary tract), and the drugs' pharmacokinetics and pharmacodynamics.

It is of great concern that a significant proportion of antimicrobial use, particularly broad-spectrum agents, both in the inpatient and outpatient setting, are often inappropriate.[14,15] Antibiotic use is clearly associated with the emergence and dissemination of antibiotic-resistant organisms, with this occurring far more commonly in ICUs than in non-ICU inpatient areas, and more commonly in inpatient than outpatient settings.

GENERAL PRINCIPLES OF ANTIMICROBIAL THERAPY

Minimal Inhibitory Concentration and Minimal Bactericidal Concentration

Antimicrobial therapy designed to treat active infection is predicated on the reliable *delivery* of the drug to the site of infection at the *concentration* required to contain the infection for the *time* required to produce this effect. Antimicrobials may exert a *bactericidal* (killing) effect on the targeted organisms or a *bacteriostatic* (inhibition of growth) one. Although it seems likely that bactericidal therapy is inherently superior to bacteriostatic therapy, in most instances of clinical infection either form of therapy is effective. There are, however, a few instances in which there is an absolute requirement for a bactericidal regimen:

- Systemic infection in a severely neutropenic patient.
- Staphylococcal and, presumably, other forms of osteomyelitis.
- Cardiovascular infection (e.g., endocarditis).
- Central nervous system (CNS) infection, both meningitis and cerebritis/abscess (in which a trough level of bactericidal effect >1:8 is achieved).
- Infection in the face of a foreign body that remains in place.

The most effective therapy for tuberculosis deploys three bactericidal drugs; isoniazid, rifampin, and pyrazinamide. Such a regimen permits shortening of the duration of therapy, and its use is associated with greater efficacy.

If there are no bactericidal regimens that can be formulated for these conditions because of the nature of the invading organism, then high-dose and prolonged bacteriostatic therapy in association with aggressive surgery becomes the alternative management strategy.

Modern microbiologic techniques permit not only the isolation and identification of the infecting microbe, but also can determine the susceptibility to different antibiotics, thus guiding the choice of antibiotics for a particular patient. When exposed in vitro to possible therapies, bacteria may be killed or their growth may be inhibited without being killed. The lowest concentration required to prevent growth is termed the *minimal inhibitory concentration* (MIC) (a variant of which is the MIC_{90}, which is the concentration of drug required to inhibit 90% of strains of the same species); similarly, the *minimal bactericidal concentration* (MBC), presents the lowest concentration required to kill the bacterial isolate (with the MBC_{90} defining the lowest concentration of drug needed to kill 90% of isolates of the same spe-

cies). The MBC is technically much more difficult and time-consuming to determine than the MIC; it is subject to multiple potential errors and is not needed for routine clinical care.[16]

These in vitro results are then interpreted in terms of blood levels that are attainable when appropriate doses of the antimicrobial agent in question are administered. One of three results is registered: *susceptible, resistant,* or *intermediate*. *Susceptibility* suggests that blood levels attainable with the therapeutic doses of an antibiotic should be effective in the management of infection caused by this organism. Whether such efficacy is obtained depends on other factors, particularly the site of infection; for example, blood levels may not provide adequate concentrations at sites such as the eye, the brain, or the prostate gland. Thus, in vitro susceptibility is only the first step in choosing the appropriate antimicrobial.

In contrast to the sometimes complex assessments that are required after a drug is shown to be effective in vitro, *resistance* is more easily interpreted. The organism in question is not inhibited by usually achievable systemic concentrations of the agent with normal dose schedules and/or fall in the range where specific microbial resistance mechanisms are likely and when clinical efficacy has not been reliable in treatment studies. In other words, prescribing a drug to which resistance has been demonstrated in vitro is strongly associated with therapeutic failure.

Intermediate sensitivity means that MICs of the organism(s) in question are higher than blood and tissue levels that are achievable without potential toxicity. For the most part, the use of antimicrobial agents to which the bacterial isolate only exhibits intermediate susceptibility should be avoided. However, particularly when dealing with a broadly resistant infection in the urinary tract, the issue is not attainable blood levels, but rather the relationship between the isolate's MIC and the attainable urine concentration. For example, *Pseudomonas aeruginosa* strains isolated from the urine that are "resistant" to routine therapy can often be effectively treated by tetracycline. The reason for this phenomenon is the dissociation between blood and urine levels of tetracycline that can be expected in the blood (<5 μg/mL) and in the urine (≤500 μg/mL).

Pharmacologic Principles in the Successful Use of Antimicrobia

The application of certain pharmacologic principles is important in optimizing the effectiveness of antimicrobial therapy.

Pharmacokinetics and Pharmacodynamics

The terms *pharmacokinetics* (PK) and *pharmacodynamics* (PD)[17] are used to describe the interaction of the drug administered with the individual receiving the therapy. PK describes the effects of the individual's bodily functions on the drug, specifically absorption, distribution, metabolism, and excretion. PD summarizes the effects of the drug, both toxic and beneficial, on the individual.[18,19] Perhaps the most useful measure of change in drug levels over time is to determine the area under the curve (AUC) and divide it by the dosing interval. This permits the determination of drug concentration at a particular site over the dosing interval. Determining the PK–PD relationship is the foundation of efforts to define the appropriate dose in the context of human therapeutics.

The *volume of distribution* is the ratio of the drug concentration in blood or plasma that is assumed to be in equilibrium with all spaces where it distributes to the amount of drug administered. Theoretically, the volume of distribution cannot exceed total body water but the calculated values may be far greater than total body water. This *apparent volume of distribution* may exceed the true volume of distribution because of tissue binding or protein binding if only free drug is measured. This value is also altered by lipid solubility, the drug's blood–tissue partition coefficient, perfusion, volume status, and pH.

High serum protein binding of a drug can alter the PK behavior of the molecule without significant effects on the PD profile. Because unbound drug is the only form of the drug that is able to manifest antimicrobial activity, the protein "buffers" uptake from plasma so that there is little change in the concentration of free drug. Because albumin is the major binding protein, the greatest amount of binding usually occurs in the plasma. In addition, at sites of active inflammation, there can be leakage of serum proteins, accounting for higher concentrations of drug at these sites.

The nature of the capillary bed at a particular site is an important factor in the distribution of drugs. At most sites the capillary bed has small pores (fenestrations) that allow for the unencumbered movement of substances with molecular weights of <1000 daltons (the great majority of antibiotics are of that size—so-called small molecules). There are, in addition, specialized sites, such as the retina, the brain, and the prostate gland, where the capillaries are unfenestrated. Because the antimicrobial molecules must pass through these capillaries, the lipid solubility of the molecules (as well as their size) becomes the major determinant of tissue diffusion. A final mechanism contributing to the distribution of antimicrobial molecules is active transport pumps. These pumps act on organic anions and are present in the choroid plexus, the retina, the proximal tubules of the kidney, and the biliary ducts. β-Lactam drugs are pumped out by these active transport pumps, with probenecid competitively inhibiting this mechanism.

Pharmacokinetics and the Choice of Antimicrobial Therapy

Three pharmacokinetic issues should be considered in the choice of antimicrobial therapy: the ability of the drug to penetrate to the site of presumed infection, the presence of local factors at the site of infection that might modify the efficacy of particular antimicrobial agents, and the route of delivery that should be employed. Thus if infection of the CNS is suspected, drugs that reach effective concentrations within the CNS should be employed in doses adequate to achieve this objective (Table 17–1). However, there are exceptions. For example, although not recommended, meningitis caused by high-level penicillin-resistant *Streptococcus pneumoniae* has been successfully treated with antibiotics that typically do not penetrate the CNS well. This may be a result of increased penetration resulting from inflammation.

Local factors that modify the effectiveness of particular antimicrobial agents include the following: (a) Inadequately drained infections limit the effectiveness of aminoglycoside therapy even if the organisms present are sensitive in vitro because these drugs are far less effective in the presence of

TABLE 17–1.

Penetration of the Cerebrospinal Fluid by Different Antimicrobial Agents

Penetrate noninflamed meninges: chloramphenicol, trimethoprim-sulfamethoxazole isoniazid, rifampin, pyrazinamide, flucytosine, fluconazole

Penetrate to therapeutic levels in the presence of inflammation: penicillin, ampicillin, oxacillin, nafcillin, ticarcillin, azlocillin, mezlocillin, piperacillin, cefuroxime, ceftriaxone, ceftizoxime, ceftazidime

Penetrate poorly or unreliably even in the presence of inflammation: cephalothin, cefazolin, cephapirin, cefoxitin, cefotetan, all aminoglycosides, vancomycin, fluoroquinolones, ketoconazole, itraconazole, amphotericin B

pus (both aminoglycosides and vancomycin are bound by pus, limiting their antimicrobial activity) and in conditions of low pH and low oxygen tensions.[20] (b) The requirement for oxygen-dependent transport for aminoglycosides to penetrate the outer membranes of susceptible bacteria explains the latter point and why they are generally ineffective against anaerobic bacteria.[21] (c) In the presence of mixed infections, β-lactamases produced by such organisms as *Bacteroides fragilis* can cause local inactivation of β-lactam antibiotics and failure to clear organisms from the site that are sensitive in vitro to the β-lactam drug.[20] (d) Penicillins and tetracyclines bind to hemoglobin, thus rendering therapy with these drugs less effective with infected hematomas.[22] (e) In most instances, the continuing presence of a foreign body at the site of infection will prevent the elimination of the microbial invaders even with the best antimicrobial regimen available.[23] Finally, antimicrobials such as trimethoprim-sulfamethoxazole, fluoroquinolones, and fluconazole can be administered orally and still achieve blood levels that are comparable to those obtained with parenteral therapy, provided gastrointestinal function is adequate and, at least in the case of levofloxacin, food or substances containing divalent metal ions are not given at the same time. In addition, even if therapy is initiated intravenously, completion of a course of treatment can be accomplished with a more cost-effective oral regimen once the patient stabilizes.

Absorption

The amount of drug that reaches the systemic circulation from the gastrointestinal tract after oral administration is expressed as a percentage of the total amount administered via this route. Although such measurements can be carried out from any site of administration, the term *bioavailability* is usually reserved for the evaluation of the degree and reliability of oral administration. A number of factors which, if present, can have an effect on bioavailability must be kept in mind: *the first-pass effect* in which drugs that are absorbed in the small intestine are metabolized in the liver; *metabolism* by drug-metabolizing enzymes in the gut; and the *presence of diseases* such as inflammatory bowel disease, parasitic infestation, and diarrhea of any etiology.

Postantibiotic Effect

Some antibiotics continue to suppress the growth of certain bacteria after the antibiotic is no longer detectable in the media; a phenomenon termed the *postantibiotic effect* (PAE). For example, following a 2-hour exposure of susceptible staphylococcal cultures to penicillin, growth is still inhibited for 1.4–1.6 hours after multiple washings removed the penicillin.[24] Although PAE can be demonstrated for virtually all antimicrobials, the bacteria affected and the duration of the effect are highly variable. β-Lactam antibiotics, with the exception of carbapenems such as imipenem, have significant PAEs only for some gram-positive bacteria. In contrast, most antimicrobials that inhibit protein or nucleic acid synthesis in gram-negative bacteria generally exhibit a PAE for these organisms. For example, for gram-negative bacteria, aminoglycosides and fluoroquinolones produce PAEs of 1–4 hours in duration, whereas β-lactams have essentially no PAEs. Importantly, the PAE duration tends to be reduced for aminoglycosides and fluoroquinolones in acidic media as might be encountered in necrotic tissue. A related but poorly understood phenomenon is that during the PAE phase, bacteria are more susceptible to killing by leukocytes, an effect termed *postantibiotic leukocyte enhancement* (PALE).[25,26] In addition, the PAE itself may be prolonged by leukocytes.

Concentration-Dependent and Time-Dependent Killing Agents

The distinction between time-dependent and concentration-dependent killing coupled with the presence or absence of a PAE has important clinical ramifications, particularly with respect to dosing intervals. For antimicrobial–bacteria combinations that exhibit time-dependent killing, especially when there is no PAE, the duration that the antimicrobial level is above the lethal range should be important. There is general agreement that for β-lactams to be effective, their concentration must be well above the MIC for most of the dosing interval. This is especially true for gram-negative bacteria, which usually do not exhibit PAE for β-lactams. However, there are very few human studies with continuous infusions and it is puzzling that continuous infusions of β-lactams have not uniformly proven superior to more conventional dosing schedules in animal models of infection.[27]

In contrast, for antibiotic–bacteria combinations that do exhibit concentration-dependent killing and significant PAEs, it may be more important to achieve very high peak levels and allow the trough to decrease below the MIC because efficacy will still be maintained by the PAE while toxicity might be minimized. This is the theoretical basis for the success of once-daily dosing of aminoglycosides. For combinations of antibiotics, the situation is more complicated. The PAEs for gram-positive bacteria are increased either additively or synergistically when aminoglycosides are added to cell-wall active antibiotics. However, this does not occur with gram-negative bacteria except when imipenem was used with an aminoglycoside.[28]

These considerations led to the concept that administering aminoglycosides in large doses once daily would prove more beneficial and less toxic than the usual standard of three times daily.[29] In particular, because aminoglycosides exhibit concentration-dependent killing, concentrations that reach a level 8–10 times the MIC will rapidly kill all susceptible bacteria and suppress the survival of higher MIC mutants. Because of the PAE, suppression can be sustained during the period that the concentration drops below

the MIC. The maintenance of drug-free intervals for a period before the next dose may also help prevent adaptive resistance, which may occur from decreased aminoglycoside uptake by bacteria exposed to lower levels of the drug. Finally, because renal uptake is saturable, the very high initial levels are not accompanied by proportionally increased renal uptake. Consequently, renal toxicity should not increase. Numerous studies show that in most patients, and even in febrile neutropenic patients, these tenets seem to hold: efficacy is at least equal to multiple daily dosing and renal toxicity is not increased.[30,31]

Resistance

General Concepts

Bacteria may be intrinsically resistant to antimicrobials or they may acquire resistance. *Intrinsic resistance* reflects a natural resistance to an antimicrobial, and is demonstrated when bacteria encounter an antimicrobial that has no effect on the organisms, even though no new genetic information has been acquired. For example, vancomycin is ineffective against gram-negative bacteria because it cannot penetrate their outer membrane. *Acquired resistance* reflects a genetic alteration in the bacteria that renders a once effective antimicrobial ineffective. The general mechanisms for bacterial resistance to antimicrobials are (a) decreased permeability to the antimicrobial, thus preventing its entry; (b) increased efflux pumps that keep the antimicrobial concentrations in the space between the inner and outer membranes of gram-negative bacteria and/or the cytoplasms low; (c) antimicrobial inactivation; (d) modification of the antimicrobial target; and (e) development of pathways that bypass the target. The genes encoding these phenotypes may be chromosomal or plasmid/transposon in origin, inducible or constitutive. Methicillin-resistant *Staphylococcus*, vancomycin-resistance in *Enterococcus*, and broad-spectrum β-lactam resistance in gram-negative organisms have important diagnostic and therapeutic implications, particularly in the hospital setting.[32–36]

In gram-negative bacteria, antimicrobials usually must penetrate the outer membrane via specialized channels termed porins. Alterations in the permeability of porins to specific antimicrobials can either prevent sufficient quantities from entering the bacteria or limit the rate of entry to the extent that even a relatively low inactivation rate is sufficient to render them ineffective. The former is a frequent cause of *P. aeruginosa* resistance to aminoglycosides and carbapenems, and the latter allows many gram-negative bacteria to inactivate β-lactams via β-lactamases. Increased active efflux of antimicrobials is a less common mechanism of resistance but can be important for macrolides, fluoroquinolones, some β-lactams, and, possibly, meropenem.

Inactivation is the predominant mechanism of resistance for several classes of antimicrobials. Aminoglycosides can be inactivated by both gram-positive and gram-negative bacteria, usually by plasmid-mediated enzymes. These enzymes modify specific sites on the aminoglycoside molecule, such that acetylation, adenylation, or phosphorylation takes place. These modified aminoglycoside molecules bind poorly to the ribosome target, rendering them inactive in their interaction with normally susceptible bacteria.

Perhaps the most comprehensively studied and categorized inactivating enzymes are the β-lactamases. There are an enormous number of these enzymes. They are often characterized by their genomic sequence and the β-lactams they can hydrolyze. Virtually every β-lactam, monobactam, or carbapenem can be inactivated by one or more of these enzymes. Target modifications in penicillin-binding proteins account for methicillin resistance in staphylococci and penicillin resistance in pneumococci and enterococci. Finally, bypass pathways account for vancomycin resistance in *Enterococcus faecium* and resistance of many bacteria to folate antagonists such as trimethoprim-sulfamethoxazole.

Specific Mechanisms

Perhaps the best-studied and most problematic mechanism of antimicrobial resistance is the β-lactamases. There are at least 340 different β-lactamases, one or more of which can inactivate virtually any β-lactam–based antimicrobial. The classification of β-lactamases is constantly evolving and is based both on phenotype and genotype. The class A β-lactamases comprise the largest group and include the extended-spectrum β-lactamases that can inactivate third-generation cephalosporins and aztreonam. Fortunately, most of these enzymes can be inhibited by β-lactamase inhibitors that may be used in conjunction with selected β-lactams.

Class C β-lactamases can inactivate virtually all classes of β-lactams except the carbapenems and are not inhibited by β-lactamase inhibitors. These enzymes are largely derived from the chromosomal *Escherichia coli* ampC gene but they may also be plasmid borne. They tend to be produced by *Enterobacter, Citrobacter, Serratia, Pseudomonas*, and some species of *Proteus*. Certain β-lactam antibiotics induce this enzyme. Clinical failure associated with the emergence of resistance often occurs when serious *Enterobacter* infection is treated with a cephalosporin despite initial cephalosporin susceptibility.[37] Thus, cephalosporins should be used carefully in the setting of infection with the above-mentioned gram-negative pathogens. [32]

Although β-lactamases are produced by some gram-positive bacteria, notably staphylococci (but not streptococci) and many anaerobes, the efficacy of these β-lactamases is limited because they are diluted by the extracellular space as opposed to being confined in the periplasmic space in gram-negative bacteria.[38] Although plasmid encoded β-lactamases cause staphylococcal resistance to many penicillins, resistance of some staphylococci and other gram-positive bacteria can also occur by completely different mechanisms. For example, methicillin-resistance in *Staphylococcus aureus* (MRSA) is a result of the chromosomal presence of the mecA gene, which decreases the binding affinity of methicillin to penicillin binding proteins. Similarly, ampicillin-resistant *E. faecium* has an altered penicillin-binding protein that has a greatly reduced affinity for these antibiotics and most β-lactams. In contrast, vancomycin resistance in enterococci is related, in the majority of cases, to a multigene plasmid, which is easily spread among enterococci. This plasmid alters a terminal amino acid group in one of the cross-linking amino acids that prevents vancomycin from binding to the growing cell membrane.[39,40]

It is astonishing that the first time vancomycin-resistant enterococci (VRE) were observed was in 1986,[41] and within 15 years it represented more than 24% of U.S. ICU enterococcal isolates. Unfortunately, there are limited options for the treatment of severe infections relat-

ed to VRE, which are typically also resistant to ampicillin and aminoglycosides. Several new agents that have efficacy against VRE and other resistant gram-positive bacteria have been approved by the FDA: quinupristin-dalfopristin, a combination of streptogramins; linezolid, an oxazolidinone; and tigecycline, a glycylcycline.[42,43] The optimal treatment programs using these drugs, however, remain to be defined.

There is great concern that *S. aureus* will acquire the vancomycin-resistance determinant from enterococci. This was first shown to be possible in the laboratory,[44] and scattered clinical cases have now been reported of MRSA strains with both decreased vancomycin susceptibility known as vancomycin-intermediate *S. aureus* (VISA), and vancomycin-resistant *S. aureus* (VRSA).[45] The mechanism for this diminished susceptibility appears to be a consequence of a thickening of the cell wall leading to decreased antibiotic penetration and sequestration of vancomycin, rather than the transfer of vancomycin-resistance genes from enterococcus leading to an altered vancomycin-binding target.[46–48]

Emerging Bacterial Resistance

In the last decade, there has been a dramatic increase in the development and dissemination of antibiotic-resistant organisms. Many factors have contributed to the marked increase in resistance; however, indiscriminate broad-spectrum antibiotic use is an important factor.[49] Other factors that will select for resistance include the use of too low a dose for too short a period of time. Thus, it is critically important to use antimicrobials judiciously, as overuse will facilitate the propagation of pathogens that are difficult or impossible to treat. One example of antimicrobial misuse is in farming, where the widespread deployment of antimicrobials to animals has not only resulted in resistant flora on the farms, but also with the spread of such resistant organisms to humans.

Combination Antimicrobial Therapy

A common practice, in the hospital use of antimicrobial agents, is "double coverage" in an effort to improve efficacy and "prevent resistance from developing." Indeed, in vitro studies often suggest benefits from such an approach, with at least the following five reasons justifying the combination therapy proposed: (a) prevention of the development of antimicrobial resistance; (b) known or suspected polymicrobial infection; (c) initial therapy; (d) decreased toxicity; and (e) synergistic therapy.

Prevention of the Development of Antimicrobial Resistance

Combination therapy to prevent development of resistance is most effective when the mechanism for resistance involves chromosomal mutations, with the merits of combination therapy being most easily seen with tuberculosis. The microbial burden in a particular patient and the known rate of mutational resistance to each of the antituberculous drugs are the major determinants of the most effective regimen for a particular patient. Thus, in a nonimmunosuppressed host, primary tuberculosis is associated with a microbial burden of $\sim 10^4$ organisms; noncavitary, reactivation disease of the lungs, a microbial burden of 10^{6-8}; cavitary disease, a microbial burden of 10^{8-10}, and so forth. The rate of mutation to resistance for the drugs is as follows: 1 in 10^6 for isoniazid and ethambutol; 1 in 10^8 for rifampin; and 1 in 10^5 for streptomycin. Consequently, the treatment for primary tuberculosis typically requires a single drug (usually isoniazid), noncavitary reactivation disease requires two drugs, and so forth. Although other factors enter into the design of the therapeutic program, the approach outlined fits with the efforts to avoid resistance. However, chromosomal mutation is an uncommon mechanism of resistance (the great majority of bacterial resistance is a result of the acquisition of a plasmid or transposon that mediates resistance). Thus, the prevention of development of resistance is not an adequate reason for combination therapy of pyogenic infection.

Known or Suspected Polymicrobial Infection

This is a legitimate reason for deploying multiple drugs. For example, a perforation of the distal colon will result in the release of anaerobes (particularly *B. fragilis*), gram-negative bacilli, and bowel streptococci (including enterococci) into the peritoneal cavity. This event has traditionally required a 2- or 3-drug regimen (e.g., ampicillin, metronidazole, and gentamicin) to deal with the range of organisms. The only difference today is the availability of single agents with a spectrum of activity that will accomplish the same task. Such single agents as carbapenems, β-lactam–β-lactamase combinations, and newer fluoroquinolones can provide the same coverage as the older multidrug regimens.

Initial Therapy

When the initial assessment of a patient suggests the possible presence of a therapeutic emergency, then broad-spectrum therapy is obligatory, at least until the results of cultures are available. The issue that remains controversial is whether this is best accomplished with a single drug or multiple drugs. There is incomplete evidence that the combination of a β-lactam with an aminoglycoside provides a higher probability of success than a single drug, particularly if *P. aeruginosa* is thought to be involved. Our approach is to initiate therapy with an antipseudomonal β-lactam and an appropriate aminoglycoside, and then discontinue the aminoglycoside once the patient has "come under control."

Decreased Toxicity

A principle of cancer chemotherapy is that the toxicity of such therapy can be decreased by using multiple drugs with different mechanisms of action and toxicities at lower doses. Unfortunately, the efficacy of this approach in the treatment of significant infection remains to be demonstrated.

Synergistic Therapy

In vitro synergistic killing of both gram-positive and gram-negative bacteria has been demonstrated. The greatest evidence for this is when appropriate β-lactams are combined with aminoglycosides. Whether this can be demonstrated in clinical situations is unknown. The best evidence of the usefulness of synergistic therapy comes from the study of patients with endocarditis. Treatment of enterococcal endocarditis with penicillin (or ampicillin) alone results in a bacteriostatic regimen, and a distinctly inferior clinical outcome compared with that achieved with the addition of streptomycin or gentamicin to the penicillin. Enterococcal strains with high levels of aminoglycoside resistance (MIC >2000 μg/mL) do not have the potential for bactericidal therapy, and have a distinctly poorer outcome. Nonenterococ-

cal streptococci also can be shown to benefit from combination therapy requiring shorter courses of therapy if a penicillin is combined with gentamicin.

Part of the problem with existing studies is the lack of stratification of patients into "therapeutic emergency" versus "a need for parenteral therapy" versus "outpatient management." As a result, even with the lack of definitive evidence, our approach to staphylococcal endocarditis is as follows: stable patients will get single-drug therapy with nafcillin; those who are more ill (e.g., hemodynamically unstable, evidence of emboli) receive potentially synergistic therapy with a minimum of two drugs. A similar approach is taken with infection caused by *P. aeruginosa*. Many experienced clinicians employ potentially synergistic therapy of this type for other serious gram-negative infections, particularly those occurring in compromised hosts, despite a lack of compelling evidence.

CLINICAL PHARMACOLOGY: GENERAL PRINCIPLES OF THERAPEUTIC ANTIMICROBIAL USE

Effective antimicrobial therapy requires the integration of a sizable body of information regarding the patient, the invading microbe(s), and the antimicrobial agents themselves into an effective antimicrobial prescription. Several factors must be considered in creating such a prescription, including those discussed below.

Identity of the Organism

The identity of the infecting organism(s) must be known, or at the very least, it must be possible to make a high probability assessment of the most likely culprit(s). The initial choice of antimicrobial agents is usually based on probability assessments of the most likely pathogen(s) causing a particular clinical syndrome, with subsequent adjustment of the regimen once specific microbiologic information becomes available. Important factors to be weighed in determining the likely infecting organism include the probable source (e.g., vascular access device, lung, or urinary tract) and whether the infection is likely to be community-acquired or nosocomial. Other issues of importance include recent antibiotic use, the presence of such growth factors as iron and elevated blood sugar, and the presence of devitalized tissue.

Urgency of Treatment

The key question is whether one is dealing with a therapeutic emergency or a diagnostic dilemma. In the former case the broadest possible regimen should be used initially with later modifications based on precise microbiologic information. This is often termed "front loading" of the antimicrobial regimen. In the latter case, narrower spectrum initial therapy is possible, with fine-tuning of the regimen once specific information is available.

Epidemiology

Epidemiologic considerations must also be factored into antimicrobial decision making. When dealing with primary illnesses acquired in the community, the nature and timing of possible exposures must be considered. Important exposures include the geographically restricted systemic mycoses (*Blastomyces dermatitidis, Coccidioides immitis,* and *Histoplasma capsulatum*), *Mycobacterium tuberculosis*, influenza, group A streptococci, *Legionella*, and meningococcus. Even more important is the special epidemiology of the nosocomial environment, be it a nursing home, a hospital, or a specialized area of the hospital such as an ICU. Specifically, the microbiologic flora within a hospital, of even a particular ICU within the hospital, and their respective resistance patterns are essential information. The rising incidence of infection with difficult to treat organisms such as methicillin-resistant *S. aureus*, vancomycin-resistant enterococci, and multiresistant gram-negative bacilli is having a profound influence on the initial choice of antibiotics. For example, vancomycin is usually preferred over nafcillin as initial therapy for suspected staphylococcal infection, and advanced-spectrum β-lactam agents such as imipenem rather than cefazolin or gentamicin for gram-negative infection that could be caused by highly resistant *Klebsiella* species.[50,51] It is likely that these problems with antibiotic resistance will increase, not just in terms of these organisms but also with rising incidences of infections with penicillin-resistant pneumococci[52,53] and ampicillin-, vancomycin-, and gentamicin-resistant enterococcal (Table 17–2).[53] These considerations highlight the importance of the reservoir of a given organism and the selective pressure that reservoir is under, for example, *Salmonella* and *Campylobacter* in domestic animals versus *S. pneumoniae* in the community at large versus resistant gram-negative rods in the nosocomial environment.[54,55] By understanding the reservoir, the prevalence of antimicrobial resistance in the reservoir, and the risk of exposure of a patient to a given organism, one can determine appropriate initial antimicrobial therapy. The implication of these principles is 2-fold. First, every hospital and patient area within the hospital must engage in ongoing surveillance of the most common organisms and antimicrobial susceptibility patterns causing nosocomial in-

TABLE 17–2.

Emergence of Antibiotic Resistance

		% Resistance by Year		
Resistant to	**Bacteria**	**1998**	**1998–2002[a]**	**2003**
Vancomycin	Enterococci	23.9	25.4	28.5
Methicillin	*Staphylococcus aureus*	46.7	53.6	59.5
Third-generation cephalosporin	*Klebsiella pneumoniae*	10.7	14.0	20.6
Third-generation cephalosporin	*Enterobacter* spp.	34.0	33.1	31.1
Imipenem	*Pseudomonas aeruginosa*	17.1	18.3	21.1
Quinolones	*Pseudomonas aeruginosa*	23.3	27.1	29.5

fection in their particular units. Second, decisions about antimicrobial use should take into consideration such information, particularly in patients who have been subjected to the selection pressures of previous courses of antibiotics that will have rendered them more vulnerable to colonization and/or invasion with resistant flora.

Host Factors

A number of host factors must be considered in formulating an antimicrobial regimen. These can be divided into three groups: those that increase a patient's risk for a specific type of infection; those that increase a patient's risk of complications from an infection such as the presence of prostheses such as artificial joints, synthetic vascular grafts, or cardiac valves, and those that increase the risks of treating an infection with specific drugs.

Specific Drug Risks

Perhaps the most important consideration is the history of previous adverse reactions to the drugs in question. Great precision is needed in defining the nature of the adverse reaction. For example, nausea, vomiting, and diarrhea, particularly after oral administration, do not preclude the use of an antimicrobial agent, especially intravenously. In contrast, a history of anaphylaxis, Stevens-Johnson syndrome, toxic epidermal necrolysis, or allergic interstitial nephritis does preclude further use of an antimicrobial agent. Commonly, the exact nature of the allergy is unclear. In this circumstance, either the class of drug implicated should be avoided or else skin testing with a subsequent desensitization regimen should be performed.

The presence of renal dysfunction in the patient being treated can also have a profound effect on antimicrobial therapy (Table 17–3). Antimicrobials cleared by the kidney require an alteration in the dosage regimen with renal impairment. Unless such adjustments are made, toxic side effects may occur, such as injury to the eighth cranial nerve or renal injury with aminoglycosides,[56] seizures with penicillin and imipenem,[57] and bleeding caused by platelet dysfunction (added to that already caused by the uremic state) induced by ticarcillin, mezlocillin, and piperacillin.[58] Although many drugs are cleared or metabolized by the liver, hepatic dysfunction usually requires less adjustment of antimicrobial therapy than does renal dysfunction. In general, little dosage adjustment is required until the bilirubin exceeds 5 mg/dL. With hepatic dysfunction chloramphenicol, clindamycin, the tetracyclines, and the antituberculous drugs isoniazid and rifampin should be avoided, if possible.[59] (In the case of the antituberculous drugs, if they are required for emergency therapy, then special effort should be made to monitor blood levels in the face of serious hepatic dysfunction.) When both renal and hepatic dysfunction are present, then therapy with essentially all β-lactam antimicrobial agents should be carried out with great care.[60]

Impaired Host Defenses

Special considerations need to be extended to those patients who have specific impairments in host defenses. Impairment may be anatomical such as cutaneous ulcerations or mucosal abnormalities, or it may be secondary to functional host defense defects such as neutropenia, asplenia, malignancy, immunosuppressive therapy, and HIV infection. Patients with prosthetic heart valves, prosthetic joints, vascular grafts or other prostheses, can suffer dire consequences from metastatic spread of infection if initial therapy is inadequate. Therefore, such patients should be considered for front-loading of the regimen, ideally with a bactericidal drug, even if their initial clinical state would not normally require it.

Pregnancy

A critically ill patient who is pregnant, and for whom termination of the pregnancy is not an option, represents a particular challenge. First, the pharmacokinetics of many antibiotics are altered in pregnancy because of a larger volume of distribution and increased glomerular filtration rate. Second, the database on the safety of different antibiotics during pregnancy is woefully incomplete. However, the following appear reasonable at the present time. Penicillins (except ticarcillin, which is teratogenic in rodents), cephalosporins, and macrolides appear to be relatively safe. Aminoglycosides and isoniazid should only be prescribed if absolutely necessary because the former may be associated with eighth cranial nerve dysfunction in the infant and the latter with an increased incidence of psychomotor retardation, myoclonus, and seizures. Metronidazole, ticarcillin, rifampin, trimethoprim, the fluoroquinolones, and the tetracyclines should be avoided completely because of the potential for injuring the developing fetus. In addition, tetracycline use in the pregnant woman is associated with acute fatty necrosis of the liver, pancreatitis, and possibly renal injury.[61]

TABLE 17–3.

Use of Antimicrobial Agents in the Presence of Renal or Hepatic Dysfunction

Contraindicated in the presence of renal failure: tetracyclines (except doxycycline), nitrofurantoin, cephaloridine, long-acting sulfonamides, methenamine, paraaminosalicylic acid

Require no dosage change in the presence of renal failure: erythromycin, azithromycin, clarithromycin, clindamycin, chloramphenicol, doxycycline, cefoperazone, nafcillin, oxacillin, rifampin, amphotericin B, ceftriaxone, metronidazole, grepafloxacin, minocycline, linezolid, quinupristin/dalfopristin

Require dosage adjustment with moderate renal failure: carbenicillin, ticarcillin, cefazolin, all aminoglycosides, vancomycin, imipenem, flucytosine, penicillin G, 5-fluorocytosine, fluconazole

Require dosage adjustment only with severe renal failure: ampicillin, cefoxitin, cefotaxime, ceftizoxime, piperacillin, isoniazid, ethambutol, trimethoprim-sulfamethoxazole, cefotetan, ceftazidime, cefuroxime, mezlocillin, meropenem, nalidixic acid, ciprofloxacin, ofloxacin, levofloxacin, norfloxacin, itraconazole

Avoid or dose adjust in the setting of significant hepatic dysfunction (e.g., bilirubin >5 mg/dL): quinupristin/dalfopristin, chloramphenicol, clindamycin, lincomycin, all the tetracyclines, cefoperazone, ceftriaxone, metronidazole, nafcillin, nitrofurantoin, fusidic acid, isoniazid, rifampin, rifabutin, pyrazinamide, rimantadine, ketoconazole, fluconazole, itraconazole

PRACTICAL ASPECTS OF DRUG ADMINISTRATION: ANTIMICROBIAL THERAPY OF PARTICULAR CLINICAL SITUATIONS

When choosing the appropriate antibiotic therapy it is critical to decide if the infectious process is nosocomially acquired or present at admission, that is, community acquired. Of the nosocomially acquired infections, the National Nosocomial Infections Surveillance (NNIS) system has demonstrated that almost 80% occur in three sites: 24% in the respiratory system, 17% in the bloodstream, and 36% in the urinary track. The majority of the remaining 19% of nosocomial acquired infections are associated with the gastrointestinal tract, cardiovascular system, skin and soft tissue, surgical site, or ear, eye, nose, and throat, as shown in Fig. 17–1. Table 17–4 lists the primary pathogens associated with these various sites. It is important to recognize that gram-positive pathogens, particularly *Staphylococcus epidermidis, S. aureus,* and enterococci are the leading bloodstream pathogens, whereas *S. aureus* and gram-negatives, particularly *P. aeruginosa*, are the predominant pathogens associated with nosocomial pneumonia. In addition to *S. aureus* and *P. aeruginosa*, *E. coli* and *Candida albicans* are the primary pathogens found in urinary tract infections, with the great majority of these being associated with urinary tract instrumentation.[62–68] These data are consistent across continents.[68]

It is of interest that *Candida* species now account for the fourth most common cause of nosocomial bloodstream infection. Ten years ago it was 24th, a testimonial to the increasing importance of this organism, particularly in ICU patients.

The incidence of nosocomial infections is highly associated with the use of devices such as ventilators, vascular access catheters, and urinary cathe-

CCU, critical care unit; MICU, medical intensive care unit; SA, *Staphylococcus aureus*; SNC, coagulase-negative Staphylococcus.
Data derived from the National Nosocomial Infections Surveillance (NNIS) database elucidating the relative frequency of various pathogens by site of infection and by type of ICU (MICU vs. CCU). Data were obtained from 1992 to 1997.
Adapted from Richards MJ, Edwards JR, Culver DH, et al;[65,66] National Nosocomial Infections Surveillance;[131] el-Ebiary M, Tomes A, Fabregas N, et al;[133] and Kauffman CA, Vazquez JA, Sobel JD, et al.[134]

ters. This is likely a result of the breakdown of normal host defenses and clearance mechanisms. In addition, the various devices may support various microorganisms differently. For example, the development of biofilms on urinary and central venous catheters enhances the adherence of certain microorganisms such as *E. coli* and impairs the penetration of antimicrobials, whereas the condensation of water in ventilator circuits is a conducive environment for *Pseudomonas* and *Acinetobacter*.[66] The rate of device-related infections per 1000 device days also varies by type of ICU from 3.0 (cardiothoracic) to 6.7 (burn) for urinary catheter-associated urinary tract infections; from 2.7 (cardiothoracic) to 7.0 (burn) for central line-associated bloodstream infections; and from 4.9 (medical) to 12.0 (burn) for ventilator-associated pneumonia.[62]

Catheter-Related Infections

Intravascular access devices are common causes of bacteremia and fungemia. A catheter-related infection is defined as a bacteremia or fungemia in a patient with a central venous catheter who has at least one positive blood culture drawn at a peripheral site, clinical manifestations of an infection and no apparent source for the infection except the catheter. A positive semiquantitative (>15 colony-forming units [CFU]/catheter segment) or quantitative (>1000 CFU/catheter segment) culture of the same organism from a catheter segment (usually the tip) should also be present.[69,70] The most widely used diagnostic technique to assay for catheter infection is a semiquantitative method, which involves rolling the catheter tip across an agar plate and then counting the number of CFU after overnight incubation. A positive culture drawn through a catheter is relatively nonspecific but a negative culture generally rules out a catheter-related infection because of the low false-negative rate. It is difficult to find current data on the risk of bacteremia associated with various vascular devices, probably because of the large variation in type of catheter (antibiotic coated or not), techniques (skin preparation), care of the site, and barrier precautions between regions of the country and hospitals within a region.

To put this risk in perspective, it is worth noting that 50,000–100,000 patients in U.S. hospitals develop nosocomial bloodstream infections (BSIs) each year, with 70–90% of these infections being related to central venous catheters of various types.[62,71] Such infections are associated with a mortality of 25–35% and a 2- to 3-fold increase in attributable mortality. The Infectious Diseases Society of America has published guidelines for the management of intravascular catheter-related infections, as has the Centers for Disease Control and Prevention (CDC).[69,70] Although the guidelines state that "there is a notable absence of compelling clinical data to make firm recommendations for an individual patient," understanding the pathogenesis and virulence of the typical organisms involved still permits this problem to be approached rationally.

For nontunneled central catheters, the organism usually comes from a colonized catheter, often the hub or lumen. These organisms usually reflect the flora of the skin. *S. epidermidis, S. aureus, Enterococcus* species, and *Candida* species are the prime culprits, but gram-negative bacilli also cause infection. The latter is particularly true when there is gram-negative infection of the respiratory tract or surgical wounds and drains as they increase the incidence of gram-negative skin colonization and hence the reservoir of organisms from which infection is derived. This pathogenic mechanism explains the increasing infection rate associated with central line position (femoral > internal jugular > subclavian). Presumably, internal jugular catheter infection is more likely than subclavian catheter infection because the former is more likely to be exposed to orotracheal secretions. One solution has been to use antibiotic-impregnated catheters, which have been shown to prevent microbial contamination of the catheter and subsequent bacteremia in some, but not all studies. In one study, catheter-associated bacteremia decreased from 3.4% to 0.3% with the use of a minocycline- and rifampin-impregnated catheter.[72] However, these results should be interpreted cautiously because these coatings may lead to false-negative culture results.

Initial therapy of suspected intravascular catheter infection usually includes vancomycin because of the high prevalence, in the nosocomial environment, of methicillin-resistant *S. aureus* and *S. epidermidis*. Additional coverage directed at gram-negative organisms should be considered if gram-negative infection is present at other bodily sites or if the patient manifests cardiovascular instability that is thought to be a result of infection. Empiric therapy directed at vancomycin-resistant enterococci is rarely indicated, as this organism is an unusual cause of acute hemodynamic instability. Antifungal therapy is also not initiated unless there is microbiologic evidence of fungal infection. Once the offending bloodstream pathogen is identified and its resistance profile known, focused antimicrobial therapy should be used.

There are several important issues to consider in the treatment of the common BSI pathogens. *S. epidermidis* is often a contaminant. However, when it does cause a BSI, it typically behaves as a relatively avirulent pathogen. Consequently, it usually can be treated with removal of the catheter and a short course of antibiotics. Nonetheless, this organism has a propensity to adhere to prosthetic devices such as cardiac valves and artificial joints. Therefore, when *S. epidermidis* bacteremia occurs in such a patient, one must carefully evaluate the prosthetic device for evidence of secondary infection. In light of these considerations, patients with indwelling prostheses should be considered at higher risk for consequences of central catheter placement, and they should be discontinued at the earliest opportunity.

S. aureus, on the other hand, is an extremely virulent organism, which in the setting of bacteremia, often disseminates and causes osteomyelitis, endocarditis, and other severe, destructive infections. Thus when a bacteremia with this organism is confirmed a careful evaluation for metastatic infection should occur and prolonged therapy (2–4 weeks) is often recommended. Enterococcal BSI behaves in a similar manner as *S. epidermidis* and typically responds to removal of the catheter. However, endocarditis may occur, particularly in the setting of prolonged bacteremia. The optimal therapy for this organism is ampicillin plus an aminoglycoside although some of the newer antibiotics show therapeutic promise. When *C. albicans* is cultured from the blood, the patient should be evaluated for metastatic infectious foci (e.g., hepatic, ocular, and skin), the catheter should be removed, and antifungal therapy initiated, typically with

fluconazole.[73] If metastatic foci of candidal infection are found, the optimal management of these complications will determine the duration of therapy.

Prophylaxis

Surgical

Need for Prophylaxis The need for antibiotic prophylaxis for surgery depends on the risk of *surgical site infection* (SSI), generally defined as purulence within the wound. SSIs are related to the wound classification, patient-related factors such as immunocompetence, the bacterial milieu and hospital infection rate for various procedures, and factors relating to the wound itself. Wounds are usually classified as clean (class I), clean-contaminated (class II), contaminated (class III) and dirty-infected (class IV).[74] A clean wound is atraumatic in which there has been no break in sterile technique and the respiratory, alimentary, or genitourinary tracks have not been entered. Clean-contaminated wounds result from surgery in areas known to harbor bacteria, such as the biliary, respiratory, alimentary, and genitourinary tracts, when there is no spillage of contents. Contaminated wounds occur with a major break in sterile technique, or with surgery on a traumatic wound, or gross gastrointestinal spillage, or entrance into an infected biliary or genitourinary tract. Dirty-infected wounds are those for which infection existed before the surgery, such as old wounds with devitalized tissue or surgery for patients with perforated viscera. This classification scheme indicates the risk of postoperative infection and is thought to be related to the bacterial burden except for dirty-infected wounds, which are, by definition, already infected. However, careful microscopic examination shows that even clean wounds are contaminated with skin flora.[75]

Staphylococcus species are the most common wound pathogens for most SSIs. Prophylaxis is debatable for some clean procedures such as an inguinal hernia repair or mastectomy. However, for other clean procedures, especially for cardiothoracic and vascular surgery, hip or knee arthroplasty, and any procedure when bone is excised or a prosthesis is inserted, gram-positive coverage, usually with cefazolin, is recommended. However because of the increasing incidence of methicillin-resistant *Staphylococcus* not only in hospitals but also in the community, the trend seems to be shifting back toward vancomycin. Prophylactic antibiotics should be administered for all clean-contaminated and contaminated wounds, as well as for hysterectomies and most urologic procedures. Sterilization of the urinary tract is recommended before any urologic procedure if possible. Even with successful treatment of urinary tract infection (UTI), deep-seated infection of the prostate gland can be reactivated by manipulation and/or surgery of the prostate gland. Prophylaxis is advised for high- and moderate-risk patients undergoing procedures involving infected tissues and should include antistaphylococcal antibiotics for cellulitis and osteomyelitis. Similar coverage is advised for patients receiving prosthetic cardiac valves. Patients with urinary tract infections should receive antibiotics active against gram-negative bacilli such as fluoroquinolones, third-generation cephalosporins, or an aminoglycoside. Convincing evidence of prophylactic antimicrobial benefit is also found in patients undergoing endoscopic manipulation of the biliary tree or in patients undergoing manipulation of an infected urinary tract. For these conditions antibiotics such as ampicillin-sulbactam and piperacillin-tazobactam are reasonable choices.

Timing of Prophylaxis It is generally believed intravenous administration of prophylactic antibiotics should be initiated no more than 1 hour before incision. The major impetus for this practice comes from Classen's study that looked retrospectively at the timing of prophylactic antibiotic administration in patients in whom a wound infection was reported.[76] The investigators found that patients who developed wound infections were more likely to have received prophylaxis between 24 and 2 hours prior to surgery or postoperatively. Often missed in this study was that the incidence of wound infection was statistically no different if the antibiotics were initiated within the first 4 hours following incision or in the 2 hours before incision. When the data were subjected to a multiple logistic regression, the only variables related to wound infection were underlying disease, nursing service, type of surgery, duration of surgery and time after the start of surgery for the first dose of prophylactic antibiotics. Notably, of the 41 wound infections, 58% were resistant to the antimicrobial drug used.

Thus, although this study is widely quoted as showing that prophylaxis must be given within 1 hour of the incision, these data does not support this conclusion. Moreover, this study does not address when the antibiotic infusions were completed and a prospective study validating these retrospective findings has never been published. Finally, an animal study widely cited as documenting the need to have the antimicrobial given before the incision lacks statistical testing, uses very high inocula and varying doses of antimicrobials.[77] Interestingly, a recent study of vancomycin prophylaxis in 2048 cardiac surgical patients indicated that vancomycin initiated from 16 to 60 minutes before incision and administered over 1 hour was associated with the lowest rate of surgical site infections.[78]

Although it seems logical to have adequate tissue levels of prophylactic antimicrobials before skin incision, supporting data are only inferential and it is likely that the importance depends upon the size of the inoculum. Nonetheless, Classen's study[76] apparently led the Center for Medicare and Medicaid Services to set a standard that all preoperative antibiotics should be administered within 1 hour of skin incision except for vancomycin which can be administered 2 hours prior to skin incision, presumably because it is often infused over 1 hour. These recommendations also specify that therapy should be stopped within 24 hours except in special circumstances, notably cardiothoracic surgery for which it may be extended to 48 hours. The latter exception occurred because of a document drafted by the Society of Thoracic Surgeons that made the following points: (a) although prolonged use of antibiotics can lead to the emergence of resistant infections, there are no data that this can occur with administration for under 48 hours; (b) antibiotic prophylaxis for 48 hours is "clinically effective in minimizing infectious complications in cardiac surgery" and is as effective as prophylaxis administered for more than 48 hours; and (c) antibiotic prophylaxis should not be used for indwelling catheters of any type or chest tubes.[79] There is general agreement on this last point for all types of

surgery with the possible exception of transplantation.

ICU

Comparable successes with prophylactic antimicrobial regimens in ICU patients have been more difficult to prove as have attempts to prevent infection with selective gut decontamination regimens. The latter involves using either nonabsorbable antimicrobial agents or fluoroquinolones to eliminate the aerobic gram-negative flora while leaving the anaerobic flora intact, which provides some protection against colonization with a variety of potential pathogens, so-called colonization resistance. Similarly, aerosolized antibiotics, particularly polymyxin or aminoglycosides, do not prevent pneumonia. Topical antibiotic ointments do not decrease the incidence of intravenous access related bloodstream infection.

Preemptive Therapy

Recently the concept of preemptive therapy has come to the fore. Preemptive therapy was initially defined in transplant patients, where the initiation of ganciclovir therapy in bone marrow transplant patients with evidence of cytomegalovirus (CMV) replication either in the blood or in the respiratory secretions, at a time when they were asymptomatic, prevented the development of otherwise life-threatening CMV pneumonia. In organ transplant patients, the initiation of preemptive ganciclovir during intensive antirejection therapy markedly decreases the incidence of systemic CMV infection normally associated with such therapy.[1,2]

The efficacy of prophylaxis for fungal infection has not been well established. Data for fungal prophylaxis suggests that fluconazole may be effective prophylaxis for certain high-risk patients such as bone marrow transplant recipients and patients undergoing reoperation for gastric or upper small bowel perforations that are the anatomic sites where large numbers of *Candida* species are normally found. However, there is no evidence that this reduces mortality.[80,81] Such studies are difficult to interpret, however, because the diagnosis of invasive fungal infection is often difficult and the ability of the clinician to distinguish between candidal colonization and invasion is not very great. Several studies show that when a patient is colonized at three or more sites, there is a 30–60% incidence of invasive disease, with a high associated mortality. There is some agreement that preemptive therapy should be initiated only following recent abdominal surgery with recurrent gastrointestinal perforations or anastomotic leaks and is not necessary for the initial surgery even if there is soilage, so long as it has not been present for a relatively long period.[82] However, this issue is further complicated by the emergence of fluconazole-resistant *C. albicans* and the change in common fungal species to more resistant yeast such as *Candida krusei* and *Candida glabrata* which are sensitive to newer antifungal drugs.

Bacterial Endocarditis

Although there are generally agreed upon guidelines for surgical prophylaxis for bacterial endocarditis there are no studies that definitively show that antibiotic prophylaxis prevents bacterial endocarditis during procedures that can produce a bacteremia. Nonetheless, given the consequences of endocarditis and the minimal risk associated with prophylaxis, the use of antibiotics to prevent cardiac infection is sensible in high-risk procedures. A summary of the most recent recommendations is available from the American Heart Association.[83] These recommendations are based on the risk of a procedure producing a significant bacteremia with an organism likely to produce endocarditis and the risk of a patient developing bacterial endocarditis with such a bacteremia. They are also predicated on cardiac conditions that are associated with an increased risk of endocarditis even without surgery. Patients considered to be at highest risk of endocarditis are those with prosthetic heart valves, a previous history of endocarditis, complex cyanotic heart disease and those with surgical systemic-pulmonary shunts or conduits. Moderate risk patients include those with uncorrected ventricular septal defects, primum atrial septal defects, patient ductus arteriosus, aortic coarctation, bicuspid aortic valves, acquired valvular dysfunction and hypertrophic cardiomyopathy. Prophylaxis for mitral valve prolapse is an enlightening controversy for several reasons. First, prolapse can occur in normal mitral valves under conditions that reduce the end-diastolic volume of the left ventricle such as hypovolemia or enhanced contractility, especially in young adults. Second, prolapse without regurgitation is not thought to increase the risk of bacterial endocarditis because the regurgitant jet seems to produce the valvular abnormalities that make bacteria more likely to adhere to the valve. Thus, it is thought that only patients with mitral valve prolapse who also have mitral regurgitation should receive antibiotic prophylaxis. However, this is further complicated by the observation that regurgitation may occur only with exercise. Consequently, it might be missed on routine examination. In addition, men older than age 45 years with mitral valve prolapse are at higher risk for developing bacterial endocarditis.

Procedures such as central catheter placement through skin that is otherwise normal and has been cleansed with povidone-iodine or chlorhexidine are not associated with significant bacteremias and therefore do not warrant prophylaxis. In contrast, patients undergoing dental procedures associated with bleeding or patients with poor dental hygiene should receive prophylaxis. Viridans streptococci (α-hemolytic streptococci) are the most common cause of endocarditis in association with dental or oral surgical procedures. A single oral dose of 2 g of amoxicillin given 1 hour prior to the procedure is the recommended prophylaxis. If oral medications cannot be used, intravenous ampicillin or penicillin is recommended. Clindamycin or azithromycin are alternatives for penicillin allergic patients. Other procedures for which similar prophylaxis is recommended include rigid (but not flexible) bronchoscopy, esophageal stricture dilation, and sclerotherapy (but not banding). Surgery that involves the biliary tree or intestinal mucosa or endoscopic procedures of the pancreatic or biliary tree is also associated with bacteremia with organisms that cause endocarditis, especially *Enterococcus faecalis*. The recommended prophylaxis for high-risk patients undergoing such procedures is ampicillin and gentamicin. Vancomycin may be substituted for ampicillin in penicillin-allergic patients. Gentamicin may be omitted in medium-risk patients.

Endocarditis prophylaxis is recommended for some clean procedures such as abdominal and lower-extrem-

ity vascular procedures, craniotomies, orthopedic procedures with hardware insertion and any procedure that includes implantation of permanent prosthetic material. In contrast, the need for prophylactic antibiotics for orthopedic procedures such as laminectomies and spinal fusions is controversial.

The rate of endocarditis-causing bacteremia with genitourinary tract surgery or instrumentation is high in patients with urinary tract infections, prostatitis, and prostatic surgery. *E. faecalis* is the most common bacterial species, but *Klebsiella* species are also common. Prophylaxis recommendations are the same as for intestinal or biliary tract surgery but attempted sterilization of the urinary tract before any procedure is also thought to be beneficial. Prophylaxis is not recommended for uncomplicated vaginal delivery, cervical biopsy, or manipulation of an intrauterine device in the absence of infection. However, because bacteremia following removal of an intrauterine device is thought to be relatively common, prophylaxis similar to that used for other genitourinary procedures is recommended.

Pneumonia

Patients with pneumonia can be divided into two general categories: those with community-acquired and those with nosocomial pneumonia (particularly ICU-acquired).

Community-Acquired Pneumonia

It is useful to consider community-acquired pneumonias (CAP), in three different categories. First are the typical pneumonias of conventional bacterial origin, which are characterized by the abrupt onset (within less than 24 hours) of fever, chills, systemic toxicity, cough, purulent sputum production, and dyspnea, often after a preceding viral illness. Second are the atypical pneumonias, characterized by a subacute onset of fever, nonproductive cough, and malaise, with a gradual progression over a several days. Legionnaires disease, which combines features of both, has an abrupt onset of fever, rigors, nonproductive cough, systemic toxicity, and increasing dyspnea, often after a several-day prodrome of gastrointestinal upset, headache, malaise, and encephalopathy. Although there is considerable overlap among these presentations, initial therapy can be guided by such categorization and by considering the different etiologies within each category (Table 17–5).

TABLE 17–5.

Etiology of Community-Acquired Pneumonia

Etiology	Incidence (%)
Typical (acute onset or abrupt deterioration after viral prodrome, with productive cough, systemic toxicity, and a lobar infiltrate)	
Streptococcus pneumoniae	20–60
Haemophilus influenzae	5–20
Staphylococcus aureus	2–10
Enterobacteriaceae	4–8
Others (*Branhamella catarrhalis*, anaerobes, *Pseudomonas aeruginosa*)	5–10
Atypical (subacute onset, nonproductive cough, interstitial infiltrate)	
Viral (influenza, RSV, parainfluenza, adenovirus)	30–60
Mycoplasma pneumoniae	20–40
Chlamydia pneumoniae	4–15
Legionella	1–15
Others (PCP, Q fever, psittacosis RSV, PCP, *Pneumocystis jiroveci*)	1–2

PCP, *Pneumocystis carinii* pneumonia; RSV, respiratory syncytial virus.

The bacterial species or virus causing CAP is never identified in approximately 40–60% of patients. However, *S. pneumoniae* is the most common cause, accounting for approximately two-thirds of bacteremic pneumonias. Other relatively common typical bacteria are *Haemophilus influenzae*, *S. aureus* with an increasing frequency of methicillin resistant strains, *Neisseria meningitidis,* and *Moraxella catarrhalis*. The atypical bacteria are *Chlamydia pneumoniae*, *Mycoplasma pneumoniae,* and *Legionella* species. The most common viruses are influenza A and B, depending on the season, respiratory syncytial virus, and adenovirus.[84,85] The choice of appropriate antimicrobial therapy is helped by Gram stain of sputum; urinary *Legionella* antigen assays that detect more than 80% of cases of pneumonia caused by *Legionella pneumophila* type I but not other *Legionella* species or types; polymerase chain reaction (PCR) test for mycoplasma and/or IgM titers for chlamydia; detection of the appropriate antigen for respiratory viruses; and special studies for other pathogens. In most patients, however, antimicrobial therapy needs to be initiated in the absence of clear-cut microbiologic information. Patients without a predisposing host defense defect or history of a gross aspirational episode, in whom a typical pneumonia is suspected as a cause of respiratory failure, should have initial therapy especially directed against *S. pneumoniae, H. influenzae,* and possibly *S. aureus*. Recommended empirical therapy for such inpatients is either a β-lactam plus a macrolide, usually azithromycin, or a fluoroquinolone, such as levofloxacin, alone. For ICU patients, the recommended therapy is either a β-lactam plus a fluoroquinolone or a β-lactam plus a macrolide, although the supporting data are very limited. If *S. aureus* is suspected and the incidence of MRSA in the community is high, adding vancomycin may be appropriate until the organism and its sensitivities are confirmed. If atypical pneumonia is suspected, then a fluoroquinolone such as levofloxacin, or erythromycin, or one of the newer macrolides (azithromycin or clarithromycin), with or without trimethoprim-sulfamethoxazole, would constitute reasonable initial therapy. For patients with a *Legionella*-like presentation, high-dose erythromycin is the traditional therapy of choice; however, azithromycin or levofloxacin combined with of one of the regimens used for the treatment of typical bacterial pneumonia such as ampicillin-sulbactam or ceftriaxone might be preferable if resistant pathogens are a concern. It is also important to consider viral pathogens because they are a common cause of community-acquired pneumonia; rapid diagnostic tests are available, and the possibility of antivi-

ral therapy exists. Although the initiation of empiric therapy is often obligatory, invasive diagnostic techniques, such as bronchoalveolar lavage or lung biopsy, should be considered for any patient with respiratory failure in whom the etiologic diagnosis is not quickly apparent or in whom there is a failure to respond to therapy. This is especially important for individuals with underlying conditions that predispose them to a broader range of pathogens such as alcoholics and the immunocompromised.

Nosocomial Pneumonia

Nosocomial pneumonia can be divided into three groups: hospital-acquired pneumonia (HAP), which occurs at least 48 hours after admission; ventilator-associated pneumonia (VAP), which occurs at least 48 hours after endotracheal intubation and healthcare-associated pneumonia (HCAP), which occurs at least 48 hours after admission of patients who had a previous infection within 90 days or resided in a nursing home or long-term care facility or received intravenous antibiotics or wound care within the last 30 days.[86] These infections can be divided further into early onset, within the first 2–4 days of hospitalization, and late onset, 5 or more days after hospitalization. Early onset nosocomial pneumonia is less likely to result from multidrug resistant (MDR) organisms and has a better prognosis than late-onset pneumonia. Infections in HCAP patients usually are similar to those in late onset HAP or VAP.

The etiology of nosocomial pneumonia, especially when acquired within the ICU, is vastly different from the etiology of community-acquired infection. The pathogenesis is typically an extension of a tracheobronchitis into a bronchopneumonia. In the hospital setting, relatively antibiotic-resistant, aerobic, gram-negative bacilli had been the most frequent invading pathogens but this has been surpassed by gram-positive bacteria. This is thought to be a result of the increased rate of oropharyngeal and gastric colonization with these organisms, with such colonization serving as a reservoir for the introduction of this flora into the lower respiratory tract, usually as a result of aspiration, and the impaired ability to clear these organisms. This is especially true among intubated patients, those with previous lung injury, significant atelectasis, and immunocompromised patients.

Although Tables 17–4 and 17–5 list the etiologies of nosocomial pneumonias caused by different bacteria nationally, it should be emphasized that the etiology of nosocomial pneumonia in each individual hospital may be very different from the national average. Although, gram-negative bacillary pneumonia had been the major problem, gram-positive bacteria, especially MRSA, are rapidly overtaking gram-negative bacteria. Regardless, the type of the bacteria causing infection and their antibiotic sensitivity patterns will vary widely in different hospitals and even in different areas within a hospital. Thus, precise antibiotic recommendations for initiating therapy must be based on ongoing surveillance of the resident bacterial flora and antibiotic sensitivities in the particular hospital area.

Initial therapy should reflect the ongoing surveillance information and be modified on the basis of sputum examinations including Gram stains that provide important information about the relative importance of a particular organism found on culture. Initial therapy is usually accomplished with a single, advanced-spectrum, anti–gram-negative drug such as ceftazidime, piperacillin-tazobactam, imipenem, ciprofloxacin, or levofloxacin for less-severe disease, and perhaps one of these drugs with an aminoglycoside for patients with more-severe illness.[87] Because of the increasing prevalence of MRSA, vancomycin is often appropriate pending more definitive bacterial identification. As noted previously, clear-cut evidence in humans that two-drug, potentially synergistic therapy is more effective than a single drug is controversial, but such therapy is used by many clinicians in the face of rapidly progressive *Pseudomonas* or *Klebsiella* infection.[88] Because some species of *Klebsiella* are sensitive to cefazolin, it can be substituted for the more expensive advanced-spectrum drugs once the sensitivity is confirmed.

In immunocompromised patients, pulmonary infection is the most common form of life-threatening infection. Although a detailed discussion of the approach to pulmonary infection in these patients is beyond the scope of this chapter, certain principles are worth noting here in terms of antimicrobial strategies. As outlined in Table 17–6, particular host defense defects are associated with particular infections, and initial therapy should reflect these associations. Even more than other ICU patients, these immunocompromised individuals are especially susceptible to nosocomial infection, both with the resident gram-negative flora and with *Aspergillus* species. Because of the importance of such infections in these patients, precise diagnosis is essential, using invasive techniques if necessary.

Bacteremia

Bacteremias occurring in hospitalized patients can be considered as arising from two separate pathogenic routes. One route is a consequence of definable tissue infection at an anatomic

TABLE 17–6.

Frequent Causes of Pneumonia in Patients with Various Defects in Host Defenses and Initial Antimicrobial Therapy

Host Defense Defect	Pulmonary Infection	Initial Therapy
Impaired antibody formation or splenectomized	*Streptococcus pneumoniae*; *Haemophilus influenza* type B	Levofloxacin, azithromycin or ampicillin + β-lactamase inhibitor
Depressed cell-mediated immunity	*Pneumocystis jiroveci; Mycobacteria* species; fungi; *Nocardia; Legionella;* herpes group viruses; *Strongyloides stercoralis*	Trimethoprim-sulfamethoxazole
Decrease in the number and/or function of granulocytes	Oral bacterial flora; *Enterobacteriaceae; Pseudomonas aeruginosa; Aspergillus*	Ceftazidime, carbapenem, ± an aminoglycoside
Oral and tracheobronchial ulcerations	Oral bacterial flora; *Enterobacteriaceae*	Ceftazidime, carbapenem

site. Common causes of bacteremia of this type are biliary and urinary tract sepsis, usually caused by gram-negative bacilli and/or enterococci; peritonitis caused by a disruption of bowel integrity (mixed infection caused by such anaerobic organisms as *B. fragilis*, the Enterobacteriaceae, especially *E. coli*, and bowel streptococci, especially enterococci); and pneumonia. The incidence of bacteremia with pneumonia varies according to which organism is causing the infection. For example, 30–50% of patients with pneumococcal infection will have demonstrable bacteremia compared to less than 10% with gram-negative or aspiration pneumonia. In pneumococcal infection, the bacteremia is typically a result of hematogenous seeding from the pulmonary infection, whereas in gram-negative VAP, the bacteremia is likely related to heavy oropharyngeal colonization leading to skin contamination with consequent seeding of a central venous catheter. Thus, in the setting of VAP, all vascular access devices should be carefully evaluated, especially for duration of implantation, exit-site erythema, and drainage, and by blood cultures. The initial antimicrobial therapy of bacteremia secondary to invasive tissue infection is identical to that which would be prescribed in the absence of bacteremia.

Urinary Tract Infection

Urosepsis is relatively uncommon unless complicating factors such as obstruction to urine flow, diabetes, advanced age, spinal cord injury or bladder catheterization are present. The likely bacteria are also different than in uncomplicated urinary tract infections, UTI, or asymptomatic UTIs. In these two instances likely organisms are *E. coli* or other Enterobacteriaceae, and *Pseudomonas* can be treated with a fluoroquinolone or trimethoprim-sulfamethoxazole. In patients with complicating factors, gram-positive and antibiotic-resistant gram-negative bacteria, including *P. aeruginosa*, are more common.[89] Consequently, therapy should be initiated with broader-spectrum antibiotics, usually fluoroquinolones or advanced spectrum β-lactam agents such as ceftazidime, ampicillin-sulbactam, ticarcillin-clavulanate, aztreonam, and imipenem. As with all infections, antimicrobial therapy should be adjusted so that the spectrum is as narrow as possible.

A more common problem in hospitalized patients, especially those with urinary catheters, is nosocomial bacteriuria. The etiology of such infections is far different from that observed in community-acquired infections. Whereas *E. coli* account for more than 85% of community-acquired urinary tract infections, it is responsible for only one-third of nosocomial infections. Enterococci, *P. aeruginosa*, relatively antibiotic-resistant Enterobacteriaceae such as *Klebsiella, Proteus, Enterobacter*, and *Serratia* species, as well as *Candida* species, now account for the majority of these infections.[90] Antibiotic therapy can delay the appearance of bacteriuria for a while, but the price to be paid if catheterization is maintained is that when infection does occur, it will be relatively resistant. Treatment of asymptomatic positive cultures when the catheter is still present is generally not indicated because this represents colonization rather than invasive infection and long-term benefits of such therapy are unlikely. However, when to treat critically ill patients may be problematic because they may not be able to relate symptoms. Usually a quantitative colony count of $>10^5$ CFU is used as a criterion for treatment with the choice of antibiotic guided by the culture. Treatment if symptoms develop and/or instrumentation of the urinary tract is to be carried out is clearly indicated.

Other Syndromes

Clostridium difficile

Clostridium difficile is the leading cause of gastrointestinal infection in the nosocomial environment. This pathogen is an important cause of fever and leukocytosis, which may precede the diarrheal phase. The pathogenesis of this disease is typically mediated by enterotoxin A or cytotoxin B and bacteremia is extremely rare. The diagnosis is confirmed with the detection of either of the aforementioned toxins. The spores from *C. difficile* are extremely hearty and impervious to antimicrobial therapy, which explains the 10% relapse rate in successfully treated patients. Metronidazole is the therapy of choice even in relapsing cases; however, in recalcitrant cases where there is no response to metronidazole therapy, oral vancomycin can be considered. In patients being treated with other antibiotics for an ongoing pyogenic process, the treatment of *C. difficile* is particularly vexing. In this setting, where continued broad-spectrum antibiotic use is required, we recommend continuing the *C. difficile* therapy in parallel with the other antimicrobial agents and extend the course of therapy for *C. difficile* for several days after completion of the other antibiotics, typically 5–10 days. The extended *C. difficile* course of therapy is required because of the role of antibiotic therapy in provoking *C. difficile* disease by altering the normal bowel flora. Future antibiotic therapy needs to be considered with great care in a previously infected patient as *C. difficile* can be provoked with subsequent antibiotic courses, in part due to the latent spores. In patients who are severely ill from *C. difficile* several adjuvant approaches should be considered including minimization of other antimicrobial therapy, toxin binding resins such as cholestyramine, fecal enemas, and in severe cases surgical resection of the colon, for example, in the setting of toxic megacolon. In a patient who undergoes a colectomy for *C. difficile* toxic megacolon, the rectal stump, if one is left behind, may be a source of residual disease. Patients receiving immunosuppressive therapy appear to be at particularly high risk for severe *C. difficile* disease.

Acute Pancreatitis

Antibiotic management in acute pancreatitis is challenging because the severity of illness often indicates a therapeutic emergency so that the traditional markers of infection may not be present and there may be limited supporting clinical data. Depending on the degree of pancreatic injury, these patients may present with septic physiology, including hypotension, tachycardia, hypoxemia, tachypnea, metabolic acidosis, leukocytosis with a left shift, thrombocytopenia, and coagulopathy. These findings are all consistent with the pathogenesis of this disease where an inciting event such as alcohol, gallstones, or trauma leads to pancreatic injury and inflammation which, in turn, leads to autodigestion, liquefaction and, necrosis. This tissue necrosis results in a cytokine release, which can mimic all aspects of septic physiology. If the necrotic pancreatic tissue becomes infected, by biliary reflux, which is often polymicrobial, colonic bacterial translocation or hematogenous seeding, there is an associated increased morbidity

and mortality.[91] It is important to note that infection is rarely the inciting event but rather a consequence of pancreatitis and often occurs weeks into the hospital course. Abdominal imaging, with a contrast CT scan, has enabled stratification of those patients at risk for developing superimposed infection with increasing degree of pancreatic necrosis. Infection of the pancreatic bed is extremely rare in the absence of necrosis.[91] Unfortunately imaging, like the physical examination and laboratory evaluation, cannot reliably distinguish an infectious from sterile inflammation. The most reliable means of making this determination is through a Gram stain and culture of the peripancreatic fluid. As an infected necrotic pancreas requires surgical debridement in addition to antibiotic therapy and supportive care, a diagnostic procedure, such as an ultrasound-guided fine-needle aspirate is extremely helpful prior to initiating antimicrobial therapy.[92] Once cultures have been obtained, the microbiologic results should guide antibiotic therapy, given the high sensitivity of the Gram stain from the pancreatic aspirate (>90% in one study).[93]

In the critically ill patient in whom it is too risky to delay antimicrobial therapy, targeting the typical infecting organisms, which includes aerobic enteric gram-negative rods and gram-positive cocci, is appropriate. A variety of antibiotics have been shown to achieve pancreatic levels above the MIC for the commonly encountered bacteria—fluoroquinolones, imipenem, ceftazidime, cefepime, metronidazole, clindamycin, chloramphenicol, doxycycline, and fluconazole. Two reasonable combinations are (a) ceftazidime, a fluoroquinolone, or piperacillin plus metronidazole or (b) imipenem or a carbapenem.[94] Imipenem-cilastatin 500 mg three times a day for 2 weeks is frequently used preemptively in patients with documented pancreatic necrosis because it has been shown to decrease the need for surgical intervention. However, *S. aureus* species, which are not sensitive to carbapenems, and *Candida* species, including *C. glabrata*, which is generally not susceptible to fluconazole, are emerging as significant pathogens in severe acute pancreatitis. If empiric antibiotics were initiated and Gram stain is negative and the microbiologic cultures are sterile, typically at 48–72 hours, then antimicrobial therapy should be discontinued. Otherwise therapy should be directed at the pathogens identified. Surgical debridement is considered an essential element in documented pancreatic necrosis with infection.

Antiretroviral Therapy in the Patient with HIV Infection and AIDS

A remarkable body of information regarding the treatment of HIV infection has emerged since 1981, when AIDS was first recognized. The occurrence of oral thrush, *Pneumocystis jiroveci* pneumonia, *Toxoplasma* encephalitis, and other opportunistic infections in apparently healthy gay males was quickly recognized as something unusual; that is, the net state of immunosuppression should not have been great enough to allow such infections to occur. Very quickly the characteristics of this epidemic emerged: profound and progressive immune compromise; efficient transmission from infected individuals by intimate contact, blood transfusion, organ transplantation, intravenous drug abuse, and perinatal transmission. In 1984, the identification of the cause of these events, infection with a unique retrovirus now known as the human immunodeficiency virus (HIV) was reported. HIV is now recognized as the cause of a worldwide pandemic of infection (particularly those caused by opportunistic organisms), Kaposi sarcoma, and other malignancies. More than 30 million individuals are believed to have been infected by HIV since 1981, with devastating consequences.[95–97]

Three different phases of disease have been recognized once HIV has been acquired[98,99]:

1. *Primary HIV Infection:* A mononucleosis-like illness is observed in ~50% of individuals 2–6 weeks after infection. Primary infection is associated with a marked increase in plasma viremia (this can exceed 1,000,000 copies per mL); a significant decrease in the CD4 T-lymphocyte count; and a large increase in the blood CD8 T-lymphocyte count.
2. *Chronic Asymptomatic Stage:* An extended phase of clinical latency occurs, persisting for 10–12 years in the majority of individuals. An estimated 20% of individuals ("rapid progressors") have an accelerated course, having full-blown AIDS in less than 5 years; conversely, ~10% ("slow progressors") remain free of AIDS for 15 or more years.. At the end of this period the level of viremia rises rapidly and there is a significant fall in the CD4 T-lymphocyte count. AIDS-defining opportunistic infections begin to appear.
3. *Overt AIDS:* In the absence of effective therapy, there is a progressive decrease in CD4-positive lymphocytes and an increase in viral load. These events are correlated with recurrent opportunistic infection, the occurrence of certain malignancies, and death in 2–3 years.

The specifics of anti-HIV therapy are still evolving, although certain principles remain constant: HIV replication remains at a very high level throughout the stages of illness. This high rate of replication is coupled with a remarkable amount of errors in the function of the reverse transcriptase (the daily production of ~10^8–10^{10} virions and a mutation rate of 3×10^3). The frequency of these events virtually guarantees the presence and the rapid development of mutants that are responsible for drug resistance. Resistant clones of HIV may be present even before the initiation of any therapy. Such findings mandate that multiple drugs will be needed to effectively treat this infection.

The general principle that applies to HIV therapy is "hit early and hit hard," with multiple drugs being started simultaneously.[99–101]

Although the precise point when therapy should be instituted is still being studied, at present it is recommended that highly active antiretroviral therapy (HAART), which consists of multidrug regimens, be initiated in asymptomatic patients who have circulating CD4 T-lymphocyte counts <500 cells/mL and/or an HIV RNA load of 5000–10,000 copies/mL. Table 17–7 lists the drugs currently available. Commonly used combinations include two nucleoside reverse transcriptase inhibitors plus one protease inhibitor and two viral protease inhibitors plus a nucleoside inhibitor or a nonnucleoside inhibitor. The goal of HAART therapy is to lower the HIV burden to undetectable and to maintain it at that level. Such an approach has been quite effective, but there are several issues that must be kept in mind. There are at least two mechanisms that are opera-

TABLE 17–7.

Antiretroviral Drugs Available for Highly Active Antiretroviral Therapy (HAART) Combination Regimens

Nucleoside Reverse Transcriptase Inhibitors (NRTI)	Nonnucleoside Reverse Transcriptase Inhibitors	Protease Inhibitors
Zidovudine	Delavirdine	Saquinavir
Didanosine	Nevirapine	Ritonavir
Zalcitabine	Efavirenz	Indinavir
Lamivudine		Nelfinavir
Stavudine		
Abacavir

tive in the antiviral effects of these drugs: they act as "chain terminators," and they competitively bind to reverse transcriptase at key sites of the virus. Protease inhibitors bind to the catalytic site of the HIV aspartic protease to produce their effect. We appear to be in a new era for the treatment of HIV. There are now a large number of drugs that are available for HAART regimens. Two key issues must be kept in mind: side effects (e.g., pancreatitis, hepatotoxicity, and a lipodystrophy syndrome), drug–drug interactions, including changes in drug metabolism by the hepatic cytochrome P450 enzymes, and the development of drug resistance. Of these, drug resistance is the most important, with the occurrence of clinically important resistance being particularly likely when the level of mutants is particularly high, the ability of the mutant strain to replicate is relatively high, and the presence of quasispecies suggests persistence of a given mutation.[101–104]

Antifungal Therapy for the Treatment of Invasive Fungal Infection

The incidence of invasive fungal infection in recent years has increased greatly, as a result of the marked increase in immunocompromised patients, for example, AIDS patients, transplantation and cancer patients, and patients with autoimmune disease, surviving as the therapy for their primary conditions has improved. The most common cause of invasive fungal infection has long been *Candida* species, and this is still true, but there has been an increase in the range of fungal species causing serious infection, as well as an increase in antimicrobial resistance. In addition, new sites of infection are being seen. For example, in the intensive care unit the use of invasive vascular access devices is becoming an important source for candidemia. Whereas in the past nosocomial bloodstream infection was uncommonly caused by *Candida* species (more than 20 other microbial species, particularly gram-negative and staphylococcal infection, were far more common), today *Candida* are the sixth most common nosocomial isolate, and fourth most common cause of nosocomial bloodstream infections. As this has occurred, the range of candidal species has changed from azole-susceptible *C. albicans* to more resistant non-*albicans* infection.[105–107]

The risk of invasive fungal infection is largely determined by the interaction of four factors.[105] The *environmental exposures* to which a patient is subjected is an important factor in the occurrence of many fungal infections, with the density of organisms that are aerosolized and then inhaled, the critical first step in the initiation of many infections. These exposures can occur in the community or within the hospital. In the hospital, the patient is vulnerable to organisms that are aerosolized and inhaled on the ward where the patient resides (*domiciliary* exposure) or to exposure to aerosols while traveling through the hospital for an essential procedure (*nondomiciliary* exposure). In both instances, construction activities are the most common activity resulting in aerosolization of infectious organisms, particularly *Aspergillus* species. In addition, person-to-person spread on the hands of medical personnel is a not uncommon event, with the spread of antimicrobial-resistant *Candida* species being a particular problem.[105–109]

The patient's *net state of immunosuppression* is a a complex function determined by host defense deficits from the underlying disease and its therapy, infection with immunomodulating viruses (including HIV, cytomegalovirus, and the hepatitis viruses), and the presence of protein-calorie malnutrition.[105]

The presence of foreign bodies, such as orthopedic prostheses, devitalized tissues, undrained fluid collections, and invasive vascular catheters, contributes significantly to the pathogenesis of invasive *Candida* infection. These *technical/anatomic* problems are commonly the substrate for developing opportunistic yeast infection. Whether one is dealing with candidemia associated with vascular access catheters, peritonitis in association with peritoneal dialysis catheters or orthopedic prosthesis infection, the chances of successful therapy are greatly enhanced by the removal of the foreign body in association with effective antifungal therapy.[105,110,111]

Darwinian factors can play an important role as well. Thus, prolonged therapy with broad-spectrum antibacterial drugs will create an ecologic niche easily occupied by *Candida* species. The presence of excess growth factors such as glucose and iron can have a significant effect on the occurrence of mucocutaneous candidiasis, invasive mucormycosis and other types of invasive infection. Unless the ecologic niche is eliminated, recurrent fungal infection may occur. For example, therapy with the newer azoles can be associated with the development of mucormycosis.[105,107,109,110]

The fungal species capable of causing invasive infection can be divided into three general categories. The *geographically restricted systemic mycoses*, blastomycosis, coccidioidomycosis, and histoplasmosis, are important in North America. In addition, paracoccidioidomycosis in Latin America and penicilliosis in southeast Asia exhibit similar clinical and epidemiologic patterns. These are *dimorphic fungi* that grow in the soil as molds and yeast-like forms in tissue. Invasive infection with one of these is greatly amplified by the presence of immunocompromise. Treatment of these infections at present has two parts: induction therapy with amphotericin to gain control of the disease, and then prolonged oral

therapy with an azole to consolidate the antifungal effects. At present, itraconazole is the therapy of choice for this purpose, with the exception of prescribing fluconazole in the treatment of coccidioidomycosis.[105,110,111]

The *opportunistic fungi* are ubiquitous in the environment where they are nonpathogenic, particularly for normal hosts, but can cause invasive infection when the inhaled inoculum harbors a high microbial burden and when the host is immunocompromised. These organisms include *Aspergillus* species, *Cryptococcus neoformans,* and *Sporothrix schenckii.* Voriconazole is currently the treatment of choice for *Aspergillus* infection, fluconazole for cryptococcal infection (often following induction therapy with amphotericin plus flucytosine); sporotrichosis can be treated with saturated potassium iodide or itraconazole.[105,110,111]

The *newly emerging fungi* now account for approximately 10% of invasive fungal infections, with the major species involved including the following: Mucorales, *Fusarium,* and *Trichosporon.* These species tend to be more resistant to fluconazole, echinocandins, and even amphotericin. Drugs such as voriconazole and the newly licensed posaconazole (the first really effective agent for mucormycosis, particularly when combined with surgery) should be considered as the first choice for therapy.[105,110,111]

There are two types of exposure that are important in the development of invasive fungal infections, the effects of both being amplified if immunocompromise is present. Infection with *Candida* as a consequence of contaminated vascular access devices is common, particularly in the intensive care unit. A less common variant on this theme is when the mucocutaneous surfaces are compromised, not only is candidal infection a concern, but invasion by *Aspergillus,* the Mucorales, and other fungal species can occur.[106,107,111,112]

The other portal of entry is the respiratory tract. Inhalation of the organisms can result in invasive fungal infection of the nasal sinuses and the lungs, with *Aspergillus species* being the most common invader recognized. The first host response to these organisms is the migration of polymorphonuclear leukocytes, dedicated phagocytic cells, which can kill the inhaled inoculum. If the inhaled organisms escape this first defense, then a number of events occur: bloodstream invasion with the potential for metastatic spread; tissue invasion both at the primary site of infection and metastatic sites that mobilizes the major host defense—cell-mediated immunity, which includes alveolar macrophages. In the particular case of histoplasmosis, persistent infection of macrophages is established, making lipid-associated amphotericin B particularly effective by targeting the macrophages with the lipid moiety. Thus, an increased risk of invasive aspergillosis and other such infections, for example, fusariosis, is to be expected in patients with either or both neutropenia and impaired call mediated immunity.[108,109,111–114]

Drugs that are available for the treatment of invasive fungal infection can be listed as follows:

- *Amphotericin B and the lipid-associated amphotericin products:* Amphotericin B is a broad-spectrum polyene that acts by binding to fungal cell membranes, specifically ergosterol (for which it has a >500-fold increase in affinity when compared to binding to cholesterol in mammalian cell membranes). Binding to ergosterol results in increased membrane permeability and cytolysis, the probable mechanism of fungal injury and death. Amphotericin B remains the broadest spectrum antifungal known, producing fungicidal effects against the majority of pathologic fungi, including those that are resistant to other antifungal compounds. The dose-limiting toxicity is to the kidneys, which is particularly important when such nephrotoxic drugs such as gentamicin or cyclosporine are administered to a patient receiving amphotericin. In addition, the administration of amphotericin B usually produces a "cytokine storm" which can include not only fever and chills but also hypotension. These "storms" are usually not a problem after the first several days of therapy. Lipid-associated amphotericin appears to decrease but not eliminate both the febrile reactions and the renal toxicity. However, as with all the amphotericin products the optimal dose (3–5 mg/kg/d for a lipid-associated drug and 0.1–1.5 mg/kg/d for the standard amphotericin molecules) is not known, and the optimal duration of therapy is unclear. Our practice is to treat until all overt disease is gone and then add a buffer for safety. The duration of this buffer is a clinical decision usually determined by the nature of the original infection and the speed with which the patient responded.
- Flucytosine is mentioned in this context because its optimal use is in patients with cryptococcosis in conjunction with amphotericin. This synergistic regimen protects against a single-step mutation to flucytosine resistance. Dose-related hepatic and/or bone marrow toxicity can occur with the use of flucytosine. A common approach is to administer amphotericin and flucytosine for 7–10 days to gain control of the process, and then complete the course of therapy with oral fluconazole.[115,116]

Azoles act by blocking the enzyme lanosterol synthetase, a cytochrome P450-associated enzyme. This results in an inhibition of ergosterol synthesis. The effect is fungistatic. There are five azoles that have been approved for the treatment of systemic fungal invasion.

- *Ketoconazole and miconazole* are essentially of historical interest only and are rarely prescribed today.
- *Fluconazole*, in contrast, was a major event, with the only weakness of the drug being a rather narrow spectrum of activity, limited mostly to *Candida* species and *C. neoformans.* Pharmacokinetically, the drug is well behaved, able to penetrate the urinary tract, the eye, and the brain, as well as the spleen, liver, and other sites. The bioavailability when given by mouth is complete, and thus the dose given by mouth is the same as the parenteral dose. Side effects are seen, but are relatively uncommon or minor: a measles-like rash, hepatocellular dysfunction, and minimal GI complaints. Fluconazole does interact with cytochrome P450 enzymes, as do all the azoles, and thus can increase the blood levels of such important therapies as cyclosporine and tacrolimus.[116]
- *Itraconazole* has an appealing spectrum of activity, including *Aspergillus* species and other fungal species. The problem has been poor and unreliable drug delivery. With substitution of an oral suspension, more reliable bioavailability has been

achieved, and the usefulness of the drug should be reassessed. Up to now, the major use of this drug has been in oral "wrap up" therapy after amphotericin had gained control of the infection.[116]

- *Voriconazole* is the newest of the azoles. It can be administered either orally or parenterally. It appears that voriconazole is the most effective of the current anti-*Aspergillus* drugs, as well as has efficacy for other resistant molds. Side effects are similar to other azoles (e.g., rash, hepatocellular dysfunction, nausea). Voriconazole does have a unique side effect, the occurrence of visual effects including bright colors and lights, akin to that seen with digitalis toxicity. Such symptoms appear to be most common with high doses, and appear to be caused by retinal dysfunction. All such symptoms disappear when the drug is stopped, and extensive study has failed to reveal any persistent visual or structural consequences. Voriconazole appears to be the drug of choice for invasive aspergillosis. Treatment with voriconazole, however, carries a small risk of selecting for Mucorales infection (mucormycosis).[116,117]

The echinocandins are large lipopeptide molecules that damage fungal cell walls by inhibiting B-(1,3)-glucan synthase. In vitro these compounds are fungicidal for *Candida* and fungistatic for *Aspergillus* species. These molecules appear to have activity against candidal strains that are amphotericin, fluconazole, and itraconazole resistant. On the other hand, species such as *C. neoformans and* the Mucorales are inherently resistant to echinocandin therapy, presumably because they do not possess significant amounts of B-glucan in their cell walls.[118]

- Three echinocandins, caspofungin, micafungin, and anidulafungin are approved by the Food and Drug Administration. The echinocandins, with the limited evaluation in the clinical arena that has occurred thus far, appear to be useful in the treatment of both drug-resistant candidiasis and invasive aspergillosis. The results thus far suggest comparable efficacy to that achieved with amphotericin and the licensed azoles. The possibility of achieving better results with combination therapy that includes an echinocandin is particularly intriguing. The cell wall damage that is caused by echinocandins is reminiscent of synergistic therapy of enterococcal infection with ampicillin and gentamicin with the echinocandin playing the role of a cell wall active agent that potentiates the penetration of additional drugs. Indeed, the echinocandins have been called "the antifungal penicillins."[118–120]

The Future of Antifungal Therapy

Since the advent of new drugs for the treatment of fungal disease great progress has been made in terms of efficacy and adverse events. What we need now is a new generation of diagnostic tests that will inform us on the appropriate drugs to use, how long to treat, whether multiple drugs should be deployed, and a determination to define microbial load objectively that will allow us to treat preemptively rather than empirically. The present data on the use of (1-3)-B-D-glucan testing in defining the presence or absence of invasive fungal infection suggests that we are getting closer to that possibility.

NEW DIAGNOSTICS

One of the greatest frustrations when caring for a potentially septic patient is having to wait 1–2 days for culture results to find out if the patient is infected, and then to wait another 1–2 days to discover the identity and later the susceptibility profile of the infecting organism. With the molecular biologic revolution, new tests have emerged, typically PCR-based technology, enabling the rapid identification of specific pathogens directly from the infected body site. Nonetheless, this technology is prone to interpretation challenges. For example, does a positive result represent colonization or disease? To help both diagnostically and prognostically, the development of new assays are focusing on the levels (or presence) of mediators in the inflammatory cascade or on circulating bacterial moieties, such as endotoxin or nuclear factor-κB, to improve our ability to risk stratify patients or determine the infecting pathogen.[121–124]

A broad array of pathogens can now be identified by molecular techniques, including viruses (HIV, CMV), fungi (*Candida, Aspergillus*), and bacteria (VRE, *E. coli, M. tuberculosis*, *Bacteroides*).[125–130] As learned for HIV-positive patients, monitoring the HIV viral load has become an important parameter in gauging the success of therapy. The development of technology may allow us to provide pathogen-directed therapy earlier in a patient's illness enabling more focused narrow spectrum antimicrobial use. This would diminish the selective pressure, which leads to the emergence and dissemination of resistance as well as yielding novel markers to gauge the duration and intensity of therapy.

SUMMARY

Antimicrobial therapy is complicated by the increasing incidence of microbial resistance. As a result, a broader range of antimicrobial agents has come into use, with the basic approach to antimicrobial therapy in these patients being front loading broad-spectrum antimicrobials. This therapy is then modified to relatively narrow spectrum specific therapy. The regimens chosen and the doses prescribed are based on the principle that effective therapy is dependent on the delivery of a level of antimicrobial agent to the site of infection that significantly exceeds the MIC of the invading organism. Bactericidal therapy is essential when dealing with cardiovascular infection, CNS infection, prosthesis associated infection, osteomyelitis, and infection in the neutropenic patient. Synergistic therapy may be important when dealing with life-threatening enterococcal, *P. aeruginosa*, and perhaps other gram-negative infections, but the definition of synergy varies and the clinical efficacy is not firmly established. Finally, it is hoped that a better definition of high-risk patients will permit the more effective use of preemptive antimicrobial regimens. It is clear that many questions remain unanswered and that many therapeutic decisions must be based on a thorough understanding of the properties of antimicrobials and the pathogenesis of infections rather than efficacy demonstrated in clinical studies.

CHAPTER 18

Preoperative Assessment of the Newborn

Myron Yaster, MD, and
Richard A. Elliott, MD

The newborn presenting for surgery is among the most daunting and challenging patients facing the anesthesiologist. Critically ill and hemodynamically unstable, these tiny and fragile patients demand a level of specialized knowledge, skill, and attention to detail that is inversely proportional to their size and gestational age. Providing safe anesthesia is only possible when the specialized equipment and techniques necessary to conduct an anesthetic are in the hands of individuals who understand the anatomic, physiologic, and pathologic differences that characterize these patients during their transition from intra- to extrauterine life.

The types of surgical procedures in the newborn span a wide variety of life-threatening congenital anomalies, each with its own set of unique management strategies. Nevertheless, there are many aspects of preoperative and intraoperative anesthetic management common to all neonates. This chapter focuses on neonatal physiology and its impact on anesthetic and surgical techniques. Emphasis is placed on those aspects of preoperative assessment, monitoring, and supportive care that are pertinent to newborn patients in general, with special attention to disease states, anesthetic agents, and surgical interventions that can influence the infant's transition from fetal to newborn existence.

Historically, the newborn has been undertreated for pain and for painful experiences, including surgery. For example, in 2006, healthy newborn males are routinely circumcised without analgesia or anesthesia.[1] It is our belief that, except for extraordinary circumstances, all newborns require anesthesia for surgery.[2–4] Why this even remains an issue of debate in the 21st century is discussed in detail in Chap. 62.

FAMILY INTERACTIONS AND PREPARATION

The parents of critically ill children require substantial support and reassurance that their newborn child will perceive no pain during a procedure and will be as safe as possible. Parents experience an acute emotional crisis when their newborns face surgery. Aside from the deprivation of contact with their child, parents experience anticipatory grief and a profound sense of failure.[5,6] When confronted with surgery and anesthesia, many parents undergo a period of mourning for the loss of the perfect infant or anticipate their infant's death or mutilation. The overwhelming nature of the situation may deafen parents to explanations during the preoperative interview and repetition may be necessary. The child's parents should be counseled that the overwhelming majority of children not only survive their surgery but grow up to live healthy and productive lives. Without being inappropriately optimistic or avoiding the issues of informed consent, it is important to emphasize the normal, healthy aspects of the baby and give positive affirmation regarding the correction that will be achieved by surgery. Failure at this may significantly impact the parents future interactions and bonding to their child.

The newborn undergoing surgery must be optimally prepared within the constraints of performing an emergent procedure. Essential to this process is a thorough history and physical examination. This evaluation must focus on maternal and peripartum history, neonatal physiology and its relation to anesthesia, as well as the presence of coexisting anomalies in the child.

Maternal and Peripartum History

A thorough review of maternal past medical history and prenatal assessments is essential for the preoperative evaluation of the neonate. Maternal

KEY POINTS

1. Except for extraordinary circumstances, all newborns require anesthesia for surgery.
2. Maternal factors associated with increased perinatal risk include hypertension, diabetes, prolonged rupture of membranes, drug abuse (tobacco, alcohol, opioids, amphetamines) and use (antipsychotics, antidepressants, anticonvulsants), collagen vascular disease, and maternal infection (prolonged rupture of membranes) or inflammation.
3. The younger the infant, the more fragile the neurologic, pulmonary, and gastrointestinal systems, and the more likely the severity of complications.
4. The presence of a congenital anomaly should always alert the anesthesiologist to the potential for others.
5. The presence of any midline defect is almost always associated with another defect.
6. The newborn is an obligate nose breather.
7. The narrowest part of the infant's airway is at the level of the cricoid ring and not the vocal cords.
8. Premature infants are at risk of developing postanesthesia apnea for weeks after birth (48–60 weeks postconception age) whenever a potent vapor or ketamine is used.
9. Arterial hypoxemia, hypercarbia, acidosis, hypothermia, or pain may reverse this transitional circulation and restore the fetal circulatory pattern; it is referred to as either *persistent fetal circulation* or *persistent pulmonary hypertension of the newborn*.
10. The newborn's myocardium is less compliant than that of the adult or older child and cardiac output is primarily heart-rate dependent.
11. The most common cause of bradycardia in the newborn is hypoxia. Unexplained bradycardia in the operating room should always be considered caused by hypoxia until proven otherwise.
12. Hypoglycemia is common in infants born to diabetic mothers and in infants who require resuscitation, are premature, or who are small for gestational age.

TABLE 18–1.

Maternal History

- Pregnancy
  - Polyhydramnios
    - High intestinal obstruction, e.g., duodenal atresia, congenital diaphragmatic hernia, omphalocele
    - Central nervous anomalies, e.g., hydrocephalus, spina bifida
    - Respiratory abnormalities, e.g., pulmonary hypoplasia, pleural effusions
    - Genitourinary tract abnormalities, e.g., posterior urethral valves, urethral structure
    - Maternal diabetes
    - Rh-isoimmunization
    - Multiple pregnancy
  - Oligohydramnios
    - Renal failure
    - Hypoplastic lungs
    - Marked crowding of fetal limbs causing multiple skeletal contractures
    - Neonatal infection (chorioamnionitis)
  - Toxemia of pregnancy
    - Frequency associated with decreased placental perfusion and premature separation of the placenta; associated problems include small for gestational age infants, hypoglycemia, and anemia; magnesium used in blood pressure control produces neonatal hypotonia and apnea
  - Diabetes: large for gestational age infants; hypoglycemia despite enormous glucose loading, prematurity (yet > 2,500 gram birth weight); congenital heart disease; anencephaly; sacral agenesis
  - Maternal seizures 2–3 × greater incidence of congenital malformations
  - Intra-uterine infection: prematurity; fetal infection; particularly pneumonia; persistent fetal circulation; heart defects (rubella)
  - Medication: teratogens, e.g., anticonvulsants, warfarin, anti-metabolites; hypoglycemia, floppy infant
  - Drug abuse
    - Fetal alcohol syndrome: growth retardation, mental deficiency, heart defects, flexion contractures
    - Opioid withdrawal: seizures; jittery, irritable infants; hypoglycemia; diarrhea
    - Amphetamines: congenital heart disease
  - Maternal age: trisomy 13, 18, 21
  - Single umbilical artery: renal malformations

TABLE 18–2.

Peripartum History

- Prolonged labor
  - Abnormal fetus, e.g., hydrocephalus, abdominal wall defect, breech presentation
- Premature rupture of membranes
  - Prematurity
  - Infection, pneumonia
  - Oligo- or polyhydramnios
- Traumatic delivery
  - Intracranial hemorrhage, skull fracture, vocal cord paralysis, brachial plexus injury
- General anesthesia
  - Hypotonia, respiratory distress
- Prematurity (< 37 weeks post-conceptual age or birth weight < 2,500 grams)
  - Hyaline lung disease
  - Hypocalcemia, hypoglycemia, hypomagnesemia
  - Infection
  - Necrotizing enterocolitis
  - Patent ductus arteriosus
  - Hyperbilirubinemia
  - Increased risk of oxygen toxicity to the eyes (retinopathy of prematurity or "retrolental fibroplasia")
- Postmaturity (> 42 weeks post-conceptual age)

medical history and pathology may indicate the likelihood of an anomaly or be its possible cause (Table 18–1). Maternal factors associated with increased perinatal risk include hypertension; diabetes, prolonged rupture of membranes; drug abuse (tobacco, alcohol, opioids, amphetamines) and use (antipsychotics, antidepressants, anticonvulsants); collagen vascular disease; and maternal infection (prolonged rupture of membranes) or inflammation. Maternal exposures to teratogens such as thalidomide, phenytoin, or ethanol are well described and are associated with specific anomalies. Less dramatic are the effects of tobacco and opioids, which can affect brain development or somatic size. Additionally, maternal intravenous drug addiction, particularly to opioids, can result in acute withdrawal and seizures or in HIV virus infection in the neonate. Finally, some perinatal conditions provide insight into potential future problems. For example, polyhydramnios is associated with high intestinal obstruction and oligohydramnios is associated with renal and lung hypoplasia (Tables 18–1 and 18–2).

The peripartum history is of equal importance for the evaluation of the neonate (Table 18–2). Prolonged labor and premature rupture of membranes are indicators of potential infectious complications in the neonate. Moreover, a traumatic delivery or abnormal fetal presentation can imply fractures or nerve injury. Other factors that can imply coexisting disorders are an abnormal umbilical cord or placenta, and the child's age, birth weight, and Apgar scores.

Infants who are asphyxiated at birth must be identified prior to surgery. These newborns have depressed myocardial function and decreased perfusion to the brain and gastrointestinal system. Additionally, a variety of metabolic derangements, such as hypoglycemia, hypocalcemia, and hyperkalemia, occur in asphyxiated newborns. Other problems seen in these infants are clotting abnormalities, meconium aspiration, and intracranial hemorrhage. The latter is particularly devastating and may be a result of impaired autoregulation of the cerebral circulation and/or large swings in blood pressure, cardiac output, and arterial blood gasses.

Gestational Age

Babies born at term, 37–42 weeks post-conception age, can either be normal in size, small (< 10th percentile) for gestational age (SGA) or large (> 90th percentile) for gestational age (LGA). SGA and LGA babies often have glucose homeostatic instability and require 10% glucose infusions to maintain normoglycemia (60–100 mg/dL). Additionally, calcium homeostasis may be ab-

normal in these infants. The well-accepted definition of prematurity is an infant born at < 37 weeks of gestation. Like the full-term infant, premature infants can be SGA or LGA. The physiologic variability between 24 and 36 weeks of gestation is enormous and it is probably best to subdivide this group into infants on the edge of survivability (< 26 weeks of gestation), fragile infants (between 27 and 30 weeks of gestation), and more robust infants (between 31 and 35 weeks of gestation). The younger the infant, the more fragile the neurologic, pulmonary, and gastrointestinal systems, and the more likely the severity of complications.

Patient History—Congenital Anomalies

The presence of a congenital anomaly should always alert the anesthesiologist to the potential for other anomalies. Currently, approximately 2% of liveborn infants have a congenital anomaly recognized at birth.[7] Congenital anomalies fall into 4 broad categories. The first is known as a *congenital malformation*. This is a primary structural defect that results from a localized error of morphogenesis, such as a cleft lip or a ventricular septal defect. The second category is a *malformation syndrome*. This is a recognized pattern of malformations believed to have the same etiology, but which are not the result of a single error of morphogenesis, such as trisomy 21. The third category is known as an *anomalad*. It is described as a single localized error of morphogenesis, as in Pierre Robin syndrome. Finally, patterns of recognized malformations that occur in a nonrandomized fashion and are called an *association*. The VATER (vertebral defects, imperforate anus, tracheoesophageal fistula, and renal defects) association, which is currently also known as the VACTERL (vertebral defects, imperforate anus, congenital heart disease, tracheoesophageal fistula, renal and limb defects) association, is a classic example.

Table 18–3 is a concise list of the more common congenital anomalies, syndromes, and associations. Table 18–4 provides a more detailed account of the anesthetic implications of some of the more common syndromes and malformations. A wonderful Internet resource can be found at the website of the National Center for Biotechnology Information's (NCBI) Online Mendelian Inheritance in Man (OMIM) (http://www.ncbi.nlm.nih.gov/omim). The presence of an anomaly or an associated defect can often be inferred from a detailed history and physical examination of the patient, as well as from the child's parents and referring physician. Finally, a good rule of thumb to remember is that the presence of any midline defect is almost always associated with another defect.

REVIEW OF SYSTEMS AND DEVELOPMENTAL PHYSIOLOGY

Head and Neck

The newborn is an obligate nose breather. If both nostrils are obstructed, respiratory distress occurs. Choanal atresia, an anomaly in which there is absence or complete obstruction of the nasopharynx bilaterally, is diagnosed by respiratory distress in the delivery room that is easily treated by oral intubation and by an inability to pass a catheter through the nostrils. A subset of patients with choanal atresia have the CHARGE syndrome: colobomas of the eye, congenital heart disease, atresia choanae, retardation, genital hypoplasia, and ear abnormalities. Occasionally, respiratory distress is caused by obstruction of the nasopharynx by a nasogastric tube and overzealous taping that occludes the opposite nostril. The airway must be evaluated for any abnormality that may result in a difficult intubation, such as a small or receding jaw (micrognathia: Pierre Robin syndrome, Treacher Collins syndrome), or a large tongue (Beckwith syndrome, glycogen storage diseases, hypothyroidism, Down syndrome). In many of these patients, intubation with conventional laryngoscopy is extremely difficult, if not impossible, and alternative methods (e.g., laryngeal mask airways, lightwands, and fiberoptic bronchoscopy) and surgical backup should always be available. Additional lesions that make intubation difficult or impossible are airway hemangiomas, lymphangiomas, cystic hygromas, and laryngeal webs and cysts. The presence of a hemangioma should always raise a "red flag"; some of these lesions trap and consume platelets and may produce a bleeding diathesis. When an impossible airway situation arises and the patient's condition is known in utero, the EXIT (ex utero intrapartum treatment) procedure may be lifesaving.[8,9] In the EXIT procedure, which was originally designed for fetal surgery, the infant is partially delivered via a cesarean section and intubated in a controlled manner, prior to delivery of the placenta. The placenta acts as a "heart–lung machine" and the procedure avoids a "crash" intubation or tracheostomy at birth in the delivery room. At the other end of the spectrum, cleft lips and palates do not usually present intubation problems. Indeed, the cleft may provide more room for the laryngoscope blade and facilitate endotracheal intubation.

TABLE 18–3.

Commonly Encountered Lesions in the Neonate

- Airway lesions
  - Choanal atresia
  - Pierre Robin syndrome
  - Upper airway obstruction
  - Cystic hygroma
  - Cleft lip and/or palate
  - Upper airway cysts and webs
- Thoracic lesions
  - Tracheoesophageal fistula (TEF) or atresia
  - Congenital diaphragmatic hernia
  - Congenital heart disease
  - Pneumothorax, pneumomediastinum, pneumopericardium
  - Lobar emphysema, cystic adenomatoid malformation
  - Mediastinal masses
- Abdominal lesions
  - Omphalocele
  - Gastroschisis
  - Intestinal obstruction
  - Malrotation and volvulus
  - Imperforate anus
  - Exstrophy of bladder or cloaca
  - Hirshsprung's disease
  - Biliary atresia
  - Incarcerated hernia
  - Necrotizing enterocolitis (NEC)
- Neurosurgical lesions
  - Myelomeningocele
  - Encephalocele
  - Craniosynostosis
  - Intracranial masses
  - Arteriovenous malformations (vein of Galen)
  - Skull fractures
  - Hydrocephalus
  - Subdural hemorrhage
  - Spinal tumors

TABLE 18–4.

Anesthetic Implications of Syndromes and Unusual Disorders

Name	Description	Anesthetic Implications
Arthrogryoposis multiplex	Multiple congenital contractures; congenital heart disease	Possible airway problems due to limitations of mandibular movement
Asplenia syndrome	Absent spleen; complex congenital heart disease; malrotation of abdominal organs	Cyanotic heart disease very common; echocardiography essential preoperatively
Beckwith's syndrome	Birth weight › 4000 gms; macroglossia, visceromegaly	Airway problems due to large tongue; hypoglycemia common
Cherubism	Fibrous dysplasia of the mandible and maxilla	Intubation may be extremely difficult; tracheostomy may be the only way to secure the airway
Congenital hypothyroidism	Goiter; large tongue; respiratory depression; hypoglycemia; hypotension	Airway obstruction secondary to large tongue, particularly in supine position; slow to awaken at the completion of surgery
Crouzon's disease	Craniosynostosis, hypertelorism, hypoplastic mandible	Intubation may be difficult
Dandy-Walker syndrome	Hydrocephalus	Increased intracranial pressure rare in newborn period; head may be enormously enlarged
DiGeorge's syndrome	Thymus and parathyroids absent; hypocalcemia, immune deficiency; aortic arch abnormalities	Irradiate all blood products to prevent graft vs. host disease; stridor may be due to hypocalcemia
Down's syndrome (trisomy 21)	Large tongue, unstable cervical spine, small mouth; high incidence of congenital heart disease, particularly AV canal; intestinal obstruction	Intubation may be difficult; ? in line traction during intubation, ? cervical spine films prior to intubation in older children; echocardiography required prior surgery in the newborn
Ehlers-Danlos syndrome	Collagen abnormality-hyperelasticity and fragile tissue; dissection aneurysm of aorta; bleeding diathesis; heart, lung, GI problems	Poor tissue and clotting defects may lead to hemorrhage; spontaneous pneumothorax
Ellis-van Creveld syndrome	Ectodermal and skeletal defects; congenital hear disease; cleft lip and palate, mandibular hypoplasia; hepatosplenomegaly	Airway problems, intubation may be difficult; chest wall anomalies cause poor lung function
Epidermolysis bullosa	Skin cleavage at dermal-epidermal junction, minor trauma denudes skin	Do not use adhesive tape of any sort; avoid instrumentation of the airway if possible; use a well padded mask or apply ointment to rim; secure IV, monitoring devices with Kerlex; sterile technique
Familial dysautonomia (Riley Day syndrome)	Poor suck and swallow; hyper- and hypotension; insensitivity to pain; absent sweating and lacrimation	Recurrent aspiration and pneumonia; respiratory center insensitive to CO_2; labile intraoperative blood pressure
Fetal alcohol syndrome	Growth retardation; microcephaly, craniofacial abnormalities; congenital heart disease; renal abnormalities	Intubation is usually not difficult; ventricular septal defects are common and require SBE prophylaxis
Glucose-6-phosphate deficiency	Hemolytic anemia caused by drugs and infection	Aspirin, sulfa, methylene blue cause anemia
Goldenhar's syndrome	Hemifacial microsomia, congenital heart disease	Very difficult intubation; vertebral instability
Hemangioma with thrombocytopenia	May involve the airway; bleeding, anemia	Airway involvement may require radiation therapy; transfuse components as necessary
Jeune's syndrome (asphyxiating thoracic dystrophy)	Severe thoracic malformations, renal failure	Respiratory failure prolonged mechanical ventilation; care with drugs excreted by kidneys
Klippel-Feil syndrome	Hemi- or fused vertebra	Intubation may be difficult
Maple syrup urine disease	Inability to metabolize leucine, isoleucine, and valine	Acid base inbalance; avoid preoperative fasting, start glucose early and check frequently
Mucopolysaccharidoses (Hurler's, Hunter's, Morquio's syndrome)	Bony abnormalities, dwarfism, kyphoscoliosis, abnormal facies, congenital heart disease	Very difficult intubations, unstable necks, respiratory failure perioperatively
Myasthenia congenita	Similar to adult form	Avoid muscle relaxants and narcotics

(continued)

TABLE 18–4.

Anesthetic Implications of Syndromes and Unusual Disorders (Continued)

Name	Description	Anesthetic Implications
Osteogenesis imperfecta	Pathologic fractures; abnormal platelets, vascular fragility	Extreme caution when positioning and during intubation; blood pressure cuff may cause fractures
Pierre-Robin syndrome	Cleft palate, micrognathia, glossoptosis, congenital heart disease	Very difficult intubation, may require tongue suture or awake tracheostomy; best nursed in prone position
Prader-Willi syndrome	Hypotonia, obesity	Hypoglycemia common; assisted ventilation may be required postop
Prune-belly syndrome	Agenesis of the abdominal musculature, renal failure	Respiratory failure common, postoperative ventilation, avoid drugs excreted by the kidneys
Treacher Collins syndrome	Micrognathia, mid-face hypoplasia, congenital heart disease	Very difficult intubation, may require tongue suture or awake tracheostomy; best nursed in prone position
Thrombocytopenia with absent radius syndrome	Episodic thrombocytopenia precipitated by stress, infections, surgery; congenital heart disease	Platelet transfusions prior to surgery; SBE prophylaxis
Trisomy 18	Congenital heart disease; micrognathia; renal malformations; most die in infancy	Ethical considerations concerning surgery in a patient with a fatal anomaly; assess cardiac status carefully
Trisomy 21 (see Down's syndrome)		
VATER syndrome	Vertebral, Anal, Tracheal, Esophageal fistula, Renal; cardiac	Examine carefully for associated anomalies

Infants with a history of endotracheal intubation who are stridulous or who have a weak cry may have developed subglottic stenosis or subglottic granulomas. Unlike in an adult, the narrowest part of the infant's airway is at the level of the cricoid ring and not the vocal cords.[10] Furthermore, the infant's trachea may be only 4–5 cm in total length, making endobronchial intubation extremely easy to accomplish even by very experienced practitioners. To minimize this risk, we use the "1-2-3…7-8-9" rule to assist in correct endotracheal tube positioning. The "1-2-3" refers to the patient's weight in kilograms and the "7-8-9" refers to the position of the endotracheal in centimeters at the patient's lip. Thus, a 1-kg infant would have the tip of his endotracheal tube taped at the 7-cm mark at the lip. The trachea is very easily injured and explains in part the use of noncuffed endotracheal tubes in this age group.[11] Typically the trachea of most infants can be intubated with a 3.0-mm endotracheal tube. Premature infants occasionally require smaller, 2.5-mm tubes. In infants in whom subglottic narrowing is anticipated or who require intubation with tubes smaller than 2.5 mm, tracheostomy and/or bronchoscopy should be considered and discussed with the parents prior to surgery.

Gas Exchange and Oxygen Consumption

During fetal life, respiratory gas exchange occurs at the placenta. The first breath after birth generates a negative intrapleural pressure of 80 cm H_2O, expands the lungs, establishes the residual volume and the functional residual capacity, increases alveolar oxygen content, and causes pulmonary arterial vasodilatation.[12] Gas exchange in the lungs is maintained with successful removal of the lung fluid from the airways and alveoli. This is achieved by drainage and increased pulmonary lymphatic flow for several hours after birth and by the presence of surface active phospholipids (surfactant).[13–15] The increase in arterial oxygen content that occurs with the successful transition to extrauterine life decreases pulmonary vascular resistance and leads to the functional closure of the ductus arteriosus and atrial septum.[12,16–18]

Oxygen consumption in the newborn is 2–3 times that of older children and adults. Unfortunately, the newborn responds to hypercarbia and hypoxia paradoxically when compared to the adult or older child.[19–25] Unlike the adult, the newborn's response to hypoxia during the first 3 weeks of life is biphasic and paradoxical; that is, rather than maintaining an increased minute ventilation they rapidly develop apnea.[19,20,26,27] Furthermore, hypoxia that normally increases the respiratory response to hypercapnia, paradoxically depresses the newborn's ventilatory response to carbon dioxide. Indeed, apnea may also occur in response to hypothermia or when energy reserves are limited (e.g., in the premature infant).[28] Thus, a devastating cascade of events may be set in motion. Increased oxygen consumption, depressed respiratory function, and limited reserves lead to hypoxemia. Hypoxemia results in apnea and cardiovascular collapse. Other disadvantages of the newborn include a very compliant rib cage, which tends to collapse the chest wall, inefficient diaphragmatic contraction, and a low percentage of fatigue resistant type I muscle fibers in the diaphragm.[29,30] The combination of high work of breathing, increased oxygen consumption, and less resistance to

muscle fatigue can produce abnormal breathing patterns, such as periodic breathing and apneic episodes, and respiratory failure.

The respiratory depressant effects of opioids and inhalational agents are also profound and long-lasting. Morphine penetrates the newborn's brain more easily than the adult and achieves levels that are 2–4 times higher.[31,32] Furthermore, the μ opioid receptor is exquisitely sensitive to respiratory depression in the newborn when compared to the adult.[33,34] Thus, a history of prematurity and or apnea must alert the anesthesiologist to possible respiratory compromise in the postoperative period, particularly if a narcotic based anesthetic is used. Indeed, premature infants are at risk of developing post anesthetic apnea for weeks after birth (48–60 weeks postconception age) whenever a potent vapor or ketamine is used.[35–38]

Neonates suffering from respiratory distress syndrome (hyaline membrane disease) have low lung compliance, a diminished functional residual capacity, and diffuse microatelectasis. These infants are often hypoxemic and hypercarbic and exhibit tachypnea, expiratory grunting, and inspiratory retractions. They are often intubated and either positively pressure ventilated or spontaneously ventilating on continuous positive airway pressure (CPAP). Maintaining normal gas exchange in these infants requires careful monitoring and respiratory support. Increased peak inspiratory pressures and positive end-expired pressures may be needed to maintain adequate oxygenation. Unfortunately, this may lead to pneumothorax, pneumomediastinum and interstitial emphysema. Indeed, the perioperative development of pulmonary barotrauma should alert the anesthesiologist to the possibility of intraoperative pneumothorax, which will manifest itself by catastrophic and sudden cardiovascular collapse.

Cardiac Physiology

The fetal circulation is characterized by the preferential shunting of "arterialized" placental ("right-sided") blood across the foramen ovale and ductus arteriosus into the systemic ("left-sided") circulation.[39,40] This right-to-left shunting of blood is caused by the increased pulmonary vascular resistance and decreased systemic vascular resistance that characterizes the fetal circulation. The combination of breathing room air and clamping the umbilical cord reverses these resistances and results in the functional closure of the foramen ovale and the ductus arteriosus. Bidirectional shunting through the ductus arteriosus or an incompletely closed foramen ovale may normally persist for 24–72 hours and underscores the need to meticulously debubble all IV tubing. Unfortunately, arterial hypoxemia, hypercarbia, or acidosis will reverse this transitional circulation and restore the fetal circulatory pattern, and is referred to as *persistent fetal circulation* or *persistent pulmonary hypertension of the newborn*.[41–43] It has catastrophic consequences. The increased pulmonary artery hypertension caused by arterial hypoxemia reduces pulmonary blood flow and reopens the foramen ovale and ductus arteriosus. This further exacerbates the hypoxemia and acidosis. It can occur with sepsis, hypotension, meconium aspiration, diaphragmatic hernia, and inefficient ventilation. Treatment with some combination of inhaled nitric oxide, oscillatory ventilation, and/or extracorporeal membrane oxygenation (ECMO) is increasingly successful.[42,44]

On the other hand, closure of the foramen ovale and ductus arteriosus may be detrimental in patients with certain types of congenital heart disease. Patients with transposition of the great vessels, complete or partial tricuspid, or pulmonary valvular obstruction or atresia, and hypoplastic left-heart syndrome are critically dependent for their very survival on continued flow across these shunts. Indeed, intravenous infusion of prostaglandin E_1, to maintain the patency of the ductus arteriosus, may be life-sustaining in these patients.

The newborn's myocardium is less compliant than that of the adult or older child and cardiac output is primarily heart-rate dependent.[45–47] The heart has incomplete or decreased sympathetic innervation, with reduced catecholamine stores.[48] Studies performed in newborns during exchange transfusions have revealed that the newborn has reduced capacity for peripheral vasoconstriction during hypovolemia.

Several powerful reflexes control the cardiovascular system of the neonate. The arterial baroreceptor is the most powerful of these and consists of the carotid sinus and aortic arch baroreceptors. These receptors are stretch receptors stimulated by pressure deformation of the vessel wall tissue in which they reside. An increase in transmural pressure stretches these receptors and increases the rate of baroreceptor firing. Afferent nerves carry these signals to the vasomotor centers of the medulla and parasympathetic and sympathetic efferent fibers slow the heart rate, strengthen contraction, and reduce venous and arterial resistance. A reduction in arterial blood pressure has the opposite effect causing a central afferent sympathoadrenal discharge which increases systolic and diastolic blood pressure. The arterial baroreceptor reflex is intact in healthy full-term newborns, but may be significantly depressed in stressed or premature infants. Anesthetics, particularly halothane, may also significantly depress this response.[49,50]

The arterial chemoreceptors form a second powerful cardiovascular reflex arc. The carotid and aortic chemoreceptor bodies are responsible for the cardiovascular response to acute hypoxia. The primary central response to hypoxia is bradycardia. The peripheral chemoreceptors once stimulated cause tachypnea and increased sympathetic discharge to the heart and peripheral tissues. These receptors are stimulated by hypoxic hypoxia (low Pao_2) and decreased cardiac output, but not by reduced oxygen content as a result of anemia. Once again, the stressed or premature infant, or the full-term infant anesthetized with halothane may have a blunted or absent sympathetically mediated response to hypoxia. Indeed, the most common cause of bradycardia in the newborn is hypoxia, and in the operating room, unexplained bradycardia should always be considered due to hypoxia until proven otherwise.

Consequently, it may be dangerous to anesthetize a stressed neonate who is either hypovolemic or dehydrated, particularly with the potent inhalational anesthetic vapors. Hypovolemia or dehydration should be assumed in septic patients (necrotizing enterocolitis), ventilated patients who are being treated with diuretics and fluid restriction (hyaline membrane disease, patent ductus arteriosus), and when hemorrhage occurs in the operating room.

Central Nervous System

The central nervous system is the least-mature major organ system at birth. This structural immaturity predisposes the newborn to certain risks, including intraventricular hemorrhages, seizures, respiratory depression, and retinopathy

of the premature.[51–53] Hypoxia, hypercarbia, hypotension, acidosis, and pain may produce any or all of these complications. The stressed premature infant is particularly at risk. Indeed, intraventricular hemorrhage, in which subependymal hemorrhage occurs, is now the leading cause of death and morbidity in these infants, particularly in the premature infant born at less than 28 weeks of gestation, and has an incidence as high as 50%.[51,52,54,55]

Hydrocephalus also occurs frequently either as noncommunicating hydrocephalus, in which the flow of cerebral spinal fluid is obstructed (aqueductal stenosis, spina bifida) or as communicating hydrocephalus, in which the flow of cerebral spinal fluid is unimpeded but resorption is affected (intraventricular hemorrhage). Increased intracranial pressure secondary to hydrocephalus may or may not be present because the newborn's cranial sutures are open at birth and allow for intracranial decompression. On the other hand, the resulting large head may present very difficult airway management problems. Furthermore, the stretching of cranial nerves that may occur with hydrocephalus or with other intracranial pathology such as the Arnold-Chiari malformation, may cause vocal cord paralysis and/or stridor.[56] Finally, autoregulation may be disrupted during hypoxia, acidosis, seizures, or in the presence of a patent ductus arteriosus. Thus, rapid increases in blood pressure may produce intracerebral bleeding and rapid decreases may produce ischemia.[57–60]

Thermoregulation

The newborn infant, even the premature infant, is quite capable of maintaining a stable core temperature in the face of modestly changing ambient temperatures. This is accomplished by balancing heat production with skin blood flow, sweat production, and changing minute ventilation. However, when exposed to cold, neonatal compensatory mechanisms operate only within a narrow temperature range. For adults, the lower range of thermoregulation is 32°F (0°C), whereas for full-term newborns it is 71.6°F (22°C). Premature infants require even higher ambient temperature to ensure thermal homeostasis. Indeed, at ambient temperatures of less than 89.6–93.2°F (32–34°C), the premature infant must significantly increase its oxygen consumption in order to stay warm. The ambient temperature at which a state of thermal equilibrium exists, that is in which heat loss and heat production are equal and occur without an increase in oxygen consumption, is called the neutral thermic state.[61,62]

Following delivery, the newborn infant rapidly looses heat because of its large surface area relative to its body mass and because of its lack of heat insulating subcutaneous tissue (fat). The infant loses heat by evaporation, convection, conduction, and radiation. Evaporative heat loss is the major source of heat loss in the perioperative period.[63,64] Physical factors that govern evaporative losses include relative humidity, velocity of air flow, and minute ventilation. The driving force for evaporative heat loss is the difference between vapor pressure on the surface of the skin and vapor pressure in the environment. Physiologic factors that affect evaporative loss relate to the infant's ability to sweat and to increase minute ventilation. Premature infants less than 30 postconception weeks of age have underdeveloped sweat glands and do not perspire. Preventing or minimizing evaporative heat loss is the primary means of heat control in the perioperative period. Wrapping newborns inside plastic bags is one of the easiest ways of minimizing evaporative heat losses and should be used not only in the operating room during a procedure, but also in transport.[65,66]

Heat production is achieved by voluntary muscle activity, shivering, and nonshivering thermogenesis. Shivering is rarely observed in the newborn and with the small muscle mass present, is not very effective. Nonshivering thermogenesis is a heat-producing and oxygen-consuming mechanism stimulated by cold, in which there is a generalized increase in metabolism and a marked increase in the metabolic activity in certain specialized tissues, most notably in the brown adipose tissue ("fat").[67] This tissue, is principally located in the interscapular region, mediastinum, and the tissues surrounding the kidneys and adrenal glands. Unlike white fat, it has a rich blood supply and very high oxygen consumption when metabolically active. Morphologically, brown fat contains multiloculated cells with numerous mitochondria. The mitochondria appear densely packed with cristae and have increased respiratory chain components. It is also abundantly enervated by the sympathetic nervous system. In fact, the metabolism of brown fat is stimulated by the local release of catecholamines, particularly norepinephrine.[67]

Thus, the control of heat-producing mechanisms depends on skin (not central) thermoreceptors. When skin temperature decreases, central control mechanisms trigger increased metabolic activity in brown adipose tissue. This is mediated by the sympathetic nervous system. Unfortunately, vapor anesthetics can paralyze these systems and convert the infant into a poikilotherm. Alternatively, hypoxia may interfere with thermoregulation. Hypoxia impairs heat production and impairs heat conservation by producing peripheral vasodilatation.

The infant can be protected from unnecessary heat loss quite easily. Aside from wrapping the infant in plastic bags and humidifying the anesthetic vapors, heat can be conserved by warming the operating room to 85°F (25°C), using a forced air heating blanket, warming intravenous fluids, blood, and irrigation solutions, and using a radiant heater with a servocontrol mechanism.[68]

Renal Physiology and Metabolism

The glomerular filtration rate in a newborn is less than a quarter of an adult's. Furthermore, the newborn's ability to concentrate urine is significantly reduced. In fact, the maximum concentrating ability of the newborn's kidney does not exceed 700 mOsm/kg compared to 1400 in the older child.[69] Thus, the newborn requires sodium-containing fluids intraoperatively.[70] Not only will these infants lose salt intraoperatively through the third space and hemorrhaging, but they continue to lose sodium through obligate urinary losses because of tubular inability to increase sodium reabsorption.

Glucose Metabolism

Another physiologic transition that must occur at birth involves glucose and energy homeostasis. Prior to birth, all of the newborn's nutritional needs are continuously provided by the maternal circulation. Following birth, major physiologic and metabolic changes are required to adjust to intermittent enteral feeding. Glucose is the substrate used for the energy production necessary for

maintenance of body temperature, respiration, and muscular activity.[71–73] Blood glucose concentration is normally maintained at a relatively constant level by a fine balance between hepatic glucose output and peripheral glucose uptake. Hepatic glucose output depends on adequate glycogen stores, sufficient supplies of endogenous gluconeogenic substrate, a normally functioning gluconeogenic and glycogenolytic system, and a normal endocrine system for modulating these processes. The newborn has limited glycogen stores, which may be rapidly depleted. However, endogenous gluconeogenic substrate availability is not a limiting factor nor is the liver's gluconeogenic and glycogenolytic systems.

Hypoglycemia is common in infants born to diabetic mothers and in infants who require resuscitation, are premature, or who are small for gestational age.[72–74] By definition, hypoglycemia is a blood glucose level less than 45 mg/dL in the infant during the first 3 days of life.[72–74] After 3 days of age glucose values should be greater than 75–90 mg/dL. The clinical manifestations of hypoglycemia include tremors or jitteriness, apnea, cyanotic spells, convulsions, limpness or lethargy, hypothermia, sweating, refusal to feed, and cardiac failure or arrest. These are nonspecific signs and symptoms and must be differentiated form birth asphyxia, central nervous system abnormalities, such as hemorrhage or cerebral edema, congenital heart disease, sepsis, drug withdrawal, apnea, and other metabolic abnormalities such as hypocalcemia, hypomagnesemia, and hyponatremia.

Symptomatic babies must be treated rapidly to prevent neurologic damage. Treatment should be started with a 250–500 mg/kg bolus of glucose (25% dextrose [D_{25}]-containing solution), followed by an infusion of 4–6 mg/kg/min (65–100 mL/kg/h) of a 10% dextrose (D_{10})-containing solution. Failure of this regimen to produce blood glucose concentration of 80–120 mg/dL should alert the physician to the possibility of hyperinsulinism. Hyperinsulinism and hypoglycemia occurs in maternal diabetes, erythroblastosis, Beckwith-Wiedemann syndrome, SGA and LGA infants, polycythemia, and in insulin-secreting tumors (nesidioblastosis).

Calcium

Calcium in the blood circulates as 3 fractions—protein bound, complexed, and ionized—and is tightly regulated by the intricate interplay of parathyroid, renal, and skeletal factors.[75,76] Ionized calcium is the only physiologically active fraction, whereas the protein-bound calcium provides a reserve of available calcium should a need for increased ionized calcium arise acutely.[75,76] In fact, if total calcium levels in the blood are reduced as a result of low plasma protein, and if the ionized fraction remains normal, there may be no physiologic changes. Conversely, if total calcium levels are normal, but the ionized levels are low, as might occur when chelating agents are used (e.g., as with citrated blood products), significant physiologic effects occur.

During pregnancy, there is rapid transfer of calcium from mother to fetus, via an active placenta pump.[77] At birth there is an abrupt termination of maternal-to-fetal calcium supply. Furthermore, dietary calcium in the first few days of life is significantly less than the amount normally received from the mother. A decrease in serum calcium is expected. In the sick newborn, even greater deprivation of calcium is common because of the conventional withholding of milk feeding and the substitution of calcium-free intravenous feeding.

Consequently, neonatal hypocalcemia is common in the first few days of life. Definitions vary as to the level of serum calcium required for the diagnosis, but most agree that in infants up to 3 months of age, hypocalcemia is defined as a serum total calcium level of less than 8.8 mg/dL or ionized calcium less than 4.9 mg/dL (1.22–1.4 mmol/L).[76] Infants at particular risk are those born prematurely or to diabetic mothers, or who are small for gestational age, or who have received large volumes of citrated blood products or sodium bicarbonate. Additionally, infants who are alkalotic secondary to hyperventilation, or who experienced birth asphyxia, or who are hypoparathyroid or born with the DiGeorge syndrome also present with hypocalcemia.

The classic clinical signs and symptoms of hypocalcemia, namely the Chvostek sign (facial muscle twitching when stimulated) and the Trousseau sign (carpal spasm after constriction of the upper arm), are of little value in the newborn. Rather, nonspecific symptoms occur; namely, jitteriness, twitching, convulsions, and, occasionally, hypotension. An electrocardiogram will reveal prolonged QT intervals. The treatment of symptomatic hypocalcemia is the administration of calcium salts. Acute intravenous administration of 1–2 mL/kg of either 10% calcium gluconate or chloride should be administered and the heart rate monitored continuously. In the newborn, the acute administration of calcium can produce significant bradycardia. The other important complication of this therapy relates to extravasation of calcium into the soft tissues when a peripheral intravenous catheter is used. This can cause skin sloughing and necrosis.

SUMMARY

Except for extraordinary circumstances, all newborns require anesthesia and analgesia for surgery. During the first month of life, the newborn must function independently and adapt to extrauterine life. This involves anatomic, physiologic, and pharmacologic changes to maintain homeostasis and to insure the infant's survival. Disease, congenital anomalies, surgery, and anesthesia may interfere with these adaptations and threaten survival. This chapter has provided an in-depth review of developmental physiology and pathophysiology that is essential in the provision of safe anesthesia to the newborn.

CHAPTER 19

Evaluation of Children

Randall C. Wetzel, MBBS, MRCP, LRCS, MBA, FAAP, FCCM

The preanesthetic evaluation of the child requires not only an understanding of the different surgical procedures children undergo, but also an understanding of the unique psychology, development, and physiology of children. There are many obvious differences between adults and children that affect anesthetic management. Apart from the differences of size, communication skills, and issues involving parents, there also are multiple, less obvious differences in the physiology, psychology, anatomy, and pharmacology of children. The most characteristic and important feature of childhood is development. Not only does children's responsiveness to other people follow recognized patterns of psychological development that require appropriate responses from the anesthesiologist, but virtually every organ system undergoes distinct, well-described development that is relevant to the anesthetic management of children. The key to understanding pediatric anesthesiology

KEY POINTS

1. The percentage of total body composition that is water decreases with age; intracellular fluid increases, whereas extracellular fluid decreases.
2. Fat and muscle mass increase from 13 to 22% and 20 to 50%, respectively, with age.
3. The distribution of blood flow varies, with a decreased percentage of flow going to the vessel-rich groups with increased age.
4. Infants have a large tongue and relatively small jaw. Infants usually are described as having an anterior and cephalad displacement of the airway with the narrowest segment at the level of the cricoid. The epiglottis generally is large and floppy compared with that of adults.
5. Younger children tend to experience airway closure and alveolar collapse with atelectasis because the end-expiratory lung volume from which tidal breathing occurs is close to closing capacity.
6. Although the functional residual capacity in mL/kg is smaller in infants compared with adults (30 vs. 34), increased oxygen consumption is the major factor in the rapid desaturation of infants.
7. The perioperative risk of reversion to a transitional circulation is related to pulmonary hypertension triggered by hypoxemia, hypercarbia, hypothermia, acidosis, and increased catecholamines.
8. Cardiac output depends on heart rate in infants and young children. Infants have parasympathetic hypertonia, decreased sympathetic innervation, and a ventricle with less muscle and more noncontractile mass per unit volume. These all lead to a myocardium that is less able to generate adequate force than in adults.
9. A hematocrit nadir of approximately 35 at about age 3 months is the so-called physiologic anemia of infancy.
10. The glomerular filtration rate/1.73 m^2 increases from 40–130 mL/min with age. Ability to concentrate urine is limited, and maximal osmolarity may be only 700 mOsm.
11. Slack lower esophageal sphincter tone with reflux is common in infants aged less than 6 months, but the maintenance of low gastric volumes by nothing-by-mouth (NPO) regulations should be balanced by awareness of the risk of hypoglycemia.
12. The liver is functionally immature in children, affecting synthetic and metabolic function.
13. Defending the thermoneutrality of infants is a cornerstone of pediatric anesthesia.
14. Cold stress in neonates can increase oxygen consumption and decrease oxygen delivery, leading to increased hydrogen ion concentration and decreased glycogen and glucose. This may result in respiratory distress, disseminated intravascular coagulation, shock, and persistent fetal circulation.
15. The large surface-area-to-mass ratio in children and decreased subcutaneous tissue mass lead to increased heat loss via conduction, convection, radiation, and evaporation.
16. The large volume of distribution noted in neonates is related to decreased protein binding and a greater proportion of extracellular water.
17. In preoperative evaluation, the anesthesiologist should prepare himself or herself, the family, and the child for the procedure. The primary objective is to ensure that the child is in optimal condition. Developmental milestones and growth charts should be reviewed to assist in the general assessment of well-being. Optimal drug levels (e.g., anticonvulsants and theophylline) should be ensured.
18. Many congenital anomalies are associated with airway and cardiac abnormalities.
19. In children with known cardiopulmonary disease, it is imperative that the anesthesiologist be completely familiar with the child's current status and be assured that therapy has been optimized preoperatively.
20. In infants, feeding is the major exercise, and failure to thrive may indicate compromised cardiovascular function.
21. The "runny nose" remains a controversial area, but whenever possible, surgery and anesthesia should be delayed at least 2 weeks when the child has a runny nose associated with lower respiratory or systemic symptoms.
22. Routine laboratory testing for healthy children remains controversial and should be dictated by clinical situation.
23. The trend of NPO status is toward a more liberal NPO restriction for clear liquids.
24. Rigorous, compulsive, and systematic evaluation of critically ill children is essential.

is to recognize the dynamic processes that occur at the various developmental stages of childhood. The mindset required is not that of understanding anesthesia that is appropriate for adult physiology and adapting this approach to children, but rather to flexibly approach the child as the child grows from fetus to adult. A specific anesthetic plan appropriate to developmental stages should be designed for each child. Because the developmental characteristics of children determine anesthetic management, this chapter focuses on those changes that occur after the neonatal period. Chapter 18 discusses neonatal physiology. This chapter familiarizes the anesthesiologist with the anesthetic implications of development from neonates to adults.

DEVELOPMENTAL IMPLICATIONS

Growth is not solely a process of proportional enlargement. Total body composition, including proportional fluid content, the relationship of head-to-body size, and cardiorespiratory function, all change disproportionately during development. For example, the head becomes proportionately smaller with relatively little change in the size of the cranial vault after 2 years of age. At the same time, major changes in facial configuration occur. Most striking is the development of the mandible, which develops from being small and obliquely set to the skull of infants to becoming proportionately larger, less obliquely set, and more mobile in adults.

The development of body composition is important because it is an essential determinant of developmental pharmacology. In the fetus, 90% of total body composition is water; at full term, 75% of total body composition is water, but by age 1 year, 60% of total body content is water.[33] Adult water composition is attained by age 1 year. There is also a change in the relative proportion of extracellular water over the first years of life. Extracellular water volume demonstrates a greater decrease than intracellular volume, which undergoes a complementary increase. Intracellular fluid increases from approximately 20% in premature infants to 30% in term infants and to 40% in adults, whereas extracellular fluid falls from 60% in premature infants to 45% in term infants and 20% in adults.[104] The percentage of body composition that is muscle in premature infants is less than 20% and increases to more than 20% at term, and attains 50% in adults.[33] Fat likewise increases with age, from 13% in term infants to 22% of total body weight in adults.[33] There also is an age-dependent change in the relative proportion of blood flow to the various organs. Distribution of blood flow to various organ groups defined by their vascularity (vessel-rich group [VRG], muscle group [MG], and vessel-poor group [VPG]) also demonstrates major developmental change (Table 19–1).[27] For example, there is a decreased percentage of flow going to VRGs with increasing age. The VRG in neonates accounts for 22% of total body volume, whereas in adults, it only accounts for 10%. Thus, an anesthetic caregiver would expect a smaller portion of blood flow to VPGs in infants and a more rapid attainment of the plateau phase of the alveolar end-tidal concentration (FA)-to-inspired concentration (FI) ratio with use of inhalational anesthetics. This has clear implications for the induction of inhalational anesthesia in children, and, not surprisingly, the uptake and distribution of inhalational anesthetics in children.[27]

TABLE 19–1.

Tissue Type Volume As Percent of Body Volume

Age	Vessel-Rich Group	Muscle Group	Vessel-Poor Group
Neonate	22	39	13
1 year	17	39	25
4 years	17	41	23
8 years	13	45	21
Adult	10	50	22

Modified from Gregory G. Pharmacology. In: Gregory G ed. Pediatric Anesthesia. New York: Churchill Livingston, 1989;396.

Respiratory System

The major features of the respiratory system that undergo important developmental changes are (a) the upper airway, (b) airway caliber, (c) respiratory system (chest wall and lung) mechanics, (d) central control of breathing, and (e) respiratory muscle characteristics. Each is described in the following material.[22]

The upper airway undergoes major development (Fig. 19–1). The first developmental difference is that an infant's tongue is relatively large compared with the rest of the airway. Intubation may be hampered by the overlarge tongue situated in the relatively small jaw. Infants usually are described as having an anterior, cephalad-displaced glottis, with the airway forming an inverse cone (Fig. 19–2). The narrowest segment of the airway is at the cricoid cartilage and remains so until puberty. These factors are important for intubation. An endotracheal tube that will be admitted to the glottis may be too tight for the subglottic area. The presence of an air leak below 30 cm H_2O airway pressure always should be assured for routine anesthesia.

In infants, the glottis is located at C2, 2–3 vertebral bodies higher than in adults, in whom the glottis is located at C4–C5. The cricoid cartilage is found at C4 in children and at C6–C7 in adults. The obliquity of the vocal cords also changes with age. In infants, these are slanted down and anteriorly compared with adults. This makes the angle for intubation more acute and more difficult in children, and makes blind nasal intubation difficult. Another difference in the child's airway is the nature of the epiglottis. The epiglottis in small children is relatively larger, longer, more curved (omega [Ω] shaped), and floppy compared with that in adults. Maturation begins to occur at age 2 years, and the adult configuration is achieved sometime near puberty, when the epiglottis is shorter, smaller, blunter, and less curved rather than Ω shaped. These anatomic differences in the airway have a major effect on which intubation techniques will be useful in children. For example, a straight laryngoscope blade (e.g., Miller blades) that can lift directly the epiglottis out of the larynx during glottic visualization is useful in children.

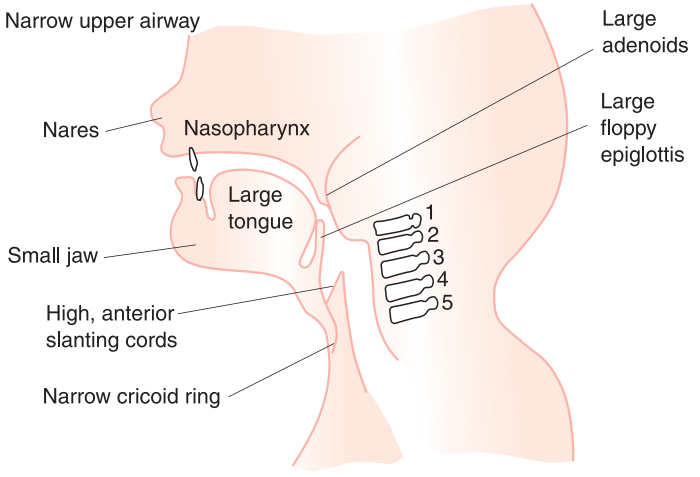

FIGURE 19–1. Diagram of a coronal section through the airway of an infant. Areas where there are important differences from adults are highlighted. (Reproduced with permission from Wetzel RC.[107])

Airway caliber undergoes continuous developmental change from the nares to the small airways. Although airway branching has been completed by birth, the caliber of the airways continues to increase. Airway resistance is inversely proportional to the fourth power of the radius, as seen in the Poiseuille equation:

$$\text{Resistance} = 8\ Ln/r^4$$

where L is the airway length, n is the viscosity of the fluid, and r is the radius of the airway. It should be noted that total airway resistance is affected by consideration of caliber from the nares to the alveoli. Small airways have high resistance. The consideration of size also makes the seriousness of airway edema greater in younger children. A proportional increase in mucosal thickness in children increases resistance to a greater extent than it does in adults because equal mucosal thickening proportionately decreases caliber more in children. Airway resistance decreases approximately 15 times from infancy to adulthood, with a dramatic change occurring near age 8 years.[41] This decrease in resistance with increasing age largely results from an increase in diameter of the small airways.[111] Infants are obligate nose breathers, and nasal obstruction can cause severe respiratory embarrassment, which is more severe in premature infants.[66]

Respiratory mechanics change dramatically from birth to adulthood. These changes result from increased alveolarization, increased airway size, and changes in the chest wall. Only as the rib cage ossifies does its configuration change and become more rigid. In infants, the chest wall is soft and pliable because of its largely cartilaginous structure, which makes the chest wall highly compliant. This compliance promotes chest wall collapse when increased work of breathing requires more negative intrathoracic pressure. The clinical consequences associated with these chest wall factors are seen in infants with respiratory distress as marked sternal and subcostal retractions. In infants, the chest wall is at a mechanical disadvantage during breathing because greater pressure is required per unit of tidal volume moved. In addition to the compliance of the chest wall, there is also a decrease in elastic recoil of the total respiratory system and chest wall. This low elastic recoil tends to alter the relationship between closing volume, functional residual capacity (FRC), and residual volume.

The respiratory system undergoes major neuromuscular development. Central respiratory control, muscle fiber makeup (type I vs. type II), and neural innervation of the chest wall show distinct developmental changes in infants and small children.[49] The central respiratory control undergoes dramatic developmental changes. For example, full and preterm neonates demonstrate depression of the CO_2 response curve and secondary apnea with hypoxia.[81,82] This contrasts with the characteristic adult response, which is increased CO_2 responsiveness in the presence of hypoxia, resulting in tachypnea. The impact of hypoxia in the presence of this paradoxic, immature response can be catastrophic in neonates.[81] This infantile pattern of respiratory control is related to the risk of postanesthetic apnea in neonates.[57] Anesthetic effects on the CO_2 response curve are similar in infants and adults. The CO_2 response curve undergoes depression by potent inhalational anesthetic agents and narcotics in children as it does in adults.[51]

Respiratory muscle type does not reach the adult pattern of distribution until approximately age 2 years. This predisposes the infant to fatigue. Type II muscle fibers predominate and do not have the ability to perform repeated exercise against increased workloads as do type I fibers.[49] Type I fibers become predominant around age 2

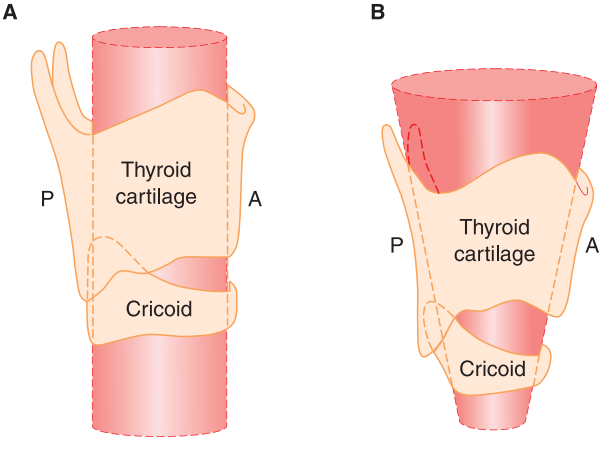

FIGURE 19–2. Schematic of an adult (**A**) and infant (**B**) airway. Note the comparison between the cylindrically shaped airway with uniform diameters in the adult and the conically shaped airway of the child with the narrowest region at the cricoid. A, anterior; P, posterior. Reprinted from Cote CJ, Todres ID. The pediatric airway. In: Ryan JF, Todres ID, Cote CJ, et al., eds. A practice of anesthesia for infants and children. Philadelphia: WB Saunders, 1986;35–58, with permission from Elsevier.

years. Regarding neural innervation, reflex responses and spindle innervation of the thoracic cage also undergo developmental changes. For example, the Hering-Breuer response is accentuated in preterm infants compared to full-term infants, and leads to apnea with lung inflation in preterm infants.[76] These characteristics have a major impact on cyclic respiration as can be seen from the immature respiratory pattern of periodic breathing. In addition, sleep-state-dependent respiratory patterns show distinct developmental differences.[44]

These changes in chest wall recoil, elasticity, compliance, and neural control have a major effect on lung volumes (Fig. 19–3). One of the most important factors is the tendency in younger children for airway closure and alveolar collapse with atelectasis to occur. Children breathe from an end-expiratory lung volume (EELV) close to closing capacity (CC). Their FRC is actually below CC in premature infants and term neonates, increasing with age. Airway closure may occur even during normal tidal respiration in small infants.[88] Induction of anesthesia is associated with decreased elastic recoil and airway tone and decreased respiratory muscle tone. Thus, an expected lung volume decrease occurs with tidal respiration falling below closing volumes. These factors and those responsible for the decrease in EELV to less than FRC on induction of anesthesia, in part account for the rapid occurrence of hypoxemia in apneic infants during induction of anesthesia. The other major factor related to the rapid occurrence of hypoxemia in apneic infants is their relatively increased oxygen consumption. In neonates, oxygen consumption is approximately 7 mL/kg/min.[40] On a consumption-to-weight basis, this is approximately double that seen in adults, in whom oxygen consumption undergoes a gradual decrease with age. Although FRC/kg is less (30 mL vs. 34 mL) in infants than adults, increased oxygen consumption is the major cause of the rapidity of desaturation in infants and small children who are apneic. Table 19–2 summarizes the developmental differences in respiratory physiology between infants and adults.

In addition to oxygenation issues, development of the respiratory system also affects ventilation. For example, V_{DS}/V_T, the ratio of dead space gas

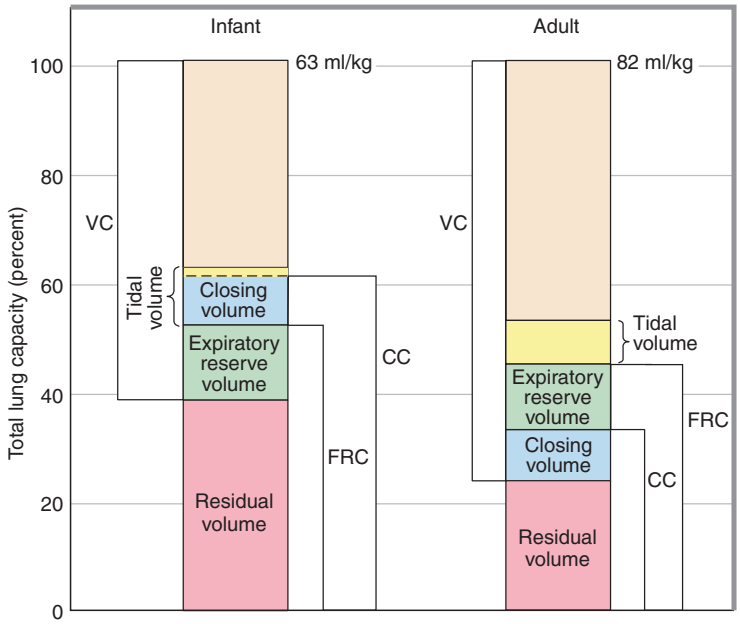

FIGURE 19–3. Bar graphs representing proportional lung volumes in infants and adults. Note the relationship of functional residual capacity (FRC) to closing volume and how this changes with age. CC, closing capacity; VC, vital capacity. (Smith CA, Nelson NM. The Physiology of the Newborn Infant. Springfield, IL: Charles C Thomas, 1976. volume to tidal gas volume ventilation, is approximately 33% in neonates and adults.[110] Thus, an infant would be expected to have a 7-mL dead space gas volume with a 20-mL tidal gas volume. The addition of a few milliliters of dead space gas volume by the superimposition of anesthetic equipment may increase dead space gas volume from 7–12 mL and have a serious effect on V_{DS}/V_T and CO_2 clearance in neonates. The dead space gas volume of all ventilatory equipment, endotracheal tubes, and especially face masks and anesthesia circuitry should be minimized.

Cardiovascular System

The cardiovascular system also undergoes dramatic developmental changes.[32,68] The most obvious and dramatic changes occur perinatally, and these are detailed in the section on perinatal physiology. Even in full-term infants, there is a perioperative risk of complications related to the transitional circulation. Any factor that contributes to pulmonary hypertension (e.g., infection, acidosis, hypoxia, hypercarbia, hypothermia, and aspiration) may lead to a serious decrease in cardiac output, hypoxemia, and hypotension. These factors should be avoided in the anesthetic plan for infants.

Multiple developmental changes occur in myocardial function. Changes in the proportion of muscle to connective tissue with development lead to an alteration in myocardial compliance.[32] Developing left ventricular dominance also alters ventricular characteristics. Nearly every determinant of cardiac output (heart rate,[68] contractility,[79] afterload,[98] and preload relationships[50]) undergoes distinct developmental changes (Fig. 19–4).[107] Although myocardial ischemia only rarely plays a role in the anesthetic management of children,

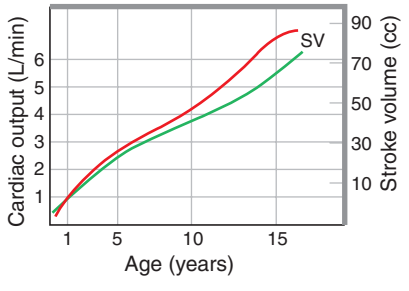

FIGURE 19–4. Stroke volume and cardiac output increase with age. Data from Wetzel RC, Rogers MC. Pediatric hemodynamic monitoring. In: Shoemaker WC, Thompson WL, eds. Critical Care-State of the Art. Fullerton, CA: The Society of Critical Care Medicine, 1983.

these factors and the varying responses to pharmacologic agents can lead to rapid, and occasionally catastrophic, hemodynamic decompensation in children undergoing anesthesia.[109]

In neonates and infants, heart rate is the predominant determinant of cardiac output.[86] The infant's heart is able to sustain greater rates than that of the adult while maintaining preload, contractility, and myocardial oxygenation before there is a decrease in cardiac output (Fig. 19–5). Figure 19–6 shows the normal heart rates for infants and children. Bradycardia can drastically and seriously decrease the cardiac output in infants and children. Increasing cardiac output by increasing heart rate should be considered early in responding to intraoperative decreases in cardiac output as represented by hypotension. Bradycardia results from a predisposition to parasympathetic hypertonia, which is common in young children and can be induced by painful stimuli or hypoxia. Laryngoscopy, intubation, eye surgery, airway surgery, abdominal traction, and herniorrhaphy frequently are associated with marked increases in vagal tone and profound bradycardia. Under these circumstances, the cardiac output of the heart rate-dependent infant heart can decrease dramatically. That children adapt to changes in cardiac output by changes in heart rate accounts for the wide ranges in heart rate seen in healthy children. Anesthetic suppression of atrial conduction and loss of P waves on the electrocardiograph with nodal escape rhythms are seen in children during anesthesia, and the resultant bradycardia can be dramatic. Heart-rate depression during anesthesia is readily treated with atropine and is the reason many anesthesiologists make atropine part of any inhalational anesthetic plan in infants and small children. Sinus dysrhythmia, a variation in the heart rate with respirations, is so common in children that it is considered normal, although it can be confused with extra systoles or sinus arrest during anesthesia.

As Friedman originally reported in 1973, the myocardial length–tension relationships vary between the hearts of children and adults, and developmental differences in contractility are clearly seen.[32] These differences are explained by changes in muscle mechanics, innervation, myocardial blood flow, and histologic structure, all of which have been implicated in children's relative inability

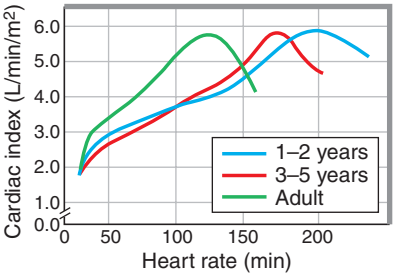

FIGURE 19–5. Cardiac output is shown as it relates to heart rate in healthy children and adults. Data from Wetzel RC, Rogers MC. Pediatric hemodynamic monitoring. In: Shoemaker WC, Thompson WL, eds. Critical Care-State of the Art. Fullerton, CA: The Society of Critical Care Medicine, 1983.

to increase contractility. Fetal myocardial muscle sarcomeres are active and have about the same contractile power as the adult sarcomere.[32] The fact that neonatal ventricular tissue contains less muscle mass and more noncontractile mass per unit volume than adult tissue accounts for the fact that the neonatal myocardium is less able than the adult myocardium to generate adequate force.[97] The neonatal heart is only innervated partially by the autonomic nervous system (this innervation increases until mid childhood). Therefore, not only is the myocardium less able to develop inotropic force, but sympathetic innervation also is decreased. The Frank-Starling preload relationship also appears to be altered by differences in the fiber makeup of the infant myocardium and by the relationship of the right and left ventricles.[32] These changes in compliance characteristics frequently make the infant heart preload insensitive. Volume load may generate higher filling pressures over a narrower proportional range in infants and small children than in adults.[85] Normal adult contractility and compliance is reached between 1 and 2 years of age.

The final determinant of cardiac output—afterload—also changes with age. At birth, systemic resistance greatly

Normal Range of Blood Pressures

Age	Mean Systolic/ Diastolic
Premature neonates	Systolic 40–60
Full-term neonates	75/50
1–6 months	80/50
6–12 months	90/65
12–24 months	95/65
2–6 years	100/60
6–12 years	110/60
12–16 years	110/65
16–18 years	120/65
Adult	125/75

Approximate ranges: pressure ±20% = 95% confidence limits. Females are approximately 5% lower than these levels. Data from Lowry GA: *Growth and development of children*, ed 6, Chicago, 1975, Year Book Medical Publishers; and Report of the Task Force on Blood Pressure Control in Children, National Heart, Lung, and Blood Institute, *Pediatrics* 59(suppl):803, 1977.

increases with removal of the placenta, whereas afterload in the pulmonary circuit decreases dramatically.[85,97] Adjustment to this massively increased afterload in the systemic circulation occurs rapidly, but further increases in afterload may be poorly tolerated in the first year of life. Right and left ventricular mass and wall thickness are relatively equal in neonates. During the next year or so of life, the left ventricle becomes markedly dominant. As a result of the factors mentioned previously, optimal cardiac output occurs at lower filling pressures in neonates compared with adults.[85]

All of these factors lead to optimal cardiovascular function at higher heart rates and lower blood pressures in infants than in adults (Fig. 19–5). Familiarity with the normal range of blood pressures (Table 19–3) is essential to guide appropriate intraoperative management.

Congenital heart defects can affect the determinants of cardiac output: heart rate, contractility, preload, afterload, and oxygenation. Left-to-right intracardiac shunting alters preload, potentially alters contractility, and even alters right ventricular afterload as pulmonary vascular resistance increases. Right-to-left shunting affects systemic oxygenation. Valvular disease can increase preload (regurgitant lesions), decrease preload (mitral and tricuspid stenosis), or increase afterload (aortic and pulmonic stenosis). Congenital and surgically acquired lesions can alter conduction and give rise to cardiac dysrhythmias. Thus, careful evaluation of all aspects of cardiac function is necessary in assessing children with congenital heart disease. The specific anatomic diagnosis, the presence of intracardiac shunts, and myocardial function all have a bearing on the conduct of the anesthetic in children.

Hemoglobin content and oxygen affinity also vary with age.[13] In the infant born at term, the normal hemoglobin concentration falls dramatically during the first year of life, reaching a nadir around age 2–3 months, the so-called physiologic anemia of infancy.[13] Although a physiologic hematocrit at this age could dip below 29%, a hemoglobin of < 10 g/dL is rare. In the preterm infant, the hemoglobin concentration may fall to between 6 and 8 g/dL within the first 6–8 weeks of life.[92] Although not unusual, this should not be considered "physiologic," and the same concern regarding a hematocrit of < 25% in older children is appropriate. The hematocrit slowly increases to adult levels after puberty. Knowledge of these normal levels is necessary to guide blood transfusion and the timing of elective surgery that may be associated with significant blood loss.

Circulating blood volume is greater in neonates than in adults on the basis of body weight. Intravascular volume for neonates generally is 80 to 90 mL/kg (Table 19–4). Understanding this relative change in total estimated blood volume (EBV) (body weight × estimated blood volume/kg) is necessary when determining allowable blood loss (ABL) in children. The following formula is useful for estimating how much blood children can lose before the hematocrit is unacceptably low (ABL):

$$\text{ABL} = \text{EBV} \times \frac{\text{Hct}_1 - \text{Hct}_2}{\text{Mean Hct}}$$

Hct_1 is the starting hematocrit; Hct_2 is the minimum desired or allowable hematocrit; and the Mean Hematocrit is the simple arithmetic mean of Hct_1 – Hct_2. Thus, in a 12-kg, 1-year-old child with an initial hematocrit of 37% in whom a final hematocrit of 25% is acceptable, the ABL is:

TABLE 19–4.

Intravascular Blood Volume

Age	Blood Volume/ Kilogram Body Weight (mL/kg)
Infants	
Premature	90–100
Full-term	80–90
Less than 1 year	75–80
1–6 years	70–75
>6 years and adult	65–70

From Wetzel RC: Evaluation of Children. In Longnecker DE, Tinker JH, and Morgan GE, et al, eds., *Principles and Practice of Anesthesiology*, Vol I, 2 ed, Mosby, Inc., 1998.

$$\text{ABL} = 12\ \text{kg} \times \frac{75\ \text{mL}}{\text{kg}} \times \frac{0.37 - 0.25}{0.5(0.25 + 0.37)} = 348\ \text{mL}$$

A comparison of the estimate of expected intraoperative loss with the estimate of allowable loss should be made before surgery. If possible, preoperative therapy should be designed to decrease the need for blood transfusion. Iron and nutritional supplements may be beneficial. Erythropoietin should be considered in some children to increase the preoperative hemoglobin concentration when the child is chronically anemic, where there are religious reasons to refuse transfusion, or if the child is erythropoietin deficient, e.g., renal disease. Preoperative treatment with erythropoietin has been advocated to increase the hematocrit in children to facilitate autotransfusion, either in directed autotransfusion with preoperative blood collection, or to facilitate intraoperative autotransfusion.[34]

Renal Function

Renal function changes dramatically with age.[17] For example, glomerular filtration rate (GFR)/1.73 m^2 changes from less than 40 mL/min at birth to 100 mL/min in the first year of life, which compares with 130 mL/min in adults (Table 19–5). These changes in renal function and GFR are accompanied by changes in the ability to regulate salt and water metabolism and by responses to changes in antidiuretic hormone (ADH) that occur during anesthesia.[8] Although the factors regulating neonatal kidney function are com-

plex in the transitional phase, the net result is that water is excreted in excess of sodium. The neonatal kidney wastes sodium, and there is a tendency toward hyponatremia in the premature and full-term neonate. The kidney of the full-term infant is able to conserve sodium.[91] The ability of the kidney to concentrate urine is limited, and maximal osmolarity may be only 700 mOsm/L in infants.[8,17] Thus, infants are less able to defend intravascular volume against water deprivation.

Complete maturation of renal function usually occurs by about age 2 years. These developmental aspects of renal function have an effect on pharmacology. The effects of these changes are most prominent in the first few months of life and require careful fluid management in neonates and attention to sodium and potassium balance.[6] Blood pressure regulation and the characteristics of hypertensive renal disease also show distinct differences in children.[38] In children with renal disease, hypertension should be looked for because intraoperative blood pressure regulation may be difficult.

Dentition

Although teeth occasionally are present at birth, they may not erupt until nearly 1 year of age. The mean age for the development of the first tooth, usually a lower incisor, is around 6 months. By 1 year, children usually have upper and lower teeth present. By age 6 years, permanent teeth begin to appear, and the average 6-year-old has an intubation gap between the front incisors. The importance of deciduous teeth is that they fall out, and they should not fall out during anesthesia. Children younger than 12 years of age, especially those with loose incisors at around age 6 years, should be questioned and examined for the presence of loose teeth. Loose and carious teeth are at increased risk for dislodgment by the placement of oral airways, laryngoscope blades, and endotracheal tubes. A history of endotracheal intubation in the neonatal period is associated with subsequent development of abnormal dentition in neonates.[70] Whether this is a result of direct trauma from the laryngoscope or from long-term placement of an endotracheal tube is not clear.[106] Attention to children's oropharynx and condition of dentition is an essential part of the anesthetic evaluation.

Gastrointestinal System

Developmental changes in the gastrointestinal (GI) tract also have important anesthetic implications. At birth, gastric pH is alkalotic; however, by the second day of life, the normal physiologic range of gastric pH is achieved. The secretion and amount of gastric contents in full-term infants is similar to adults. Although fasting gastric contents and pH in children are similar to those in adults, the reflex coordination of swallowing and lower esophageal sphincter (LES) function is not fully mature until age 6 months.[10,11,108] Slack LES tone with reflux is common in this age group. This is relevant to the question of preoperative fasting. The maintenance of low residual gastric volumes by nothing-by-mouth (NPO) regulations (a questionable assumption) should be balanced against the propensity of fasting children to develop hypoglycemia.[10,11] This especially is true if the infants or children are born prematurely, small for gestational age (SGA), nutritionally deprived, or with increased metabolic needs because of conditions such as fever, sepsis, increased respiratory effort, or the condition that requires surgery. To assure a suitable period of fasting, especially in small, ill children, preoperative intravenous (IV) supplementation with dextrose-containing solutions is indicated.

Development of the GI tract generally is complete at birth. Problems caused by congenital malformations or developmental anomalies generally are obvious within the first few days after birth.[10] Upper GI obstruction (e.g., duodenal atresia, malrotation) is indicated by bilious vomiting and regurgitation within the first few days of life. Lower intestinal anomalies (e.g., volvulus or atresia of the small or large bowel) are manifested by failure to pass stools and by abdominal distension. Pyloric stenosis, another major cause of GI dysfunction in the first year of life, usually presents between ages 3 and 6 weeks. Its major symptoms are failure to gain weight and projectile vomiting.

The liver in neonates and young infants is functionally immature. This functional immaturity generally is a result of two main causes: (a) the development and growth of enzyme systems that, although present at birth, are not fully induced, and (b) relatively decreased hepatic blood flow.[103] The ability of the liver to conjugate and catabolize circulating substrate and pharmacologic substances is diminished at birth. For this reason, drugs tend to have longer half-lives in neonates compared with older children. This functional immaturity of the liver is reflected by decreased concentrations of products of hepatic synthesis, such as albumin, in neonates.[42] These decreased concentrations lead to decreased protein binding of many pharmacologic agents, which alters pharmacokinetics and pharmacodynamics.[5,46] Hepatic function usually reaches adult levels within the first few months of life.

Thermoregulation

Perhaps no area is of greater concern to the pediatric anesthesiologist than the need to maintain normal body temperature perioperatively. The need for thermoregulatory control is underemphasized in adults but is critical in the treatment of children. Defending the thermoneutrality of infants has been a cornerstone of pediatrics since the 19th century. In 1900, Pierre-Constant Boudin demonstrated that there were striking differences in the survival of infants weighing less than 2000 g that depended solely on their rectal temperatures.[12] The mortality rate for infants with core temperatures less than 95°F (35°C) was greater than 90% and for those with temperatures greater than 95°F (35°C) was only 23%. Boudin designed an incubator that provided heated air and humidity and then

conclusively demonstrated that its use could dramatically improve the survival of neonates.[12] This observation found its way to Julius Hays Hess, who is considered the founder of premature care in North America.[95] He recognized the importance of these observations, and in 1922, opened the first premature infant center at the Michael Reese Hospital in Chicago.

Thermoregulation is a complex process involving peripheral and central thermoreceptors, the central nervous system (CNS), and hypothalamic integration with central thermoreceptors.[37] A complex integration of responses leads to alterations in cutaneous blood flow and thermogenesis from shivering and nonshivering sources.[16] This complex system is necessary to maintain mammalian core temperature within a normal range. Sources of heat production include basal metabolism, movement, shivering thermogenesis, and nonshivering thermogenesis. Basal metabolism is responsible for the greatest amount of baseline heat production. Shivering thermogenesis is the uncontrolled, rapid contraction of skeletal muscles, and is common on emergence from anesthesia in older patients. Nonshivering thermogenesis is under direct control of the autonomic nervous system and produces heat by mobilizing fat from muscles, liver, and brain.[14] Although neonates metabolize both white and brown fat, brown fat is used by neonates to a greater extent than by adults. This is important because neonates cannot respond to cold stress with shivering thermogenesis until age 6 months to 1 year. Brown fat is distributed around the back of the neck, mediastinum, and interscapular regions, and around the kidneys and adrenals. Brown fat owes its color to a high content of mitochondria and rich blood supply, which mirror its metabolic capability. Brown fat metabolism increases heat production when stimulated by autonomic catecholamine release.[14] Cold stress also leads to norepinephrine secretion, which causes adipocytes to release glycerol and fatty acids from brown fat depots. Brown fat metabolism provides the only possibility of increasing body temperature in the immobile, anesthetized infant with decreased metabolic rate. Cardiac output is diverted from other organs to brown fat depots. Vasoconstriction of the systemic and pulmonary circulations occurs as a result of norepinephrine release. Consequently, cold stress can lead to peripheral vasoconstriction, pulmonary vasoconstriction, decreased cardiac output, and shunting of cardiac output away from other organ systems to brown fat depots, all of which may pose a serious threat to neonates. Importantly, inhalational anesthetics inhibit brown fat-dependent thermogenesis, which explains the propensity of neonates to become hypothermic during inhalational anesthesia.[75] This complex system can compensate for heat loss, but at a high cost. Avoiding cold stress is preferred.

During anesthesia, environmental challenges to thermal integrity should be minimized, especially as inhalational anesthetics inhibit brown fat thermogenesis.[75] Hypothermia increases cardiorespiratory demand because of increased oxygen demand and the need for thermogenesis, and alters every basic enzyme system. Environmental cold stress in neonates leads to increased oxygen consumption, hypoxia, acidosis, respiratory distress, depletion of glycogen stores, hypoglycemia, pulmonary vasoconstriction, pulmonary hypertension with persistence of the fetal circulation, shock, and even disseminated intravascular coagulation. Altered drug metabolism, delayed emergence, prolongation of the effects of neuromuscular blocking agents, and other pharmacologic effects accent the need for intraoperative thermoregulatory control in children.[95]

Heat loss occurs through four basic mechanisms: conduction, convection, radiation, and evaporation. Each of these, under certain circumstances, can be the major cause of heat loss. Conductive heat losses can be eliminated by minimizing the direct contact of children with surfaces colder than themselves. The use of a warming pad or heating blanket in the operating room can eliminate heat loss to the cold operating room table. Warming of the operating room greatly reduces conductive heat loss. Convective heat losses can be further limited by the use of an incubator, by surgical drapes and warm blankets for the child. Radiant heat losses also should be minimized. Heat is radiated to objects of lower temperature. Warming objects in the patient's environment will lead to decreased radiant losses. This is the principle that underlies "radiant" neonatal warmers.[24] The use of double-walled incubators decreases radiant losses. Transportation of neonates to the operating room in double-walled isolettes probably is optimal, but the use of radiant warmers that minimize convective loss also is acceptable. Finally, evaporative losses intraoperatively should be curtailed to minimize heat loss.

The use of warmed solutions for skin preparation and irrigation is important. The use of heated humidified air for ventilation also contributes to the thermoregulatory control of children. It is the Children's Hospital of Los Angeles' routine practice to use humidifiers in all pediatric circuits, maintain warm operating rooms with a high humidity, and use heating pads for all children who are anesthetized. For newborns and small neonates, the operating room should be maintained at 80°F (26.7°C), for infants ages 0–6 months at 78°F (25.6°C), and for children age 6 months to 2 years at 76°F (24.4°C), always maintaining a minimum of 80% humidity. Warming of intravascular fluids and rapidly transfused blood also is necessary. Factors that contribute to infants becoming cold are basically related to their large surface-area-to-mass ratio. In addition, areas richly supplied with blood, such as the head and cranial vault, are proportionally larger in infants, giving rise to heat loss. In premature neonates, this situation is aggravated by their decreased subcutaneous tissue. Some method should be used to eliminate heat loss from the skin surface, especially the head, such as the use of plastic wraps and blankets. Convective warming with forced warm air devices is probably more effective than conductive (heat pad) warming and appears to decrease postoperative thermal stress when used in the recovery area.[2,15]

GENERAL PRINCIPLES OF PEDIATRIC PHARMACOLOGY

The developmental differences among neonates, infants, and adults impact pediatric pharmacology. Until recently, our understanding of pediatric pharmacology was at best, sketchy, and at worst, incorrect. Pharmacokinetic principles that govern the distribution and metabolism of anesthetic agents in adults are not directly applicable to children. Pediatric drug dosages initially were determined by calculating the proportionate amount of an adult dose

on a weight basis. Some assumptions about converting adult dosages to children's dosages on a per kilogram, surface area, or age basis have been proven incorrect.[5] Perhaps no other area demonstrates more clearly that children are not small adults. There are many reasons why merely scaling down dosages on a per-kilogram basis does not yield equivalent drug concentrations or pharmacologic effects. During the development from fetus to adult, factors that affect drug uptake, distribution, metabolism, and sensitivity to drugs change. Volume of distribution, elimination half-lives, drug sensitivity, side effects, organ function, protein binding, and clearance undergo major changes with age.

Complex issues of clinical investigation contribute to the poor knowledge of pharmacokinetics in children. Medicolegal and ethical issues affect the ability to obtain data directly applicable to children. These factors have resulted in a largely empiric approach to pediatric anesthesia. This empiricism is yielding to better-designed, better-informed studies in small children, aided by the advent of microassay techniques that require smaller volumes of blood sampling. There are now several excellent studies of the pharmacokinetics of many agents, including local anesthetics, narcotics, and sedatives, and of the uptake and distribution of inhalational agents in children.

Drug Administration

Anesthetic agents may be delivered orally, rectally, transnasally, percutaneously, conjunctivally, intramuscularly, intravenously, or by inhalation. Administration of drugs across mucous membranes requires passive diffusion, which depends on the concentration and the chemical properties of the agents used and on the amount of surface area exposed. The fact that agents are absorbed across the mucous membrane in the rectum has made this route of administration popular for numerous sedatives and induction agents, such as methohexital, midazolam, thiopental, and ketamine.[62] Because the degree of ionization generally depends on pH and surface area, formulation is particularly important. Rectal absorption is generally slow and uneven, but can be enhanced by large volumes of dilute solutions, which come in contact with a greater surface area.[30] Analgesic agents also can be administered by this route, allowing mild analgesia without the need for oral administration perioperatively. This route is acceptable for most children younger than 5 years old.

Intranasal and transconjunctival administration of benzodiazepines, ketamine, and narcotics has been reported.[1,39,102] Formulation, solubility characteristics, desired end points, and concentration affect the rapidity, duration, and depth of sedation and define an agent's suitability to induce anesthesia. Novel formulations, such as oral transmucosal fentanyl citrate, have yet to find a place in routine clinical practice.[9,62]

Intramuscular administration is not recommended in children because of pain on injection and pain after injection, which may last for several days.[72] Induction, neuromuscular blocking, and analgesic agents may be administered intramuscularly. When no other route of administration of an induction agent is possible, intramuscular ketamine (5–10 mg/kg) might achieve anesthetic induction in agitated, uncooperative children within 5–7 minutes. Although intramuscular administration of narcotics is time-honored, it is generally avoided. Administration of diazepam is associated with burning and muscle pain; however, water-soluble midazolam appears to be less irritating. Pain on injection and its variable duration make intramuscular administration rarely used in children.[72]

The distribution of drugs administered intravenously depends on many factors, most of which are affected by developmental changes. Degree of binding to circulating blood elements, such as proteins and erythrocytes, blood–tissue partition coefficients, distribution of blood flow to various tissue beds, and changes in tissue volumes, affect the distribution of intravenously administered agents.

Drug Distribution

The existence of the free, nonbound, water-soluble moiety in the circulation is required for a drug to cross the endothelium and other cell membranes (where its effect is achieved) and for plasma clearance. The bulk of protein binding is by albumin, however, α_1-acid glycoprotein also is a significant circulating protein to which drugs bind. The concentration of the latter and its contribution to protein binding appear to be greater in older children than in adults. In contrast, infants have low concentrations of α_1-acid glycoprotein, therefore, they may have a larger, unbound, circulating concentration of certain drugs.[112] Curare, metocurine, propranolol, lidocaine, bupivacaine, digoxin, barbiturates, and narcotics demonstrate protein binding. Their protein affinities have a major effect on the pharmacokinetics of drugs in infants and children. Because the protein-bound fraction acts as a reservoir for the drug to maintain tissue and plasma concentrations, concomitant presence of substances that displace drugs from binding sites, such as bilirubin in the neonate, will alter the pharmacology of highly protein-bound agents. Substances that reduce protein binding include free fatty acids, maternal steroids, and sulfonamides. Protein binding affects a drug's volume of distribution. Agents that are poorly protein bound have a larger apparent volume of distribution because the free drug penetrates tissues more easily. Thus a reduction in plasma protein binding causes an increase in the apparent volume of distribution, which partially explains the large volume of distribution frequently found in neonates. Nearly twice as much barbiturate and morphine is bound in the neonatal CNS as compared to what is bound in adults and older children, at least partly as a result of reduced plasma protein binding in neonates.[36] Plasma protein binding also may have a major effect on determination of blood–gas and blood–tissue partition coefficients and leads to developmental differences in uptake and distribution of anesthetics.[20]

The developmental changes of blood flow to various tissue compartments and body fluid composition cause differences in drug distribution with increasing age.[5] Distribution is altered by the relatively small muscle mass and fat stores in neonates, which results in greater flow to the central organs, such as the liver, brain, blood, heart, and kidneys. A water-soluble drug may require a larger initial dosage to achieve a desired blood level. This is relevant for most antibiotics and, most notably, for succinylcholine. The increased volume of distribution also has an effect on clearance, causing delayed excretion and metabolism and prolonged half-lives. A further effect of change in body composition is seen with fat-soluble drugs. Drugs that rely on redistribution

into fat for the termination of their therapeutic effects, such as thiopental, may have a more prolonged clinical effect in younger children. Those that redistribute into muscle, such as narcotics, also have a prolonged effect.[52]

Other factors may alter the uptake and distribution of anesthetic agents. First is the change in the blood–brain barrier that occurs perinatally.[5,88] The integrity of the blood–brain barrier is immature at birth. Because many anesthetic drugs are lipid soluble, this leads to a more rapid uptake of anesthetic agents by the neonatal CNS than occurs in adults. The proportion of blood flow to the brain is higher in neonates than in adults, and for highly lipid-soluble drugs, diffusion across the blood–brain barrier leads to higher brain concentrations and a larger apparent volume of distribution in neonates compared with adults. A second factor that may affect uptake of anesthetic agents arises from differences in dose–response relationships, which may result from receptor affinities, changes in receptor density, or sensitivity with age. With uptake and distribution considered, the minimum alveolar concentration (MAC) of inhalational anesthetics, the hypnotic dose of thiopental, and the sensitivity to succinylcholine have age-related differences that can be explained by potential differences in receptor sensitivity to these agents.

The termination of a drug's effect depends on distribution, metabolism, and excretion. Distribution, as shown previously, varies dramatically with age. Drug metabolism and the enzyme systems responsible, especially cytochrome P450 and hepatic conjugation, also undergo distinct developmental changes.[36,88] Finally, the developmental differences in renal function also have an effect on the clearance and termination of drug effects.

Myriad developmental differences and multiple factors varying dramatically with age determine the uptake, distribution, metabolism, and excretion of anesthetic agents. Thus it is not surprising that there is no simple relationship between age and a dosage calculated on a mg/kg basis.

PREOPERATIVE EVALUATION AND PREPARATION

Examining and preparing children for anesthesia and surgery require a specialized approach because of the unique physiologic and psychological needs of children and their families. The same basic goals of preoperative examination that should be achieved in adults also are applicable to children, but in addition, the emotional and psychological needs of not only the child but the child's family should be addressed. Familiarity with the specific perioperative needs of children and their families is necessary for the anesthesiologist to obtain an appropriate history, physical examination, and thorough preoperative evaluation from a wailing infant, a hyperactive child, or a shy, frightened 5-year-old, without undue trauma for all concerned. In these situations, although it may be difficult, it is necessary to thoroughly examine children. Understanding the physiology and psychology of children is necessary.[47,61]

Purpose

The two goals of preoperative evaluation are (a) for the anesthesiologist to obtain, through interview history and physical examination of the patient, information pertinent to the child's physiologic and emotional preparedness for surgery, and (b) for the patient, to allay the anxieties of the child and parent and prepare them for surgery. Both of these goals are important and should be viewed as necessarily compatible in the anesthetic treatment of children. From the outset, both goals should be constantly kept in mind (Box 19–1).

The anesthesiologist's first contact with the child and family necessarily sets the stage for the remainder of the anesthesia management. The information obtained and the interactions that occur during the preoperative evaluation will determine the quality of the intraoperative management and the postoperative recovery. Although this is obvious when examining the physiologic status of the child, which is used to guide the choice of preoperative medication, induction agent, and anesthetic maintenance, as well as the postoperative requirements, it likewise is true for addressing the emotional and psychological needs of the child and family. Not only should the preoperative evaluation familiarize the anesthesiologist with the child and the parents, it also should provide an excellent and critical opportunity for the child and family to become comfortable with the

BOX 19–1.

Purposes of Preoperative Evaluation

Prepare the anesthesiologist
Prepare the child and family

anesthesiologist and to understand the anesthesiologist's responsibilities. The preconceived notions of children and their families about the events that will occur in the perioperative period and the personnel with whom they will interact form the background for the preoperative interview. The skilled and experienced anesthesiologist is aware of these preconceptions and addresses them whether or not they are mentioned by the child or the family. This anticipatory approach to the child's needs frequently smoothes the path for induction and emergence from anesthesia for the child, the family, and, not unimportantly, the anesthesiologist.

The key to smooth anesthetic management is not only the complete familiarity of the anesthesiologist with the child's medical and psychoemotional background but also of the child's and family's understanding of the procedures associated with anesthesia and surgery. A comfortable and competent anesthesiologist, familiar with all aspects of the perioperative course of surgery in children, is able to optimize this experience for all concerned. This approach applies to infants or older children, as well as to inpatients and outpatients. The exact setting and the child's unique characteristics determine the specific technique for dealing with each circumstance. Whereas it may be necessary in one case to separate the child from the family early and use preoperative sedation, in another case, parental presence during induction and emergence may be the optimal approach. The knowledge and experience of the anesthesiologist are important in determining which approach is best for which child.

The first objective of preoperative examination and preparation is to assure that the child is in his or her optimal status for the procedure planned. The question of whether or not the child can tolerate the anesthetic and surgery is less relevant than in the past. Pediatric anesthesiologists are capable of providing the most advanced physiologic support for children who require complex surgery. It almost al-

ways is possible to provide monitored critical care and analgesia for any surgical procedure. What does vary from patient to patient is not the ability of the anesthesiologist to deliver anesthesia care and assure survival, but the risk to the child for each set of circumstances. The all-important question of whether the anesthetic and surgical risk to the child is greater than the benefits of the procedure should be addressed. Concerns of survival largely are replaced by a precise, accurate, and clear evaluation of the risks of anesthesia for each child, which then can be realistically compared with the child's surgical needs. The underlying goal is that for each child, given the circumstances, the best possible preoperative status will be attained for the procedure. This varies tremendously if the child is undergoing decompression of an epidural hematoma after a traffic accident in which the child has sustained bilateral femoral fractures, a ruptured spleen, pulmonary contusion, and intracranial injury with little time for preoperative assessment compared with myringotomy in a child with Down syndrome and a recently diagnosed atrioventricular canal defect who also happens to be wheezing. Both of these children can be anesthetized and are likely to survive the anesthetic; however, the wisdom of immediately proceeding varies considerably based on the results of an analysis of the specific risk-to-benefit relationship.

It is the anesthesiologist's responsibility to ensure that an accurate assessment of the risks and benefits of the anesthetic is as clear as possible to the child, the parents, the surgeon, and the pediatrician. Careful attention to these details is essential in evaluating and preparing children for anesthesia. Questions of preoperative preparation, timing of surgery, specific surgical procedure, and anesthetic plan are within the anesthesiologist's purview. These should be addressed by the anesthesiologist in the preoperative evaluation. A thorough and adequate examination of the child is essential for identifying and predicting physiologic as well as psychological and emotional problems that the child might encounter intraoperatively and postoperatively.[18,47] The anesthesiologist, armed with this extensive background information, can provide the best intraoperative care and advise on postoperative treatment (Box 19–2).

BOX 19–2.

Preparation for Surgery

- Goal
  - Optimal physical and mental status for surgery
- Contingencies
  - Medical judgment
  - Optimization of medical therapy
  - Timing
  - Psychoprophylaxis of child and family

General Approach

Preconceptions

It is essential to understand some of the preconceived notions that the child and family may have acquired from society and the surgeon. Most parents think that anesthesia is a source of some risk to their child; the spectrum may vary from fear of postoperative nausea, vomiting, headaches, and behavioral disturbances, to fear of a serious threat to the child's life. It is important to recognize, inquire about, and address these issues because these preconceptions frequently differ from the anesthesiologist's view.

Whereas the anesthesiologist may view a child whose American Society of Anesthesiologists physical status (ASA PS) score is P1 for a unilateral myringotomy as being at extremely low risk and very low on the anxiety scale, parents do not necessarily always appreciate this (Box 19–3). They frequently may demonstrate a parental "Moro response" to any perceived threat to their child, no matter how trivial the threat. Any threat to their child naturally may trigger defensive and protective responses, as well as high levels of anxiety in families. The underlying concerns and anxieties experienced by parents of children undergoing what to anesthesia caregivers may be a routine procedure frequently do not qualitatively differ from those of parents whose children have been admitted to the pediatric intensive care unit. For parents of former premature infants and critically ill children, the perception of vulnerability, not surprisingly, heightens anxiety.[3] Although anesthesia caregivers may consider this parental response inappropriate, it is important to recognize that the parents of a child undergoing a routine procedure may be terribly concerned for their child's well-being. A sympathetic and understanding approach to this parental response is a crucial ingredient of expert management. Insuring calm, informed, confident parents is frequently the most essential aspect of insuring calm, cooperative children. Terrified, nervous, defensive, angry, ill-informed parents are incapable of allaying their child's anxieties for the upcoming procedure.[101] Time taken to explain, answer questions, anticipate and allay anxieties, and demonstrate care and concern for the child is time well spent.

BOX 19–3.

Sources of Parental Anxiety

- Anesthesia complications
  - Brain damage
  - Death
- Results of surgery
  - Disfigurement
  - Dismemberment
  - Death
- Separation, loss of control
- Hostility generated by
  - Poor information and communication
  - Apparent lack of due concern by caregivers and physicians

Areas of Childhood Anxiety

Childhood anxieties in the perioperative period center on 5 areas (Box 19–4).[18] The first, fear of injury, is universal; fear of death (even for minor procedures) often is present. Fear of pain and the potential for resulting body disfigurement is common. Second, fear of parental separation (separation anxiety) is common in children age 6 months or older and can be a concern in adolescents. Common sense dictates that the less time the conscious child is separated from the parents the better for all concerned. Apart from obvious humanitarian concerns, a calm, comfortable, nonscreaming child is more aesthetic physiologically and is better able to tolerate anesthesia and surgery than a distraught child.[101] The third

BOX 19–4.

Sources of Childhood Anxiety

- Fear of pain, injury, and death
- Fear of parental separation
- Fear of loss of autonomy
- Fear of the unknown
- Fear of punishment

area of anxiety that correlates with the developmental stage of separation—individuation—concerns fears centered on the loss of individuality and autonomy, which may be a source of considerable stress in children. Taking a child who has spent several years learning to walk, who is comfortable away from his or her parents only for short times, and who has independent control of major functions, and suddenly reducing the child to lying on his or her back, surrounded by what appear to be giants, with no control of the situation, certainly provokes anxiety. Along with the loss of autonomy is the threatened loss of function and loss of control that were won so recently. Anything that can be done to encourage and enhance the child's autonomy and control of the situation, such as allowing choices (e.g., position [sitting, lying, standing], method of induction, which stuffed animal to bring to the operating room, or color of gown) can help calm the child's fears.

The fourth issue is fear of the unknown. Children often are intimidated by the new. Most children will not have undergone either anesthesia or surgery in the past, and this generates anxiety. Recognition of this issue, followed by frank, honest, and as complete a disclosure as possible of the procedures and occurrences that the child will experience is necessary. The child's knowledge reduces the dark, mysterious areas of ignorance and uncertainty. The phrases "it won't hurt" or "you have nothing to worry about" can be some of the most anxiety-provoking words an anesthesiologist can utter. The child knows it is not true and suspects a coverup.

The fifth area, and perhaps the least obvious, is the child's fear of breaching behavioral standards and eliciting from authority figures, including parents, a reprimand. The fear of transgression and punishment is a characteristic underlying anxiety of childhood (and frequently extends into adulthood) and may be a major source of concern to the child. Explaining the permissibility of crying appropriately, of expressing anxiety and fear about the procedure, and of having a negative attitude toward the procedure, thus validating the child's emotions, decreases the anxiety associated with this childhood concern.

These areas should be always remembered and addressed consciously by the anesthesiologist in his or her approach to the child.[47,61] Openness, honesty, and cheerful confidence are the main tools for allaying child and family anxieties and in producing a setting that is most conducive to obtaining information by history and by physical examination. Children are capable of seeing through fraud and spotting lack of confidence. Once their trust is lost, the ability to provide them with the best anesthesia care also is lost. Honestly telling a child that an IV start might be unsuccessful and will be painful is preferable to saying "it won't hurt" and then repeating this painful procedure unsuccessfully several times. Spending the extra time to gently talk a child through a mask inhalational induction frequently may be more rewarding (although more time-consuming) for the child, the parent, and the anesthesiologist, than walking into the room, and with little preparation, jabbing a needle in the child's thigh. Developing the skills necessary to approach children and their families increases the facility with which the anesthesiologist provides the best anesthesia care and increases the rewards of anesthesia practice.[83,115]

From Wetzel RC: Evaluation of Children. In Longnecker DE, Tinker JH, and Morgan GE, et al, eds., *Principles and Practice of Anesthesiology,* Vol I, 2 ed, Mosby, Inc., 1998.

Developmental Stage

Just as an adult approach is inappropriate for the child, so is an approach that does not consider the developmental stage of the child. The anesthesiologist's approach to a 6-month-old infant is different from the approach taken with a 14-year-old pubertal adolescent. Developmental stage determines approach (Table 19–6).

Neonates and Infants Younger Than 6 Months Probably because infants and neonates are unable to express themselves, it is assumed that the psychological ramifications of separation and surgery are minimal. This assumption may be as erroneous as the assumption by earlier medical practitioners that infants were unable to feel pain. Although infants do not have the apparent adverse responses to strangers that are seen in older children (older than 6 months of age) and can be comforted by a nurse or physician, they unquestionably recognize their mother and are comforted by her presence.[53] Consequently, it is judicious to minimize the time children are separated from their parents. For this age group, although direct psychological preparation of children is not possible, parental preparation can form the basis of the approach to neonates and young infants. Experience indicates that fretful, anxious, uptight parents frequently convey this attitude to their young infants. Psychological preparation should be directed toward the child's family. Parents know that anesthesia and surgery present a threat to adults and reason that this threat is much greater for frail infants. Specifically addressing this frequent, although false, assumption, and pointing out that a robust infant undergoing routine surgery is more likely to recover rapidly from the stress of surgery and anesthesia than a grandparent or a parent, is important. Such information can alleviate anxiety and remarkably calm the parents, who, in turn, calm the infant.

Nine months to 5 years Older infants and preschool children ages approximately 9 months to 5 years are in a difficult stage. They are aware of their environment and surroundings, are able to perceive a threat, and can remember painful experiences. Unfortunately, this is combined with an inability to reason and a poor perception of reality. Although these children are able to recognize stressful situations, they are unable to express their fears by modes of communication other than crying, regressive behaviors, sullen withdrawal, or other nonspecific responses to stressful situations.[26] Even though it may not be possible to determine exactly what is most disturbing to a child, attention to the areas mentioned previously and a specific explanation can alleviate their concerns. There is value in explaining what is going to happen and in familiarizing the child with the procedure, even though the child might not appear to be receptive. If this has no benefit other than to demonstrate the anesthesiologist's concern for the child's well-being to the parents, it is worthwhile.

Five Years to Adolescence This developmental stage of childhood is characterized by an increasing capability of expression and reasoning. Gaining control over behavioral and emotional responses is one of the major tasks of this period. The ability to understand and trust adults, even strangers, generally develops during this time. Disclosure of anesthetic procedures and careful, honest, and compassionate explanation of the events that surround surgery generally is rewarded in this age group. Explaining to the child and parents the anesthesiologist's role and what happens during the perioperative period decreases anxiety. In this age group, and throughout adolescence, children's imaginations are well developed. Frequently, this imagination, aided and abetted by exposure to the hyperkinetic modern media (e.g., television), can lead to vivid and distorted anticipation of what actually goes on inside an operating room. As much realistic exposure to personnel, equipment, and methods of dress as possible before the procedure may drive some of these vivid, preconceived, and frequently terrifying notions from the child's (and parents') mind.[61,83] It often is informative to ask the child what he or she anticipates, and, if one is fortunate to have a communicative child, this can be worthwhile.

In older children and adolescents, an underlying fear is that of death. This fear may be reinforced by well-meaning parents, friends, and adults, as well as by medical personnel. Saying that the child "will be put to sleep" or the anesthesiologist's reference to "getting him down" may be counterproductive. Unfortunately, these statements may remind a child of what happened to a pet. In adolescents, the fear of death can be strong, and this, coupled with the loss of control and autonomy that accompanies anesthesia, frequently worries children and teenagers. Talking expectantly and openly about the postoperative period is worthwhile. Discussing how the child will feel and what steps will be taken to awaken him or her and to relieve pain will confidently lead the child away from any notion that he or she will not awaken after surgery.

A "macho" attitude in teenagers may lead them to be trapped in silence with their fears. In dealing with adolescents, it is worthwhile to specifically ask if they have any fears and specifically ask if there is concern about pain and dying. The frequency with which these questions are answered affirmatively is revealing. Understanding these underlying anxieties and specifically, honestly, and openly addressing them is valuable and certainly rewards the time required to do it. This is true even if the adolescent bravely denies such fears.

Preoperative Psychologic Preparation

Psychologic preoperative preparation begins for children before coming to the hospital. Informing the parents that they should explain openly and honestly to the child what is about to occur can begin the child's psychological preparation at home.[114] Honesty and an open demeanor cannot be overemphasized as the cornerstones of this reassurance.[47,83,101] Many hospitals have programs for inpatients and outpatients designed to introduce children and their families to the hospital and operative setting in an enjoyable manner. There are many alternatives for accomplishing these goals, including a preoperative film, a puppet show, a coloring book, a tour of the hospital, and a friendly meeting with doctors and nurses.[47,53] Selecting from these options is not as important as implementing a program to ensure that the child's association with the hospital or surgical center begins on a positive note. This provides a major contribution to the preoperative preparation of children. Younger children, and occasionally older children, should be encouraged to bring familiar things to the hospital. They should bring their stuffed animals and their own pajamas, arrive in their own clothes, and be allowed to retain them as long as possible. Comforting, familiar books and toys certainly should be encouraged. Parents should be reminded of the importance of this. Encouraging older children to be involved in the planning of the surgery also can be beneficial. Allowing them to select the time of surgery and participate in the planning process can raise the young adult's spirits and reassure the child.

During the preoperative evaluation, it should be remembered that the evaluation is a two-way process. Not only does the medical establishment (whether it is a nurse, nurse practitioner, or anesthesiologist) gain information pertinent to the anesthetic management of the child, but the child and family gain information that is useful for building confidence and anxiolysis about the anesthesiologist and hospital setting. It is useful to remember that throughout the interview with the family, the child is the center of attention.[115] The battle may be lost with the parent and child if the anesthesiologist interacts only with the parent to obtain information about the child, tells the parent the procedure, and leaves the room. The initial contact should be made with the child with a cheerful greeting and an attempt made to win the child's confidence before beginning the medical interview. Assuring the child that the main intent is not to inflict injury but to get to know him or her is crucial. No one will appreciate this more than the parents. Making it clear to the child and family that the anesthesiologist takes the child's procedure as seriously as the child does and is there to help, not only during the painful times but also during the anxiety-provoking times, is beneficial. Explanations of how the child will awaken and what will be done to manage pain are worthwhile.

Many parents will expect to be with their child during the induction of anesthesia. This may frequently be a pleasant experience for the child, parent and

practitioner. The benefit for the child has been greatly debated recently.[47] Parents seem to prefer to be present, whereas practitioners prefer they are not. The focus should be on the child and, after much study, parental presence does not appear to provide a significant benefit over preoperative medication. Clearly, tearing a terrified child away from the comforting arms of a parent is difficult for the child, the parent, and the caregivers. If this parental separation cannot be achieved comfortably with preoperative psychoprophylaxis and behavioral modification as described above, or with pharmacologic means, such as preoperative medications including benzodiazepine and barbiturates, then there may be a need to defer parent–child separation until general anesthesia has been induced. Medicating the child preoperatively with an oral benzodiazepine more frequently provides smooth, calm conditions for induction than does parental presence without medication.[47] A confident, competent anesthesia practitioner may be able to reduce the need for preoperative medication. Parental presence appears neither to decrease emergence phenomena nor the incidence of postoperative behavioral changes and does not add an advantage over that provided by preoperative sedative medication, such as oral midazolam.

PREOPERATIVE EVALUATION

Just as psychoemotional preoperative preparation of the child should begin before the anesthesiologist meets the child, the anesthesiologist also should have prepared before the meeting. The anesthesiologist should be familiar with the surgery that the child requires, the surgeon's needs, and the anesthetic implications of the surgical procedure. The anesthesiologist should be as familiar as possible with the child's medical background as documented in the medical records. Communication with the pediatrician and surgeon before meeting the child and family will reveal areas of particular interest to the anesthesiologist before the interview.[115] An anesthesiologist who is aware of the child's name, age, general background, medical problems, and surgical procedure, and who has communicated with the child's pediatrician and surgeon is in a strong position to win the confidence of the child and family. When a child has an extensive previous medical history, it is worthwhile reviewing old records. Specific attention should be directed to the presence of congenital anomalies and pediatric syndromes that may be associated with anomalies that are unrelated to the surgery but that could complicate the anesthetic management. A review of the drug and allergy history may provide information critically important to the anesthetic management.

Finally, if there were any previous anesthetic procedures, careful review of these records may provide an opportunity to improve anesthetic management. Specifically noting whether premedication was necessary, its effect when given, the response to various anesthetic agents, airway management, and emergence particularly may be useful. There may be information in this record that the anesthesiologist wishes to have before speaking to the parents. If the child, after what appeared to be a minor procedure, was intubated and ventilated in the intensive care unit for 3 days, the parents would be, not surprisingly, somewhat skeptical should the anesthesiologist be unaware of this occurrence. In children who have had several operations consideration of latex allergy is important. A review of the previous anesthetic records for unexplained hypotension or wheezing should raise the consideration of latex allergy and the need for latex precautions.[78]

It may be worthwhile to discuss areas of concern with the surgeon and the child's physicians before meeting the family so the family can have the most complete information possible at the preoperative assessment. When meeting with the family, the anesthesiologist can determine the child's general health, level of activity, interests, favorite toys, background, and mental and medical condition. Knowledge of the parents' nickname for the child might be useful during emergence. Finding out which fingers or thumb the child sucks as a guide to IV placement may make the difference between a calm patient and an inconsolable patient postoperatively.

A systems review of appropriate depth always is indicated. A history of current and recent drugs and a history of allergies should be completed in all patients. Specific questioning about previous anesthetics and any history of siblings or family members who have had prolonged awakening, cancelled surgery while in the operating room, intraoperative cardiorespiratory catastrophes, or unexplained fevers specifically should be sought in each case. Frequently, no one else will have asked questions concerning potential drug allergies, malignant hyperthermia, or adverse anesthetic reactions.

Physical Examination

The examination of the child should begin as soon as the physician enters the room. During the time spent obtaining the history from the parents and, when appropriate, from the child, important observations can be made. This period is invaluable for establishing rapport with the child and family. Constant efforts to gain the child's confidence (e.g., by getting down to the child's level [sitting down is necessary], offering a toy, or interacting with the child), are of tremendous help. While discussing the child with the family, attempting to interact with the child and desensitizing the child to the close presence of the anesthesiologist is critical. Briskly walking into the room, interrogating the mother or father, and turning to the child will not yield optimal information from the physical examination. Interacting with, humoring, reassuring, and playing with the child during the interview not only calms the child, but can also provide valuable information regarding the child's general health status, developmental status,[31] respiratory condition, level of activity, state of hydration and perfusion, and level of anxiety concerning hospitalization.

The examination of the child falls into 3 areas: (a) general health and systems examination, (b) areas specifically related to the provision of anesthesia, and (c) areas related to surgery. The physical examination is guided by the findings in the history and interview and the needs of the surgical procedure. As mentioned above, the examination begins when the anesthesiologist first meets the child. A great deal can be learned about the patient's perfusion, hemodynamic status, and respiratory status by general observation. Determining the child's growth and weight (e.g., short stature, failure to thrive) are essential because they guide anesthetic management and may indicate the necessity for closer evaluation (Figs. 19–7 to 19–10).[26,53]

The airway can be assessed by observing phonation, inspiratory sounds, and

respiratory rate; evidence of respiratory distress, such as retractions or tachypnea, are readily noted without interfering with the child. Coughs, runny noses, and upper respiratory tract infections can be detected without hands-on examination of the child. With specific regard to airway evaluation, determining the presence of airway anomalies, such as cleft lip or palate, large tonsils, the state of the child's dentition, loose teeth, or absent teeth is essential. A small jaw or a skeletal anomaly that may indicate a difficult intubation should be noted. It is possible to obtain a fairly comprehensive impression of the child's overall status without actually having to physically examine the child.

Familiarity with the surgical procedure also is necessary. The anesthesiologist should have a fair idea of how extensive the surgery is, whether it will affect airway management, what sort of blood loss to expect, and if there are any particular factors complicating anesthesia management. Concerns about positioning and duration of surgery should be addressed. The presence of a cystic hygroma, for example, should dictate meticulous examination of the airway, auscultation for upper airway sounds, and determination if any airway involvement may have occurred. Discovery of capillary hemangiomas also may indicate the need to rule out airway involvement.

Systems Review

Neuromuscular System

Much will be apparent about the developmental stage of the child's CNS during the initial contact. Conversely, assessment of anesthetically relevant neurologic conditions will depend on the child's age and developmental status. Familiarity with the development of children gives the anesthesiologist a background by which to assess the child (Fig. 19–11). A wide spectrum of neuromuscular disorders that are important to the anesthesiologist accompanies various childhood conditions. In all children, information concerning mental and developmental stage, gestational age, gross motor function, presence of a seizure disorder, and any preexisting neurologic sensory deficits should be sought.

Cerebral Palsy and Mental Retardation A common problem in children who present for surgery for either multiple congenital anomalies or complications after prematurity is mental retardation or cerebral palsy. It should be stressed that not all children with cerebral palsy, even those with severe neuromuscular involvement, are mentally retarded. Incapacitating hypertonicity and spasticity, which may render a child unable to readily express himself or herself, do not necessarily interfere with the ability of the child to understand or the anesthesiologist's responsibility to inform the child about the course of the perioperative period. The anesthetic implications of mental retardation and cerebral palsy are legion. The response to a host of anesthetic drugs, including muscle relaxants, sedatives, analgesics, and hypnotics, varies and is less predictable in these children compared with healthy children. Older children with mental retardation and cerebral palsy also may have significant pulmonary complications that arise from musculoskeletal anomalies caused by imbalance of muscle groups, resulting in scoliosis and kyphosis and leading to restrictive lung pathology. Pharyngeal discoordination, difficulty with handling secretions, and the not infrequent association of gastroesophageal reflux in children with mental retardation and cerebral palsy can lead to recurrent, chronic, pulmonary parenchymal injury, which may complicate the anesthetic management. The presence of gastroesophageal reflux should be sought because it is frequent in this patient population. This may have particular relevance to NPO precautions and may indicate the need for histamine receptor (H_2) antagonism, antacids, agents that hasten gastric emptying, and rapid sequence intubation. Specific questioning about gastroesophageal reflux, recurrent aspiration, recurrent pneumonias, and wheezing should be directed toward the parents, and the anesthetic should be altered accordingly.[108]

Seizure Disorders Children with a history of epilepsy or seizure disorders also are of concern perioperatively. In the past, problems have resulted from a failure to maintain adequate anticonvulsant levels perioperatively. Most oral anticonvulsants can be given on the morning of surgery and have a sufficiently long half-life to assure adequate levels intraoperatively. Sodium valproate and carbamazepine may be exceptions. The anesthesiologist should ensure that the optimal serum levels of anticonvulsants are achieved preoperatively and that these are maintained perioperatively. If a prolonged NPO status postoperatively is anticipated, alteration of anticonvulsant therapy preoperatively may be indicated to include agents that can be given parenterally. A consultation with the child's pediatrician or pediatric neurologist may be required. Preoperative awareness of the child's epilepsy should lead to avoiding epileptogenic anesthetic agents, such as methohexital and possibly etomidate.

Intracranial Hypertension The management of anesthesia for children with intracranial hypertension requires special care. Recognition of the classic triad of hypertension, bradycardia, and apnea in children who may require neurosurgical procedures, or ventricular peritoneal shunts, or who have suffered acute head injury is crucial in determining the anesthetic management of these children. In younger children with chronically elevated intracranial hypertension, the need for perioperative management of intracranial pressure is indicated by complaints of nausea, vomiting, headache, irritability, lethargy, and finding on physical examination of the sunsetting sign. Careful questioning for an acute change in the child's status may indicate the need preoperatively for measures directed at decreasing intracranial pressure, such as diuresis and osmolar therapy. Intraoperative provision of deep anesthesia and controlled ventilation to maintain normocapnia would be wise.

If the child has an existing decompressive shunt, the anesthesiologist should be aware of it. If it contains a valve and pump mechanism, its function should be evaluated. Perioperative fluid shifts may alter cerebrospinal fluid (CSF) function and upset the balance of CSF production and drainage, leading to elevated intracranial pressure and perioperative catastrophe, especially in the anesthetized child. Assurance of shunt patency and functional history is necessary.

Muscular Dystrophy Congenital neuromuscular disease, such as muscular dystrophy, myotonic dystrophy, and acquired diseases, such as myositis, dermatomyositis, and collagen vascular

FIGURE 19–11. Denver Developmental Screening Test serves as a guide to the development of language, motor, and social skills of children aged from 1 month to 6 years. (Reproduced with permission from Frankenberg WK and Dodds JB.[31])

diseases, raise questions concerning the use of muscle relaxants. In patients with myotonic dystrophy, the use of succinylcholine should be avoided.[67] Although this is less clear in patients with some of the muscular dystrophies, the occurrence of rhabdomyolysis and the suspicion of an increased incidence of malignant hyperthermia in patients with Duchenne muscular dystrophy suggests caution in the use of depolarizing muscle relaxants and inhalational

BOX 19–5.

Neuromuscular Diseases in Which Neuromuscular Agents Should Be Used with Caution

- Muscular dystrophy
  - Facioscapulohumeral
  - Duchenne
- Myasthenia gravis
  - Eaton-Lambert (very rare)
- Cerebral palsy
- Myotonias
  - Myotonia congenita
- Spinal muscle atrophy
- Spina bifida (thoracic level)

anesthetics.[65] The use of nondepolarizing muscle relaxants in children who have muscle weakness and neuromuscular impairment should be guided by meticulous perioperative monitoring and perhaps are best avoided when possible (Box 19–5).

The majority of neurologic deficits and impairments will be obvious from a review of the patient's records, the parents' interview, and observation of the child. If detailed neurologic examination and documentation are required, or if the presence of serious CNS disease is suspected, a pediatric neurologist should be consulted. With the increasing use of regional anesthesia, it is wise for the anesthesiologist to search for and document existing neurologic deficits before performing nerve blocks.

Respiratory System

A host of illnesses and congenital abnormalities affect respiratory function in children. Many congenital anomalies are associated with small, difficult-to-visualize airways, upper airway obstruction, and difficult intubation. All of these conditions should specifically be sought and investigated whenever the suspicion arises (Table 19–7). The relatively small diameter of a child's airway, a child's different anatomic makeup, and high oxygen consumption relative to FRC put children at increased risk for developing hypoxia, decreasing the margin for error.

Specific questioning about airway obstruction (e.g., snoring), recurring episodes of croup, tonsil or adenoid hypertrophy, and any history of apnea, is part of routine history taking in pediatric anesthesia. Noticing characteristic facies, such as those associated with Treacher Collins syndrome, Pierre Robin syndrome, or Hunter and Hurler mucopolysaccharidosis, is an essential skill of the pediatric anesthesiologist in detecting the potential for difficulty with intubation and upper airway obstruction perioperatively. Careful examination of the nares, of the oropharynx for loose teeth, and for the presence of respiratory distress indicating airway obstruction should be part of every examination. Routine attention to these airway issues may prevent potentially lethal complications in the operating room.

Assessment of children with chronic respiratory disease also is necessary. The high frequency of chronic lung disease (bronchopulmonary dysplasia [BPD]) in former premature infants who required ventilatory support in the neonatal period should be remembered.[93] Evidence should be sought for this in the patient's record and by questioning the parents. BPD may range from mild recurrent wheezing to a chronic oxygen requirement—even mechanical ventilation at home. In children with BPD and asthma, the anesthesiologist should be completely familiar with the child's respiratory status and ensure that therapy has been optimized preoperatively. The child's exact therapy should be ascertained, and when possible, an effort should be made to ensure that an appropriate doses of bronchodilator therapy have been achieved. A history of recent steroid use should be sought, and consideration should be given to initiating steroid therapy preoperatively.

Particular attention should be directed to the history of exercise tolerance in children with or suspected of having chronic lung disease. In patients with musculoskeletal disease, especially kyphosis or scoliosis, one should seek evidence of restrictive lung abnormalities. Preoperative investigations in children with chronic lung disease may include determination of blood gases and pulmonary function tests. A cardiac examination with electrocardiography and possibly echocardiography may be necessary to discover and define the severity of pulmonary hypertension and cor pulmonale.

Acute lung disease is an indication for canceling elective surgery. Pneumonia, croup, and acute asthma pose serious perioperative threats, both acutely as well as after apparent resolution. Airway reactivity is increased for several weeks after an acute asthmatic attack.[7,94] Deteriorating pulmonary status caused by viral or bacterial infection, superimposed on BPD, cystic fibrosis, or asthma may cause serious intraoperative hypoxia, increased secretions with the risk of endotracheal tube obstruction, and difficulty in maintaining airway patency. Postoperative atelectasis and pneumonia can be serious complications after surgery. Specific questioning about episodes of apnea should be included because these may be associated with fatal postoperative respiratory difficulties.[54]

Runny Nose Problem Frequently, the problem of the child with a runny nose arises. Rhinorrhea can be caused by an acute viral or bacterial upper respiratory tract infection (URI), allergic rhinitis, or foreign object. There is evidence that recent URIs increase airway hyperreactivity for 6–8 weeks after infection.[7] Anecdotally, most anesthesiologists believe that URIs are associated with increased secretions, incidence of laryngospasm and bronchospasm, endotracheal tube obstruction, and intraoperative respiratory difficulties.[63] An increased incidence of postintubation stridor and other postoperative respiratory complications also has been reported.[19] Experience in recent years has failed to substantiate an increased risk of complications in patients with simple URIs.

When is it appropriate to cancel elective surgery on the basis of rhinorrhea? The patient should be in optimal condition before induction of anesthesia. The recent onset of mucopurulent rhinorrhea, especially if accompanied by pharyngitis and fever, is an indication for cancellation of elective surgery. The child who always has clear rhinorrhea on the basis of allergic rhinitis probably is at no increased anesthetic risk. Multiple considerations, such as the inconvenience to the family because of long travel or arranged time off work, the potential of complications from delaying surgery, and the risks of proceeding, need to be weighed when deciding whether to proceed. With healthy children who are afebrile and have clear rhinorrhea, we proceed with elective surgery. Anesthesia caregivers are more cautious with other respiratory diseases, especially asthma and BPD.[7,94] Although this topic remains controversial, whenever possible, surgery and anesthesia should be delayed for at least 2 weeks.[43]

TABLE 19–7.

Common Syndromes Associated with Difficult Intubation

Syndrome	Airway	Associated Anomalies
Achondroplasia	Small nares and mouth	Hydrocephalus
	Midface hypoplasia	Atlantoaxial instability
	Megacephaly	Atropine sensitivity
Apert	Narrow, occasionally cleft palate	Mental retardation
	Small maxilla	Cardiac anomalies
	Craniosynostosis	Renal abnormalities
	Flat facies	Syndactyly, often severe
Arthrogryposis, congenital	Small mandible	Scoliosis
	Cleft palate	Ventricular septal defect
	Torticollis, contracture	
	Klippel-Feil syndrome	
Beckwith-Wiedemann	Large tongue	Retardation
	Prognathism	Hypoglycemia
		Exomphalos
		Gigantism
Cornelia de Lange	Micrognathia	Cardiac abnormalities
	Short neck	Retardation
	Cleft palate	
	Mandibular spurs	
Crouzon	Small maxilla	Proptosis
	Large tongue	
	Craniosynostosis	
Down	Large tongue	Cardiac abnormalities
	Small mouth	Atlantoaxial instability
	Small mandible	Hypotonia
Goldenhar	Small mandible and zygoma	Cervical spine defects
	Cleft palate	
	Macrostomia	
Congenital hypothyroidism	Large tongue	Hypothermia
		Retardation, if untreated
		Umbilical hernia
Freeman-Sheldon (whistling face)	Very small mouth	Scoliosis
	High palate	
Klippel-Feil	Short neck, limited extension	Deafness
		Ventricular septal defect
Marfan	Narrow face	Cardiac anomalies
	Narrow palate	Scoliosis
		Restrictive lung disease
Möbius	Small mandible	Talipes equinovarus
	Small mouth	Ptosis
	Aspiration	Cranial nerve palsies
Mucopolysaccharidosis	Large tongue	Cardiac abnormalities
	Narrow airway	
	Limited opening	
Pierre-Robin	Micrognathia	
Robinow	Small mouth	Hemivertebra
	Micrognathia	Hypertelorism
	Crowded teeth	Atrial septal defect
	Large tongue	
Rubinstein-Taybi	Small maxilla	Retardation
	Narrow palate	Cardiac anomalies
		Cervical instability
Russel-Silver	Small stature	Hypoglycemia
	Small mandible

Cardiovascular System

Because of the multiple cardiovascular effects of anesthetics in children and the frequency with which cardiac anomalies accompany other congenital malformations, particular attention to the cardiovascular system is necessary (Table 19–8). Recognition of the setting in which congenital heart disease may occur, coupled with careful attention to the previous history and questioning of the family, help define the type and severity of the defect. Examination of the child may lead to discovery of hitherto undiagnosed cardiac defects or to the presence of a cardiac murmur and demonstrate the need to alter the anesthetic plan and perhaps to seek further pediatric cardiology consultation. The cardiovascular system undergoes significant developmental changes, and reference to normal age-related values is essential in assessing children (see Figs. 19–4, 19–5, and 19–6).[84,80]

Poor exercise tolerance, as in adults, is a hallmark of inadequate cardiovascular function. Children who tire easily, become tachypneic, have dyspnea on exertion, or have orthopnea must be evaluated carefully. In infants, the major exercise is feeding. An irritable child with a history of poor feeding accompanied by diaphoresis and tachypnea may have borderline cardiac function. Failure to thrive may indicate compromised cardiac function. In younger infants, clubbing is never present, and cyanosis may be difficult to detect. Palpation and auscultation remain the cornerstones of the cardiology examination. Particular attention should be paid to the presence of a brachial–femoral delay, indicating coarctation, and for left and right ventricular heaves. Detection of a new murmur frequently raises the question of whether it is benign or significant. Differentiating between a venous hum or ventricular outflow murmur and more serious murmurs requires specific examination (Table 19–9). When in doubt, consultation with a pediatric cardiologist is indicated. The child with a murmur who is asymptomatic, acyanotic, healthy, and gaining weight along appropriate percentiles and who has a normal S_1 and S_2, almost certainly will tolerate routine anesthesia without serious complications. Questions arise regarding the need for further cardiology followup, evaluation and subacute bacterial endocarditis (SBE) prophylaxis (Table 19–10 and Box 19–6). When the history and physical examination indicate possible serious cardiac disease, a hematocrit, electrocardiogram (ECG), chest radiograph, and oxygen saturation (pulse oximetry) form the basis of the laboratory workup. In patients with known serious heart disease, the anesthesiologist should understand the anatomy and physiology of the defect. A hemodynamically inconsequential atrial septal defect, ventricular septal defect, mitral valve prolapse, or the presence of a bicuspid aortic valve may predispose the child to an untoward intraoperative event, and consultation with a pediatric cardiolo-

BOX 19–6.

Subacute Bacterial Endocarditis Prophylaxis

- Indications
- Moderate risk (routine)
  - Congenital or acquired valvular heart disease (rheumatic heart disease)
  - Hypertrophic cardiomyopathy
  - Mitral valve prolapse with regurgitation
  - Subaortic stenosis
- High risk (maximal)
  - Surgically constructed shunts (Waterston, Blalock-Taussig, Potts, etc.)
  - Complex cyanotic heart disease (single ventricle, transposition of the great arteries, tetralogy)
  - Prosthetic valve
  - Previous bacterial endocarditis
- Procedures
  - All genitourinary or gastrointestinal operations
  - Tonsillectomy/adenoidectomy
  - Endoscopic retrograde cholangiopancreatography, stricture dilation, biliary tract surgery
  - Dental extractions, implants, where gingival bleeding is anticipated, endodontics, periodontal surgery, initial placement of orthodontic bands
  - Incision and drainage procedures
  - Airway surgery or rigid bronchoscopy
- Prophylaxis not necessary for secundum atrial septal defect or patent ductus arteriosus repaired >6 months ago, endotracheal intubation, tympanostomies

gist may be indicated. For most children with heart disease, it is prudent to obtain a recent consultation with the child's pediatric cardiologist.

Renal System

Asymptomatic renal disease, apart from bacteriuria, is rare in children. The likelihood of discovering a new renal lesion during routine physical examination done for the preanesthetic evaluation is almost nonexistent. The presence of hypertension (see Table 19–3) should indicate the need for urinalysis and electrolyte analysis.[38] The unexpected presence of anemia also may indicate chronic renal disease. The anesthetic implications of renal disease in the presence of normal electrolytes, normal

growth and development, and normotension, are minimal. In infants, there may be the inability to concentrate urine or to handle a large fluid load, both of which dictate cautious fluid management perioperatively.

In the presence of serious preexisting renal disease, careful attention should be paid to the child's preoperative preparation. If the child requires dialysis (peritoneal dialysis or hemodialysis) to maintain optimal electrolyte levels and growth, consideration of dialysis on the day before surgery is indicated. Antihypertensive therapy, if required, should be optimized. Electrolytes should be monitored carefully. Particular attention is necessary concerning the serum potassium concentration. Serum potassium greater than 5.5 mEq/L is worrisome in children with renal disease. The propensity of succinylcholine to induce hyperkalemia in patients who may have a concurrent metabolic acidosis puts these patients at particular risk. Elective surgery should be cancelled in the presence of a potassium level higher than the acceptable upper level of normal for the individual hospital's laboratory (5.5 mEq/L, generally). Regarding hematocrit in patients with chronic renal failure, there is some controversy. It is usual practice to accept a lower hematocrit (20%) in these children than would be normally tolerated. This is based on the assumption of chronic adaptation, which includes increased blood volume and increased cardiac output. These may be compromised during anesthesia. Although the child may be chronically adapted, it should be remembered that the reserve necessary to tolerate the stresses that may accompany anesthesia and surgery is markedly decreased. Preoperative erythropoietin therapy and transfusion before surgery may be administered if time allows.

Gastrointestinal System

The major anesthetic issues concerning the GI system center on a predisposition to aspiration pneumonitis. Children with increased gastric residual volumes and gastroesophageal reflux should be identified preoperatively. Those children who have a history of tracheoesophageal fistula, mental retardation, cerebral palsy, apnea, and recurrent aspiration pneumonia always should be suspected of having gastroesophageal reflux (Box 19–7).[77,108] Careful scrutiny of medical records and questioning of the parents may indicate that gastroesophageal reflux has been evaluated in the past. If not, consultation with pediatricians might prove worthwhile. The history of recurrent aspiration pneumonia in a child with a predisposing condition raises the likelihood of aspiration during anesthesia, and a rapid sequence induction is indicated. The treatment of children with gastroesophageal reflux includes administration of antacids, histamine (H_2) receptor antagonists, agents that encourage gastric emptying (metoclopramide), and the Sellick maneuver during induction and intubation.[58] Consider awake intubation in young infants.

BOX 19–7.

Conditions Associated with Gastroesophageal Reflux

Apnea
Prematurity
Recurrent pneumonia syndromes
Cerebral palsy or mental retardation
Gross obesity
Tracheoesophageal fistula
Bronchopulmonary dysplasia
Pregnancy
Recurrent, persistent vomiting

Halothane hepatitis developing de novo in children appears to be exceedingly rare, occurring in perhaps less than 1 in 50,000–250,000 anesthetic inductions.[56] The relationship between the occurrence of halothane toxicity in patients with previous liver damage and resulting hepatitis is unclear. Many premature infants have abnormal liver function tests and elevated bilirubins. Some children also may have hyperbilirubinemia and elevated transaminases. Although the advisability of using halothane under these circumstances is not clear, it probably is best avoided because suitable alternatives are available. Currently, sevoflurane has almost entirely replaced halothane in practice, and reports of hepatitis following sevoflurane are extremely rare.

Laboratory Investigations

It may seem surprising that the American Society of Anesthesiologists, the American College of Surgeons, and the American Academy of Pediatrics do not make any specific recommendations for preoperative testing in children.[4] Specific laboratory testing that is indicated by information obtained from the chart review, history, and examination of the child is straightforward. Routine testing for healthy children remains controversial. In the past, guidelines that had been developed for adults were applied to children. These tests included a complete blood count, urinalysis, and chest radiograph. With the streamlining influence prevalent in healthcare systems today, critical appraisal of the need for these examinations has been undertaken. All aspects of the preoperative laboratory investigation have been questioned. The standard that required a routine chest radiograph in healthy children without symptoms or signs was abandoned.[113] Recent experience with large numbers of outpatient anesthetics has raised serious questions about the need for routine performance of other laboratory tests. In general, preoperative laboratory testing should be dictated by the child's condition and status, rather than merely by the need for an anesthetic.[61]

Hematology

It generally is accepted that a preoperative hematocrit is unnecessary in most healthy children for operations in which significant blood loss is not expected. The value of a complete blood count and whether there is a role for determination of platelets and coagulation studies are also unclear. These decisions should be guided by patient considerations. There are developmental differences in the standard level of hematocrit (Table 19–11).[71] For years, "normal" hematocrits were required for elective surgery. Later, the lower limit of normal (i.e., hematocrit of 30% or a hemoglobin of >10 g/dL) became the requirement. Elective surgery probably should await attaining this level, short of transfusion. Iron and nutritional support are indicated. In the emergent situation, transfusion therapy may be indicated as directed by patient need, such as anticipated blood loss and cardiorespiratory status. Transfusion should not rely on arbitrary and unsupported boundary of "normal" hemoglobin.[73]

What are the essential considerations? In a healthy child with normal cardiorespiratory function, a fully saturated hemoglobin of 10 g/dL would require a cardiac index of 3.4 L/min/m^2 to provide an oxygen delivery 3 times the average oxygen consumption. If the child's hemoglobin were 7 g/dL (hematocrit approximately 20%), a cardiac

TABLE 19–11.

Mean Hematocrit and Hemoglobin versus Age

Age	Hct (SD) %	Hgb (SD) g/dL
1–3 days	56 ± 5	18.5 ± 2.0
2 weeks	53 ± 4	16.6 ± 1.6
1 month	44 ± 5	13.9 ± 1.6
2 months	35 ± 4	11.2 ± 0.9
6 months	36 ± 3	12.6 ± 0.7
6–24 months	36 ± 2	12.0 ± 0.8
2–6 years	37 ± 2	12.5 ± 0.5
6–12 years	40 ± 3	13.5 ± 1.0
12–18 years	43 ± 4	14.5 ± 0.7
Adult	41 ± 2	14.0 ± 1.0

From Rowe PC. Laboratory values. In Oski FA, De Angelis CD, Feigin RD, et al, editors: *Principles and practice of pediatrics*, Philadelphia, 1990, JB Lippincott.

index of 4.8 L/min/m^2 is required to maintain the same level of oxygen delivery. This is well within a healthy child's cardiac reserve and should represent no major difficulty. The assumptions underlying this are that the child remains 100% saturated, receives no cardiac-depressant drugs, and loses little blood. These circumstances frequently cannot be guaranteed during surgery and anesthesia, and this lack of guarantee is the key issue. The major concern is not for healthy children having minor surgery, but when surgery will result in blood loss and lower this margin of reserve further. A child whose hemoglobin drops to 5 g/dL from 10 g/dL should double cardiac output to around 6.6 L/min/m^2 to maintain oxygen delivery. This remains well within the average child's cardiac reserve. If a child's hemoglobin drops to 2 g/dL from 7 g/dL intraoperatively, the child requires a cardiac index of nearly 17 L/min/m^2 to maintain a marginal oxygen delivery, which is beyond the ability of even the healthy child's cardiovascular system to compensate for, especially when anesthetized.

A third issue that frequently is raised is adaptation. The classic teaching is that children with renal disease tolerate lower hematocrits because they have had time to adapt. There is little evidence to demonstrate this is so; 2,3-diphosphoglyceric acid may not be increased in children with renal disease, and there is no reason to suggest that they have a shift in the oxyhemoglobin dissociation curve. The concept that they can adapt to lower levels of oxygen delivery or consumption is unsupported. If serious blood loss is expected perioperatively, the margin of safety is considerably less in patients who begin with low hematocrit.

As mentioned above, there are no absolute guidelines for preoperative hematocrit, and at present, each anesthesiologist should decide on a standard for each child. Motoyama and Glasner[69] found that a hemoglobin of 7.5–8.5 g/dL will deliver oxygen to the tissues of children equivalent to what a hemoglobin of 10 g/dL will in adults. In neonates, 12–13 g/dL is necessary. This is largely related to shifts in the P50 (partial pressure of oxygen at which hemoglobin is 50% saturated).[69] It seems reasonable that a hemoglobin of 8 g/dL in an ASA PS P1 child may be acceptable if no major perioperative blood loss is expected. A child who has chronic restrictive lung disease and is about to undergo scoliosis repair probably should have a hemoglobin higher than 10 g/dL (at least initially).

Many abnormalities can be discovered during preoperative laboratory screening.[48] These abnormalities fall into two categories: those that are relevant to the anesthetic management of the child and those that are relevant to the child's general health. The degree to which a preanesthesia screening clinic wishes to be responsible for the general healthcare of children needs to be determined by each facility. There is a responsibility to ensure followup evaluation for abnormal laboratory tests that may be discovered coincidentally with preoperative assessment. O'Connor and Drasner[74] reported that 17% of children who had a complete blood count (CBC) were anemic or had a microcytosis. Only 2 of these children had surgery cancelled because of anemia (hemoglobins <10 g/dL).[74] A mechanism to arrange followup evaluation with the pediatric clinic should be available, and communication should be assured.

Sickle Cell Disease The American Academy of Pediatrics recommends that a sickle preparation or other screening test be performed in all children of African descent.[99] Is it reasonable for the anesthesiologist to insist on receiving the results of a sickle cell preparation in all children of African descent requiring anesthesia and surgery?[28] Is anesthetic management different for those who have sickle trait than for those who do not? Is it necessary to have a sickle cell preparation in nonanemic at-risk children? Anesthetizing a child with sickle cell disease who is anemic and with 95% sickle hemoglobin poses a major threat to that child and should never be undertaken without good reason. The likelihood of a child older than age 2 years with a normal hemoglobin having sickle cell disease is extremely low. If all children with hemoglobins less than 10 g/dL require further investigation, among the factors to be investigated, in addition to iron deficiency, is sickle hemoglobin status in at-risk children. This might not apply to neonates or infants who may have hemoglobin concentration greater than 10 g/dL and have sickle cell disease and high levels of sickle hemoglobin. Unless a sickle hemoglobin preparation is performed, cases might be missed in this population which is at risk for hypoxia and low cardiac output during anesthesia. Common practice is to perform a sickle cell preparation on all children of African descent unless their status is known and to screen for anemia in all other children. In those with positive sickle screen, hemoglobin electrophoresis is required.[23,60] It should be noted that infants younger than age 4 months have maternal antibodies that interfere with performing a quick sickle index preparation. These children require hemoglobin electrophoresis to determine their sickle cell disease status.

Does sickle trait pose a threat to older children who may not be anemic but who have some amount of sickle hemoglobin? Although there are some anecdotal stories of sickling and rare vasoocclusive phenomena in children with sickle cell trait during anesthesia with resulting hypothermia, ischemia, and hypoxia, sickle cell trait generally is associated with less than 40% of hemoglobin S in the circulating blood.[60] This is the target level that is obtained with transfusion protocols for sickle cell disease. Prudent avoidance of tourniquets that cause blood stasis and hypoxia in the affected limb probably is wise in patients with sickle cell trait. Anesthetic management will not vary because the routine goals of anesthesia (avoidance of hypoxia, hypothermia, hypovolemia, and hypotension) are as important in routine anesthetic management as they are for patients with sickle cell trait.[29,60]

In patients with sickle cell disease, preoperative treatment is directed at reducing sickle hemoglobin to less than 40%. Chronic transfusion, exchange transfusion, and acute blood transfusion are reported to be useful in achieving this goal.[99,100]

Leukocyte Counts In one study, leukocyte counts were abnormal only in patients who were ill or otherwise suspected of having an infection.[61,71] No occult leukocytosis was discovered in 463 preoperative screening evaluations.[74] When indicated by suspicion of sepsis, infection, fever, or respiratory tract infection, a CBC might be useful in arriving at the diagnosis; however, routine leukocyte determination does not appear to be warranted.

Urinalysis

Routine urinalysis is part of preoperative recommendations in children. Apart from providing a possible contribution to routine health screening, the relevance to anesthetic management is unclear.[55,61] In children who are febrile, have congenital anomalies of the urinary tract, or have suspected renal function anomalies, urinalysis might be beneficial. In otherwise healthy children in whom urinalysis can be difficult to obtain and unreliable, abnormal results appear to occur in 15% of children and usually are asymptomatic bacteriuria.[74] The majority of these are either false-positive results, clinically insignificant, or previously known. In only 2 of 453 cases was surgery cancelled, and both of these were cancelled because of suspected colonization or asymptomatic bacteriuria, which was of no anesthetic relevance. In afebrile, ASA PS P1 children with no history of renal disease, most centers have abandoned routine urinalysis.

Screening for pregnancy varies widely from center to center. The evidence that anesthesia, per se, is deleterious to the continued pregnancy or the fetus is extremely sparse. On the other hand, the logistic, behavioral, privacy, and social implications of testing all female children of child-bearing age for pregnancy, with or without consent, are quite complex. Each institution must resolve these issues for itself.

Drug Levels

In children who are receiving therapeutic drugs, it frequently is worthwhile to know whether the therapeutic level has been achieved. The two major areas in which this is of concern are in children with epilepsy and asthma. Obtaining routine blood levels of theophylline (although now only rarely used) and anticonvulsants to ensure compliance with therapy and adequate levels for the perioperative management appears to be a wise precaution. It is not so clear what should be done when an abnormal result is found. Does an asymptomatic healthy child with a nontherapeutic drug level require therapy? Should therapeutic levels of indicated drugs be achieved before elective surgery? These decisions may require input from the child's primary care physician and perhaps a pediatric neurologist in children with epilepsy. Frequently, it is worthwhile to inform the primary caretaker that the level is subtherapeutic, so that the drug can be discontinued before surgery. There is a caveat. Discontinuing anticonvulsants may lead to withdrawal seizures, which is not a pleasant prospect perioperatively. Asymptomatic children with low theophylline levels may not be wheezing on the day of examination but may develop wheezing on the day of surgery and may have serious underlying bronchial hyperreactivity, which may pose difficulties intraoperatively. Our current practice is if a child requires theophylline to suppress wheezing episodes, the child requires therapeutic theophylline levels perioperatively. If this is not possible, knowing the level will allow the anesthesiologist to specifically direct therapy intraoperatively if required. Further testing is guided by the patient's underlying medical condition.

Preoperative assessment for elective surgery should be done early enough to allow all special investigations to be performed before surgery. Consultation with other services and the performance of other investigative procedures, such as computed tomography (CT) scans, ECGs, and echocardiograms, should be timed so that the results will be available to the anesthesiologist before induction of anesthesia. Deciding that such information is important preoperatively but acting before it is obtained or reported sets the stage for medical or legal misadventures.

NPO Status and Preoperative Fasting

Of all the shibboleths of pediatric anesthesia, perhaps the one most time honored and most frequently under attack is the duration of preoperative fasting. The days of NPO after midnight for all children who require surgery is over. For years, we have realized that small infants, with their unique glucose and fluid requirements, do not benefit by being NPO for 12 hours before surgery. Serious hypovolemia with intraoperative hypotension and hypoglycemia is the result.[61,105] Concerns have been raised about hypoglycemia occurring in older children after a prolonged fast.[45,96,105] There also are concerns about comfort and the need for the imposition of starvation on children preoperatively. The goal is to reduce gastric volume and minimize the risk of aspiration pneumonia perioperatively. There are many studies looking at factors predisposing to gastric acid aspiration and lung injury and their relationship to gastric residual volumes. The fact remains that perioperative aspiration pneumonia is remarkably rare (a fact that may attest to the success of severe NPO restrictions).

There is little evidence that in a healthy child prolonged fasts are required to ensure minimal gastric volumes. NPO for solid foods and large meals for 8 hours before surgery should be maintained because gastric volumes may be increased for up to 6 hours. The question becomes less clear with fluids. Several studies demonstrate that ad lib clear liquids up until 2 hours before surgery are associated with lower gastric volumes and higher pHs than those found in fasting patients.[59,87] If this is the case, the recommendation ought to be to encourage oral clear fluids preoperatively rather than to limit them. Studies demonstrate that not only is there no major burden of hypoglycemia placed on the healthy child by fasting, but that feeding the child clear liquids is not associated with increased gastric volumes.[64]

The final factor that needs to be considered is whether one should change an age-old guideline for a more liberal approach that may be confusing and lead to unintended changes in other requirements. The guideline of NPO after midnight perhaps is draconian, but it is clear to all concerned. No solids after midnight and clear liquids up to 1 hour before surgery ad lib, if the patient is healthy, without gastroesophageal reflux, or other significant GI disease, certainly is less

clear. These liberal rules are bound to be applied in inappropriate situations, potentially leading to catastrophe. Some major institutions allow clear liquids until 1–2 hours before surgery in their outpatients, and a large series reported from the Children's Hospital of Philadelphia reports no incidence of gastric aspiration after years of this approach.[87] ASA guidelines indicate fasting for clear liquids from 2 hours preinduction. Communication, education, monitoring current protocols, and flexibility in approach, based on known facts, should form the guidelines for anesthesia practice. This is no less true regarding preoperative fasting rules. The trend is toward more liberal fasting requirements for clear liquids (Table 19–12).[21,25]

One final question: What are clear liquids? Water, glucose water, and commercially available pediatric electrolyte solutions are clear. Some institutions consider breast milk a clear liquid and cow's milk a solid food. Breast milk is not emptied as rapidly as clear liquids from the stomach and the ASA guidelines state breast milk should not be given within 4 hours of induction. Some institutions encourage gelatin (no additives) and fruit juices, including pulp-free orange juice, as perfectly allowable. It is unlikely that there will be hard scientific data to aid the anesthesiologist in these decisions. The application of common sense and the provision of clear instructions for families are essential. Simplicity is best. Adhering to local protocols is important to avoid confusion and ignoring stated regulations is detrimental to the organized anesthetic care of children.

TABLE 19–12.

Fasting Guidelines Childrens Hospital Los Angeles: The 2-4-6-8 Rule

Time Prior to Anesthetic	All Age Groups	Example
Up to 8 hours	Full diet	
Up to 6 hours	Liquid diet, infant formula, milk	Formula, jello
Up to 4 hours	Breast milk, clear liquids	
Up to 2 hours	Clear liquids only	Electrolyte, glucose, water solutions, apple juice
From 2 hours before	NPO	

EVALUATION OF THE CRITICALLY ILL CHILD

Intraoperative treatment of critically ill children can present the anesthesiologist with great challenges. The use of cardiovascularly active anesthetic agents in critically ill children can demand the most meticulous anesthesia care. Thorough preoperative evaluation and preparation is essential to assure optimal intraoperative management. A rigorous, compulsive systematic evaluation of critically ill children is essential, and although it follows the basic outline of systems review, the underlying assumption is that the severity of illness in each system is much worse than in the patient for elective surgery.

Establishing rapport with a child in an intensive care unit can range from difficult to impossible. An unconscious, heavily sedated, paralyzed child requiring mechanical ventilation and neuroresuscitation will not be communicative. Discussing the anesthesia care with the child's family often may be awkward because survival is the parents' primary concern. Before contacting the family, it is essential that the anesthesiologist be completely familiar with the child's problems so that the parents can be confident that all physicians who are caring for their child are knowledgeable and concerned. Many parents have bonded with the intensive care unit staff, and transferring their child's care to other physicians can provoke anxiety. The anesthesiologist needs to demonstrate concern and state that the intraoperative care and management will be as meticulous as that provided for the child in the intensive care unit. Although it is natural to focus entirely on the child's immediate surgical needs or indication for admission to the intensive care unit, other problems that may have anesthetic importance should be sought as they would be in a routine evaluation. A systems review, previous drug and allergy history, and family history should not be neglected.

Neurologic Status

The level of consciousness, presence of CNS injury, intracranial pressure, and neurologic deficits specifically should be determined. Psychotropic drugs, sedatives, and other obtunding agents that may supplement, augment, or interact with anesthetic agents should be identified. Some children in the intensive care unit will be essentially anesthetized at transfer to the operating room, whereas others may have received little medication. Complete review of current neurologic status and psychotropic drugs is mandatory.

Respiratory Status

Respiratory evaluation should be meticulous. The level of oxygen required, respiratory rate, ventilatory rate, tidal volume, airway pressures, and arterial blood gases form the basis of this information. If the child requires a ventilator, it is necessary to be familiar with the degree of ventilatory support the child requires, including the fraction of inspired oxygen (FiO_2), mean airway pressure, peak end-expiratory pressure, and respiratory rate. A blood gas just before transfer to the operating room may provide critical information. Anesthesia machine ventilators, although more than adequate for patients with normal pulmonary function, may be inadequate in those with advanced stages of lung disease. The anesthesiologist should be able to organize sophisticated ventilatory support in the operating room when indicated. This should be done before transfer of the child to the operating room in conjunction with respiratory therapy.

Cardiovascular System

Complete familiarity with the child's hemodynamic function is essential. All patients in the critical care unit should be suspected of having compromised cardiovascular function and borderline oxygen delivery. Complete evaluation of perfusion status, temperature, and hemodynamic information as obtained from invasive monitor catheterization should be reviewed

and optimized. Optimization of intravascular volume and the hematocrit and availability of blood products should be ensured. Finally, a review and optimization of cardiovascular drugs the child is receiving should be undertaken. It is necessary to ensure that constant, uninterrupted delivery of cardiovascular drugs and infusions be continued during transportation. Finally, an ECG and review of the child's rhythm history for the presence of cardiac dysrhythmias should be conducted.

Renal Status

Recent urine output, fluid requirements, creatinine, and blood urea nitrogen (BUN) should be reviewed. Renal function should be assessed and may have an important bearing on the use of neuromuscular relaxants, intraoperative fluid requirements, and electrolyte status. Electrolyte abnormalities are common in those with critical illness and may lead to cardiorespiratory failure and cardiac dysrhythmias intraoperatively. These, in general, should be corrected preoperatively.

Gastroenterology

All patients who are ill enough to require admission to an intensive care unit should be suspected of having full stomachs. Acute, critical, and chronic illnesses delay gastric emptying. Even though the child may have been NPO for a prolonged period, hypersecretion and high gastric acid content may predispose the child to aspiration on induction. Patients who have suffered trauma and for whom no NPO history is available should, as a precaution, be treated as having full stomachs.

Laboratory Tests

Laboratory investigation should be reviewed thoroughly. At a minimum, baseline CBCs, electrolyte profiles, calcium, and blood gases are essential. Therapeutic levels of drugs, such as theophylline and anticonvulsants, are indicated, if the child is receiving them. A final check to ensure crossmatched blood is available, when indicated, is prudent.

CHAPTER 20

Evaluation of the Geriatric Patient

Stanley Muravchick, MD, PhD, and Katherine Grichnik, MD

The term *geriatrics*, created early in the 20th century, describes the clinical subspecialty area of medicine that focuses on care of the elderly patient.[1] Since then, advances in medical science and healthcare have continued to increase the relative "agedness" of industrialized societies to the point that the economics of healthcare for the elderly have, for the first time, assumed roles of major social and political importance. Elderly patients now account for more than one-half of all hospital care days in the United States. In addition, almost one-third of all surgical patients are 65 years of age or older, with an even larger fraction anticipated in the next 2 decades. Virtually every nonpediatric hospital provides a wide range of surgical services for elderly adults; consequently, almost every anesthesiologist in contemporary practice is expected to have expertise in geriatric medicine as it relates to anesthetic practice.[2]

As they age, adults exhibit an increasingly varied array of physical responses to lifelong exposure to environmental and socioeconomic conditions and to the accumulated stigmata of prior traumatic injuries and medical therapies. Prolonged longevity also reveals all intrinsic physiologic strengths and weaknesses and full expression of genetic differences that might not be fully apparent over shorter life-span intervals. The terms *elderly* and *geriatric* are used synonymously in this chapter to describe patients who are 65 years of age or older. The term *aged* is used to describe individuals older than 80 years of age.

As you shall see, neither elderly nor aged surgical patients require a "special" anesthetic. Rather, as advocated prophetically more than a half century ago,[3] a well-conducted anesthetic of any type can be both safe and appropriate for an elderly patient if the anesthesiologist (a) adheres to high standards of preoperative assessment, (b) closely controls and monitors preexisting disease, and (c) pays meticulous attention to drug dosage and to the details of pain management and postoperative care.[4] The sections that follow describe some of the current concepts of human aging that are relevant to contemporary anesthetic practice, examine common disease states, and review common surgical procedures in the elderly.

CONCEPTS AND THEORIES OF AGING

The exact mechanisms that control the aging process remain unknown. However, it is very clear that aging is not simply the result of accumulated disease. Aging is a physiologic phenomenon that manifests itself in mammalian species as universal and progressive degenerative changes in both the structure and the functional capacity of organs and tissues. The implied consequence of aging in all species is an increasing probability of death as a function of time. Currently, there is no consensus as to when the geriatric era begins in human subjects or whether any single physiologic marker can identify an elderly or an aged patient.

Throughout adulthood, increasing levels of oxygen-derived free radicals, or reactive oxygen species (ROS), create oxidative stress within the mitochondria and disrupt the structural and enzymatic machinery of oxidative phosphorylation.[5] Investigations of oxidative phosphorylation in aging mitochondria suggest that aging is associated with progressive impairment of bioenergetic efficiency and increases in the incidence of defects in DNA, primarily mitochondrial DNA (mtDNA), presumably because of increasing levels of ROS.[6] As the ability of the cell to scavenge these byproducts of aerobic metabolism declines, ROS may create a self-perpetuating "cycle of aging" within the mitochondria (Fig. 20–1).[7] Many gerontologists have concluded that changes in mitochondrial bioenergetics largely explain much of normal human aging and that these appear to play a central role in the diffuse deterioration of cellular and organ function that characterizes human senescence.[8]

The mitochondria, by modulating both bioenergetics and programmed cell death, or apoptosis, may serve as "biosensors" for oxidative stress as well as the final mediators of both declining energy production and termination of cell function.[9] Viewed from this perspective, the unique life span demonstrated by each species probably reflects the net result of interaction between the genetically determined bioenergetic attributes of each species and the randomly destructive environmental factors that produce disorder in biologic systems.

Two recent observations support this concept. Cellular resistance to oxidative stress has been shown to be intrinsically involved in both aging and longevity,[10] and an experimental mtDNA mutation has produced what appears to be premature aging in laboratory animals.[11] There is also a general correlation between species longevity and the capacity to repair damaged DNA but still no solid evidence that the ability to recover from random oxidative DNA damage is progressively or universally compromised in older human subjects.[12] In addition, although it has been shown that there is more defective mtDNA in the cells of older subjects,[13] it is not certain that

KEY POINTS

1. The elderly are the fastest-growing segment of the population.
2. A healthy elderly patient may have normal organ function but less reserve.
3. There are normal organ and overall functional changes of aging that do not imply disease but must be considered when planning an anesthetic.
4. Elderly patients have a high incidence of chronic disease states.
5. Elderly patients do not require a "special" anesthetic, but rather require strict attention to meticulous preoperative assessment, detailed management of intraoperative variables and concurrent disease states, and cautious titration of drug administration and dosages.

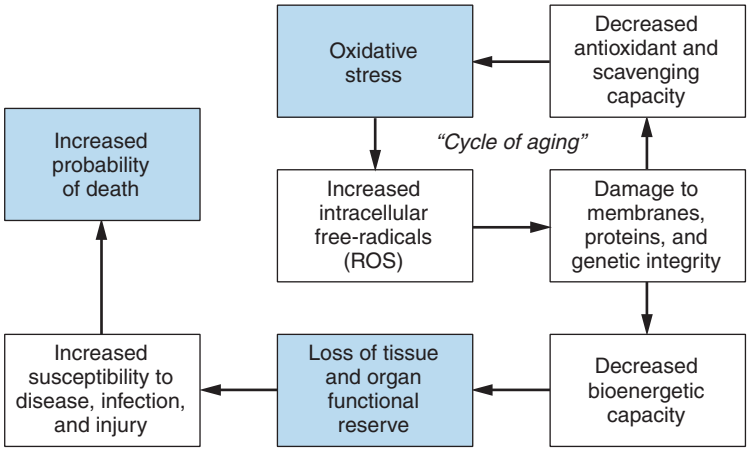

FIGURE 20–1. There may be a self-sustaining "cycle of aging" in which accumulated oxidative stress as a result of aerobic metabolism eventually damages the metabolic machinery and the genetic integrity of mitochondria.

this actually produces a critical reduction of the macromolecules needed for normal bioenergetics.[14]

Organ System Senescence

Classically, age-related physiologic change was represented as a linear decline of maximal organ system function. The physiologic decline was believed to begin early in young adulthood and continue inexorably downward thereafter. However, contemporary analysis suggests that there is a more complex relationship, with relatively minor decrements in maximal organ function first becoming apparent just after peak of somatic maturation, in the fourth decade of human life. Additional decrements of average maximal function or functional capacity during the middle adult years also appear to be relatively subtle but subsequently become more obvious during the seventh decade of life and beyond (Fig. 20–2).

Nevertheless, although some decline of maximal function is inevitable, the competence of integrated organ system function varies greatly from one elderly patient to the next, even in the absence of disease. Functional capacity is significantly altered by differences in physical and mental activity level, comorbidities, social habits, diet, and genetic background. Those elderly patients who maintain greater than average functional capacities are considered "physiologically young." However, when organ function declines at an earlier age than usual, or at a more rapid rate, elderly patients are often described as "physiologically old."
